SYSTEM OF SURGERY;

PATHOLOGICAL, DIAGNOSTIC, THERAPEUTIC
AND OPERATIVE.

BY

SAMUEL D. GROSS, M. D.,

PROFESSOR OF SURGERY IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA;
SURGEON TO THE PHILADELPHIA HOSPITAL;
MEMBER OF THE IMPERIAL ROYAL MEDICAL SOCIETY OF VIENNA, ETC. ETC.

ILLUSTRATED BY

TWELVE HUNDRED AND TWENTY-SEVEN ENGRAVINGS.

SECOND EDITION,

MUCH ENLARGED AND CAREFULLY REVISED.

IN TWO VOLUMES.

VOL. I.

TO
THE NUMEROUS PUPILS
WHO, DURING THE LAST QUARTER OF A CENTURY,
HAVE ATTENDED HIS LECTURES,
AND WHO ARE NOW SETTLED IN EVERY SECTION OF THE UNITED STATES
IN THE
HONORABLE PURSUIT OF THEIR PROFESSION,
These Volumes,
DESIGNED TO ILLUSTRATE ONE OF THE MOST IMPORTANT AND VALUABLE BRANCHES
OF THE HEALING ART,
ARE RESPECTFULLY AND AFFECTIONATELY INSCRIBED
BY THEIR FRIEND,
THE AUTHOR.

P R E F A C E.

IN preparing for the press a new edition of this work, I have carefully revised every chapter, introduced a large amount of new matter, and added nearly three hundred illustrations, a portion of them expressly engraved for its pages. The subject of gunshot wounds, invested at this moment with such a fearful interest on this Continent, has received more than ordinary attention. Notwithstanding these additions, it will be seen that the volumes, in consequence of the employment of a smaller type, are somewhat less bulky than the original ones. The general arrangement of the work is the same as in the first edition; and the new matter will be found to be essentially of a practical nature.

For the flattering manner in which the work has been received by the profession, and for the encomiums bestowed upon it by the periodical press, both at home and abroad, I feel under deep obligations. Such testimony is the highest reward which an author can expect for his labors. A translation of the work into the Dutch language is now in progress at Nieuwediep, in Holland, and will appear at an early day.

To Dr. Richard J. Dunglison I am indebted for important aid afforded me in correcting the press, and in preparing the new index and table of contents.

S. D. GROSS.

JEFFERSON MEDICAL COLLEGE,

PHILADELPHIA, January 1st, 1862.

THE FIRST PART

The first part of the work is devoted to a general survey of the subject, and to a description of the various methods which have been employed for its investigation. It is in this part that the reader will find the most interesting and valuable information, and it is to be hoped that it will be read with the same interest and attention as the whole work.

The second part of the work is devoted to a detailed description of the various methods which have been employed for the investigation of the subject. It is in this part that the reader will find the most interesting and valuable information, and it is to be hoped that it will be read with the same interest and attention as the whole work.

The third part of the work is devoted to a detailed description of the various methods which have been employed for the investigation of the subject. It is in this part that the reader will find the most interesting and valuable information, and it is to be hoped that it will be read with the same interest and attention as the whole work.

The fourth part of the work is devoted to a detailed description of the various methods which have been employed for the investigation of the subject. It is in this part that the reader will find the most interesting and valuable information, and it is to be hoped that it will be read with the same interest and attention as the whole work.

The fifth part of the work is devoted to a detailed description of the various methods which have been employed for the investigation of the subject. It is in this part that the reader will find the most interesting and valuable information, and it is to be hoped that it will be read with the same interest and attention as the whole work.

The sixth part of the work is devoted to a detailed description of the various methods which have been employed for the investigation of the subject. It is in this part that the reader will find the most interesting and valuable information, and it is to be hoped that it will be read with the same interest and attention as the whole work.

The seventh part of the work is devoted to a detailed description of the various methods which have been employed for the investigation of the subject. It is in this part that the reader will find the most interesting and valuable information, and it is to be hoped that it will be read with the same interest and attention as the whole work.

The eighth part of the work is devoted to a detailed description of the various methods which have been employed for the investigation of the subject. It is in this part that the reader will find the most interesting and valuable information, and it is to be hoped that it will be read with the same interest and attention as the whole work.

The ninth part of the work is devoted to a detailed description of the various methods which have been employed for the investigation of the subject. It is in this part that the reader will find the most interesting and valuable information, and it is to be hoped that it will be read with the same interest and attention as the whole work.

The tenth part of the work is devoted to a detailed description of the various methods which have been employed for the investigation of the subject. It is in this part that the reader will find the most interesting and valuable information, and it is to be hoped that it will be read with the same interest and attention as the whole work.

PREFACE TO THE FIRST EDITION.

THE object of this work is to furnish a systematic and comprehensive treatise on the science and practice of surgery, considered in the broadest sense; one that shall serve the practitioner as a faithful and available guide in his daily routine of duty. It has been too much the custom of modern writers on this department of the healing art to omit certain topics altogether, and to speak of others at undue length, evidently assuming that their readers could readily supply the deficiencies from other sources, or that what has been thus slighted is of no particular practical value. My aim has been to embrace the whole domain of surgery, and to allot to every subject its legitimate claim to notice in the great family of external diseases and accidents. How far this object has been accomplished, it is not for me to determine. It may safely be affirmed, however, that there is no topic, properly appertaining to surgery, that will not be found to be discussed, to a greater or less extent, in these volumes. If a larger space than is customary has been devoted to the consideration of inflammation and its results, or the great principles of surgery, it is because of the conviction, grounded upon long and close observation, that there are no subjects so little understood by the general practitioner. Special attention has also been bestowed upon the discrimination of diseases; and an elaborate chapter has been introduced on general diagnosis.

The work, although presented, as its title indicates, as a formal and systematic treatise, is founded upon the courses of lectures which it has devolved upon me to deliver during the last twenty years; first in the University of Louisville, for a long time the most flourishing medical school in the Southwest, and more recently in the Jefferson Medical College of this city, in which I had the honor, in 1828, to receive my degree. During all that period, I have been unceasingly devoted to the duties of an arduous practice, both private and public; to the study of the great masters of the art and science of medicine

and surgery; and to the composition of various monographs having a direct bearing upon a number of the subjects discussed in these volumes. The work should, therefore, be regarded as embodying the results of a large personal, if not of a ripe, experience, of extensive reading, and much reflection; in a word, as exhibiting surgery as I myself understand it, and as I have, for so many years, conscientiously taught it. If, upon certain points of doctrine, I have been obliged to differ from colaborers of acknowledged authority and of the highest professional eminence, it is because I have found it impossible to do otherwise. As Luther said at the diet of Worms, "hier stehe ich, ich kann nicht anders," so I may declare that what I have here written, I have written under a solemn conviction of its truth, though certainly not without a strong sense of my fallibility and shortcomings.

In the composition of a work so extensive as this, comprising so many and such diversified topics, no man, however great his opportunities for observation, could possibly rely entirely upon his own resources; for there are certain diseases, and also certain accidents, so infrequent in their occurrence as hardly to come under notice even once in a long lifetime; and it is, therefore, only by availing himself of the recorded experience of the profession that an author can hope to be able to communicate full and satisfactory information respecting them. I have, accordingly, made free use, wherever this was deemed necessary, of the labors of my contemporaries, both among systematic writers and the contributors to the periodical press of this and other countries. To the excellent works of Erichsen, Miller, and Fergusson, so well known on this side of the Atlantic, I have frequently referred as embodying the latest résumé of the art and science of surgery among our British brethren: while I have not neglected to consult some of the more recent treatises in the French and German languages, as well as numerous monographs.

Of the engravings which adorn the volumes, nearly four hundred are original, the remainder having been borrowed from different writers, as Liston, Cooper, Fergusson, Marcet, Bennett, Miller, Curling, Tamplin, Lawrence, W. Jones, Dalrymple, Pirrie, Erichsen, Druitt, Ashton, Toynbee, Barwell, and Mütter. To Mr. Gemrig, the eminent cutler, I am indebted for numerous illustrations, many of them specially prepared for the work, of the latest and most approved styles of instruments. Mr. Kolbe, another excellent manufacturer, has also placed me under obligations for several similar favors.

To Professor Wright, of Montreal, Dr. E. Williams, of Cincinnati, Dr. Lente, of New York, and Dr. Packard, Dr. James Darrach, and Dr. Walter F. Atlee, of this city, my acknowledgments are due for

various favors received during the progress of the work. To Dr. Bozeman, of Alabama, a valued friend and former pupil, I am indebted for a complete series of drawings illustrative of his peculiar mode of operating for the cure of vesico-vaginal fistule. The index, which will be found to be unusually elaborate, has been prepared, with great care, by my son, Dr. S. W. Gross.

The mechanical execution of the work will, I doubt not, meet with general approval. The publishers have spared neither pains nor expense to render it as perfect, in this respect, as possible. To Messrs. Baxter and Harley, engravers, and Mr. Collins, printer, my best thanks are due for the able manner in which they have executed their respective tasks.

S. D. GROSS.

July 8, 1859.

CONTENTS OF VOL. I.

PART FIRST. GENERAL SURGERY.

	PAGE.
PRELIMINARY OBSERVATIONS.	35
CHAPTER I.	
IRRITATION, SYMPATHY, AND IDIOSYNCRASY . . .	37
CHAPTER II.	
CONGESTION.	50
CHAPTER III.	
INFLAMMATION.	
SECT. I. General Considerations	54
1. Causes of inflammation	55
2. Extension of inflammation	59
3. Varieties of inflammation	61
4. Terminations or events of inflammation	63
II. Acute Inflammation	63
1. Local symptoms	63
2. Constitutional symptoms	72
3. Changes of the blood in inflammation	76
4. Intimate nature of inflammation	79
5. Treatment of inflammation	87
I. Constitutional treatment	88
II. Local treatment	105
III. Chronic Inflammation	116
CHAPTER IV.	
TERMINATIONS AND RESULTS OF INFLAMMATION.	
SECT. I. Delitescence and Resolution	121
II. Deposition of Serum	122

	PAGE
SECT. III. Lymphization or Fibrinous Exudation	125
1. Uses of plastic matter	130
2. Injurious effects of plastic matter	132
Treatment	133
IV. Suppuration and Abscess	134
Abscesses	140
1. Phlegmonous abscess	141
2. Diffuse abscess or purulent infiltration	149
3. Scrofulous abscess	151
4. Multiple abscess or pyemia	156
5. Hectic fever	163
V. Hemorrhage	167
VI. Mortification	168
1. Acute mortification	169
2. Chronic mortification	177
VII. Hospital Gangrene	182
VIII. Ulceration and Ulcers	189
Ulcers	192
1. Acute ulcers	194
2. Chronic ulcers	197
IX. Granulation	205
X. Cicatrization	207

CHAPTER V.

TEXTURAL CHANGES.

SECT. I. Softening	210
II. Induration	211
III. Transformations	213
IV. Hypertrophy	216
V. Atrophy	218
VI. Contraction and Obliteration	220
VII. Fistule	221

CHAPTER VI.

CONGENITAL MALFORMATIONS.	225
-----------------------------------	-----

CHAPTER VII.

TUMORS OR MORBID GROWTHS.

SECT. I. General Observations	228
II. Benign Tumors	231
1. Hypertrophic tumors	232
2. Vascular tumors	233

	PAGE
3. Fatty tumors	234
4. Horny tumors	238
5. Fibrous tumors	240
6. Cartilaginous tumors	243
7. Osseous tumors	244
8. Calcareous tumors	245
9. Neuromatous tumors	245
10. Encysted tumors	247
11. Hydatid tumors	250
12. Polypoid tumors	251
13. Myeloid tumors	254
Excision of benign tumors	255
SECT. III. Malignant Tumors	256
1. Scirrhus	258
2. Encephaloid	264
3. Epithelioma	268
4. Colloid	271
5. Melanosis	273
Treatment	278

CHAPTER VIII.

SCROFULA.

Scrofula and Tubercle	287
Treatment	292

CHAPTER IX.

WOUNDS.

SECT. I. General Considerations	298
1. Mode of dressing wounds	299
2. Mode of healing of wounds	306
II. Incised Wounds	310
III. Lacerated Wounds	313
IV. Contused Wounds	315
V. Punctured Wounds	318
VI. Tooth Wounds	322
VII. Gunshot Wounds	323
Question of amputation in wounds	340
Secondary effects of wounds and contusions	343
Maggots in wounds	345
VIII. Poisoned Wounds	346
1. Wounds inflicted by poisonous insects	346
2. Wounds inflicted by venomous serpents	348
3. Wounds inflicted by rabid animals	352
4. Glanders, farcy, or equinia	359

PART FIRST.

GENERAL SURGERY.

VOL. I.—3

THE JOURNAL OF THE

PART FIRST.

GENERAL SURVEY.

SYSTEM OF SURGERY.

PRELIMINARY OBSERVATIONS.

UNDER the division of GENERAL SURGERY, I shall consider, at some length, the leading facts illustrative of the great principles of surgical diseases and injuries, and of the operations necessary for their relief, removal, or cure. Beginning with the subjects of irritation, sympathy, and congestion, as intimately concerned in the production and maintenance of many of the most common and interesting morbid phenomena, I shall pass successively in review all that relates, generally speaking, to inflammation and its effects, textural changes, new formations, whether benign or malignant, wounds, and poisons; as all these affections are liable to occur in every organ, tissue, and region of the body. To this division of the work, also, naturally appertain the subjects of general diagnosis, surgical instruments, and other appliances; and, lastly, anæsthetics, or the means of averting pain during the performance of surgical operations, and in the reduction of hernia, fractures, and dislocations. Such an arrangement is suggested not less by common sense than by sound experience; for it is just as necessary in surgery to pass from the known to the unknown, or from the more simple to the more complex portion of the various topics which fall within its province, as it is in the study of mathematics, or any other abstruse science.

The above subjects being disposed of, we shall come to that of SPECIAL SURGERY, embracing an account of the various surgical diseases, injuries, and malformations of particular organs, tissues, and regions of the body. The general principles or great doctrines of surgery being understood, a knowledge of the various topics discussed in this part of the work will be a comparatively easy task.

The word surgery is a corruption of *chirurgery*, derived from a Greek compound, literally signifying manual procedure. Hence, surgery was for a long time regarded merely as a kind of handicraft, fit to be exercised only by men of inferior attainment, ability, and skill. For many ages, in fact, the *chirurgion* was nothing but the servant of the physician, without whose advice and direction he was never permitted to perform any operation, however simple. He had no agency whatever in preparing the system for the approaching ordeal, nor any hand in the after-treatment of the case. His task was completed when he had made his incisions, spilt a certain quantity of blood, and relieved the suffering organ from impending danger, by restoring it to its natural position, or ridding it of foreign substances. His occupation was a mere mechanical one; and, although there can be no doubt that he often possessed great manual dexterity, yet it is obvious that his very education unfitted him for the exercise of the more lofty duties of his profession. The contrast between the surgery of former times and that of the present

day, forms one of the brightest pages in the history of human progress and human achievement. Redeemed and purified by the genius of modern discovery, it is no longer a handicraft, but a science and an art, reduced, if not to perfection, to principles as accurate as any that have been introduced into the study of the natural sciences in general, of which, in fact, it forms one of the most interesting and useful branches.

Surgery, thus improved and perfected, can no longer be separated from medicine; any attempt to produce such a severance must prove abortive. They are, in point of fact, one and the same science, and therefore indivisible. No surgeon can practise his profession with credit to himself, or benefit to his fellow-creatures, if he is not an enlightened physician, or deeply grounded in a knowledge of the great doctrines of disease. He may, it is true, be an excellent operator, a good mechanic; but unless he is an able pathologist and therapist, he is unworthy to be intrusted with the health and life of the humblest citizen.

Surgery has occasionally been separated into two distinct branches, medical and operative; the former treating, as the name implies, of the principles of the science, or of the nature of disease, and of its management by drugs; the latter, of the various manual, instrumental, and mechanical procedures considered necessary for the cure of external affections, and the repair of mutilated structures. Upon this plan have been constructed several very excellent modern works, as those of Liston, Miller, Fergusson, Sédillot, Blasius, Velpeau, Pancoast, and Smith; but it is questionable whether such a manner of treating the subject is altogether judicious, as it is certainly calculated to invest the operative part of surgery with a degree of importance that does not legitimately belong to it, and which may lead, especially on the part of the young practitioner, to erroneous conceptions of the true province and dignity of surgery, considered as a science and an art. A work on surgery, or, indeed, on any subject, without principles, may be compared to a vessel at sea without helm or rudder to guide it to its place of destination. If, therefore, there is any one part of the present treatise upon the study of which I would insist more than upon that of any other, it is that which treats of the great principles of surgery, as comprised under the head of inflammation, wounds, morbid deposits, new growths, and morbid poisons. Let the student make himself fully acquainted with these details, and he can hardly fail to become an enlightened and judicious practitioner. Let him learn principles, and he will be able to form a more just appreciation of what is merely operative.

CHAPTER I.

IRRITATION, SYMPATHY, AND IDIOSYNCRASY.

It is perhaps impossible, in the present state of the science, to offer any satisfactory definition of irritation, or to assign to this expression its true pathological and practical import, without an intimate knowledge of sympathy, or of those various and mysterious relations, anatomical and functional, which exist among the different organs and tissues of the body, and which thus serve to bind them all up into one harmonious, uniform, and connected system. Irritation and sympathy are not only closely associated together, in all the great operations of the economy, but they so constantly run into each other, as to render it impossible always to draw a precise line of distinction between them, or to determine what part they respectively play in the production, propagation, and effect of disease. Much of what has been written upon these topics has necessarily been exceedingly obscure, depending not merely upon the intrinsic difficulties of the subject—great and perplexing as they certainly are—but upon the unphilosophical manner in which they have, for the most part, been discussed by surgeons, whose authority has not only never been disputed, but regarded with a blind devotion as surprising as it has generally been unaccountable. To arrive at any other conclusion from an attentive perusal of their writings, is impossible. Every page, nay, almost every paragraph, bears testimony to the fact that they have constantly confounded together affections of a very different, and even of an opposite nature; that they have, in numberless instances, violated their own definitions of disease; and that they have attempted to establish systems of treatment based upon principles of the most erroneous and unfounded character.

What is irritation? Is it an entity, or a mere myth, a certain undefinable something, which no one can see, but which every one may recognize by its effects? Perhaps the best definition we can give of it is, that it is a disordered state of the nerves of the affected part, attended with more or less pain and functional disturbance, but not with inflammation, although it may lead to that result, if not timeously arrested; in other words, irritation is a disease whose predominant symptom is nervous derangement. Viewed in this light, it may be considered as bearing the same relation to the nervous system that inflammation bears to the vascular; the one consists essentially in disordered sensation, the other in disordered circulation; in the one there is pain, but it is the pain of perverted sensation, in the other there is pain also, but it is the pain of inflammation, as is evinced by the concomitant vascular injection, discoloration, and tumefaction, which are wanting in the former. The differences between irritation and inflammation have sometimes been defined by stating that the former terminates where the latter begins; just as congestion may be said not to be inflammation, but the prelude to that affection. Both may be merged in the latter disease, and may, consequently, serve to augment and perpetuate it.

Irritation may be of limited extent, as when it is confined to one particular organ, or part of the body, and is then said to be local; on the other hand, it is sometimes widely diffused, manifesting itself at numerous points, and constituting what is termed general irritation, of which one of the most

familiar illustrations occurs in nervous shock, consequent upon severe injury. It is also divided into direct and indirect; in the former case, the irritation displays itself at the place of the morbid impression; in the latter, on the contrary, it occurs at a situation more or less remote, sympathy and reflex action being the agents of its transmission. An example of direct irritation is afforded in the intolerance of light which results from over-fatigue of the eye, and of the indirect, in the convulsions which supervene upon the presence of worms in the alimentary canal, the irritation being communicated here from the nerves of the bowels to the spinal cord, or the cerebro-spinal axis, and from thence to the nerves of the voluntary muscles, the seat of the spasmodic action.

Local irritation may manifest itself in a great variety of ways and circumstances. It is generally excited by the contact of some extraneous substance, or agent, foreign to the part, and, therefore, a source of offence to it. Thus, a drop of alcohol, falling upon the eye, instantly produces pain, and injection of the conjunctiva, with an abundant flow of tears; the organ resents the aggression, and the consequence is a marked perversion both of sensation and circulation, which, the exciting cause ceasing to operate, soon passes off, the parts regaining their comfort and accustomed action; or, the cause continuing in play, violent and even destructive inflammation may succeed, the minor evil being merged into the major. A pinch of snuff will excite sneezing by the irritation which its presence induces in the pituitary membrane; on the same principle, some emetics cause vomiting, some cathartics purging, and some diuretics an increased secretion of urine. When the hand is held near a hot stove, or rubbed with spirits of ammonia, the skin presently shows signs of irritation; its sensibility is perverted, it burns and stings, and becomes intensely red. All these, and numerous other analogous cases that might be easily adduced, if it were necessary, are examples of local irritation, or of perverted nervous action, accompanied by vascular determination, but not by inflammation, although such an event is certain to occur, if the exciting cause of the irritation be not promptly removed.

Indirect, or reflex irritation, like the direct, also displays itself in different ways, and not unfrequently in a manner not less singular than perplexing, defying all effort at explanation. The subject offers a wide field for contemplation and study. Time and space will permit me to glance only at a few of the more prominent facts which naturally connect themselves with such a discussion. To do anything even like partial justice to the subject, it will be proper to consider it in relation to the principal organs of the body, a procedure which will necessarily bring up the question of sympathy, as a knowledge of the latter is indispensable to a correct appreciation of the former, and conversely.

It would be out of place in a work of this kind to inquire into the nature of sympathy. All that we know respecting it is, that there exists, both in health and in disease, an intimate relationship between certain organs and tissues, the result either of a continuity of structure, similarity of tissue, or of ties, of which anatomy and physiology have failed to point out the true character. In health, this action is carried on so imperceptibly as to escape attention; but, whenever there is any serious disorder of the system, it manifests itself at every point, serving at once, at least in many cases, to indicate the nature of the lesion, and the particular tissues, or set of textures, which it implicates. It is not difficult to account for the sympathy that exists between parts that are united together by continuity of structure, as, for instance, the eye and nose, or the bladder and urethra; or by similarity of structure, as the fibrous membranes, whose diseases, as gout and rheumatism, are sometimes suddenly transferred from one to another; but, in other cases—and these constitute some of the most interesting and important exceptions—no

connection of any kind can be traced, and we are therefore left in doubt in respect to its real character. It is only, then, by studying these effects, as they exhibit themselves in different parts of the body, and under different circumstances, that our knowledge of them can be made practically available at the bedside.

1. *Brain*.—The brain, from its elevated position in the scale of organs, and its importance to health and life, is subject, in a remarkable degree, to the causes which develop and influence irritation. Connected, either directly or indirectly, with every other organ and tissue of the body, its functions are liable to be disturbed in every variety of way, and in every possible degree, from the most simple and almost imperceptible departure from the normal standard to the most complete and thorough perversion, amounting, at times, to total annihilation of sensation. Hence, it is not surprising that while the brain is itself a source of irritation to other parts, it should, in its turn, be more or less seriously affected by irritation having its seat in remote structures operating upon it through sympathy, or reflex action. It is in this manner that are developed many of the most distressing diseases of the cerebrum and cerebellum, and, also, as a natural consequence, of the mind; and, what is remarkable is, that some of the most disastrous lesions often have their origin in apparently the most trivial cerebral irritation, which, but for neglect or ignorance, might usually be relieved by the most simple treatment. The arachnitis of infancy generally begins in reflex irritation, which has its seat in the bowels, stomach, liver, skin, or gums, fretted, perhaps, by the pressure of an advancing tooth. Such cases are of constant occurrence in this country, during our hot summer months, and there are none which are more justly dreaded by the practitioner. The influence of this kind of irritation is often forcibly exhibited in traumatic delirium, or that excited state of the brain consequent upon accidents and operations, especially in subjects of intemperate habits and of a nervous temperament; the brain appears to be in a state of the utmost tension from pent-up irritability, which nothing but the most liberal use of anodynes can generally control; all the symptoms are such as to preclude the idea of the existence of inflammation in the cerebral substance, nor is it by any means certain that there is always gastritis, although usually there is marked derangement of the stomach. In disorder of the uterus, the brain is often affected by reflex irritation, as is plainly evinced by the eccentric phenomena which so generally attend hysterical diseases.

On the other hand, disease of the brain is often productive of serious irritation, or disease in other parts. Thus, after concussion of this organ, it is by no means uncommon, after the main symptoms of the accident have subsided, to meet with paralysis of one side of the face, occasional vomiting, constipation of the bowels, irritability of the bladder, or disease of the sphincters, causing involuntary discharges of urine and feces.

The sympathetic relations between the cerebellum and testes have always been a matter of observation, and afford a ready explanation of the occurrence of certain diseases, which, but for a knowledge of this fact, would be impossible. Military surgeons long ago noticed that wounds of the occiput, even when they do not involve the substance of this portion of the brain, are often followed, at variable periods after recovery, by atrophy of the testicles. Injuries of the cerebellum have been known to be succeeded within a short time after their infliction by the most violent sexual excitement. In a case of gunshot wound, the particulars of which have been related to me by Dr. Donne, of Kentucky, this sexual irritation existed in a most remarkable degree. The man was twenty-five years of age, and the ball, discharged from a common rifle, penetrated the skull near the lambdoidal suture, whence it passed obliquely downwards and backwards, lodging, there was every reason to

believe, in the cerebellum. The reaction, which was very slow, was attended with excessive excitement of the genital organs. Intense priapism supervened on the fifth day, attended with the most extraordinary salacity, which formed the all-absorbing topic of his remarks during his semilucid intervals up to the time of his death, nine days after the receipt of the injury. Nocturnal pollutions and the habit of onanism, in their most degrading forms, are often excited and kept up by a diseased state of the brain operating prejudicially upon the testes and seminal vesicles. The effect may be produced simply by inflammation of the cerebral tissues, or by the pressure occasioned by some morbid growth, as a fibrous, scrofulous, or encephaloid tumor.

2. *Spinal Cord*.—The study of the sympathies and irritations of the spinal cord naturally follows that of the brain. Connected as this cord is, on the one hand, by the nerves which are detached from its substance, with the organs of volition and of special sensation, and, on the other, by the anastomoses of these same nerves with those of the great trisplanchnic system, its sympathies and relations are as universal as they are close and intricate. Hence whatever has a tendency to derange these consentaneous movements, must necessarily be a source of disease, often of a wide-spread, if not of an all-absorbing character. Concussion, for example, of the spinal cord, when not immediately followed by death, is generally productive of excessive prostration of the vital powers, hardly less extensive and fatal than that of the brain itself. Life often hangs literally for hours upon a mere thread; the face is ghastly pale, the pulse weak and fluttering, the breathing hardly perceptible. In the milder forms, the mind is frequently disordered for days, the bladder is excessively irritable, the bowels are costive, the eye sees objects confusedly, and the ear is incapable of accurately noting sound. There are many diseases which may induce spinal irritation; I shall allude only to inflammation, ulceration, and displacement of the uterus, the practice of self-pollution, constipation of the bowels, and chronic gastric disorder. On the other hand, spinal irritation is capable of sending its baneful influence through every portion of the system, deranging the functions of every organ, and causing a train of phenomena frequently as distressing as they are enigmatical, or difficult of interpretation. Nervous headache, hemicrania, partial paralysis, imperfect sight, partial aphonia, embarrassed respiration, palpitation of the heart, gastric irritation, vitiated appetite, costiveness, and disorder of the menstrual secretion are often directly traceable to disease of the spinal cord and its envelops; and no practitioner can make much progress towards a cure in these affections without bearing in mind the sources whence they spring. The renal secretion is often greatly deranged by disease and injury of the spinal cord, and a very common effect of such lesions is a tendency to various deposits, especially the lithic and phosphatic. The bladder is also apt to suffer under such circumstances; becoming irritable, inflamed, and the seat of calculus, especially when the spinal cord has been severely concussed, wounded, or compressed. Many cases of neuralgia, gout, and rheumatism owe their origin, there is reason to believe, to disorder of the spinal cord, or the spinal cord and brain.

3. *Nerves*.—The nerves, those agents which convey to and from the brain and spinal cord the impressions made upon the various organs of the body, are themselves not unfrequently the seats of serious diseases and injuries, serving to modify and pervert their functions. A spiculum of bone, a ball, or the point of a needle, pressing upon a nerve, or partially imbedded in its substance, has often been productive of epilepsy, partial paralysis, loss of sensation, and other unpleasant symptoms, which promptly vanished upon the removal of the foreign body.

4. *Heart*.—As the heart is sympathetically connected with every portion of the body, so there are few diseases which are not capable of exerting a prejudicial influence upon its action, exalting it at one time and depressing it at another. It may be irritated and fretted in a thousand different ways; now by this thing and now by that; at one time by the solids, and at another by the blood, its natural and proper stimulus. Both the surgeon and physician daily witness examples of these disturbing agencies, and prepare to meet them by the judicious exercise of their clinical knowledge, often sadly tried by the perplexing and dangerous features of the case. There is no organ, the brain hardly excepted, whose action varies so much as that of the heart within the limits of health, and none which suffers more frequently and profoundly in disease and accident. The blood which, on the one hand, serves to animate and rouse it, and which, on the other, it is obliged at every moment to propel to every portion of the body, is itself one of the greatest sources of irritation to which it is so constantly exposed. At one time the cause of the irritation perhaps is plethora, at another anæmia; in one case it may be due to an undue proportion of saline matter, in another to the presence of some extraneous substance. Among the more prolific sources of cardiac irritation are disorder of the digestive apparatus, mechanical obstruction to the circulation, however induced, mental emotion, and derangement of the liver, uterus, and kidneys.

In injuries, derangement of the sympathetic relations of the heart is of constant occurrence, exhibiting itself in various forms and degrees, from the slightest disorder of its functions to almost complete annihilation of its muscular powers. In shock, the pulsations of the heart are weak and fluttering; in compression of the brain, slow and laboring; in hemorrhage, thrilling and vibratory; in plethora, strong and full; in anæmia, quick, jerking, and accompanied with a peculiar systolic murmur.

Irritation of the heart is often aroused by compression of the cardiac nerves by various kinds of tumors, by aneurism of the great vessels, and by diseases resident in its own tissues, causing them to act in an irregular and imperfect manner.

As the heart's action may be disordered by various diseased states of the body, so may this organ, in its turn, occasion derangement and irritation in other structures, leading not unfrequently to violent inflammations which no remedial measures, however judiciously applied, can always arrest and subdue. These disordered states form a wide field of study, which it would be out of place to pursue in a work of this kind. The intelligent reader will not fail to appreciate their pathological and practical import.

5. *Lungs*.—The action and reaction which are so incessantly going on between the lungs and the rest of the system cannot fail to strike the most superficial observer. From the importance of their functions, and their extensive sympathetic relations, these organs are subject to numerous and diversified changes, the influence of which, upon the general health, can only be duly estimated by a profound study of the subject. Whatever seriously affects the functions of the more important structures is sure, sooner or later, to exert an unfavorable impression upon the lungs, disordering the respiratory movements, and untowardly interfering with the aeration of the blood, or the introduction of oxygen, and the elimination of carbonic acid. Hence, a perfectly healthy state of these organs is a matter of paramount importance in the treatment of every case of injury and disease. Among the more common objects of attention, with this view, should be a pure state of the atmosphere, the use of wholesome food, and the correction and improvement of the secretions, without which our best directed efforts will often fail to avert irritation

and disease, or to combat them successfully when their development has been unavoidable.

6. *Stomach*.—The stomach, possessing a wide range of sympathy, is often the seat, not less than the cause, of severe irritation. Food and drink are the natural stimulants of this organ, and, rationally employed, seldom fail to prove wholesome. But when the laws of digestion are contravened by dietetic debauch and indiscretion; or, in other words, when the stomach is overloaded with indigestible articles, nausea and vomiting, with more or less cerebral and other disturbance, are the necessary and inevitable consequences. In children and delicate nervous females, such abuse often manifests its effects in the most violent convulsions, from the irritation it provokes in the cerebro-spinal axis and the nerves which are distributed to the voluntary muscles. An overloaded stomach frequently brings on a severe attack of asthma, palpitation of the heart, indistinctness of vision, and distressing noises in the ears.

Affections of the œsophagus often create excessive irritation of the stomach, manifesting itself in nausea and vomiting. Examples of this morbid sympathy occur in scirrhus of the œsophagus, as well as in ulceration and ordinary stricture of that tube. I have seen a foreign body, as a common cent, lodged in the œsophagus of a child, keep up nausea and vomiting until it was extracted. The irritation of the stomach, produced by tickling the fauces, is well known to every one. On the other hand, the œsophagus is liable to suffer very seriously from disease of other parts of the body. Thus, spasmodic stricture of this tube, sometimes of an exceedingly severe and intractable character, may be produced by disorder of the stomach, bowels, uterus, or spinal cord, which can only be relieved by addressing our remedies to the seat of the primary affection.

7. *Bowels*.—Disorder of the bowels is a prolific source of irritation, exhibiting itself in different viscera and tissues; for there are few organs whose sympathetic relations are of a more varied and extensive character. We have already alluded to the effects occasioned by the presence of worms in the alimentary canal; the retention of irritating matter often produces similar impressions upon the great nervous centres, followed, in many cases, especially in infants and delicate nervous persons, by violent convulsions, disease of the arachnoid membrane, and palpitation of the heart. Itching of the nose, and various affections of the lips, tongue, and fauces, are frequently directly chargeable to dyspepsia, constipation and other gastro-enteric derangement. What is called sick headache affords a familiar illustration of cerebral irritation dependent upon disorder of the stomach and bowels, or of these organs and of the liver. Costiveness never fails, when long continued, to oppress the brain, and produce a sense of general *malaise*.

8. *Rectum*.—There is an intimate sympathetic connection between the bladder and the rectum; also between the urethra and the lower bowel. In dysentery, hemorrhoids and fissure of the anus, strangury and spasmodic retention of urine are by no means uncommon, and sometimes constitute a source of real suffering. The ligation of a pile not unfrequently compels the surgeon to use the catheter for drawing off the urine; and I have known the vesical irritation in such a case to continue for several days. The same affections not unfrequently produce spasmodic stricture of the urethra.

9. *Teeth*.—A very lively sympathy exists between the teeth and some of the other parts of the body; more intimate and extensive than would at first sight seem possible. Children, from the pressure of the teeth upon the gums, are extremely liable, especially during our hot summer months, to vomiting,

diarrhœa, fever, and convulsions. Arachnitis occasionally supervenes upon difficult dentition; and certain affections of the skin, as eczema and porrigo, are frequently directly traceable to its effects, and rendered obstinate, if not temporarily incurable, by its persistence. A heated and tumid state of the gums, with thirst and redness of the skin, should be promptly met by the free division of these structures; otherwise, what is originally a mere irritation of the brain, stomach, or bowels, may soon be transformed into a fatal inflammation.

A decayed tooth, even when it does not itself ache, will often cause severe pain in the face, temple, neck, throat, or ear; generally, but by no means always, on the corresponding side, doubtless because all these parts are supplied by nerves derived from the same sources. When the ear is involved, the pain is propagated along the nervous cord of the tympanum, a filament of the second branch of the fifth pair of cerebral nerves. A carious tooth occasionally creates violent pain in a sound one, though at a distance from it; and the suffering ceases the moment the offending tooth is extracted. I have known a severe attack of pleurodynia kept up by a diseased tooth; the patient was bled and purged, but relief came only with the removal of the affected stump. Enlargement of the lymphatic ganglions of the neck, ulcers of the chin, epilepsy, hysteria, dyspepsia, and various other affections, sometimes of a very obstinate and distressing character, may be produced by carious teeth. It is difficult to conceive how a diseased tooth could keep up an attack of rheumatism of the hip, and yet the possibility of such an occurrence is established by some well-authenticated cases. Dysmenorrhœa has been cured by the extraction of several of the large grinders; and writers refer to instances of intermittent fever which were relieved in a similar manner, after the fruitless employment, for several months, of bark, and other remedies. A decayed tooth has been known to produce neuralgia of the arm, which promptly vanished upon its removal.

10. *Liver*.—The sympathetic relations of the liver are at once numerous and diversified, and any disturbance in them is generally productive of irritation in a number of the more important organs, especially the stomach, bowels, brain, heart, and lungs. The skin also frequently suffers in consequence of hepatic derangement, and, conversely, the liver from disorder of the cutaneous surface. Various medicines, as well as different kinds of food, are capable of seriously disturbing the functions of this organ; and it is well known that its secretions are often materially disordered by the direct influence of anxiety or strong mental emotion. An attack of jaundice is sometimes instantaneously produced by severe fright. The timid duellist and the affrighted soldier often suffer from this kind of irritation. Hepatic abscesses not unfrequently follow upon injury of the skull and brain; and, on the other hand, disease of the liver occasionally provokes serious cerebral irritation. Dyspnoea, palpitation of the heart, nausea, flatulence, and vomiting, are common effects of disease of this viscus. Pain in the top of the right shoulder has long been recognized by physicians as a symptom of hepatitis. Violent shock is occasionally followed by total suppression of bile; and the passage of a gallstone always causes intense gastric irritation.

11. *Kidneys*.—The kidneys have important sympathetic relations with different parts of the body, manifesting themselves in various forms of irritation, some of which are easily explicable, while others are involved in impenetrable obscurity. Thus, it is easy to understand why a renal calculus should excite pain in the urethra, and a desire to urinate, simply by remembering that there is here a direct continuity of structure, the mucous membrane of the kidney being prolonged as far as the head of the penis; but it is very

difficult, if not impossible, to comprehend why a foreign body of this kind, as it descends along the ureter, should occasion retraction of the testicles, and excessive irritability of the stomach. Severe injuries, involving great shock of the system, are often followed by total suppression of urine; and, on the other hand, there are various affections in which this fluid is poured out in enormous quantity.

12. *Bladder*.—The bladder also is variously affected by disturbance of its sympathetic relations. After injuries, as compound fractures and severe operations, the organ is often incapable of contracting upon its contents, thus necessitating the employment of the catheter; its perceptive faculties are suspended, and a few days usually elapse before they are reinstated, so as to enable the patient to pass his water without assistance. Stone in the bladder causes pain and burning in the head of the penis, and retraction of the testicle. Sometimes the pain is felt in the knee, heel, and foot; and a curious case has been reported where it was seated in the arm. For a long time the professional attendants were unable to discover the cause of the suffering; but at length, the man complaining of vesical trouble, a sound was introduced, when he was found to have stone, the removal of which put at once a stop to the unpleasant symptom. A very common effect of stone in the bladder is spasm of the sphincter muscle of the anus, which is often so great as to interfere with the passage of the finger. The introduction of a bougie into the urethra occasionally induces swooning, followed by violent rigors and high fever; and cases occur, although they are not common, of severe pain being excited in the extremity of the coccyx by such an operation. In the female, a warty tumor at the orifice of the urethra will occasionally cause intense pain in the region of the bladder and kidney, with a frequent desire to urinate, and excessive scalding in passing water; in short, a train of phenomena closely resembling that produced by vesical calculus.

13. *Uterus*.—There is perhaps no class of sympathies of greater interest, in a pathological and practical point of view, than those which subsist between the uterus and the general system. It was a knowledge of this circumstance which induced Aristotle to say that the womb was an animal within an animal. The morning sickness of early pregnancy, the hysterical convulsions, the depraved appetite, the rigors which usher in labor, and the contraction of the uterus when the cold hand is suddenly applied to the abdomen, are all examples of the mysterious relations by which this organ is bound to the rest of the body. Nowhere do these effects display themselves more strikingly than between the uterus and the mammary gland. During pregnancy, the breasts begin to sympathize at an early period, as is evinced by their tender and tumid condition: and the effect which the application of the child to these organs has, soon after delivery, in causing after-pains, is familiar to every one. A knowledge of this fact has induced obstetric practitioners to take advantage of this means as a remedy for inducing contraction of the uterus in case of tardy expulsion of the placenta, or tendency to hemorrhage of this organ. The derangement of the stomach which accompanies prolapsus of the uterus, the pain and swelling of the mammary gland from menstrual irritation, the suppression of the lacteal secretion in puerperal fever, and the occurrence of carcinomatous disease of the breast at the decline of life, may be cited as additional illustrations of the intimate connection between the womb and the rest of the system.

14. *Testicle*.—An intimate sympathy exists between the testicle and the parotid gland. In mumps, or inflammation of the latter organ, it is by no means uncommon for the testicle, after the lapse of some days, to take on

inflammation also, and generally to such an extent as to bear nearly the whole brunt of the disease. The translation of the morbid action is usually quite sudden, and the suffering of the testicle is often much greater than that of the parotid, being not only attended with severe pain and swelling, but occasionally terminating in complete atrophy of the seminiferous tubes. In what manner, or in accordance with what law of the animal economy, this occurrence takes place, it is impossible to determine, as there is no similarity of texture between these parts, or any direct nervous connection. The parotid is supplied with filaments from the ascending cervical nerves, and with branches from the fifth cranial; the testicle, with filaments from the spermatic plexus, formed by the sympathetic.

15. *Skin*.—Remarkable sympathies exist between the skin and the mucous membrane of the alimentary canal, as well as between the cutaneous tissues and other parts of the body. Irritations, the result of a disturbance of these relationships, are of frequent occurrence, and serve to explain many morbid phenomena which, but for our knowledge of this circumstance, would be a complete mystery to us. The sympathy between the skin and mucous membranes is particularly close and intimate, arising from their great similarity of structure, it being well known that these tissues are convertible the one into the other, although there is no direct connection between them, except at the various mucous outlets; here, however, it is inseparable, and this is perhaps one reason, if not the principal, why disease of the one is so apt to cause disorder of the other. The fact that various substances taken into the stomach as food and medicine often produce the most singular cutaneous affections, within a short time after their introduction, is of daily occurrence. Every one's experience informs him of certain articles which he cannot use with impunity. There is no doubt that many diseases of the skin, generally of a very simple character, are often greatly aggravated and rendered obstinate, by inattention to the diet and neglect of the bowels and secretions; and it will be readily conceded that the practitioner who is aware of all this possesses a great advantage in the cure of these maladies over one who is ignorant of the circumstance, or wilfully disregards it. It is generally supposed that the skin suffers more frequently from disorder of the mucous membranes than the latter do from derangement of the former; but this is probably a mistake. It must not be forgotten that there is a marked difference in respect to the relative frequency of the affections of these two classes of structures in different climates, and at different seasons of the year. In tropical regions the prejudicial effects of a disordered state of the skin show themselves in a great variety of ways in the mucous membranes; especially those of the stomach and bowels, as in different forms of gastric irritation, diarrhoea, and dysentery. Erysipelas, carbuncle, and furuncle are generally supposed, and very correctly, to be essentially connected with disease of the chylopoietic viscera; indeed the more common varieties of these affections usually owe their origin to derangement of the stomach and bowels, and hence the practitioner rarely makes much progress towards a cure if he loses sight of this pathological relation. An unhealthy state of the skin often produces serious disease of the eye, brain, lungs, and liver, which is promptly relieved by attention to the cutaneous surface. Observation has shown that in bad cases of burns and scalds life is not unfrequently destroyed by ulceration of the duodenum, or the upper portion of the bowel, and yet it would puzzle the most profound physiologist to account for such an occurrence by a reference to any of the known laws of health and disease.

16. *Eyes*.—It is notorious that the eyes, like all symmetrical organs, have an important sympathy, not only with each other, but also with many other

portions of the body, which displays itself both in health and disease, and not unfrequently becomes a cause of irritation and inflammation. A familiar example of this internuncial action occurs in cataract. When one eye suffers from this disease, the other, at no distant period, is very apt to become affected also. Even in ordinary ophthalmia a similar liability to the extension of the morbid action is exceedingly common. The sound eye either soon takes on inflammation, or, if it be so fortunate as to escape this disease, it is sure to become the seat of such an amount of morbid sensibility as to render it utterly unfit, for the time being, for the purposes of useful vision. A percussion cap, or other foreign body, lodged in one eye, has not unfrequently been the cause of destructive inflammation in the other; and this disposition to the involvement of both organs, where one is originally exclusively affected, is nowhere more forcibly and painfully exhibited than in amaurosis. It is true it is not always easy, under these circumstances, to determine, in any given case, what share of the disease in the eye secondarily affected is due to the influence of consentaneous irritation, or to the operation of the same morbid agency which provoked the original malady; but it may reasonably be assumed, in the absence of positive information, that much, in the majority of instances, is the direct result of deranged sympathy. This liability of the eyes to participate in each other's diseases seems to be due to the intimate connection which exists between the optic nerves; and the same circumstance serves to explain the reason why the eyes are so frequently affected in organic disorders of the brain.

The eyes and nose are intimately related with each other, first through the distribution of the ophthalmic branch of the fifth pair of nerves, and secondly through the pituitary membrane, which is prolonged upwards through the lachrymal passages to form the conjunctiva. Hence it is easy to see how catarrhal affections should induce pain and redness in this membrane as it is reflected over the eyes; how snuff should excite a flow of tears; and how sudden exposure of the eyes to a strong light should cause sneezing. The connections which the frontal, infra-orbitary, and other nerves form with the filaments of the ophthalmic ganglion enable us to explain the occurrence of amaurosis in consequence of blows, wounds, and neuralgia of the face, eyebrows, forehead, and temples.

The eyes are connected with the abdominal viscera, particularly the stomach and bowels, through the medium of the branches of the sixth pair with the great sympathetic. The partial blindness, consequent upon gastro-enteric irritation, is readily accounted for in this way; and the same circumstance serves to explain the dilated state of the pupil which occasionally attends the presence of worms in the alimentary canal of children. It is probable that the pneumogastric nerves also play an important part in these sympathetic relations, otherwise it would be difficult to assign a reason for the excessive nausea and vomiting which now and then supervene upon injuries and operations of the eye, as severe blows and the depression of the cataract.

The eyes and teeth sometimes actively sympathize with each other, caries of the latter occasionally keeping up violent inflammation of the former, which promptly disappears upon the removal of the offending organ. I have several times seen the photophobia attendant upon strumous ophthalmia, speedily yield in this way, after the failure of numerous other remedies.

17. *Ears*.—A curious sympathy, noticed by all aural practitioners, exists between the ears and the respiratory apparatus, and also between the ears and the stomach. Thus, pruritus of the auditory tube sometimes provokes coughing and vomiting; and the former of these effects, it is well known, is not unfrequently caused simply by probing or sponging this passage in the removal of wax, or the extraction of a foreign body. Mr. Wilde, in refer-

ring to this phenomenon, says that it is by no means unusual, although it cannot be produced in all cases. "I never witnessed it," he continues, "in children or very young persons; it is most common in males of about middle life, and is in nowise connected with any previous disease existing in the respiratory apparatus. In some persons the slightest touch of the floor of the external auditory passage, about midway between its external outlet and the inferior attachment of the membrana tympani, will bring on violent irritation and spasmodic action in the larynx. In this case also the patient will generally tell us, upon inquiry, that he does not experience pain; but the moment we touch this very sensitive spot he feels a tickling sensation in his throat, which immediately increases to the feeling one has when 'a bit is gone astray.' What the nervous connection is which induces this has not been fully determined, but the fact is worthy of note."

Arnold has reported a case of chronic vomiting in a child, which long resisted a great variety of remedies; but which was promptly cured by the extraction of a bean from each ear, the foreign substances having been introduced during play. Mr. Toynbee states that he had had under his charge a patient who suffered under a cough which no treatment subdued, but which permanently disappeared upon the removal of a fragment of dead bone from the auditory canal.

18. *Age and Effects.*—All persons are liable to suffer from irritation; but there is, as might be supposed, great diversity in this respect, in different individuals. Thus, it is well known that persons of a nervous, irritable temperament are more prone to be affected with it than such as are of a sanguine or leucophlegmatic disposition, owing no doubt to the fact that they possess a more highly-wrought nervous system. Women suffer more frequently than men, both from local and general irritation; and some of the worst forms of reflex irritation that the practitioner meets with occur in hysterical females. Infants and children are extremely liable to the disease, the slightest cause often serving to light up the most distressing suffering. Loss of sleep, anxiety, grief, hard study, intemperance, inordinate sexual indulgence, impoverished diet, and the enervating effects of a hot climate, are all circumstances which powerfully predispose to the occurrence of irritation. The inhalation of the foul air of the dissecting-room is another well-known cause operating injuriously upon the system. If a young man who is nightly engaged, until a late hour, in the study of practical anatomy, pricks his finger, he will be much more likely to suffer severely than one from a similar wound who enters the dissecting-room only occasionally. In the one case the constitution is deteriorated by exposure, and is therefore incapable of resisting the effects of disease; in the other, on the contrary, it is healthy, and indisposed to take on morbid action.

An irritable state of the system often sadly interferes with the reparative process. Thus, the healing of a wound is sometimes suddenly arrested by an unhealthy state of the system, manifesting itself in a general exaltation of the nervous sensibility, altogether incompatible with the development of healthy blastema. An aneurism of the aorta, attended with constitutional irritability, has been known to prevent the consolidation of a fracture of the femur. These, and other similar facts, are of deep practical interest, as they are suggestive of valuable therapeutic measures.

Another very common effect of irritation, especially when extensive or seated in an important organ, is derangement of the secretions, not only of the parts more immediately affected, but of the rest of the system. Thus, irritation of the brain, however induced, is very certain to disorder the functions of the stomach, liver, and kidneys, as evinced by indigestion, a bilious

appearance of the skin, and a high-colored and scanty state of the urine. The salivary glands, too, suffer, the mouth becoming dry and viscid; the head aches, the pulse is excited, and the extremities are cold.

In concluding this rapid survey of irritation and sympathy, a few remarks may be offered on the subject of idiosyncrasy, as it closely connects itself with the discussion of these two topics.

Idiosyncrasy literally signifies a peculiarity of constitution, or a state of the general system in which certain articles, whether taken as food, drink, or medicine, produce an effect altogether different from what they are accustomed to under ordinary circumstances. Thus, lobster and other varieties of shell-fish, although they may be used with perfect impunity by most persons, are extremely prone in some individuals to induce urticaria, vomiting, and purging. A young lady, a patient of mine, married, robust, and of a florid complexion, cannot eat eggs, no matter how prepared, without being seized, almost immediately after, with vomiting. Some persons are overpowered by a particular odor, or by the sight of blood. I know a lady who has not been able, for many years, to eat watermelon without being almost instantly seized with hoarseness and soreness of the throat and mouth, attended with a burning, pricking sensation, nausea, and colicky pains. The use of watermelon-seed tea invariably produces a similar effect. Another lady, formerly a patient of mine, can never take an ordinary dose of laudanum without being copiously purged; opium affects her in a similar manner, but morphia does not. Laudanum, administered by the rectum, vomits freely and nauseates for many hours. These articles, however, always afford relief to her suffering. I am acquainted with several persons, among others a physician, in whom the inhalation or smell of ipecacuanha invariably excites a violent attack of asthma, generally lasting for two or three days. In the case of the medical practitioner, the perception of the presence of this substance is so keen that, if he be in the third story of a house on the first floor of which an ordinary dose of the article is compounded, he is instantly seized with spasmodic cough and wheezing. A gentleman, for many years a patient of mine, cannot drink a cup of green tea without being promptly and copiously purged; it usually operates on the bowels in from fifteen to twenty minutes after it is taken, bringing away thin, watery evacuations, accompanied with more or less griping; black tea produces no such effect, which he has experienced from the green from his earliest recollection. In two other cases, the use of green tea, even if taken only in small quantity, invariably acts as a powerful diuretic, causing an abundant secretion of urine, with a frequent desire to void it, for a number of hours.

I remember the case of a patient, an habitual asthmatic, thirty-five years of age, a tradesman by occupation, who cannot enter a room where feathers are without instantly experiencing an aggravation of his pulmonary affection. To provoke this effect, it is not necessary that he should see or smell the feathers; it is only necessary that they shall be near him. Led blindfold into an apartment thus furnished, he will at once be conscious of their presence, and be immediately compelled to retreat.

Idiosyncrasy not unfrequently displays itself in the operation of various medicines, affording thus useful hints to the practitioner in the selection of his remedies. There are many persons who cannot take opium in any form without being kept awake by it for hours and even days, besides suffering greatly from nausea, excessive itching, delirium, and other distressing symptoms. The most minute quantity of mercury will, in some persons, cause profuse ptyalism, while in others the article may be given in large doses and for a long time without the slightest effect of this kind, the system being absolutely proof against the action of the medicine in any of its forms and modes

of exhibition. Most individuals are freely purged by a drop of croton oil, and yet we occasionally meet with an instance in which hardly any operation upon the bowels is produced by twenty times that quantity.

The above instances, which might be multiplied to an almost indefinite extent from my own experience, will serve to illustrate a class of the most singular affections, whose influence in modifying, if not in inducing disease, is eminently worthy of the attention of the practitioner.

TREATMENT OF IRRITATION.

In the treatment of irritation there are several leading indications which claim special attention. The first is to remove the exciting cause; the second, to correct the secretions; and the third, to palliate the disease, both primary and consecutive.

To remove the exciting cause of irritation is not always an easy task. In many cases, indeed, it is either wholly inappreciable, or can only be guessed at. The duty of the surgeon of course plainly is to get rid of it if he can; the ball, the calculus, the splinter of wood, the dead piece of bone, and the carious tooth, are promptly extracted. Irritating ingesta are dislodged by emetics; offending feces by purgatives; worms by anthelmintics. The mortified toe is amputated; the compressed gum lanced; the suppurating felon freely laid open. Light is excluded from the inflamed eye; noise from the suffering ear; cold from the shivering surface. In all such cases the indication is plain, and in general easily fulfilled. But it is otherwise when the cause is occult. Here the disease must be met on general principles; and the judicious practitioner will do well to look into the condition of his patient's secretions, his bowels, and his diet, which are among the most common sources of the disease.

The correction of the secretions is a matter of primary importance in every case of irritation, whether local or constitutional. The manner of doing this will necessarily depend upon the character of the suffering organ; but no practitioner will fully discharge his duty if he neglect attention to this point. The viscera whose derangements are most liable to provoke reflex irritation are the stomach, bowels, liver, and uterus, and they should, therefore, always be objects of special consideration. Not unfrequently the cause of the trouble will be found to exist in irritation of the spine, or of some particular portion of the brain, demanding local depletion and counter-irritation, with perfect tranquillity of mind and body. Whatever the cause of the disturbance may be, it will be found that purgatives can rarely be dispensed with, while in not a few cases they constitute the chief anchor of our hopes. The diet, as a general rule, should be mild and unirritant, the proportions of its nutritive principles varying with the exigencies of each particular case.

The last indication is to cure the disease, or to palliate it if it be irremediable. To point out the methods of doing this in a class of affections of so protean a character as this, would be absurd. Every case must necessarily suggest its own treatment. In ordinary instances antiphlogistics, properly so called, may usually be dispensed with, and large draughts made upon the narcotic class of remedial agents, as their direct influence is to allay pain and spasm, and induce tranquillity of the system. The choice of the particular articles must be regulated by the circumstances of the case, and will often require no little judgment and experience for its successful exercise.

CHAPTER II.

CONGESTION.

It is practically a matter of no little importance that the surgeon should be able to discriminate accurately between inflammation and congestion; or, in other and more comprehensive terms, that he should possess clear and definite ideas respecting the more essential differences between these two morbid states; for upon their correct appreciation must often depend the result of his treatment. The subject, it must be confessed, is one of no ordinary difficulty, and a careful examination of what has been written upon it will serve to convince any unprejudiced mind that there are no two points in pathology concerning which there still prevails a greater amount of confusion; for what one author considers as congestion, another with equal confidence calls inflammation, and conversely; leaving thus the young and inexperienced practitioner in painful doubt not only in respect to the nature of the disease, but, what is far worse, in regard to its proper mode of management. As the subject of inflammation will be fully discussed in the ensuing chapter, I shall limit myself here to a plain and simple exposition of some of the more important facts relative to congestion, preceded by an attempt to assign to this expression its legitimate import.

Congestion signifies an accumulation of blood in a part, the result either of some mechanical obstruction, or of some vital defect in the circulation, interfering with the onward movement of the sanguineous fluid. The word is synonymous with hyperæmia, which Andral has proposed, without any just reason, as a substitute for it. It simply denotes the existence of an abnormal quantity of blood in a part, without any of the ordinary phenomena and effects of inflammation, which, however, it generally accompanies, if indeed it does not form a necessary consequence of the increased quantity of blood sent into the suffering structures in that disease. Pathologists usually divide congestion into two varieties, denominated, respectively, the active and the passive. The first, as the name implies, is characterized by inordinate activity of the part, as is evinced by its scarlet complexion, its augmented temperature, and its functional disturbance; and soon leads, if allowed to progress, to various kinds of deposits, particularly the serous and plastic. Passive congestion, on the other hand, is distinguished by the dark color of the part, the enlarged and sluggish condition of the vessels, and the chronic march of the disease. Owing to these differences in the action and aspect of the affected structures, these two varieties of congestion are often denominated arterial and venous; terms which are ill chosen, as they have a tendency to create erroneous impressions respecting the true nature of the two lesions, for it is impossible to conceive of any case of congestion, however slight or severe, in which the disease is exclusively confined to one set of vessels.

It will thus be perceived that *active congestion* is closely allied to inflammation, although it does not, properly speaking, constitute inflammation, except in the opinion of certain pathologists, who, as it seems to me, are not very felicitous in their attempts at separating the two affections from each other, although it is evident that they strive very hard to do so. They treat of congestion as a distinct entity, and yet they do not hesitate to ascribe to

it phenomena and effects which belong exclusively to inflammation, and which congestion, considered in the proper sense of that term, is utterly incapable of producing. Whenever a part, however situated in relation to the amount of blood it contains, is the seat of morbid deposits, it has passed the stage of congestion, and gone over into that of inflammation. If this be not so, then it necessarily follows that active congestion and inflammation are essentially one and the same disease, and that, consequently, it is absurd to attempt to describe them separately.

In all acute inflammations, whatever their cause or situation, active congestion is a necessary antecedent of the morbid action; one of the first links in the chain of the malady. Hence it would not be improper to say that it is part and parcel of the inflammatory process, ushering in the disease, and continuing up to the very point of effusion; or, in other words, ceasing only where effusion commences. But this is strictly true only to a certain extent; for there is in every case of inflammation a circle beyond the process of the morbid action, where the blood, playing about in eddies, has accumulated in large quantity, distending the capillaries, and destined soon to part with some of its constituents, if the disease be merged in the inflammation. A real fire is lighted up here: the part is hot, preternaturally red, and perhaps somewhat painful; nay, it may be, even a little tumid, from the dilated state of the vessels; the blood moves with unwonted force and velocity; the functional disturbance augments more and more; and presently congestion ceasing, inflammation takes its place, and goes through its allotted course. Another sign of distinction is that, in active congestion, the capillaries, although greatly crowded with blood, are more easily emptied than in inflammation: during life by pressure, and after death by injecting matter.

But active congestion is not always necessarily followed by inflammation, although prone to pass into that state if it continue even for a short time. The cause which induced it having been removed, the vessels cease to attract blood in undue quantity, and getting rid of what is redundant, speedily regain their normal caliber and function. A familiar illustration of this occurrence is afforded by the conjunctiva, when, from any transient cause, a sudden and violent rush of blood takes place to the affected part; in an instant hundreds of vessels, previously invisible, become apparent, being crowded with red blood, so as to give the surface almost a scarlet hue. Now, if we analyze these phenomena, it will be found that they depend simply upon a dilated state of the vessels of the eye and the presence of an unusual quantity of blood, containing a large number of red globules, which, in the healthy state, are either withheld from these vessels, or which are propelled along them in such small numbers as not to permit their coloring matter to become visible through their delicate walls.

Another familiar example of active congestion is furnished by what occurs in the hand when plunged into cold water, or exposed to a very low temperature. The skin soon becomes remarkably red from an unnatural afflux of blood, the parts are the seat of an unpleasant tingling sensation, and the capillaries, both arterial and venous, are exceedingly dilated; still, there is no inflammation, or any tendency to morbid deposit; the suffering structures are only irritated and preternaturally injected. Cautiously treated, the hand soon regains its natural condition; the skin recovers its former hue and sensibility, the blood ceases to accumulate, and the vessels resume their normal caliber. But it is otherwise, when the case is improperly managed; the congestion then will not only continue but it will steadily increase, and be soon merged in inflammation, or perverted action and effusion.

Now what occurs in the external parts of the body, immediately under the eye of the observer, may be supposed to happen, under similar circumstances, in the internal organs. Thus, we know that when there is a sudden repul-

sion of the cutaneous perspiration, the blood is extremely apt to collect in the lungs, causing active congestion of the pulmonary tissues, so often the precursor of pneumonia. Poison introduced into the stomach almost instantly induces active congestion of the mucous membrane of that organ, frequently followed, in a few hours, by the most intense and destructive inflammation. A ligature bound tightly around a limb affords a good illustration of the manner in which active congestion may be supposed to be induced in strangulation of the bowel in hernia and in intussusception.

A distinction should be made between active congestion in a part, and a determination of blood to a part. The former is always the effect of some morbid influence; the latter, on the contrary, may be the result simply of a natural cause. Thus, when the infant is applied to the breast there is an instantaneous determination of blood to the organ, so as to enable the vessels to furnish the necessary supply of milk; during menstruation, there is a marked determination of blood to the uterus, probably accompanied with more or less active congestion. In blushing there is a rush of blood to the cheek; in erection, to the penis; in anger, joy, and other emotions, to the brain. Excessive, sudden, and overwhelming determination of blood to the internal organs sometimes takes place during the cold stage of intermittent fever, especially in that variety of it to which Alibert and others have applied the term malignant. In the congestive fever, as it is termed, of the Southern States, death not unfrequently results within a few hours after the commencement of the attack, the system never reacting from the effects of the chill. Scarlet fever occasionally proves fatal in a similar manner; the surface is pale, or slightly livid, the extremities are deadly cold, and the internal organs are literally inundated with blood, determination and congestion co-existing in their worst forms.

In *passive congestion*, the morbid action is distinguished by its peculiarly sluggish character; the vessels are not only dilated, but frequently varicose, tortuous, elongated, and incapable of contracting upon their crowding contents; the discoloration is dark, venous, or purple, the circulation is tardy and languid, and there is often marked evidence of morbid deposits, especially of serum and lymph, occupying the cells of the areolar tissue.

Various causes may give rise to passive congestion. The most common are the following: 1st, inflammation; 2dly, mechanical obstruction; 3dly, debility; and 4thly, dependent position.

1st. Inflammation, in whatever form occurring, is almost always followed by a certain degree of passive congestion; the affected parts, exhausted by severe suffering, are reduced in strength and life-power; the vessels, dilated to their utmost capacity, and perhaps partially ruptured, are too feeble to contract upon their contents; the crippled structures are unusually vascular; and the slightest cause is generally sufficient to rekindle the disease. Indeed, as will be stated by and by, an organ that has been once severely inflamed is ever after extremely liable to become inflamed again; passive congestion often lasting for months and even years.

2dly. Mechanical obstruction is a prolific source of passive congestion. Examples occur almost without number, both in medical and surgical practice. I shall allude only to a few, as they will be sufficient for my purpose.

A good illustration of the effects of mechanical obstruction in producing passive congestion is seen in organic disease of the valves of the aorta, impeding the passage of the blood through the lungs. Compelled to remain here habitually in undue quantity, the pulmonary vessels soon fall into a state of passive congestion, which thus acts as a predisposing cause not only of inflammation, to which individuals so affected are extremely prone, but also of pulmonary apoplexy. Obstruction of the larger veins, as the femoral and iliac, is always followed by passive congestion in the parts below. In vari-

cose enlargement of the veins of the leg, attended with disease of their valves, the blood has great difficulty in finding its way to the heart, and the consequence is that the distal portion of the limb is always in a state of passive congestion, with a strong tendency to inflammation, and different deposits, especially the serous and plastic. Obstruction of the artery of the leg, by fibrinous concretions, is always followed by congestion and inflammation, if not gangrene of the foot.

The structures in the neighborhood of morbid growths are generally habitually congested; hence the profuse hemorrhage which so often attends their extirpation. Their vessels being compressed by the overlapping tumor, the passage of their contents is seriously interfered with, and hence they frequently undergo a remarkable dilatation, almost amounting to a real varicosity.

3dly. Debility of a part, however induced, is a frequent source of passive congestion. Examples of this form of the affection are seen in the retina and choroid coat of the eye from over-exertion of that organ; and in various parts of the body from loss of innervation, profuse hemorrhage, or other discharges, and from the natural wear and tear of the frame. If, under these circumstances, any particular organ is more feeble or exhausted than the rest, it can scarcely fail to become the seat of passive congestion, or congestion and inflammation.

4thly. That dependent position may give rise to passive congestion is a matter of daily observation. It is in this way that inflammation of the lungs is so often induced during the progress of lingering diseases and accidents, as typhoid fever, erysipelas, and compound fractures; the disease usually beginning in the posterior portions of these organs, in the form of passive congestion, and proceeding gradually but steadily from bad to worse, until it proves fatal, a result so much the more to be dreaded on account of its insidious character. In the so-called bedsores, consequent upon long confinement in one posture, during which the pressure of the body is concentrated with peculiar force upon the sacrum, the iliac crest, and the great trochanter, similar effects are produced. There is, both in these and similar instances, in the first place a determination of blood to the most dependent portions of the body, then passive congestion, and, finally, as a natural consequence, inflammation; often followed, in the latter case, by mortification.

Passive congestion, however induced, is a frequent cause of inflammation; often of a very destructive character, the more so, because the symptoms which attend it are so indistinct, if not so completely disguised, as to prevent the early recognition of their real import. It is for these reasons that the practitioner should constantly be on the alert whenever he has anything to do with diseases and injuries involving long confinement to one particular posture, and an unusual amount of expenditure of the vital forces.

Inasmuch as congestion may be induced by such a variety of causes, it would be folly to attempt to lay down anything like a regular systematic plan of treatment; to do so, would be to encroach upon every department of pathology and practice, both medical and surgical, of which we have any knowledge. The judicious surgeon, knowing how likely the continuance of such a condition is to be followed by inflammation, or to aggravate inflammation when these two states coexist, will do all in his power to avert the evil, or to combat it when he finds that it has already taken place. The leading indication of cure, in every case of congestion, is to equalize the circulation; but to accomplish this object often demands great judgment and an amount of pathological and therapeutic knowledge such as comparatively few men possess.

CHAPTER III.

INFLAMMATION.

SECT. I.—GENERAL CONSIDERATIONS.

A THOROUGH knowledge of inflammation is indispensable to every practitioner of surgery. It should form the principal subject of his studies during his pupilage, and the main object of his professional contemplation in after-life. When it is recollected that there is hardly any disease which comes within the province of this department of science that does not originate in inflammation, or that is not more or less affected by it during its progress, the truth and force of these remarks will appear sufficiently obvious. The smallest pimple upon the nose is, in point of fact, as much an inflammation as an erysipelas that covers the face and head. An ulcer of one of the mucous follicles of the mouth does not differ, in principle, from an ulcer of one of the glands of Peyer, which are the seat of so much disease and danger in typhoid fever. Many of the maladies, vaguely called nervous, are nothing but forms of inflammation, the nature and seat of which it is often difficult, if not impossible, to determine. Their predominant symptoms are of a nervous character, and hence the diseases which they accompany are usually considered as nervous, while in reality the reverse is too frequently the case.

All accidents, whatever may be their nature or degree, are necessarily followed, if the patient survive their immediate effects, by inflammation. The little wound made in venesection, the incision left in cupping, and the bite inflicted in leeching, would never heal without the aid of this process; the parts would remain open, and be the seat of incessant bleeding, or they would become festering and putrid sores. In a word, there would be no reparation after injuries of any kind, however simple, and operative surgery, instead of bearing healing on its wings, and being a blessing to our race, would be the merest cold-blooded butchery. Thus, it will be perceived that inflammation is capable of playing, as it were, a double game in the animal economy, being at one time a cause of death, and at another a source of life. It is for this reason that it is often designated by the terms healthy and unhealthy, according as the one or the other of these states predominates.

Inflammation may be defined to be a perverted action of the capillary vessels of a part, attended with discoloration, pain, heat, swelling, and disordered function, with a tendency to effusion, deposits, or new products. In addition to these changes, there is also an altered condition of the blood and nervous fluid as an important element of the morbid process. In what inflammation essentially consists, it would be idle to inquire, since it would be just as impossible to unravel its true nature as it would be to explain the intimate character of attraction, repulsion, gravitation, or cohesion. Hence, in studying its history, all that we can do is to examine its causes, symptoms, and effects, or, more properly speaking, to institute a rigid analysis of its appreciable phenomena. If we endeavor to step beyond this, we shall, like our predecessors, lose ourselves in the mazes of conjecture and hypothesis, those quicksands upon which so many of the noblest minds of the profession have, in all ages since the origin of medicine and surgery, been wrecked and

stranded, as if to warn us of their folly and the impossibility of further progress.

1. CAUSES OF INFLAMMATION.

The causes of inflammation are almost as numerous as the circumstances which surround us. Whatever has a tendency to affect injuriously our mental or physical organization, whether directly or indirectly, is capable of inducing disease, or, at all events, of laying a foundation for it. The division of the causes of morbid action into predisposing and exciting has long been recognized by pathologists, and cannot be dispensed with at the present day. By predisposing causes are understood those which produce in the system, or in a particular part of the economy, certain changes, states, or conditions favorable to the development of inflammation, without actually provoking it. They are usually tardy in their operation, and are either natural or acquired, according as they are inherent in the constitution of the individual or dependent upon accidental circumstances. The exciting causes, on the contrary, are such as are directly concerned in awakening the disease, or fanning it, as it were, into existence. It is not always, however, in the power of the practitioner to ascertain either the predisposing or exciting causes of the morbid action, and hence such cases, which are by no means unfrequent, are usually known as occult cases.

The natural *predisposing causes* of disease have reference to peculiarities of constitution, and to a tainted state of the economy, in consequence of hereditary transmission. To the former class belong plethora, debility, and nervous susceptibility, which prepare the system for disease, by the changes which they produce both in the fluids and solids. Persons who have naturally an undue quantity of blood, as indicated by their ruddy complexion, and the extraordinary functional activity of their organs, are peculiarly prone to inflammation; their bodies may be compared to a mass of tinder, which the slightest spark is capable of kindling into a devouring flame. Those, on the other hand, who are naturally feeble, are remarkably prone to local congestions, which, especially when they become habitual, are sure to lead to inflammation, often of a very unmanageable character, because it cannot be met by the ordinary remedies. Persons of nervous temperament are predisposed to maladies of the brain, spinal cord, and sympathetic nerves, as exhibited in derangement of the respiratory, digestive, and genito-urinary apparatus; maladies which are generally tardy in their progress, and which are often so obscurely marked as to be difficult of recognition.

The fact that some diseases are transmissible from the parent to the offspring has long been known to practitioners. There are family diseases, just as there are family likenesses, manners, and peculiarities; and, what is remarkable, they are more liable to be communicated by the mother than the father, as if it were her special prerogative to impress her vices, as well as her virtues, upon her descendants. Another law is that some of these diseases may skip one generation to reappear in another, and that it is not necessary that the parents should be actually laboring under an attack of them at the period of the child's conception. The affections which may be transmitted in this way are gout and rheumatism, pulmonary phthisis, asthma, scrofula, carcinoma, and constitutional syphilis, together with several others which it is unnecessary here to specify. It is in this wise apparently that God visits the sins of the parents to the third and fourth generation of their offspring. In what element of the economy the germ of the morbid action is locked up, neither reason nor experience has been able to determine: for a time it would seem to be latent in the blood, and then to explode, either suddenly or gradually, with zymotic violence.

Among the acquired predisposing causes of inflammation are, the effects of previous disease, plethora, and debility, however induced. When an organ has once labored under inflammation, it is extremely apt to suffer from it again from the most trifling causes. The part, enfeebled by the attack, does not recover completely from its effects for a long time, if ever. Hence, influences which, in the natural state, would not disturb its physiological relations, are, under such circumstances, peculiarly prone to excite disease. A good illustration of this fact is afforded in the tonsillitis of children, in whom a reproduction of the malady is almost sure to be awakened upon the slightest exposure to cold. It is not necessary here to enlarge upon plethora and debility as predisposing causes of inflammation. If these states of the system are capable of preparing it for the development of disease when they are a natural result of the organization, it may readily be supposed that they would be much more likely to produce such an effect when they are acquired, in consequence of the mode of life of the individual, or of the influence of structural lesion.

Age, sex, temperament, occupation, food, dress, exercise, climate, and season, are all so many predisposing causes of inflammation. Infancy is particularly obnoxious to enteritis, croup, and arachnitis; childhood, to affections of the skin, struma, parotitis, and tonsillitis; manhood, to pneumonitis, carditis, and diseases of the genito-urinary organs; and the decline of life, to gout and rheumatism, asthma, arteritis, and the various forms of malignant maladies.

The differences in regard to the liability of inflammation in the two *sexes* arises mainly from their anatomical peculiarities, and are much less common than is generally imagined. The function of parturition renders the female particularly liable to peritonitis, phlebitis, arachnitis, and carcinoma; while the male, from his occupation and mode of life, is more prone to cystitis, urethritis, gout, rheumatism, arteritis, hepatitis, pneumonitis, and pleuritis.

Of the influence of *temperament* as a predisposing cause of disease, too little is known to enable us to speak with any degree of certainty. The sanguine temperament, being characterized by plethora with inordinate capillary activity, disposes to inflammation of the internal organs; while the lymphatic is apt to be attended with affections of the skin, joints, serous membranes, stomach, bowels, and lymphatic ganglions.

Occupation is a powerful predisposing cause of inflammation. Persons who work much in the open air, and who are much subjected to the influence of cold and wet, are extremely liable to suffer from pneumonia, arthritis, tonsillitis, and enteritis. A sedentary life leads to chronic disorder of the alimentary canal; and, if conjoined with constant mental exertion, is liable to be followed by diseases of the brain and arachnoid membrane. Excessive exercise of an organ, as of the larynx in singing and speaking, is always a predisposing cause of inflammation.

The influence of *food* in disposing to inflammation is well known. The habitual use of stimulating articles of diet, especially when conjoined with a want of due exercise, is among the most powerful of the causes under notice. On the other hand, an impoverished diet, or a privation of nitrogenous food, by inducing a defective blood, leads to scurvy, chlorosis, typhoid fever, scrofula, and inflammation of the serous structures, terminating in dropsical effusions. Certain articles, as ergot, if employed for any length of time, or in any considerable quantity, dispose to arteritis and gangrene of the extremities. The habitual indulgence in alcoholic drinks leads to gastro-enteritis, hepatitis, and attacks of epidemic diseases, whenever such diseases are prevalent.

Dress may be an indirect cause of inflammation. It may keep the body too warm or too cold, or exert injurious compression; in either event, local

congestion will be apt to be induced, which the slightest circumstances may fan into disease.

A change of *climate*, whether from hot to cold, or cold to hot, powerfully predisposes to inflammation. Hence the period of acclimation is always peculiarly trying, and few persons escape without suffering. Season, too, exerts a predisposing influence. Thus, in summer, inflammation is most apt to assail the stomach and bowels; in winter, the lungs, pleura, joints, and throat.

Mental excitement is a prolific source of inflammation. Fear, grief, anxiety, hard study, and loss of sleep, by deranging the secretions, and interfering with the digestive process, all dispose to this disease. In short, whatever has a tendency to interrupt, disorder, or arrest healthy action, is apt to exert a pernicious influence. This is often the only way in which we can account for the occurrence of erysipelas, carbuncle, rheumatism, cerebritis, scrofula, and carcinoma.

The *exciting causes* of inflammation are extremely numerous, and of the most diversified nature; they act in two ways, either directly upon the parts, or indirectly through the system. Hence they are said to be local and constitutional; and the former are either of a chemical or mechanical character.

Among the *chemical* causes are, first, high degrees of heat, as hot water and iron; secondly, partial application of cold; thirdly, caustic substances, as the alkalies and acids; fourthly, acrid vapors, hartshorn, and gases; fifthly, certain secretions, as urine and bile; sixthly, blisters, embrocations, and rubefacients; and lastly, various septic agents, as those of smallpox, syphilis, glanders, and malignant pustule. All these agents act directly upon the parts to which they are applied, either destroying them by their immediate effects, or combining with them in such a manner as to change completely their structure and function. Their operation is always rapid, and the resulting inflammation is usually marked by severe symptoms, both local and constitutional.

The *mechanical* causes comprise, first, punctures, incisions, contusions, and lacerations; secondly, fractures, and dislocations; thirdly, sudden and forcible distensions, as from the accumulation of pus, serum, blood, or gas; fourthly, compression, as by bandage, ligature, posture, or effused fluids; and, fifthly, the presence of foreign bodies, as a stone in the bladder, a bean in the air-passages, a bullet in the flesh, a tubercle in the lung, or a fibrinous concretion in the brain. The manner in which these various causes act in producing inflammation is too evident to require explanation.

The *constitutional* causes of inflammation make their impression either directly upon the part, or indirectly through some remote structure. Logically speaking, it would perhaps be more proper to say that they all act in the latter way, and not in any case immediately upon the part, as is usually asserted they do. Thus, a morbid impression primarily made upon the respiratory passages, as the inhalation of some noxious gas, or the contact of malaria, instead of causing disease in the lungs, or some of its constituents, often, if not generally, explodes upon some other organ, perhaps very distantly, if at all, associated with the lungs by sympathy, or similarity of structure and function. A septic poison, for example, as the virus of smallpox, introduced into the system, acts not merely upon the blood into which it has been conveyed by the absorbent vessels, but also, and mainly, upon the cutaneous tissues, for which it has evidently a greater elective affinity than for any other part of the economy; if it produces any action at all upon other structures, it is altogether of an indirect character. In the transmission of secondary syphilis from the parent to the offspring, the force of the disease is spent, in the first instance, upon the skin and mucous membrane of the

throat and mouth ; there is no inflammation, so far as we are able to determine, in the cellular, fibrous, and serous tissues, or in the internal organs, properly so called. In tertiary syphilis the bones, periosteum, and cartilages are particularly prone to suffer, although the disorder has a more general tendency, as there is more profound contamination of the system.

Whatever doubt, however, there may still be respecting the mode of action of the above agents, there can be none about the operation of heat and cold, which are such prolific causes of inflammation. The influence of a tropical sun, acting upon an impressible nervous system, in producing hepatitis, is well known to the practitioners of our Southern States, and to those of Africa, Asia, and the West Indies. Gastritis and enteritis, in their worst forms, are often developed in the same manner. The effect of cold feet in producing tonsillitis, croup, pleurisy, pneumonia, enteritis, cystitis, and rheumatism, is familiar to every one. In all these instances the primary impression is made through the medium of the skin, by suppressing the perspiration, and throwing the onus of the functional disorder upon some internal and remote organ, between which and the cutaneous surface there is not the least direct connection.

The blood itself is a frequent source of inflammation ; sometimes, because it is overloaded with earthy salts or other irritating materials, as the poison of erysipelas, carbuncle, and various eruptive diseases ; at other times, because of its impoverished condition, rendering it unfit as a supporter of life and nutrition. There is reason to believe that the latter cause lies at the foundation of many of those low and unhealthy forms of inflammation which so often eventuate in destructive ulceration of the mucous and cutaneous tissues, as well as of some of the worst forms of morbid deposits, as imperfectly vitalized lymph, albumen, and tubercle. Deficient secretion, especially of the liver, kidneys, and skin, is a frequent cause of disease, various substances being thus retained in the circulation, much to the detriment of the general economy, as well as of particular organs, perhaps already predisposed to morbid action.

From the foregoing considerations it will be perceived that inflammation may be *traumatic* or *idiopathic*; that is, produced by external injury or by constitutional causes, the latter of which are often wholly inappreciable by our senses.

Inflammation is sometimes caused by *sympathy*. Thus, the eye occasionally suffers in consequence of disorder of the stomach, the brain of derangement of the intestines, the mamma of disease of the uterus, and the testicle of lesion of the urethra. A man who has for years habitually overtaxed his digestive powers, and in the meanwhile taken hardly any exercise, will be extremely apt, in time, to perish from carbuncle or erysipelas ; or, at all events, to have disease, in some form or other, of the skin, simply because these parts are intimately related to one another by similarity of structure and function. For the same reason disease of the skin is very liable to be followed by disorder of the alimentary canal.

Finally, inflammation may be caused by *metastasis*. The event is characterized by a transfer, for the most part gradual, but occasionally quite sudden, of irritation from the part originally affected to another, perhaps at a considerable distance from it, and in nowise related to it by structure or function. In inflammation of the parotid gland the testis is often involved in this way, but why it should be, neither our anatomical nor our physiological knowledge enables us to explain, as there is no traceable connection of any kind whatever between them. In rheumatism of the joints the heart often suffers ; and in erysipelas of the skin the morbid action frequently leaves one part of the surface and breaks out upon another. Such occurrences, which are sometimes greatly promoted by our local applications, should always be sedulously

watched, as they are generally fraught with danger, especially when they show themselves in important internal structures.

2. EXTENSION OF INFLAMMATION.

The manner in which inflammation spreads, or extends from one structure to another, is worthy of brief notice. This may happen in several ways, as by continuity of structure, through the agency of the vessels, by nervous sympathy, and probably also through the aid of the blood, which, as will be seen hereafter, is always more or less disordered in the more severe forms of the malady, however situated.

All inflammations, whatever may be their character, are, in the first instance, of a local nature, that is, they begin in, and are confined to a particular tissue, spot, or point, from which, as from a common focus, the morbid action radiates in different directions, until it becomes, so to speak, general. To illustrate my meaning, let it be supposed that the malady commences in a particular part of the mucous coat of the small bowel, as, for example, in one of the glands of Peyer. After having remained here for a short time, it gradually spreads to the fibro-cellular lamella, then to the muscular fibres, and finally to the peritoneal investment, thus involving the whole in one mass of disease. In erysipelas the same law is observed. Here the morbid action, beginning at a little point of skin, gradually extends to the deeper structures, until, as in the case of a limb, it invades cellular substance, aponeurosis, muscle, vessels, nerves, periosteum, and occasionally even bone. A pneumonia, in its progress, usually involves the pulmonary pleura and the bronchial mucous membrane. These instances will suffice to prove the position here assumed, which is the more important because it presents the characters of a general principle.

The rapidity with which inflammation extends from one texture to another is too variable to admit of any precise statement; in some instances the time is very short, perhaps not exceeding a few hours, and such cases are, it may be remarked, generally very prone to be characterized by more than usual violence. It must not, however, be inferred from this statement that the morbid action always spreads from the point originally attacked; for, although there is unquestionably a very strong tendency to this, yet there are numerous exceptions to it. In some cases this limitation is due to the nature of the disease itself; in others, it depends upon the deposit of plastic matter; while in a third series of cases it is owing to the structure of the overlying tissue, as, for example, in the periosteum, which often serves to protect the bone which it surrounds from the encroachment of disease of the soft parts.

One of the most common modes in which inflammation propagates itself is by *continuity of structure*. The morbid action, once begun, finds it easy to pass along the tissues in which it originated, and hence it often spreads rapidly over a large extent of surface, similarity of structure and function favoring the process. By continuity of surface an erysipelas of the skin, perhaps not larger at its commencement than half a dime, spreads in a few hours over an entire limb, or even over the greater portion of the body. In the same manner inflammation is liable to be propagated along the mucous canals, as is exemplified in tonsillitis, croup, and other affections of the throat and air-passages, and in the various diseases of the stomach, bowels, and genito-urinary apparatus. In duodenitis the morbid action may readily extend along the choledoch and hepatic ducts to the liver; and in gonorrhœa nothing is more common than for the disease to spread along the seminal passages to the epididymis and testis.

In the second place, inflammation may propagate itself by *contiguity of structure*, as already indicated in one of the preceding paragraphs. A phleg-

monous erysipelas of the skin has a tendency not merely to spread over the neighboring surface, in consequence of its similarity of structure and function, but also to extend in depth, thereby involving cellular tissue, aponeurosis, muscle, and, in short, every other texture within its reach. The tissues mainly concerned in the enterprise are the vascular and connective, the peculiar structure of which renders them highly favorable for the propagation of the morbid action. An inflammation, beginning in the conjunctiva, often in its progress involves the entire eye, simply from the intimate manner in which its different tunics are superimposed upon each other. In the bowels and other mucous canals the same effect is frequently witnessed. In pneumonia, especially in the more violent forms, the disease is rarely confined to the parenchymatous substance, but is almost sure, in time, to spread to the pleura and bronchia. In orchitis, although the inflammation is primarily seated in the tubular structure of the epididymis and testicle, yet it is by no means uncommon for it to extend to the albugineous coat, and occasionally even to the vaginal. An inflammation of the synovial membrane of a joint often extends, by virtue of the same law, to the articular cartilage and the head of the bone beneath, contiguity and intimate connection favoring here, as elsewhere, the propagation of morbid action.

Thirdly, the extension may be effected through the agency of the *veins* and *lymphatics*. Of the former a good example is afforded by what occasionally happens in venesection, where, apparently from the use of a foul lancet, the inflammation is sometimes spread from the little wound in the vessel, at the bend of the arm, as high up as the right auricle of the heart; and of the latter by what takes place in chancre, where the poison, taken up by the absorbent vessels of the penis, is carried by them to the glands of the groin, where it causes a hard and painful swelling, constituting what is termed a bubo. In dissection wounds the absorbent vessels always serve as vehicles for the transmission of the peculiar poison which gives to these lesions their characteristic features. For a short period after inoculation the poison is apparently latent, when its effects show themselves by one or more red lines extending up the limb as far as the axillary glands, whence, as from a common centre, its injurious consequences are radiated over the whole system.

Of the extension of inflammation by *nervous agency*, or sympathy, a familiar example is afforded in parotitis. In this disease, which attacks chiefly young subjects, the inflammation often suddenly leaves the organ originally involved, and fastens itself upon the testicle, which is then compelled to bear the whole onus of the morbid action. Of the precise manner in which this transfer is effected we are ignorant. That it is not through any direct nervous connection is sufficiently obvious, for everybody knows that no such connection exists; hence, as the only plausible explanation left us, we must conclude that it is brought about by the operation of sympathy, although of the nature of this operation it is impossible, in the present state of the science, to form any just idea. A similar relationship exists between the mamma and uterus, the stomach and lungs, and between the stomach and brain, or, rather, between the former organ and the arachnoid membrane.

Finally, inflammation may be propagated by the *blood*. This fluid, as will afterward appear, undergoes various changes in this disease, of which the most important is an increase of fibrin and colorless globules, with a strong tendency of these substances to adhere to the sides of the vessels as they are propelled along with the general circulating mass. The blood, thus altered in its properties, leads to obstruction of the capillaries in different parts of the body, thereby establishing foci of morbid action. It is not improbable that metastatic abscess, or what is now called pyemia, is generally produced in this way; at all events, this is a more rational mode of accounting for that occurrence than the one which attributes it to the absorption of pus, or the

admission of this fluid into the blood, through the agency of open-mouthed veins.

3. VARIETIES OF INFLAMMATION.

With the exception, perhaps, of the epidermis, the hair, and nails, there is no part of the human economy which is not susceptible of inflammation and its consequences. The reason why these structures are usually considered as incapable of this process is, that we are not able to demonstrate in them any bloodvessels, nerves, and lymphatics, which are the great and essential elements of organization in the more thoroughly elaborated and complex tissues. Notwithstanding this, it is extremely difficult to unite in so sweeping a conclusion, when we reflect upon the fact, of which daily observation furnishes examples, that these external coverings undergo various lesions, of form, size, color, and consistence, which can only be explained on the assumption that they are the product of inflammation, modified by the nature of the affected parts. There are other structures, as the arachnoid membrane, the cornea, and some of the cartilages, in which it is impossible to detect vessels, and yet no one would doubt for a moment, on this account, that they are incapable of disease. We should, therefore, I think, not make any exception, as it respects the possibility of the occurrence of inflammation, even in regard to the scarf-skin, the hair, and nails.

The susceptibility of a part to inflammation may be stated to be, as a general rule, in direct proportion to the amount of its vascular and nervous endowments, the importance of its functions, and the nature of its exposure. Hence it is found to be most common in the skin, cellular tissue, the mucous and serous membranes, the joints, lungs, liver, kidneys, bladder, urethra, ovaries, and uterus. The only exceptions to this law are the brain and heart, which, notwithstanding their incessant labor, the excessive delicacy of their organization, and their universal sympathetic relations, are comparatively rarely the subjects of inflammation. In the thyroid body, the salivary glands, the pancreas, the prostate, and the spleen, together with the voluntary muscles and their tendons, the nerves, vessels, fibrous membranes, and even the bones, the disease is also quite uncommon, although several of these structures are sufficiently prone to suffer from inflammation as it manifests itself in certain forms of syphilis, scrofula, and rheumatism. It is easy to know why the skin should be so frequently diseased when we reflect upon its vast extent, its wonderful vascularity and nervous endowments, its sympathy with the brain, lungs, stomach, and, in fact, almost every organ in the economy, and its constant exposure to all kinds of injurious impressions. For the same reason it is not difficult to account for the frequent occurrence of pneumonia, hepatitis, nephritis, and inflammation of some of the other viscera. The cellular tissue, although less highly organized than the skin, is yet a frequent subject of disease, growing out of the circumstance that it is the great connecting link by which the various tissues of the frame are cemented together, and also that it serves as a means of transmission of the vessels and nerves from one part to another. The functional activity alone of some of the organs affords a ready key to their liability to inflammation. Thus, the genital organs are almost exempt from disease until the age of puberty; but from that time on, when their slumbering season is over, and their fretful life begins, they are extremely prone to take on morbid action, both of a common and of a specific character.

The progress of inflammation exhibits much diversity, being at one time rapid, at another slow; hence its distinction into *acute and chronic*. An acute attack is one which runs its course swiftly, and which is characterized by well-marked symptoms, as is seen, for example, in tonsillitis consequent

upon a severe cold, and where, in the space of a few days, the affected gland acquires a large bulk from vascular engorgement and interstitial deposits, attended with great local and constitutional disturbance. Force and rapidity of action are its distinguishing features. Chronic inflammation, on the contrary, is marked by comparative slowness and feebleness of action; the attendant phenomena are also less bold, although there is generally a decided tendency to effusion. It may be the sequela of an acute attack, or it may show itself as a primitive affection: that is, it may exist for a considerable period without being discovered, owing to the absence of the usual diagnostic signs. Once in this condition, it may last almost for an indefinite time, as is exemplified in certain cases of gleet, leucorrhœa, tonsillitis, osteitis, arthritis, otorrhœa, and ophthalmia.

Inflammation may be *healthy* or *unhealthy*, according as it manifests a tendency to restoration, progress, or mischief. It would be wrong to regard inflammation always in the light of a disease, since it is the means which nature must necessarily employ whenever she wishes to repair the injury which has given rise to it. It is only when the process proceeds blindly, so to speak, that it is likely to be productive of harm by overpowering the part and system. An incised wound, occurring in a sound constitution, will, if properly managed, heal promptly by union by the first intention; but if the reverse be the case, there will not only be no immediate union, but its edges will separate, and suppuration taking place, a long time may elapse before consolidation will be completed. In the one case, the action is said to be healthy, in the other unhealthy; and it will generally be found that the nature of the action is a true index of the condition of the part and system; as the latter is, so will be the former. There are of course exceptions to this law, but they are infrequent and unimportant.

There is a form of inflammation to which pathologists have applied the term *irritable*, but which in reality does not differ materially from unhealthy inflammation, just described. The best illustrations of it occur in strumous ophthalmia, in ulcers of the extremities, in rupia, and in chronic tonsillitis, bronchitis, dysentery, cystitis, urethritis, and orchitis. It seems to depend upon an exaltation of the natural sensibility of the affected structures, aggravated by an unsound state of the nervous system.

Inflammation may be *common* or *specific*; common, when it proceeds from ordinary causes; specific, when it is produced by some peculiar poison, as the matter of gonorrhœa, syphilis, or smallpox. A more important distinction is, that certain inflammations are capable of appearing only in certain tissues. Thus, erysipelas is generally a disease of the skin; in rare instances it affects the mucous membrane of the mouth and throat, and, perhaps, also the peritoneum and pelvic veins, as in lying-in females; but it never fastens itself, as a primary affection, upon the muscles, aponeuroses, nerves, arteries, bones, cartilages, or internal viscera. Gout and rheumatism have a special fancy for the joints and fibro-serous textures; secondary syphilis, for the skin and fauces; tertiary syphilis, for the bones and periosteum; scrofula, for the lymphatic ganglions; and carcinoma, for the glandular structures, as the mamma, uterus, and liver.

Finally, inflammation may be *latent*. This expression is curious, and yet full of meaning; it simply implies that the morbid action does not reveal itself by the ordinary phenomena. Such an inflammation is always to be dreaded, because, being of a peculiarly insidious character, it is extremely apt to be overlooked. One of the best examples of this form of disease is afforded by the glands of Peyer in typhoid fever, the inflammation and ulceration of which constitute the anatomical lesions of that singular malady. Patients thus affected seldom complain of pain, or, indeed, of any other suffering directly referable to these bodies, even when the morbid action is so

extensive as to lead to perforation of the bowel. Latent pneumonia is a sufficiently common disease, and abscesses of the spine and other parts of the body often make great progress before their true nature is even suspected.

4. TERMINATIONS OR EVENTS OF INFLAMMATION.

Inflammation has various modes of termination; upon strict inquiry, however, it will be found that these amount only to two, and that all the rest are merely so many states, conditions, or events of the process. This distinction is real, not imaginary, and therefore of no little practical value. Philosophically speaking, there are but two terminations of the morbid action, the one being in health, the other in the death of the part. The former may occur by delitescence and resolution; the latter, by ulceration and gangrene. All deposits, whether serous, plastic, purulent, or sanguineous; and all changes of structure, whether in the form of softening, induration, contraction, or thickening, are to be viewed simply as so many products, effects, or results of inflammation, without necessarily involving a suspension of the process itself. This indeed may still go on, sometimes even for an indefinite period, and thus produce additional changes, more serious, perhaps, in their consequences than those which attended the act in its earlier stages. In suppuration, for example, the inflammation does not generally end the moment matter forms, or as soon as the pyogenic crisis has been fairly attained; instead of this it proceeds in a modified state, accompanied by ulceration, or still further deposits. The same remarks are applicable to lymphization and even to the production of serum, the latter of which may be regarded as one of the processes employed by nature to deplete the inflamed tissues; in this, however, she generally succeeds only by degrees, as is shown by the fact that the disease often continues for a considerable length of time after the drainage has commenced. Blood, either perfectly pure, or variously combined with the secretions of the affected surface, may be poured out quite freely, and yet the morbid action continue as actively as before, as we see exemplified in dysentery and other hemorrhagic forms of inflammation. Hence there is really no such thing as a termination of inflammation in effusion of serum, deposit of fibrin, or the formation of pus. These events occurring, the morbid action may still go on, being merely modified in its character by the influence exerted upon it by the attendant secretion or the morbid product.

The *nomenclature* of inflammation has been much simplified within the last quarter of a century. As it now stands it is based essentially upon the anatomy of the affected tissue, structure, or organ, the term *itis* being merely added to the name by which the part is generally known, as scleritis, cystitis, laryngitis. Sometimes, however, the old expressions are retained, as quinsy for inflammation of the tonsils, ophthalmia for inflammation of the eye, and gonorrhœa for inflammation of the urethra.

SECT. II.—ACUTE INFLAMMATION.

The symptoms of inflammation naturally divide themselves into local and constitutional; or those furnished by the part and those afforded by the general system.

1. LOCAL SYMPTOMS.

The most prominent external symptoms of inflammation have long been known to practitioners. They are tersely stated by Celsus to be "*rubor, calor cum tumore et dolore.*" This writer flourished in the first century of

Christianity, and was a contemporary of Virgil, Horace, and Ovid. His knowledge of inflammation, however, was extremely imperfect, and it was not until some time after the commencement of the present century that the subject began to be studied in its relations with the different organs and tissues of the body. Borden, Carmichael Smith, and Bichat, by laying the foundation of general anatomy, paved the way to a more comprehensive acquaintance with the nature and seat of morbid action, and were thus instrumental in revealing an amount of light, the beneficial effects of which can even yet be hardly foreseen. They have shown us, what might, *a priori*, have been anticipated, that the phenomena enumerated by the Roman author, as characteristic of inflammation, are liable to great and constant variations, according to the nature of the affected structure, and that the most violent morbid action may often be present, and yet nearly all of these phenomena be absent. Hence, at the present day, too much stress cannot be laid upon disordered function, inasmuch as this is frequently the only symptom that is at all appreciable, especially in inflammation of the internal organs. Modern research has shed important light upon the condition of the capillary vessels and their contents in inflammation, and has enabled us to explain much of what was before obscure and mysterious in regard to the more intimate nature of the process.

1. *Discoloration*.—The discoloration of an inflamed part varies from the slightest increase of the natural hue to the deepest purple, according to the character of the affected tissues and the intensity of the morbid action. It is always, other things being equal, most distinctly marked in those structures which are very vascular, while in such as have comparatively few vessels it is either entirely wanting, or present only in a faint degree. It is a prominent phenomenon in inflammation of the skin and mucous membranes, the cellular tissue, lungs, pleura, spleen, kidneys, and peritoneum; structures which are distinguished by their great vascularity, and by the large amount of blood which they are capable of admitting in disease. On the other hand, there is but little discoloration in inflammation, however intense, of the tendons, cartilages, bones, and fibrous envelopes, the brain, nerves, heart, and voluntary muscles. In inflammation of the arachnoid membrane the only evidence of disease observable after death is effusion of serum or of serum and fibrin; all trace of vascularity is wanting, and yet the morbid action has been sufficient to destroy life.

The discoloration of inflammation often acquires a high grade in a very short time, depending upon the activity of the circulation of the affected structures. In general, however, it proceeds rather slowly, keeping steady pace with the ingravescient action; advancing from rose to red, from red to purple, or from purple to black, as when the part is about to fall into mortification. It is always most distinct at the focus of the inflammation, from which it gradually recedes until, in most cases, it is insensibly lost in the natural hue of the surrounding healthy structures. Occasionally, however, as in erysipelas of the skin, as well as in some affections of the mucous membranes, the line of demarcation is very abrupt, the diseased surface exhibiting a red and well defined circle.

The discoloration varies not merely in degree, but also in its character, thereby throwing, not unfrequently, important light upon the diagnosis of the case. Thus, it may be scarlet, as in the skin, throat, and bowels; lilac or bluish, as in the sclerotica and the fibrous envelopes of the muscles; brick-colored, grayish, or brownish, as in iritis; yellowish, as in erysipelas, especially when associated with derangement of the biliary secretion; of a copper hue, as in the eruptions of secondary syphilis; purple, as in the edges of a scrofulous ulcer; livid, as in violent tonsillitis; and black, as in mortification.

These varieties of color, in these and other structures, are dependent, partly upon the organization of the affected tissues, partly upon the nature of the inflammation itself, and partly upon the amount, degree, or intensity of the morbid action.

The discoloration varies in extent, from the smallest speck, perhaps not larger than a pin's head, to a surface occupying many inches, if not several feet in diameter, as in erysipelas, where the disease sometimes involves the greater portion of the body. When this is the case, the discoloration is said to be diffuse; it is arborescent, when the vessels upon which it depends are spread out in dendritic lines; punctiform, when it occurs in the form of little dots, or points, as in some of the inflammations of the serous and mucous membranes; linear, when it presents itself in a distinct streak, as in phlebitis and angeioleucitis; and maculiform, when it assumes the appearance of a blotch or ecchymosis. In the latter case, as well as in the punctiform variety of discoloration, the morbid hue is due to an actual extravasation of blood, consequent upon a rupture of some of the capillary vessels of the part.

To be of value as a diagnostic sign of inflammation, the discoloration must be permanent, not transient; advancing and receding with the morbid action; disappearing under pressure, but reappearing the moment the pressure is taken off. The blush of shame vanishes in an instant, with the excitement that produced it; and the hectic flush upon the cheek of the consumptive merely denotes the existence of the fever which succeeds the afternoon's rigor; they are very different from the discoloration which marks the rise, progress, and termination of inflammation. Besides, the latter is usually associated with other symptoms, as heat, pain, swelling, and disordered function; phenomena sufficiently distinctive, in every case, to prevent error of diagnosis.

The immediate cause of the change of color in inflammation, is a preternatural afflux of blood. It was formerly supposed that it depended upon the formation of new vessels, but the fallacy of this opinion was long ago disproved by minute injection and microscopical observation. It is now well known that there is a class of capillaries too delicate to admit a sufficiency of red blood to render them visible in the natural state, but which, the moment they become involved in irritation or inflammation, are distended to such a degree as to show themselves in every direction, hundreds and even thousands appearing, and that frequently in an instant, where hardly any could be discerned before. We see this fact exemplified in the vessels of the conjunctiva, when a particle of foreign matter lodges upon the cornea; and what occurs here may be supposed to take place, under similar circumstances, in other structures. It is only in reparative inflammation, or in the inflammation which is necessary to rebuild parts that have been lost or destroyed, that vessels are ever formed. The process is entirely incompatible with ordinary inflammation.

2. *Pain*.—Pain, like discoloration, is one of the most constant symptoms of inflammation, usually setting in early in the disease, going on steadily increasing until the morbid action has attained its maximum, and then gradually abating, as the disease recedes, until it is insensibly lost. The subject of pain presents several points of interest, which, as they have a practical importance, should be well understood by the surgeon.

Pain varies in degree from the slightest change in the normal sensibility of the part, to the most excruciating agony, according to the nature of the affected structure, and the intensity of the morbid action. Doubtless idiosyncrasy also exerts an important influence, for it is well known that what causes pain in one individual occasions little, if any, in another. Most persons bear the application of a blister well, but I have seen some in whom the remedy, although retained only for a few hours, was productive of the most

exquisite torment. Such a result can only be explained on the assumption of an idiosyncrasy, or a difference in the nervous organization of our patients. The same remark is true in regard to the effects of injury. As a general rule, the pain is greatest at the focus of the inflammation; it is usually fixed in its situation, but sometimes it darts about in different directions; is increased by pressure, motion, and posture; and rarely intermits, although it often remits, especially in the morning and the early part of the forenoon.

Much diversity obtains in regard to the character of the pain, so much so, indeed, that we may often, from this circumstance alone, form a tolerably correct idea of the seat, and even of the nature, of the inflammation. Thus, in the pleura it is sharp and lancinating; in the cellular tissue, acute and throbbing, as is exemplified in boil and carbuncle; in the liver and lungs, obtuse and heavy; in the skin, prurient, itching, or burning; in the bones, dull and gnawing, as if insects were feeding upon the part; in the urethra, scalding or burning; in the conjunctiva, gritty and itching; in the teeth, throbbing, beating, or pulsatile. When inflammation is about to terminate in mortification, the pain generally becomes hot and burning.

Pain is sometimes felt at a point more or less remote from the seat of the morbid action; hence, it does not always serve to denote its existence. In coxalgia, the earliest and most prominent symptom usually is severe pain in the knee, and it has often happened, especially in the hands of the ignorant and inexperienced practitioner, that the latter has been leeches, cupped, and blistered, when all this care should have been bestowed upon the former. In inflammation of the bladder, ureters, and kidneys, a prominent symptom is uneasiness in the head of the penis; and in hepatitis, considerable suffering is often felt in the right shoulder. It is not always easy to explain these occurrences; but, in general, they are dependent either upon continuity of structure, as in the case of the urinary passages, or upon reflex action, as in coxalgia and hepatitis.

It is worthy of note that the pain is generally much more severe when the inflammation is seated in the covering of an organ, than when it occupies its proper substance. A pleuritis is always attended with severe local distress, whereas few persons ever experience any pain in pneumonitis. In inflammation of the parenchymatous structure of the liver, great disorganization may take place, and yet the patient be entirely ignorant of the fact, as far as pain is concerned; but should the fibro-serous envelop of the organ be mainly implicated, violent suffering will be a prominent symptom. The same law holds good in inflammation even of the brain and its membranes.

It is important that the practitioner should be aware of the distinction between the pain of inflammation and the pain of spasm, since it must exert an important influence upon his therapeutic measures. It has been already seen that the former is gradual, not sudden in its attack; persistent, not intermittent; increased by motion, pressure, and posture; and, moreover, it is generally accompanied by more or less febrile disturbance, and other evidences of indisposition, plainly marking its character, to say nothing of the history of the attack, which usually furnishes important light in regard to the diagnosis of the individual case. In spasm, the pain comes on suddenly, and, after having continued for a short time, intermits, or entirely disappears, only, however, to return again, and pass through the same course; in a word, it is paroxysmal, coming suddenly, and going suddenly; relieved by pressure, and nearly always attended with eructations and rumbling noises in the bowels, supposing the case to be one of colic; there is no fever—indeed, generally no constitutional excitement of any kind—and there is also an absence of the other local symptoms of inflammation, as heat, discoloration, and intumescence.

In neuralgia the pain is sharp and lancinating, often darting through the

parts with the rapidity of lightning, or like an electric shock: accompanied by a sense of soreness or aching, and generally aggravated by pressure. It is usually paroxysmal in its character, coming on perhaps once every day, lasting a few hours, and then going off gradually, or even suddenly, to reappear about the same time the following day; it is, in fact, generally an intermittent disease, with a distinct interval of freedom from pain, resembling, in this respect, an ordinary intermittent fever, and having often, like it, a miasmatic origin. The pain, moreover, is not always fixed, but is at one time here, and at another there, generally in the course of a sentient nerve.

Severe pain, especially in a nervous, irritable person, is always a formidable occurrence, as it exhausts and depresses the powers of life, and is sure, if not timeously combated, to occasion serious, if not fatal, mischief. The rule, therefore, is to arrest it promptly, and at all hazard, before the disease, of which it is a symptom, has made much progress.

A sudden disappearance of pain, unless occasioned by the use of anodynes, is generally denotive of danger, as it implies a termination of the morbid action in the death of the affected structures. The occurrence should, at all events, excite suspicion, and lead to careful investigation. An individual, for example, has been the subject of strangulated hernia; the constriction has lasted for several days, and has been characterized by severe suffering, both local and general; suddenly the pain ceases, and the patient flatters himself that he will soon be well. The surgeon, however, comes to a widely different conclusion; for the sunken features, the clammy skin, the feeble and flickering pulse, the incessant hiccough, and the trembling hand, but too plainly foreshadow the approach of death from mortification of the bowel.

Pain is not always present, even although the inflammation may be extremely violent. In typhoid fever, a disease attended with inflammation of the glands of Peyer, often terminating in extensive ulceration of these bodies, there is generally an entire absence of this symptom, from first to last, unless the case is followed by perforation of the bowel, and an escape of its contents into the peritoneal cavity. In pneumonia there is frequently no pain whatever; and the same thing is true in relation to inflammation of some of the other viscera. In scrofulous affections of the spine, particularly those forms of it known as Pott's disease and psoas abscess, pain, properly so called, is one of the rarest phenomena, especially in the earlier stages of their progress. A painless inflammation is peculiarly dangerous, inasmuch as it is very liable to be overlooked by the professional attendant, particularly by one who is in the habit of placing undue confidence in the ordinary phenomena of the disease.

How is pain produced? It has been supposed that it is caused by a development of new nerves; but that this is not so is sufficiently established by the fact that this symptom is often present, and that in a very severe degree, almost at the very commencement of the morbid action, and consequently long before it is possible for such an occurrence to take place. A more plausible opinion is that the suffering is occasioned by the compression of the nerves of the part by the dilated vessels and the effused fluids; but to render this theory complete it is necessary to go a step further, and to suppose that the various component structures of the nerves themselves are inflamed. It can hardly be imagined that these structures should escape this action even in the milder grades of inflammation, much less when the disease is fully established.

Of the intimate nature of pain nothing is known. All that observation teaches is that it is a peculiar mental perception, dependent upon a healthy state of the brain, without which it is impossible for it to occur. The individual must possess the faculty of consciousness, or he cannot take cognizance

of the mischief that disease produces in the different organs and tissues of the body. We have a convincing proof of this in what occurs in apoplexy and paralysis of the lower half of the body, in which the most violent inflammation may be set up, both in the internal viscera, and in the external structures, and yet the patient be utterly insensible of its presence. The brain and nerves are crippled; hence the latter are unable to convey, and the former unable to receive, painful impressions of any kind.

Although pain is undoubtedly a great evil, yet it is extremely fortunate that it is so generally present in inflammation, since it serves to warn the patient of his danger, and often imparts to the practitioner useful information respecting the nature and seat of the morbid action. How many persons formerly perished of typhoid fever, simply because there was no pain to guide the physician to the true lesions of the disease? Doubtless this affection has existed from time immemorial, but it has only been within the last quarter of a century that we have known anything definite of its seat and character. Were pain one of its prominent symptoms, it would long ago have pointed the practitioner to the condition of the glands of Peyer.

What is termed *throbbing* is a peculiar form of pain, generally denotive of the approach of suppuration. It is, however, sometimes felt at an early stage of the morbid action, especially when it involves the fibrous, fibro-serous, and osseous tissues. It is generally dependent, in the first instance, upon an unusually crowded state of the capillary vessels, impeding the onward flow of blood, and afterwards, when the disease is more fully developed, also upon the presence of inflammatory products. Posture exerts an important influence upon its production, as is evinced in whitlow, odontalgia, and common furuncle. In the first of these affections the pain is increased a hundred fold, almost in an instant, when the hand is permitted to hang down by the side of the trunk; a decayed tooth that is free from pain in the day, while the patient is sitting up or walking about, will ache violently the moment the head touches the pillow at night; and a boil on the buttock, which will cause hardly any uneasiness when the body is recumbent, will throb violently when it is erect. These occurrences, which are easily explained by the increased determination of blood which the affected structures receive, under such circumstances, teach a valuable practical lesson in regard to the importance of position in the treatment of inflammation.

3. *Swelling*.—Swelling is seldom entirely absent in inflammation of the external parts of the body, although it may be in that of certain internal structures, however violent or extensive the morbid action. Under the latter head may be enumerated, in particular, the fibrous and serous membranes, the tendons, cartilages, bones, vessels, and nerves, along with most of the different viscera. The mucous membranes also rarely suffer in this way; the principal points where swelling is liable to occur, as a result of inflammation, are the conjunctiva, glottis, tonsils, and vulva, for the reason that these parts are largely supplied with lax cellular tissue, which, wherever it exists, is so permissive of infiltration of serous and other fluids. Hence it is that swelling is generally so conspicuous in inflammation of the subcutaneous and inter-muscular filamentous substance, especially in the extremities, and even sometimes in the head, as is noticed in the more severe forms of erysipelas, where the scalp and face are occasionally puffed up to an enormous extent, frightfully disfiguring the features.

The progress of the swelling varies; in general it is gradual, commencing early in the inflammation, and going on steadily increasing until the morbid action has attained its height; even then, however, it does not always stop, but often continues until the vessels have parted with their more fluid contents, which sometimes occurs only after the disease has begun to decline.

Occasionally, however, cases are met with where the swelling is most rapid and extensive, spreading, in a short time, over an entire limb, or even over the greater portion of the body. The best examples of this occurrence are witnessed in certain injuries, as compound fractures and dislocations, phlegmonous erysipelas, and the inflammation consequent upon snake-bite.

The swelling varies in its character; thus it may be soft or hard, transient or protracted, beneficial or injurious. A soft swelling is usually denotive of serous effusion; a hard one, of a deposit of fibrin, or of the more solid elements of the blood. A transient swelling is a more desirable event than a protracted one, as it is less likely to interfere with the restoration of function. Swelling often proves beneficial, inasmuch as the effusion upon which it depends is a means of depletion employed by nature to relieve inflammatory action; it answers, in fact, the same purpose as topical bleeding. When, however, the deposit is very large, or composed essentially of solid material, immense harm may be produced by it, from the manner in which it compresses the capillary vessels and interferes with the transmission of their contents; in other words, the effusion acts obstructingly, and thus causes fatal constriction. In swelling of the conjunctiva, technically called chemosis, the matter poured out often compresses the vessels of the cornea in such a manner as to induce gangrene of this membrane; and a like result occasionally follows phlegmonous erysipelas of the limbs and scrotum. Swelling may prove injurious in another way; by acting obstructingly, as in œdema of the glottis, which may cause death by preventing the ingress of the air into the lungs. A similar effect may be produced by inordinate tumefaction of the tonsils. A swollen perineum may compress the urethra and occasion retention of urine.

The immediate cause of swelling is twofold; first, engorgement of the capillary vessels, and secondly, and mainly, effusion of serum and fibrin; to which, in the more severe forms of inflammation, may be added pus and blood, the latter of which is sometimes poured out in considerable quantity.

4. *Heat*.—An increase of heat is one of the most common effects of inflammation, and hence a valuable symptom of the disease. A good illustration of this occurrence is observed in tonsillitis, gastritis, pneumonia, and the so-called fevers, in which there is often a remarkable heat of the breath; and also in many of the external varieties of inflammation, where the change is rendered apparent both by the sense of touch and by the rapid evaporation of our applications. The scalding tear in inflammation of the eye is an evidence of the same fact.

The degree of heat, emitted in the act of inflammation, has been supposed never to exceed that of the blood in the heart and large vessels. The researches of John Hunter would seem to countenance this opinion. He operated upon a man for the radical cure of hydrocele; the temperature of the vaginal tunic immediately after the withdrawal of the fluid being 92° . The cavity was now stuffed with lint, and the next day the thermometer stood at $98\frac{3}{4}^{\circ}$, thus showing an increase of six degrees and three-quarters, which must have fully equalled the heat of the blood in the heart and large vessels of the subject of the observation. In repeating the experiment subsequently upon a muscular wound in the side of a dog, and upon the vagina of an ass, irritated by a solution of bichloride of mercury, he found no difference whatever, before and after the occurrence of inflammation, in the temperature of the parts. Hence, he naturally concluded that the extrication of heat during the progress of this morbid process was either very slight, or altogether inappreciable. Observations, however, made since the time of the English philosopher, conclusively show that there is frequently, if not generally, a decided increase of temperature in the inflamed structures; and, although this increase may not

render the temperature of the part equal to that of the heat of the blood in the heart, yet it is none the less real and positive. It is well known that the outskirts of the body, as the feet, hands, and ears, are habitually cooler than the trunk, head, and upper portions of the extremities, because they have naturally a more feeble circulation; hence in inflammation, although their temperature may not reach 98° of Fahrenheit, yet if there be any elevation of heat over and above what these structures enjoy in the healthy state, it is to be considered as an actual augmentation. That this will generally be found to be the fact, in all the more severe forms of inflammation, my observations, many times repeated, fully convince me. In erysipelas of the skin of the trunk, in urinous infiltration of the scrotum, in acute abscess, in tonsillitis, orchitis, bubo, and other affections, I have again and again seen the mercury rise in the instrument above 100° , and in some instances even as high as 105° , 106° , and 107° . It has been ascertained that the oviduct of a frog ready to spawn is two degrees hotter than the heart; and Professor Dunglison has seen the temperature of the uterus during labor as high as 106° . From all these facts, to which others equally convincing might be added, if space permitted, it is impossible to avoid the conclusion that there is generally an elevation of heat in inflammation, in whatever part of the body it may be situated, provided the action which accompanies it is not too slight, or too limited in extent.

Our knowledge of the nature of animal heat is hardly sufficient to justify us in expressing an opinion regarding the cause of its increase in inflammation. It may be supposed, however, in the absence of positive information, that it is due to the friction which the blood experiences in its passage through the vessels, not only in the inflamed parts, but in the system at large, and also to the rapid manner in which the oxygen of the air unites with the red particles of this fluid as it is propelled along in its turbulent course. The influence of an accelerated state of the circulation upon the production of animal heat is well exemplified in what occurs in ordinary exercise when the feet are cold. A rapid walk, under such circumstances, in the open air, soon equalizes the circulation, and sends the blood, loaded with oxygen, to every part of the body, warming and fertilizing it as it rushes on. If a horse be rode swiftly round the race track his whole body becomes immensely heated, and his blood surcharged with fibrin and colorless globules; both evidently the result of the increased friction of the blood against the coats of the vessels, and the rapid union of the oxygen of the air with that fluid. Irritating applications, as spirits of ammonia, blisters, sinapisms, and embrocations, by inviting a preternatural afflux of blood to the affected part, produce an analogous effect, accelerating the circulation, and causing an elevation of temperature. Allusion has already been made to the fact that the uterus during parturition is much hotter than it is in the natural state; a circumstance which can only be explained by the supposition of an increased activity of its vessels approximating a state similar to that which obtains in inflammation, although not identical with it. During the growth of the antler of the deer and other animals there is always a marked elevation of temperature; and phenomena of a similar kind are often witnessed during the development of malignant and other tumors. All these circumstances bear directly upon the question under consideration, if they do not positively serve to establish its truth.

5. *Functional Disorder.*—Disorder of the functions of the affected part is in general a most important symptom, being often present when all, or nearly all, the other phenomena are absent. It manifests itself in various ways, as well as in various degrees; at one time in the form of increased sensibility or irritability, at another as a suppression, alteration, or augmentation of the

natural discharge, and now as an abolition of some special sense; at one time as the slightest possible departure from the normal action of the part, and at another as a total suspension of it.

An increase of *sensibility* is one of the most common effects of inflammation. In peritonitis, gastritis, and enteritis, the sensibility of the affected structures is often so great as to render the slightest pressure of the finger a source of profound distress; and it is for the same reason that, under such circumstances, the weight even of a sheet is sometimes almost intolerable. Similar effects are noticed in some of the external diseases, as in boil, carbuncle, erysipelas, and in inflamed hemorrhoidal tumors, which are frequently the seat of the most exquisite tenderness, hardly exceeded by that which attends an inflamed eye. Parts which are devoid of feeling, or nearly so, in the sound state, as ligaments, tendons, bone, and fibrous membranes, generally become exceedingly sensitive in inflammation. The change in question is of great importance in a diagnostic point of view, inasmuch as it generally enables us to distinguish readily between inflammatory and spasmodic affections, the latter of which, as before stated, are often immensely relieved by pressure, which never fails to aggravate the former.

An increase of *irritability* is a very constant phenomenon in all inflammations of muscular parts. In cystitis, one of the earliest and most prominent symptoms is a frequent desire to urinate, arising from involvement of the muscular fibres of the bladder; in gastritis, the irritability of the stomach is often so excessive that the organ is incapable of retaining the smallest quantity of fluid, however bland; and in dysentery, the greatest distress which the patient is obliged to endure, during the progress of that dreadful malady, arises from the incessant peristaltic action of the colon and rectum, the main seats of the morbid action. An increase of the contractility of the voluntary muscles is very common in fractures and dislocations, in severe sprains, and after amputations, usually manifesting itself in spasmodic twitchings, which often require large doses of anodynes for their suppression.

Again, inflammation has the effect of diminishing, or even completely suspending, the special function of an organ. In ophthalmia, the eye cannot look at objects, however dim; the moment the effort is made the lids contract spasmodically, and the smallest ray of light that impinges upon the retina is productive of the greatest distress. In inflammation of the ear the slightest noise, which, in the healthy state would perhaps not be perceived, or which might fall as delightful music upon the tympanum, becomes a source of deep distress; and the sense of hearing is almost destroyed by the buzzing and explosive sounds which succeed the morbid action. In coryza, the sense of smell is abolished; in inflammation of the skin the patient is deprived of the sense of touch; and in glossitis there is a loss of the sense of taste. In laryngitis the voice is at first merely altered in its character, but as the disease progresses the individual often becomes completely aphonic. In cerebritis there is generally delirium, followed, if the case passes on to suppuration, by convulsions and coma, the precursors of speedy dissolution.

Another prominent symptom of inflammation, one, indeed, which is seldom absent, is disorder of the *secretions*. Thus, in inflammation of the skin, there is suppression of the perspiration; in hepatitis, of the bile; in nephritis, of the urine. Or, instead of a total arrest of these and other secretions, important changes are effected in their composition, or in their physical, chemical, and microscopical properties. In pneumonia, the characteristic symptom is a rust-colored sputum, and in dysentery, a discharge of bloody mucus.

The function of *absorption* is often seriously impeded, if not completely arrested, in inflammation. The disorder, however, is generally much more conspicuous in the advanced than in the early stages of inflammation, in

which this process is sometimes executed, even with a certain degree of vigor, as is demonstrated by the facility with which morphia and other substances are carried into the system when placed upon the skin after vesication by cantharides, ammonia, or hot water. In the more violent grades of inflammation, the function is usually kept in a state of abeyance, the action of the absorbent vessels being arrested by the morbid deposits. Afterwards, however, as the disease declines, the function of absorption is gradually re-established, and then often proceeds with great vigor, rapidly removing the fluids effused during the earlier stages of the inflammation.

It is worthy of notice that while the absorbent vessels, when the inflammation is at its height, refuse to take up extraneous matter, as, for example, morphia or belladonna, and also effused fluids, they are often very busy in removing affected textures, and that even when they are of a very firm and resisting character. A familiar illustration of this occurrence is afforded in acute abscesses, the natural evacuation of which is frequently accomplished by the agency of the absorbent vessels, where the disease is most intense. In inflammation of the joints, cartilage and even bone often suffer extensively from this cause. There is no doubt that the pressure of the effused fluids always greatly influences and promotes the occurrence.

2. CONSTITUTIONAL SYMPTOMS.

Constitutional symptoms do not always attend inflammation. The morbid action may be so mild as to prevent its recognition by the system; it is strictly a local affection, and therefore causes no general resentment. But the case is very different when the disease is severe, or when, even if it is comparatively slight, it involves an important structure; then the whole frame feels its irritating effects, and evinces a strong interest in the impending struggle. The group of phenomena thus produced constitutes what is termed inflammatory, symptomatic, or sympathetic fever, and deserves consideration as expressive of the sum of suffering of each particular organ. The period which intervenes between the establishment of the inflammation and the occurrence of fever varies from a few hours to several days, depending upon the nature of the exciting cause, the condition of the patient, the intensity of the disease, and, above all, the importance of the organ attacked. Idiopathic inflammation is generally preceded by depression or a sense of lassitude and uneasiness, attended with headache, pain in the back and limbs, bad taste in the mouth, vitiated appetite, and slight chilliness, alternating with flushes of heat. Sometimes the patient is remarkably desponding, or annoyed with disagreeable dreams, and unpleasant forebodings respecting his recovery. He feels uncomfortably, both bodily and mentally, and has a disinclination to exertion. In a word, he is unwell, or in a state intermediate between health and sickness. These phenomena, which are merely the precursors of the fever, which is as yet only in a state of incubation, may be compared, not unaptly, to the fleeting clouds which precede the outbreak of a storm; they appear and vanish for a time, but finally coalescing, they assume their allotted station in the chain of morbid changes. When fully established, the fever never intermits so long as the cause which has produced it continues in operation; but it generally remits slightly in the morning, and sometimes, though rarely, twice in the twenty-four hours. The vesperal exacerbation usually sets in late in the afternoon, and persists, with but little alteration, until towards morning, when the excitement relaxes its hold, as if in need of temporary repose to meet the gradually recurring emergency. During the calm which is now present, the patient often falls into a refreshing sleep, his thirst and restlessness subside, and the skin is bedewed with a gentle perspiration. Soon, however, the smothered fire is rekindled, and

the same suffering has to be passed through as before, now, perhaps, augmented by the spread of the morbid action, and the development of new sympathies.

In order to comprehend fully the nature of inflammatory fever, it is necessary that the surgeon should personally interrogate, as it were, every organ of the body which may be supposed to evince any sympathy with the affected structures. This inquiry should, as a general rule, embrace an examination of the heart and arteries, the countenance, skin and extremities, lungs, tongue, stomach, bowels, liver, kidneys, and bladder, together with the state of the muscles, brain, and assimilative powers.

Derangement of the *vascular system* is chiefly denoted by the state of the pulse, the principal characteristics of which are frequency, hardness, fulness, strength, and quickness. The number of beats in a minute ranges from seventy, seventy-three, or seventy-five, the average standard in the healthy adult, to eighty-five, ninety-five, one hundred, or even one hundred and twenty, according to the intensity of the disease and the vigor of the constitution. A hard pulse is firm and resisting, rolling under the finger like a tense cord, and as if the blood were sent into it with extreme power; sometimes the artery thrills or vibrates, owing to a partial displacement synchronous with the contraction of the left ventricle of the heart. When the tension is unusually great, it is difficult, by any pressure we can apply, to obliterate the caliber of the vessel. Fulness has reference to the volume of the pulse, which feels as if the artery were expanded beyond its normal size. Strength implies a sensation of preternatural resistance to the finger; while a quick pulse is one in which each beat occurs with great suddenness or abruptness. This quality of the pulse is generally associated with frequency, from which, however, it differs essentially, as the latter has reference merely to the number of strokes in a given time, and not to the rapidity with which the vessel dilates and contracts under the finger. Several of these states of the pulse may be absent, and yet the case be one of great disorder of the vascular system. Their entire co-existence, in fact, is rare; perhaps the nearest approach to it is to be found in gout and rheumatism, hepatitis, pleurisy, splenitis, and the commencement of smallpox.

In the examination of the pulse, it is not to be forgotten that its action may be materially modified by the nature and seat of the inflammation and by the idiosyncrasy of the patient. In cephalic affections, the pulse is slow, full, and laboring, in consonance with the oppressed condition of the heart; in peritonitis, it is small, frequent, and wiry, sometimes, in fact, almost indistinguishable; and in acute inflammation attended with internal venous congestion, as in certain forms of fever and injury, it is obscure and apparently feeble, but generally rises under the effects of our remedies, or the natural powers of the system. Idiosyncrasy often singularly modifies the state of the pulse. I recollect a middle aged man, once my patient, whose pulse was habitually under forty; and still more remarkable examples of the kind have been witnessed by others. On the other hand, it may be abnormally frequent, beating constantly from eighty to ninety in the minute.

The above peculiarities, whether the result of morbid action, or of individual organization, derive a special value from the influence which they must necessarily exert upon our diagnosis and treatment. Thus, in peritonitis, if the practitioner were merely governed by the state of the pulse, without any knowledge of the condition of the system which causes it, he would be almost sure to administer stimulants instead of applying leeches and blisters; thereby feeding in place of diminishing the inflammation, and so hurrying on the fatal crisis. A pulse, habitually slow, might, in inflammation, hardly attain the normal standard of frequency, and yet the system might literally be consumed by symptomatic excitement. The surgeon, aware of the possibility

of such occurrences, is wide awake; and hence he is rarely, if ever, thrown off his guard, whatever may happen.

The *countenance*, in inflammatory fever, is usually flushed, and often appears unnaturally full, as if it were slightly tumid. The eyes are reddish, suffused, and frequently intolerant of light. The skin is hot and dry, perspiration being kept in complete abeyance; and the extremities are usually so warm and uncomfortable as to be unable to bear any covering. When the excitement is excessive, the sufferer generally finds it impossible to maintain the same posture beyond a few minutes; he tosses about from side to side, and from place to place, in search of a cool spot.

The *respiratory organs* freely participate in the general disorder. The inspirations are increased in frequency, and are usually performed with a certain degree of labor; various kinds of râles are heard, and cases occur in which there are well-marked evidences of venous congestion.

The *digestive organs* always suffer in inflammation, and therefore demand careful examination. The tongue is variously affected; sometimes red and almost clean, but generally loaded, either with a whitish, yellowish, or brownish fur, contracted, and somewhat reddish at the tip and edges; nearly always dry, and easily protruded, though often a little tremulous, especially when the accession occurs in a person of nervous temperament. The taste is vitiated, or entirely arrested, the salivary secretion is suppressed, a thick, dark-colored mucus adheres to the lips, gums, and tongue, and there is a disagreeable arid feeling in the fauces and œsophagus. The thirst is intense, and can hardly be appeased by the most frequent and abundant draughts; the appetite, on the contrary, is usually destroyed, and hence the patient often loathes food, in whatever form it may be presented to him. Nausea and a sense of gastric oppression, sometimes attended with bilious vomiting, are common attendants. The bowels are generally constipated, or alternately constipated and relaxed, distended with gas, and somewhat tender under pressure; the alvine evacuations being fetid, and variously altered in color and consistence. Along with this condition of the digestive tube there is usually more or less disorder of the liver, manifesting itself in excess, deficiency, or vitiation of its secretion. Such a condition is very apt to be present in symptomatic fever consequent upon accidents and idiopathic inflammation in malarious districts. In what manner, or degree, the functions of the pancreas are affected in this disease, we are ignorant. The probability, however, is that it suffers very much in the same way as the salivary glands of the mouth, which it intimately resembles in its structure and uses.

Among the more marked changes produced by inflammation are those in the *renal secretion*. These changes relate chiefly to the quantity, color, and consistence of the fluid. In the normal state, the average quantity of urine, in the twenty-four hours, is from thirty-five to forty-two ounces; but in inflammatory fever it often does not reach one-half or even one-third this amount. Moreover, instead of being of a clear amber hue, as it naturally is, it is commonly of a deep red tint, and surcharged with an unusual quantity of extractive matter, mucus, and lithic acid; the latter of which always falls to the bottom of the receiver, in the form of brick-colored sediment. The specific gravity of the secretion is also very much increased, and the odor is often quite offensive from the presence of various kinds of animal substances. During the height of very acute inflammation, the fluid is often slightly albuminous, and even pervaded by tubular casts. The chlorides, on the contrary, are commonly remarkably diminished, especially when there is much exudation with a tendency to cell growth. The excretion of the fluid is very much as in health, though occasionally it is greatly increased in frequency. In traumatic inflammation, as after fractures, dislocations, and amputations,

the bladder is occasionally so much paralyzed as to require the aid of the catheter for the expulsion of its contents.

The *muscles* are generally the seat of great discomfort in this form of fever. Already, during the stage of incubation, the patient is harassed with a sense of lassitude, stiffness, and aching or darting pains, which, gradually augmenting in severity, at length constitute a real source of suffering. The pains in the lumbar region are particularly violent; they are always worst at night, and are often so intense as to deprive the patient completely of sleep. His back feels as if it would break into pieces, as if it were being sawed in two, or as if it were bruised, and mashed, and comminuted. Not unfrequently every joint is racked with pain, and the whole body is so exquisitely sensitive as to be intolerant of the slightest motion, pressure, or manipulation. It is this distress in the muscles that causes the patient such weary and painful nights, and which induces him to exclaim in the evening, "Oh that it were morning!" and in the morning, "Oh that it were evening!"

The suffering of the *brain* is evinced by a peevish and irritable state of the mind; by loss of sleep; by disagreeable dreams; and by occasional fits of delirium. In many cases, there is more or less perversion of special sensation; as is proved by the distracting noises in the ears, the intolerance of light, the vitiated taste and smell, and the impairment of the touch.

Finally, the *assimilative* powers being in abeyance, the body becomes gradually emaciated, and the strength fails in proportion to the impoverished condition of the blood and solids.

Such is the ordinary course of events in inflammatory fever. If the morbid action does not go on too long, or if the patient has unusual powers of resistance, he may be able to weather the storm, and finally come off conqueror. The disease, and, along with it, the fever which it has produced, will now gradually subside, the occurrence being announced by a diminution of the patient's restlessness, anxiety, and thirst, by a restoration of the moisture of the skin and mouth, and, in short, by a decided improvement in the condition of all the secretions. The sleep becomes more natural and refreshing, the appetite returns, the pulse descends to its normal standard, and the mind regains its natural equilibrium. The cessation of the fever often declares itself by the occurrence, either sudden or gradual, of a profuse sweat, to which the older pathologists applied the term critical, and by a general unlocking of all the secretions. In a word, the clouds which had so long obscured the horizon are once more succeeded by sunshine; disease has vanished, and health is regaining its supremacy.

If, on the other hand, the disease progresses, a downward tendency is gradually witnessed of evil, if not fatal portent. The symptoms, losing their inflammatory type, now assume a *typhoid* character; the pulse becomes weak, soft, and frequent, beating from one hundred and thirty to one hundred and sixty in a minute; the countenance assumes a peculiar shrunken aspect, denominated hippocratic; the surface is bedewed with clammy perspiration; the extremities are inclined to be cold; the tongue is dry and covered with a brownish or blackish fur; sordes collect upon the teeth; hiccough and twitching of the tendons supervene; and there is rapid emaciation, with corresponding failure of the strength, and low muttering delirium. Recovery is still possible, although doubtful; a well-directed plan of treatment, or even nature's unassisted efforts, may be sufficient to shake off the oppressive load, and enable the part and system to triumph over the ravages of the disease.

But typhoid fever is not always a necessary consequence of the inflammatory; it may, and often does, exist as an independent affection, coming on early in the attack, perhaps almost immediately after the commencement of the morbid action, and maintaining throughout a well-marked asthenic type. The most common cause of such an event is severe shock or loss of blood,

occurring in an unhealthy, broken state of the system, or actual blood-poisoning, from the absorption of pus, or the operation of some specific virus, as that of malignant pustule, or that generated in the dead human body, and received by inoculation in dissection. In the more severe grades of erysipelas and carbuncle, the fever soon assumes an asthenic character, whatever may have been its type in the first instance, the system being speedily overwhelmed by the depressing influence of the morbid agent.

The occurrence of typhoid symptoms early in an idiopathic, specific, or traumatic inflammation, always portends evil, as it is necessarily denotive of great and rapid waste of life-power, which neither medicine nor food can, perhaps, successfully counteract. The nervous system is deeply involved in the morbid process; the blood is gradually deprived of its plastic properties; and, nutrition being at a stand, the body soon becomes pale, emaciated, and withered. The mind is early affected, and typhomania is generally a prominent symptom throughout. The vital forces diminish more and more, the patient, engaged in constant muttering, picks at the bedclothes, has hic-cough and twitchings of the tendons, and is so weak as to be unable to support himself upon his pillow. Exhaustion, in fact, is extreme, and a few hours generally suffice to close the scene.

There is another form of fever which is often seen during the progress of inflammatory affections, and to which the term *irritative* has been not inaptly applied, as it is generally met with in persons of a nervous, irritable temperament or habit of body. The best idea that can be given of it is that it bears the same relation to the nervous system that inflammatory fever, properly so termed, sustains to the vascular; that is, the fever is characterized in the one case by irritability, or excess of sensibility, and in the other by plethora, or redundancy of vascular action. We find, accordingly, that in irritative fever there is a lively perception of pain, and an unusual exaltation of sensibility, both of the part and system; the mind is peevish and fretful, easily dissatisfied, and often filled with despondency and unpleasant foreboding; the pulse is quick, jerking, small, and sometimes wiry; sleep is imperfect and disturbed by frightful dreams; the skin is hot, dry, and difficult of relaxation; the extremities are inclined to be cold; and there are frequently nervous rigors, followed by marked reaction, and great restlessness; severe suffering is generally complained of in the loins and muscles; the slightest noise and light are a source of offence; and the head is distracted with severe pain, which often assumes a neuralgic character, and thus becomes a cause of great distress.

There are some low forms of inflammation in which the attendant fever nearly always assumes this peculiar type, being present almost from first to last. A good example of it is afforded in dissection-wounds, in certain injuries of the skull and brain, in phagedenic ulceration, in hospital gangrene, in sloughing chancres and buboes, and in tertiary syphilis, in nervous debilitated subjects.

3. CHANGES OF THE BLOOD IN INFLAMMATION.

That the blood, which plays so important a part in the economy in health, should be seriously altered in its properties in inflammation is what might, *à priori*, have been anticipated, and what observation has fully established to be a fact. Sent with increased force and rapidity through every portion of the body, however constituted, or however remote from the heart; subjected to new actions and new affinities in the suffering structures, as if it were exposed to the heat of a laboratory, and deprived, in a great degree, of the stimulus of the oxygen of the air, it is not surprising that it should be almost totally changed in its physical, chemical, and vital properties. The

most important alterations which the fluid experiences relate to the fibrin and colorless globules, the quantity and number of which are always materially increased in every well-marked case of inflammation. To form a proper estimate of the extent of these alterations it will be necessary to inquire, for a moment, into the relative quantity of these ingredients of the blood in the healthy state.

In healthy blood the proportion of fibrin to the entire mass is as 3 to 1000; in inflammation, however, it is generally very much increased, ranging from 6 to 8, from 8 to 9, and from 9 even to $10\frac{1}{2}$, according to the intensity of the disease and the general powers of the system. In what proportion the colorless globules are augmented in inflammation we are uninformed; that their number is materially increased is sufficiently obvious, but whether the change, in this respect, is as great as in the fibrin, is still undetermined. In addition to this increase in their number there is a manifest augmentation of their bulk, as well as of their cohesive properties, thereby greatly promoting their tendency to adhesion to each other and to the sides of the vessels, which, as will be seen by and by, forms so striking a phenomenon in well established inflammation.

This excess of fibrin and white globules, which is generally observable at an early period of the inflammation, goes on gradually increasing until the morbid process has attained its maximum, when it begins to decline, and finally altogether disappears with the causes that induced it. Although it is most conspicuous in the higher grades of inflammation, there are few cases in which it is wholly absent, unless the disease be so slight as to be incapable of producing any serious structural changes, or material embarrassment in the force and rapidity of the circulation in the part and system. Gout and rheumatism, pleuritis, pericarditis, pneumonia, hepatitis, splenitis, arteritis, and acute articular affections usually exhibit it in a marked degree. It is also present, but less conspicuously, in inflammation of the skin, cellular tissue, and mucous membranes. What is singular, it also exists in the blood in the latter months of utero-gestation. Where or how this excess of fibrin and colorless globules is developed is still a mooted question, which further observation alone can solve. It may be supposed, in the absence of satisfactory information, that it takes place in the arteries, in consequence of the manner in which the blood is agitated in passing through the different parts of the body, its various ingredients being forcibly pressed and rubbed against each other, and against the sides of the vessels by the increased powers of the heart. Thus a species of disintegration is brought about, which doubtless adds very greatly to the already existing excitement both of the part and of the system. The idea that attrition of the blood against the walls of the arteries is mainly instrumental in the production of the change in question derives support, of a very plausible, if not of a positively confirmatory character, from what is observed when a horse is subjected to severe exercise upon the turf. If he be bled after having been ridden very rapidly round the track, it will be found that there is a great increase of fibrin and colorless globules, in consequence, apparently, simply of the increased momentum of the circulation, and the friction which the blood has experienced in its passage through the vessels, especially the arteries. Now this is precisely what occurs in inflammation; the greater the excitement of the heart, or, what is the same thing, the more intense the morbid action, the greater will be the amount of fibrin and white globules, and the reverse.

This increase of fibrin and white globules is attended with inordinate contraction of the crassamentum, and a separation of the red particles, leading to the formation of what is called the *buffy coat* of the blood. This consists in the appearance of a whitish, bluish, or tallow-like pellicle, upon the top of the crassamentum, which begins to show itself the moment the blood com-

mences to coagulate, and attains its greatest height after the process of consolidation has been completed. Its thickness and density are greatly influenced by internal and extrinsic circumstances, as the state of the system, the intensity of the disease, and the manner in which the blood is drawn. In some instances it is a mere film, while in others it forms a layer several lines in thickness; its density is also subject to considerable diversity, being at one time very feeble, and at another very firm, so much so, indeed, as to offer a good deal of resistance to the finger. When the blood is much impoverished by protracted disease, long abstinence, or unwholesome food, the buffy coat is generally very thin, soft, dirty, and iridescent, forming a striking contrast with the characters which it exhibits in plethoric states of the system.

Various extraneous circumstances materially influence the formation of the buffy coat. Of these the most important, in a practical point of view, are the shape and capacity of the receiver, the size of the stream, and the motion to which the blood is subjected in its passage from the vein. It has been ascertained that the phenomenon is most readily produced when the fluid falls into a deep and rather narrow vessel, and when it issues from a large orifice, at the rate of from two to three ounces in the minute. If the blood runs very slowly, or in a tiny stream, or, if the stream, although quite bold, is received into a cold or shallow basin, it will either not form at all, or so very imperfectly as to be scarcely appreciable. Sometimes the blood is merely sizzly, the fibrin resting upon the top of the cruor like a bluish and imperfectly developed film.

Chemically considered, the buffy coat is found to consist essentially of fibrin, in combination with albumen and earthy salts. In fact, it is perfectly identical with the plastic matter that is deposited in inflammation upon the free surfaces and in the interstices of the organs. By a little care it may easily be detached from the upper surface of the crassamentum; and, if it be well washed in cold water and then immersed in alcohol, it will assume not only the peculiar buff-colored aspect, whence it derives its name, but also a dense, firm consistence, the two properties assimilating it rather closely in its physical characters to the substance of the unimpregnated uterus.

Of the manner in which the buffy coat is formed we are unable to offer any very satisfactory explanation. It was formerly supposed that it was owing to the more tardy coagulation of the blood, thereby permitting the red particles to disengage themselves from the fibrin and to sink, by their greater

specific gravity, to the bottom of the crassamentum. But this was evidently a mistake; for it is now well ascertained that inflammatory blood, instead of solidifying more slowly than healthy blood, generally concretes very rapidly and firmly, thus impeding instead of favoring the development of the buffy coat. The most recent opinion upon the subject is that the occurrence is due to a vital repulsion between the fibrin and red particles; or, what amounts essentially to the same thing, to an unnatural aggregation of these bodies, which, acting like a sponge, force out the fibrin from among them before the general mass of the blood is fully coagulated. Whether this explanation is correct or not, it is certain that the formation cannot occur at all without a previous disunion of the principal constituents of the fluid, thereby predisposing them to the event in question. To ascertain whether this tendency to the development of the buffy coat exists it is not

Fig. 1.

Microscopic diagram, showing the reticulated arrangement of the corpuscles in inflammatory blood. In the upper part, normal ordinary aggregation is shown in contrast.

necessary to make use of a spoliative bleeding, but simply to draw a few drops of blood, and to look at it with the microscope, which will at once detect the slightest deviation from the normal standard. The red corpuscles will be observed to run almost immediately into clusters of piles or rouleaux, as represented in fig. 1.

In certain forms of inflammation and conditions of the system the blood is not only buffed, but cupped; that is, the upper surface of the crassamentum exhibits a hollow appearance, as if it had been scooped out with a knife. This occurrence usually denotes a higher degree of morbid action than the mere presence of naked fibrin on the top of the clot, and yet it is not unfrequently witnessed under circumstances which render it very questionable whether there is any inflammation at all, as in anemia, in profuse evacuations from the bowels, skin, and kidneys, in scurvy, and in chlorosis. It is generally not easy to account for such anomalies, but of their practical import every practitioner must be fully aware. In my private collection is a beautiful specimen, which I obtained many years ago from bleeding a young man laboring under pleuro-pneumonia, in which both the buffed and cupped appearances exist in a marked degree on both surfaces of the crassamentum. The adjoining sketch, fig. 2, affords a good illustration of the preparation.

Buffy and cupped blood, from a preparation in the author's collection.

4. INTIMATE NATURE OF INFLAMMATION.

In the definition of inflammation, given in the early part of this chapter, no attempt was made to specify its true character or essential nature. To have done so would have been premature; but now that we have studied its various local phenomena and traced its constitutional effects, we are fully prepared to enter upon the subject, and to ask the question, What is inflammation?

To answer this question in an intelligible and satisfactory manner, it is necessary to consider, 1st, the nature of the capillary vessels, in which the morbid action is mainly carried on; 2dly, the character of the blood, which, as already seen, is so singularly changed in this affection; 3dly, the part played by the nervous system, or, perhaps, more properly speaking, by the nerves of the affected structures; and 4thly, the condition of the tissues at the seat of the disease.

The capillaries are those minute canals which are everywhere interposed between the arteries and veins, of which, in fact, they are only so many continuations. That their structure is similar to these vessels is analogically extremely probable, although it is doubtless somewhat modified to enable them to fulfil their various duties, since they are not merely designed as channels for the transmission of the blood, but also as organs for the elaboration of various kinds of fluids, as those of nutrition and secretion. With regard to their caliber, these vessels are divisible into two classes. The one embraces those minute tubules which, though invisible to the naked eye, are

found, when microscopically examined, to be capable of carrying a continuous stream of blood, so as to give the part in which they are situated a red appearance. The other group includes those delicate vessels, the cavity of which is so small as to admit only a single globule at a time, and which it is often difficult to detect even with a strong magnifier.

The blood, as it circulates through the body, and immediately after it has been drawn from a vein of the arm, has the appearance of a homogeneous fluid; but a careful examination shows it to consist of numerous component elements, intended for widely different purposes in the economy. Coagulation separates it into two parts, one of which is solid, and hence called the crassamentum; the other is fluid, and named the serum. The crassamentum consists of a pale, whitish, transparent fluid, known as the blood-liquor, plastic matter, plasma, or coagulating lymph, and of minute particles, globules, or corpuscles, entangled in it and suspended by it as the blood is passing the round of the circulation. The particles are of two kinds, the red and the colorless; the former, which have long been familiar to anatomists, and which impart to the crassamentum its red hue, are exceedingly abundant, and vary in size from the $\frac{1}{3000}$ to the $\frac{1}{3600}$ of an inch in diameter; they are of a flattened, globular shape, and their office seems to be to absorb oxygen from the atmosphere and to convey it to the different parts of the system, for the purpose of invigorating its several organs and tissues. The colorless or pale corpuscles have only been recently discovered; their number is very limited, except in certain forms of disease, when it is much increased; they are round, much larger than the red, and finely granulated on the surface, thus giving them a rough appearance. What the precise office of the white corpuscles is has not been determined, but it seems probable that it is connected, in some way, with the process of nutrition, which is also the case, only more certainly, with the blood-liquor, which is essentially associated with this operation.

In the vessels of the living body, the white globules seem to have no disposition to mingle with the red; on the contrary, they keep in close contact with the inner surface of the vessels, coasting, as it were, slowly along in the blood-liquor, outside of the general current. The red particles, on the other hand, pass quietly and gently along the centre of the vessels, regardless, so to speak, of the colorless, and in a much more rapid and lively manner, without any adhesion to each other, to the white particles, or to the coats of the containing vessels.

The essential elements of the inflammatory process, so far as we are able to comprehend them, are, 1st, slight contraction of the capillaries, with a retardation of the flow of blood; 2dly, dilatation of these vessels and an increased rapidity of the circulation; and, 3dly, a quiescent state of the capillaries with complete stagnation of their contents. While these changes are going on in the interior of these vessels, important changes are wrought in the blood, both in regard to its consistence, its color, the arrangement of its globules, and the character of the plasma. Finally, the coats of the vessels are themselves seriously altered, being rendered preternaturally soft and fragile, and therefore temporarily incapable of transmitting the vital fluid. These various changes are so important as to demand for each separate consideration.

If a drop of rectified spirits, or any slight stimulus, be applied to a capillary vessel in the web of a frog's foot, or the wing of a bat, the effect will be to cause slight contraction of its caliber, with a partial arrest of its contents, the particles of blood moving to and fro for a few seconds, when they will be observed to regain their proper course, and to pass on as if nothing had occurred. If the irritation be more severe, as when a drop of tincture of capsicum is applied, the vessel, instead of diminishing, is instantly dilated,

or, if there be any contraction, it is so slight and transient as to be inappreciable by the sight. However this may be, the dilatation soon becomes marked and decided, as is proved by the fact that the vessel now carries a much larger quantity of blood than in the natural state, the red particles being sent into it in increased numbers, as well as with increased force and velocity, evidently in consonance with the augmented action of the heart, which, beating perhaps from ninety to one hundred and ten in the minute, throws the blood with extraordinary impetus into the inflamed part.

The disease advancing, the dilatation of the vessels steadily and regularly augments, until, at length, its tunics having been expanded to their utmost, the artery becomes a mere passive tube, palsied and crippled in its action, and therefore not only incapacitated for transmitting its contents, but for performing any of its more delicate functions as an organ of nutrition and secretion.

In the condition now described, the capillary is not only distended to its utmost, but it is distinctly elongated and tortuous, sometimes almost knotty, as if it were affected with aneurismal enlargements, or real varices. Its coats are also preternaturally soft and lacerable, from intermolecular changes in their structure.

The blood, which is the immediate cause of this dilatation, is literally impacted in the vessel, pressing everywhere upon its sides, and thus causing, by degrees, complete remora, or stagnation. The white and red particles, instead of pursuing an orderly, quiet, and independent course, as in the natural state, are now observed to be more or less intermixed; and such is the manner in which they are crowded together, that both are materially changed in their shape, being irregularly flattened, elongated, and distorted, as well as adherent to each other and to the sides of the vessel. When there is complete stoppage, the distinction between the two sets of globules is entirely lost, the blood forming a stagnant pool, of a dark, homogeneous aspect.

These various changes, which are brought about gradually, not suddenly, may be studied with great advantage in what occurs in inflammation of the conjunctiva. If this membrane be irritated, as, for example, by the contact of a foreign body, there will be an immediate rush of blood to the part, thus causing a great seeming increase of its vascularity. In a few minutes hundreds of vessels, previously invisible, will be seen shooting out in different directions, and connecting themselves with the sides of those that appeared in the first instance. These are not new channels, but old ones appertaining to the second class of capillaries, rendered evident by the intromission of red particles, which, in the healthy state, pass along in so slow and gradual a manner as to elude detection.

It is not to be supposed that the globules of the blood, as they are sent by the heart into the irritated arteries, are able, all at once, to pass through them without any difficulty. Instead of this, after having proceeded a certain distance, they rebound against themselves and the sides of the vessels, so as to undergo a kind of oscillatory movement; but, gradually yielding to the force exerted upon them from behind, they are urged onward and onward until they reach the corresponding veins, into which, as their caliber is much larger than that of the arteries, they rush as into a vortex, and instantly disappear in the current beyond. A similar oscillatory movement of the globules of the blood is observed when the circulation is about to be re-established after it has been completely arrested. Some time is required for the detachment of these bodies, and when they have finally succeeded in effecting this, instead of passing on at once into the corresponding vein, they are propelled forward and backward until the diseased arteries have become sufficiently dilated to admit of their escape.

The dilated condition of the vessels is well seen in the accompanying cuts,

representing the two ears of a rabbit, one in the natural state, and the other in a state of inflammation, from the application of cold. They were injected simultaneously, and consequently with the same degree of force, with size colored with vermilion. Fig. 3 is the natural ear; fig. 4, the inflamed one. The contrast is striking. The vessels of the latter are not only much larger

Fig. 3.

Natural ear of a rabbit.

Fig. 4.

Inflamed ear of a rabbit.

and more tortuous than in the former, but also apparently much more numerous; the main artery in the one is likewise greatly increased in size, while in the other, namely, the natural one, it is quite small.

But it requires no experiments upon the inferior animals to prove the existence of increased vascularity in inflammation; the remarkable change in the color of the part is sufficient evidence of the fact, to say nothing of the circumstance that, if an incision be made into it, the blood will gush out in much larger quantity than from a similar cut in the corresponding healthy structure.

When the morbid action is fully established and very intense, without, however, there being as yet complete cessation of the circulation, the contents of the affected vessels not unfrequently break through their softened and lacerable walls, occasioning thus a real extravasation of blood, as seen in fig. 5, representing a magnified portion of inflamed serous membrane. Sometimes, again, although rarely, the blood escapes from the vessels, and, forcing its way through the cellular tissue, forms new channels, through which it afterwards continues to circulate.

Fig. 5.

Extravasated blood in an inflamed serous membrane.

Immediately around the seat of the greatest intensity of the morbid action, marked congestion exists, and the blood, consequently, passes along very slowly, and with difficulty. Beyond this point the phenomena are somewhat different; the excitement is less considerable, but still sufficient to cause active vascular determination; the blood moves in a continuous stream, and with extreme velocity, but unable, as it approaches the focus of the inflammation, to make its way through the stagnant tubes, it is sent onward through collateral channels, now for the first time fairly opened for its reception. Thus it will be seen that, while at the centre of the morbid action stagnation occurs, and around this a sluggish circulation prevails, an increased activity is going on in its neighborhood. The arteries leading to the affected part are distended, and pulsate strongly, but not, as some have asserted, with preternatural frequency.

The changes produced in inflammation are admirably depicted in fig. 6, from Bennett, representing a portion of the web in the foot of a young frog,

Fig. 6.

after having been irritated by a drop of strong alcohol; it is magnified two hundred diameters, and exhibits a deep-seated artery and vein, somewhat out of focus, with capillaries running over them, the whole being interspersed with pigment cells. On the left of the figure the circulation is in its normal state; at the centre it is retarded, the vessels are crowded with corpuscles, and the column of blood is oscillating; on the right there is deep congestion, with exudation: *a* represents the vein, occupied by dark blood, moving more slowly than in the artery, and running in the opposite direction; the lymph space on each side is filled with yellowish plasma, and contains a number of colorless corpuscles, some clinging to the sides of the vein, others moving tardily along; *b* represents the artery, with a rapid current, permitting nothing to be seen but a reddish-yellow broad streak, with lighter spaces at the sides. Opposite *c*, a vessel has given way, and caused an extravasation of blood, resembling a brownish-red pool. At *d*, there is complete congestion; the corpuscles are closely adherent to each other and to the sides of the vessels, which they entirely fill, being one semi-transparent reddish mass. The intervascular spaces are abnormally thick and opaque, and occupied by exudation.

The part played by the *nerves* in inflammation is very imperfectly understood. It is evident, however, that it is very important, although we are unable to define its character, or specify its degree. In traumatic inflammation, as well as in many cases of the idiopathic form of the malady, the primary impression is probably nearly always made upon the nerves, from which it is immediately reflected upon the capillary vessels, inducing, at first, contraction, and then dilatation, of their caliber, with a preternatural influx of blood, and, finally, an increase of color. The sensibility of the part being awakened, the heart is instantly roused into action, followed by serious disturbance of the circulation at the seat of the morbid impression, as if nature were making an effort to shake off the cause of the disease. It is this occurrence that generally gives the patient the first intimation of the impending mischief; the nerves, resenting the encroachment, apprise the brain, or cerebro-spinal axis, of the attack, and the consequence is that the heart, acting with unusual vigor, throws an undue quantity of blood into the suffering structures. If this explanation be correct, it follows, almost as a neces-

sary sequence, that inflammation, instead of being, as has sometimes been imagined, a process of perverted nutrition, is in reality merely an attempt on the part of the affected tissues to rid themselves of some hurtful impression. All the rest of the process is easily understood; the discoloration, swelling, pain, heat, and disordered function, being merely so many links in the chain of morbid action.

As the inflammation increases in intensity, the nerves actively participate in the morbid process, their substance becoming injected, softened, compressed, and otherwise altered, in conformity with the peculiarity of their structure and function. The effect of such a change upon the welfare of the affected textures must be extremely pernicious, as it must materially diminish the nervous current, if not entirely arrest it, and thus weaken and prostrate the vital powers of the part.

The joint agency of the nervous and vascular systems, in the production and maintenance of inflammation, has been happily illustrated by the researches of modern physiologists. It has been ascertained, for example, that, when the ophthalmic branch of the fifth pair of nerves is divided in the cranial cavity of a rabbit at the Varolian bridge, inflammation is speedily lighted up in the surface of the eye, eventuating in opacity of the upper segment of the cornea. What is still more remarkable is, that, when the nerve is cut on the petrous portion of the temporal bone, so as to involve the ganglion of Gasser, the resulting irritation is not only more violent, but much more deeply seated and deplorable, the consequence being complete disorganization of the organ.

Analogous effects follow the division of the pneumogastric nerves. When these cords are cut high up in the neck, the lining membrane of the air-passage assumes a dark color, the lungs are engorged with black blood, and an abundance of serosity is poured out into the parenchymatous texture, as well as into the pulmonary vesicles and the minute branches of the bronchiæ. The pleura generally participates in the irritation, and there is almost always more or less inflammation of the stomach, with a suspension of the secretion of the gastric juice.

Animals in which the brachial plexus of nerves has been tied are soon seized with inflammation of the integuments of the remote parts of the limb, which gradually progresses until all the soft structures are invaded by gangrene. A friend of mine removed a section of the peroneal nerve on account of a neuroma; the wound was long in healing, and two of the small toes sloughed before the patient recovered. These facts enable us to explain certain circumstances that have long been noticed by practitioners in particular morbid states of the system. A part affected, for instance, with palsy is much less capable of withstanding the ordinary impressions of physical agents than one receiving its customary supply of nervous influence. A burn in a paralytic person creates much more serious mischief than in one that enjoys perfect health; and the same is true in regard to blisters and other irritants, the injudicious application of which often leads to the destruction of large portions of the skin and subjacent cellular tissue. There is little doubt that the inflammation of the bladder, which always supervenes upon serious injury of the spinal marrow, is caused in the same way; that is, by the interruption of the natural supply of the nervous influence.

In whatever manner parts are deprived of their nervous influence, it is presumable that they are brought under relations somewhat analogous to those of a frozen limb. The temperature is lowered, the sensibility impaired, the process of nutrition perverted; in a word, the natural connection between the vessels and nerves is broken up, and hence that series of phenomena known under the name of inflammation.

The *tissues* at the seat of the inflammation, considered apart from the ves-

sels and nerves which are distributed through them, and which, as has been seen, play such an important part in the morbid process, are variously altered, becoming not only the recipients of various deposits, but experiencing, especially in the advanced stages of the disease, marked softening, and sometimes also fatty degeneration, the latter being more particularly liable to occur when the morbid action is tardy, and rather below the ordinary acute standard. The principal deposits are serum and lymph, either alone or in union with pus and blood. When these products are very abundant, there will necessarily be much swelling, and the consistence of the parts will be soft or hard, according to the structure of the affected tissues and the nature of the effusions.

A careful study of the inflammatory process leads to the conviction that, in its earlier stages, it is one of increased action, both of the capillary vessels and of the tissues through which these vessels pass, and of which, consequently, they form a most important integral part. Microscopical and clinical observations clearly prove the truth of this statement. Subsequently, however, when the disease is fully established, when the vessels are crowded to excess with blood, and when this fluid manifests a tendency to stagnation, or when stagnation has actually occurred, there is every evidence of decided debility. The capillaries are now partially paralyzed, and distended to the utmost with non-oxygenated blood; the different tissues are surcharged with inflammatory products; nutrition, secretion, and absorption, are interrupted, or completely suspended; in short, everything is indicative of enfeeblement and prostration.

Moreover, the tissues involved in the inflammatory process soon evince a disposition to become disorganized, and to undergo the fatty degeneration, especially if they are loaded with plastic deposits. The earliest indications of these changes are the confused appearance of the affected structures when viewed with the microscope, and the presence of minute globules of oil scattered through their substance. If the fibrinous matter is spoiled, or transformed into pus, the quantity of oil greatly increases, and the tissues acted upon by the absorbents and by chemical influences are liquefied and destroyed. If, on the other hand, it becomes organized, the parts are in danger of falling into a state of atrophy, being partially robbed of their nourishment, and choked as vegetables are choked by weeds.

Much discrepancy exists among writers and teachers in regard to what constitutes inflammation; some, among whom I include myself, believing that but a slight degree of action is necessary, while others maintain that the departure from the healthy standard must be very great. Thus, Dr. Miller, Professor of Surgery in the University of Edinburgh, declares that true inflammation, properly so called, is always attended with suppuration; apparently forgetting that thousands of human beings daily die from this affection, long before it has attained this crisis. Dr. John H. Bennet, another eminent Scotch professor, makes fibrinous exudation the indispensable condition of the process; and he goes so far even as to propose the word exudation as a substitute for that of inflammation. For myself, I cannot see that such a change of nomenclature would have any other effect than that of confusing the mind of the student; the term is ill chosen, and cannot, therefore, advantageously replace one which, although merely conventional, is yet sufficiently expressive for practical purposes. But there is still a more serious objection to the adoption of this word, and that is, that it does not convey a correct idea of the nature and extent of the morbid process. Dr. Bennet, and those who think and reason with him on the subject, must be aware that there are inflammations of certain organs and tissues in which the morbid action is so great as to destroy life, and yet the most careful examination, microscopical and chemical, fails to detect the existence of fibrin

in the affected structures. It is only necessary to instance the arachnoid membrane, the aponeuroses, cartilages, and nerves, in which this disease is often, if not generally, unattended by a deposition of fibrin. But while it is certain that inflammation is frequently present, and that, too, to a serious extent, without fibrinous exudation, it is equally true that this substance is usually poured out in this disease, especially if it has already made considerable progress. Much will necessarily depend upon the nature of the affected organs and tissues, some furnishing plasma much more readily, and in much greater quantity, than others. Moreover, it requires very nice judgment, particularly in the living subject, to define the boundaries between congestion and inflammation, or to determine where the one terminates and the other begins. Inflammation, in its inceptive stages, may be compared to a latent or smothered fire, kept in abeyance by a redundancy of surrounding material interfering with its development; exudation cannot occur all at once, some time is necessary to prepare the vessels for their new office; so it is with the flame in the furnace, it does not break forth immediately on the application of the kindling, and yet no one would say that fire was not actually present. Most of the disputes that have grown out of this question have arisen from a misunderstanding on the part of observers as to the amount of disease, or change in the affected part, necessary to constitute inflammation; and it is obvious that there never can be any fixed or settled views upon the subject so long as this is the case; nor can the question be satisfactorily disposed of, unless it be studied with reference to the nature and functions of the different organs and tissues of the body; or, if I may use the expression, the conduct and habits of the organs and tissues in their healthy and morbid relations.

Another source of difficulty, in the settlement of this question, is the fact that many pathologists are seemingly incapable of divesting themselves of the idea that inflammation must necessarily be treated by depletion, particularly by the lancet and leeches, purgatives and starvation. It is apparently impossible for them to disconnect the two things, and yet it requires but little reflection, and certainly no great amount of experience to show the erroneousness of such a conclusion. Cases of inflammation are daily met with which imperatively demand the use of stimulants from their very commencement; and it is not going too far to assert that there is a period in almost every attack of the disease, if at all severe, in which the patient will be greatly benefited by the use of brandy, wine, quinine, and nutritious food.

Professor Virchow, of Berlin, whose cellular pathology is now attracting so much attention, asserts that inflammation is not a real entity, or a process everywhere identical in its character, as has been so often alleged, but a process essentially similar to other morbid actions, differing, in fact, from them only in its form and course. He believes that irritation is to be considered as the starting-point in inflammation; for it is impossible, he remarks, to conceive of such an occurrence without the application or intervention of some hurtful stimulus. The principal sources of this irritation are three—the functional, nutritive, and formative—the first playing, as he imagines, the least important part in the process.

"If, therefore," to use Virchow's own language, "we speak of an inflammatory stimulus, we cannot properly intend to attach any other meaning to it than that, in consequence of some cause or other external to the part which falls into a state of irritation, and acting upon it either directly, or through the medium of the blood, the composition and constitution of this part undergo alterations which at the same time change its relations to the neighboring structures, whatever may be their nature, and enable it to attract to itself and absorb from them a larger quantity of matter than usual and to transform it according to circumstances. Every form of inflammation with which we are

acquainted may be naturally explained in this way. With regard to every one, it may be assumed that it begins as an inflammation from the moment that this increased absorption of matter into the tissue takes place, and the further transformation of these substances commences."

Virchow discards the idea that hyperæmia, or vascular turgescence, is present at the commencement of inflammation, alleging that, in certain parts, as the cornea, the cartilages and tendons, in which no vessels exist, the changes produced by this morbid process are in no respect different from those in the vascular structures. He also, as will be seen by and by, asserts that fibrin is not a transudation from the blood-liquor, but a direct product of the inflamed structures brought about by a change in their condition, and by the local metamorphosis of matter.

5. TREATMENT OF INFLAMMATION.

Two leading indications present themselves in every case of inflammation when sufficiently grave to demand interference. The first is the removal of the exciting cause of the disease; the second, the establishment of resolution.

In regard to the first of these points, it is obvious that, although the disease may be modified in its character, or rendered comparatively harmless, by treatment, yet it will be impossible to arrest it completely so long as the exciting cause is operative. Thus, for example, in strangulation of the bowels, it would be folly to expect to establish resolution of the inflammation which the strangulation has produced, without the removal of the stricture which is the cause of the morbid action. In such a case, one of two things must happen; either the sufferer must die from the effects of the disease, or he must be relieved by the knife, or by nature's operation, that is, the formation of an artificial anus. An inflammation of the lungs from the presence of a foreign body in the air-passages cannot be effectually cured so long as the foreign body remains, and keeps up the morbid action. The same thing is true in relation to inflammation of the bladder from hypertrophy of the prostate gland. The gland, acting obstructingly to the flow of urine, is the cause of the cystitis, and just so long as the cause remains will the disease continue, although, as remarked above, it may be materially modified by our therapeutic measures. But it does not follow, on the other hand, that the inflammation shall at once subside because the cause which produced it has been removed. The malady may have already made so much progress as to render the restoration of the part either impracticable, or possible only after a long time and after much suffering. In our attempts to get rid of the exciting cause by mechanical means, it is hardly possible to exercise too much care and gentleness, or to institute them too early. All officious interference, rude probing, or rough manipulation, must be carefully avoided, lest we add, as it were, fuel to the flame, aggravating and perpetuating the disease. Splinters, nails, needles, pieces of bone, are gently extracted with the finger and forceps; the calculus is cut out of the bladder; the speck of steel is picked from the cornea; and the aching tooth is lifted from its socket; all in as gentle and easy a manner as possible.

It is not always, however, that the exciting cause of the malady can be detected, even if we avail ourselves of all the lights furnished us by modern research. Very frequently the cause is latent, the morbid action having, to use a very common but unphilosophical expression, arisen spontaneously. Such an occurrence is, of course, impossible; there is always a cause for every disease, though it is not always in our power to discover it; and hence to wait for its removal before we begin our treatment might sadly endanger both part and patient.

The second indication is to establish resolution or to disperse the morbid action, with the least possible detriment to the structures and functions of the diseased parts. To effect this, various remedies may be necessary, some being addressed to the general system, others directly to the affected parts: circumstances which have given rise to the division of the treatment of inflammation into constitutional and local.

I. CONSTITUTIONAL TREATMENT.—The constitutional treatment of inflammation consists of bloodletting, cathartics, emetics, depressants, mercurials, diaphoretics, diuretics, anodynes, and the antiphlogistic regimen. It must not be supposed, however, that all these means, or even a majority of them, are necessary in every case of this disease; so far from this being true, the morbid action often disappears spontaneously, or under the mildest and simplest remedies. Whenever constitutional treatment is demanded, it should be employed as early as possible, and with a determined hand, in the hope of being able to arrest the inflammation while it is yet in its inception, and, consequently, before it has made any serious inroad upon the part and system. A few doses of medicine, judiciously administered at the outbreak of the disease, often do more good than twenty administered after it has attained its full development.

1. *Bleeding*.—General bleeding may justly be regarded as standing at the very head of the list of the constitutional remedies for inflammation, as it is at once the most speedy and the most efficient means of relief. The blood is usually drawn from one of the larger veins, and is permitted to flow until a decided impression has been made upon the system. When we consider the singular changes which this fluid undergoes in inflammation, the fact that it is sent in an unusually large quantity to the affected parts, and the circumstance that it is mainly instrumental in supporting the powers of the heart, it will not be difficult to form a correct idea of the importance of this operation, or the influence which it exerts in combating morbid action. Its value was not over-estimated by the older writers when they designated it as the *summum remedium* in the treatment of inflammation; yet, strange to say, bloodletting, notwithstanding the high rank which it has always occupied, as an antiphlogistic agent, has, of late, fallen very much into disrepute, particularly on this side of the Atlantic, where it had at one time so many advocates. A great change has come over the profession, in this respect, within the last fifteen years, and is steadily gaining ground, subverting all our preconceived notions upon the subject, and rendering it very questionable, in the opinion of many, whether bloodletting is really ever required as an antiphlogistic. Whether this change has been the result of a modification of the type of disease, of a more improved method of treatment with other remedies, or simply of the whim and caprice of a few prominent and influential practitioners, from whom the rest of the profession have imbibed their views, I am unable to assert, but the fact does not admit of a doubt that more quarts of blood were formerly spilt than ounces are spilt now. Bleeding is no longer the fashion; the operation is denounced by every one. Public sentiment has got to an extreme upon the subject, and we may therefore soon look for a reaction in favor of the opposite opinion. For myself, I cannot but regret this state of things, because I feel satisfied that it does not rest upon a just and proper basis. If we formerly bled too much, too frequently, too copiously, and too indiscriminately, it is equally certain, at least to my mind, that the operation is not often enough resorted to at the present day. Many a deformed limb, blind eye, enlarged spleen, and crippled lung bear testimony, in every community, to the justice of this remark.

General bleeding is employed with different views. In the first place, it

diminishes plethora; secondly, it changes the qualities of the blood, or, more correctly speaking, it places it in a better condition for resisting the effects of inflammation; thirdly, it weakens the powers of the heart and nervous system, and, consequently, the momentum of the circulation; and, lastly, it promotes the action of other remedies.

To obtain these effects in the most prompt and thorough manner, the blood should be taken from a large orifice in a large vein, the fluid running in a bold, full stream to the amount of at least three ounces in the minute, the patient being either seated upon a chair or standing up at the time. If the operation is performed while the patient is recumbent, a much larger quantity will be required to be drawn before the system and part become sensible of the loss. When the object of the bleeding is merely spoliative, or intended to rob the vessels of an unusual amount of their contents, it may be done in this way; but even then the better plan will be to bleed in the semi-erect position, reopening the vein a second and even a third time, if premature syncope should take place to interfere with the requisite abstraction. The difference in the effect of these two methods of bleeding is forcibly exemplified in conjunctivitis. The patient who is bled in the erect position soon begins to feel faint, and to experience relief from pain, the eye at the same time exhibiting a blanched appearance, instead of the scarlet hue which it had a moment before; whereas the one who is bled in the recumbent position will retain his strength for a much longer time, and when, at length, he is rendered unconscious, the inflamed surface will be found to be still comparatively discolored. The impression, moreover, will generally be much more permanent in the former than in the latter, and the return, consequently, of the capillary injection more slow and less perfect.

The circumstances which call for this operation are generally considered to be a hard, strong, full, and frequent pulse, a plethoric state of the system, and great intensity of morbid action. When such a conjunction exists, the surgeon cannot possibly go amiss in regard to the abstraction of blood, constitutionally considered. He may, perhaps, it is true, combat the disease without such recourse; by the use of antimony, purgatives, and other means, he may gradually bring down inordinate excitement, and thus afford the affected structures an opportunity of throwing off the burden with which they are oppressed; but if he wishes to make a prompt and decided impression, spoliative and depressive, upon the system and part, he can accomplish his object much more readily and effectually with the lancet than with any other remedy in the whole catalogue of antiphlogistics. If nauseants depress the heart's action equally with the lancet, they certainly do not produce the same effect in unloading the engorged capillaries at the seat of the inflammation, in restoring the circulation, and in reclaiming morbid structure. The operation of the one is gradual, and, at times, almost imperceptible; of the other, prompt and decisive, often cutting down the disease with a single blow; or, at all events, leaving it in a condition to be afterwards easily dealt with by other and more simple means.

When bleeding is required, the earlier it is performed the better. Ten ounces of blood taken at the beginning of an attack of inflammation will usually do more good than four times that quantity drawn after the disease is firmly rooted. Indeed, when a part is once overburdened with deposits, the salutary period for general bleeding may be considered as passed; for, although the operation may aid in reducing the force of the heart, and in promoting the action of other remedies, yet it certainly does not exercise the same happy influence upon the capillary vessels at the seat of the disease.

The quantity of blood drawn at a single operation must vary according to circumstances, the object being effect, and not ounces; for what would be a large bleeding for one person might be a small one for another. From

sixteen to twenty ounces is a good average loss. Some individuals faint almost as soon as the blood begins to flow, while others can scarcely be made to faint, no matter how they are bled, or how much blood is drawn. The best plan, therefore, always is to continue the operation until it has made a decided impression both upon the nervous and vascular systems, avoiding actual syncope, but inviting an approach to it, and then guarding against the danger of excessive reaction.

We now and then hear of enormous quantities of blood being removed for the cure of inflammation. The memoirs of the French Academy furnish us with instances where three hundred ounces were abstracted within a week; and equally remarkable examples are recorded among British writers. The late Dr. Francis, of New York, while laboring under a violent attack of croup and tonsillitis, was bled to the extent of nearly two gallons and a half in a few days. Such cases are remarkable as showing the wonderful power of endurance of the system, but they are not to be held up as examples for the imitation of the practitioner. It must be understood, however, that inflammation often engenders a tolerance of bleeding. Thus, a nervous person who in the healthy state will faint from the loss of a few ounces of blood, will, when laboring under severe inflammation, bear with impunity the loss of perhaps ten times that amount. A similar tolerance of remedies is frequently established by disease. In delirium tremens, opium may be given in doses that would destroy half a dozen healthy persons; in pneumonia, the stomach acquires an extraordinary degree of tolerance for tartar emetic; and in certain forms of syphilis mercury may be given in large quantities without salivation, the system being seemingly insusceptible of its influence.

The first effect of a loss of blood upon the system is a sense of muscular debility. Presently, the individual begins to look pale, to see indistinctly, to have a confusion of ideas, to perceive noises in his ears, and to feel light in the head. If the flow be not immediately stopped, he will next become deadly sick at the stomach, convulsive tremors will pervade his limbs, the pallor of the countenance will increase to a deadly white, the respiration and pulse will nearly cease, and, if he is not supported, he will fall down in a state of unconsciousness. He has fainted. Such an effect is sometimes produced by the loss of a drachm of blood; at other times not until many ounces have been drawn.

To recover a person from this condition, he must be immediately placed in the recumbent position, cold water dashed upon the face, and a free access of air obtained by throwing open the doors and windows of the apartment, aided, if necessary, by the fan. If he is slow in regaining his consciousness, the body is raised a little higher than the head, hartshorn is held near, not to, the nose, and sinapisms are applied to the extremities and the precordial region. Sometimes a draught of cold water will do more in reviving the patient than anything else. If, from idiosyncrasy or excessive loss of blood, the syncope assumes an alarming character, a stimulating enema is used, and mustard applied along the spine; but no stimulants are given by the mouth, unless it is certain that there is still some power of deglutition.

The reaction which succeeds the stage of depression is characterized by a gradual return of the various functions of the body to their natural condition. Color reappears upon the cheeks, the heart and lungs act with more energy, the limbs regain their warmth, the surface often becomes slightly moist, and the mind recovers from its confusion. The only treatment necessary, during this stage, is proper vigilance, lest the reaction should become too vigorous; depression being rather favored, when the morbid action is at all severe, than rapidly relieved.

When the loss of blood has been disproportionably great to the powers of

the system, the stage of depression may be succeeded by death, or reaction may at length occur, the struggle for many hours, perhaps, being one of life and death. This state may be induced by one copious bleeding, or by several small ones, establishing an undue drain upon the vital current. It is characterized by unusual pallor of the countenance, feeble pulse and respiration, coldness of the extremities, clammy perspiration, frequent sighing, great thirst and restlessness, vigilance, and a tendency to delirium. While the system is in this condition, local congestion, followed by inflammation, is not uncommon, the organs which are most prone to suffer being the brain, the arachnoid membrane, and the lungs. Sometimes the symptoms here described are mixed up with those of feeble reaction, and the countenance, perhaps, is flushed, the eye and ear are intolerant of light and noise, the respiration is quickened, the skin is hot and dry, and the pulse is thready, hard, and frequent. The proper treatment does not vary essentially in the two cases, our main reliance being upon opiates in full doses, milk punch, ammonia, and quinine, with elevation of the head and cold applications, exclusion of light and noise, and blisters, if there is marked tendency to local determination. Further bleeding would only cause further sinking.

In the abstraction of blood various circumstances are to be taken into consideration, among which the most important are the age, temperament, and habit of the patient, the character and progress of the disease, the structure and functions of the affected organ, and the peculiar constitution of the atmosphere.

As a general rule, young and robust individuals bear bleeding much better than children and aged persons, who often experience great exhaustion from the loss even of a few ounces. Old subjects, in particular, are prone to suffer in this way, the system being often a long time in reacting, while in not a few instances the operation is followed by sinking. Infants and children are also slow in recovering from the effects of bleeding, but reaction having taken place there is much less danger of ultimate exhaustion. Persons of a nervous temperament are less tolerant of the loss of blood than the sanguine and bilious. Corpulent persons are bad subjects for the lancet, and the habitually intemperate are often thrown into delirium tremens by it. The inhabitants of densely crowded cities do not bear the loss of blood nearly as well as people residing in the country. In epidemics, as erysipelas, scarlatina, smallpox, measles, and puerperal fever, bleeding in any form is generally inadmissible. Finally, the abstraction of blood must be practised with the greatest circumspection in all cases of inflammation likely to be at all protracted, and in all persons suffering under grave accidents, as fractures, dislocations, and lacerated wounds, attended with danger of excessive drainage and hectic irritation. After operations and injuries, excessive loss of blood may seriously interfere with the restorative principle.

The more violent the inflammation is, the more reason will there be, other things being equal, for early and active bleeding; so also if the organ affected be one highly essential to life. Blood is seldom taken when the inflammation is inconsequential as it respects its degree and seat, milder means generally sufficing for its subjugation.

In regard to the repetition of the bleeding, the practitioner must be governed, first, by the intensity and persistence of the morbid action; secondly, by the importance of the organ attacked; and, lastly, by the state of the blood. The disease continuing with little or no mitigation, there will be the same reason for bleeding that there was in the first instance, and the last may now, perhaps, be borne much better, the previous abstraction having, it may be, engendered a certain degree of tolerance. Intensity of action will be an additional reason for the act. The importance of the organ attacked must not be overlooked. An inflamed lung requires more energetic measures

than an inflamed skin, and an inflamed skin than an inflamed finger. As it respects the buffy coat of the blood, its value as a sign of the necessity of a repetition of the operation has already been pointed out, and need not, therefore, be again discussed here. Associated with a persistence of diseased action, and a vigorous state of the circulation, it is of some practical importance, but much less than was at one time supposed.

2. *Cathartics*.—Cathartics constitute a most important class of remedies in the treatment of inflammation, being even more valuable than bleeding, because of their almost universal applicability. Their exhibition, however, should always be premised by the abstraction of blood, provided the nature of the case is such as to admit of it. Where this is contra-indicated, they may be given at once, and there are few diseases which fall under the province of the surgeon in which they will not prove eminently beneficial. They are usually divided into purgatives and laxatives, which differ from each other merely in the one being more active than the other. The distinction, however, is not without its importance in a practical sense.

Cathartics, considered as antiphlogistic agents, are employed for different purposes. In the first place, they may be administered simply to evacuate the bowels; secondly, to deplete the mucous membrane, and thus diminish the quantity of blood in the system; thirdly, to excite the action of the liver and mucous follicles; fourthly, to produce a revulsive effect, or to set up a new action at a distance from the original one; and, finally, to stimulate the absorbents, thereby inducing them to remove inflammatory deposits.

The importance of exhibiting cathartics as mere evacuants cannot be too strongly insisted upon when we consider that an overloaded state of the bowels is one of the most fertile sources of disease. Many of the so-called idiopathic inflammations evidently owe their origin to this cause, as is proved by the fact that a dose of active purgative medicine often promptly removes them, especially if administered at the commencement of the attack. An incipient ophthalmia, tonsillitis, or fever, is frequently cut short in a few hours simply by clearing out the contents of the bowels, and getting rid of irritating fecal matter and vitiated secretions. Besides, as long as the bowels are constipated, it is impossible for other remedies to produce their specific effect, or for the various secretions to recover their natural tone.

Secondly, this class of remedies proves useful in depleting the bowels, by abstracting the serous portions of the blood from the vessels of the mucous membrane, and thereby diminishing the quantity of fluid in the general system. This practice is often beneficially adopted in inflammation of the large intestine, in what is termed dysentery, and in the milder forms of inflammation in various parts of the body, where the loss of the red particles of the blood is of questionable propriety. An ounce of Epsom salts, or half a pint of citrate of magnesia, will often bring away from eight to twelve ounces of serum from the bowels in the course of a few hours, with the greatest advantage as it respects the morbid action.

Cathartics may be given, in the third place, with a view to stimulate the liver, pancreas, and mucous follicles of the bowels. There are few inflammations, or diseases of any kind, in which disorder of the liver does not play a conspicuous part, either in exciting or maintaining the morbid action. The quantity of fluid poured out by this organ, in a state of health, in the twenty-four hours amounts to many ounces, and it is, therefore, not difficult to form a tolerably correct idea of the ill effects that must result from the interruption, modification, or complete suspension of its functions. The irritating material which it is destined to eliminate being retained in the blood, there must arise, as a necessary consequence, serious derangement of the nervous and vascular systems, as denoted by the excessive lassitude, headache, ex-

cited pulse, and other symptoms, so conspicuous in disordered states of the liver. But a diminished supply of bile is not the only difficulty; on the contrary, the fluid may be secreted in unnatural quantity, and yet, being vitiated in quality, the effects will hardly be less obvious. The pancreas, too, may have its functions deranged, which the well directed cathartic may readily restore to their normal condition. Of the vast influence exercised upon the health by the mucous follicles of the alimentary canal, it is hardly possible to form an adequate conception. Existing, as they do, everywhere in vast numbers upon the mucous surface, the suppression of their functions, even for a short time, cannot fail to be followed by local inflammation in different parts of the body, or the material aggravation of it, if it has been already lighted up. Hence, remedies calculated to restore, modify, or improve the secretions of these several structures constitute important objects of treatment, not only as preventives, but as means of cure.

Fourthly, the administration of cathartics proves useful in another way, namely, on the principle of revulsion, metastasis, or counter-irritation, by establishing a new action in a part more or less remote from that originally affected. During the action of a brisk purgative, as well as for some time after, a larger amount of blood flows to the alimentary canal than is natural to it, and the consequence is that the suffering organ is temporarily relieved of vascular turgescence, on the principle that two morbid processes cannot go on, to any extent, at the same time. This action may be intermittent or permanent, according to the character of the cathartic and the mode in which it is exhibited. In inflammation of the head, throat, and, in fact, of the supra-diaphragmatic portions of the body generally, this principle is never, for a moment, lost sight of by the practitioner, constituting, as it does, a most important element of treatment.

Finally, cathartics, by clearing out the alimentary canal, and restoring the secretions, pave the way for the more successful action of other remedies, as diaphoretics, anodynes, diuretics, and sorbefacients. They exert, in this respect, very much the same influence, only in a slighter degree, as venesection and leeching, diminishing the volume of the circulating mass, and diverting the blood from the suffering organ. Removing obstruction, restoring secretion, and establishing new action, they enable the absorbent vessels to recover from their torpor, and to render themselves useful in removing inflammatory deposits.

Cathartics are particularly valuable in inflammations of the brain and its membranes, of the eye and ear, the throat, respiratory organs, the liver, skin, and joints. In gastritis, enteritis, peritonitis, cystitis, wounds of the intestine, and strangulated hernia, they are either contra-indicated, or exhibited with the greatest possible circumspection, and only in the mildest forms. In most, if not in all, of these affections, the best purgative is the lancet, aided by large anodynes, either alone or in union with calomel. Tranquillity, not perturbation, is what is sought to be attained under such circumstances, on the principle that whatever excites peristaltic action must prove prejudicial to the inflamed surface.

Cathartic medicines must not be exhibited merely with a view to the correction of disordered alvine evacuation. Such a procedure could not fail to prove injurious. The action of these remedies is perturbing, and therefore subversive of healthy function; hence, it would be folly to expect that the passages should be entirely natural so long as they are exhibited. The more frequently they are given the more likely will this be the case.

When these medicines act tardily, their operation may be aided by injections; and cases occasionally occur where the latter remedies may advantageously, and entirely, take the place of the former.

The number of purgatives and laxatives is very great, and the surgeon

may therefore give himself considerable latitude in the choice of his articles. A few, however, either alone, or judiciously combined, will answer his purpose in nearly every case that may come under his observation. Where a merely evacuant effect is desired, nothing is better than a dose of castor oil, rhubarb, or jalap; the saline cathartics produce watery passages; calomel, blue mass, and gray powder act specifically upon the liver; and where an irritating, revulsive, or metastatic effect is wished for, the proper articles are compound extract of colocynth, scammony, gamboge, and aloes. In external inflammations, as well as in inflammations of the supra-diaphragmatic organs generally, one of the most useful cathartics, as I have found from long experience, is an infusion of senna, or of senna and Epsom salts. It operates not only promptly and powerfully upon the bowels, but also upon the liver, stimulating this organ to increased action, and proving itself hardly inferior, in this respect, to calomel and blue mass. The only objection to it is that it is apt to gripe, but this tendency may usually be effectually counteracted by combining with it some carminative. Croton oil is rarely used, except to relieve obstinate constipation. It will hardly be necessary to say that the greatest caution is required in its administration.

Injections, clysters, or enemas may be prepared of various articles, as gruel and common salt, water and mustard, castor oil, spirits of turpentine, infusion of senna, jalap, and other substances, according to the intended effect. Whatever material be used, the important rule is to mix with it a sufficient quantity of fluid, warm or cold, to distend the lower bowel. It may be administered, as I usually prefer, with a common pewter syringe, having a long nozzle, and capable of holding at least from sixteen to twenty ounces; or, where there is obstinate constipation, with an ordinary stomach tube. Recently an excellent enema-syringe has been manufactured of gum-elastic, of the same shape as the old metallic one, only much superior in its mode of action, and much more easily kept in repair. Whatever instrument be employed, care must be taken that the patient be placed upon his side or belly during its introduction, and also that he be properly held, for fear of accident, especially if he be delirious or otherwise unmanageable. Professor Pope, of St. Louis, published, some years ago, the particulars of a case of a child that perished from perforation of the rectum during the administration of an enema.

3. *Mercury*.—The reputation of mercury, as an antiphlogistic, has long been established. Although the precise mode of its action is still imperfectly known, its beneficial effects are well understood. Its virtue in controlling inflammation is hardly inferior to that of the lancet and of tartar emetic, while, during the decline of the disease, as a powerful sorbefacient, or promoter of the removal of morbid deposits, it is without a rival in the materia medica. It may, therefore, be given during the height of the malady with a view of arresting its progress, and subsequently, after this object has been accomplished, for the purpose of getting rid of effused fluids, or reclaiming oppressed and disorganized structure. The efficacy of the remedy, in both these relations, is particularly conspicuous in the phlegmasias of the fibrous and fibro-serous tissues, in gout and rheumatism, synovitis, carditis, arteritis, hepatitis, splenitis, pneumonia, laryngitis, iritis, orchitis, osteitis, and in syphilis. It is less apparent, though not without its value, in inflammation of the brain, the skin, and mucous membranes, bronchitis, nephritis, cystitis, and metritis.

It is rarely that the treatment of inflammation is commenced with the exhibition of mercury. It is only in very urgent or neglected cases that this rule is departed from, its potency and activity being always augmented by previous depletion. Whenever, therefore, there is evidence of plethora, bleeding and purgation should precede its use. There is a mercurial point,

so to speak, in inflammatory affections, prior to which the employment of this remedy either proves positively injurious, or greatly disappoints expectation. This point is characterized by softness of the pulse, a relaxed condition of the skin, moisture of the tongue, and a general tendency to restoration of the secretions. Administered during the height of the morbid action, when the whole system is enveloped, as it were, in flame, it can hardly fail to act as an irritant, and to increase the general excitement. For want of attention to this rule, a great deal of mischief is often done, and a remedy, otherwise of inestimable value, permitted to fall into disrepute.

Of the manner in which mercury acts in relieving inflammation we have, as already intimated, no very definite information. That it affords powerful aid in controlling the action of the heart and vessels, both large and capillary, is unquestionable, but how this effect is produced, whether by any direct sedative impression it may exert, or by merely correcting the secretions, is a point concerning which our knowledge is entirely at fault. Nor is our information any more reliable in regard to the changes which mercury induces in the state of the blood. We know very well how greatly the properties of this fluid are modified by inflammation, what increase there is of fibrin and white globules, and how promptly, in many cases, these changes are corrected by the judicious use of mercury; but in what manner this is effected is, in the present state of the science, altogether inexplicable. The therapist may speculate about these things as much as he pleases; he may invent theory after theory, and entertain us with the most elaborate and ingenious arguments, and yet he will utterly fail to throw any real and substantial light upon them. In a matter so abstruse as this experience alone can guide us, and this ought surely, for all practical purposes, to be sufficient.

During the decline of inflammation, and, indeed, in many cases long after the morbid action has been completely checked, the exhibition of mercury is of the greatest advantage in effecting riddance of the morbid products. Of the manner in which this is done we have occasionally direct ocular demonstration in some of the external phlegmasias. Thus, in iritis, if the system be placed under the influence of mercury, the effects of the remedy are rendered obvious by the daily progress which the affected structures make in freeing themselves of the plastic matter that was effused during the height of the inflammation, and which frequently proves so destructive to them by the changes which it induces in the pupil. Similar effects are witnessed in inflammation of the cornea, attended with interstitial deposits. The opacities which result from these deposits often vanish in a short time under the influence of slight ptyalism, the effect being frequently apparent before the action of the medicine is fairly developed. In orchitis, after the disease has measurably subsided, the swelling and induration in general promptly disappear under the use of mercurials, aided by rest, light diet, and purgatives. In all these, and similar cases, the beneficial effects of the agent are evidently due to its sorbefacient properties, or to the manner in which it stimulates the absorbent vessels, compelling them to remove the products left by the previous action.

Administered merely as a sorbefacient, the effects of this remedy are often insensible, its action being exerted in a very slow and gradual manner, yet hardly any the less efficiently. This kind of action is particularly desirable in chronic diseases, attended with a crippled condition of the tissues from semi-organized deposits, and an enfeebled state of the general system. Under such circumstances, active mercurialization is altogether inadmissible, from its irritating and prostrating effects; while a more gentle and persistent course is often followed by the greatest benefit, the gums being merely touched, or rendered slightly red, tumid, and tender, as an evidence of the silent operation of the remedy.

The best form of exhibition of the remedy is calomel, blue mass, or mercury with chalk. Where a prompt and powerful impression is desired, as when there is high inflammatory action, likely to prove speedily overwhelming in its effects, not only threatening structure but life, the medicine should be given in large and frequently repeated doses, so as to keep up a decided and well-sustained influence. For this purpose the best article is calomel, in doses of from three to five grains, administered every three, six, or eight hours, until we have attained the object of its exhibition. When the case is at all urgent, as, for example, in croup, pneumonia, or carditis, no time is to be lost; whatever is done must be done quickly, with a bold, vigorous hand, and a determined mind; the remedy must be given in full, not in small, insufficient quantities, or in a faltering, hesitating manner. There is but a short step between the disease and the grave, the struggle is one of life and death, and the victory must be accomplished, if accomplished at all, at all hazard, present or future. When the disease is less violent, or the organ involved less important to life, the medicine is exhibited in smaller doses, and at longer intervals, and then, too, instead of calomel, the milder forms may be used, as blue mass, or the gray powder. Where a chronic or insensible impression is desired, the bichloride may be given instead of calomel or blue mass, or the latter may be employed in smaller doses. Other forms of mercury, to be mentioned hereafter, as the iodide, cyanuret, and deuto-phosphate, are often beneficially prescribed in chronic disease of the skin, in glandular enlargements, in chronic affections of the joints, and in tertiary syphilis. Mercury with chalk, or gray powder, is a great favorite with some practitioners in inflammatory diseases of children and aged persons; but I now rarely use it in any case, having frequently found it to be nauseating, and generally too uncertain to be worthy of reliance.

To prevent the mercurial from running off by the bowels, it is usually necessary to combine with it a certain quantity of opium, as a fourth of a grain, half a grain or even more, with each dose, according to the exigencies of each particular case. In children, and in all cases affecting the brain, opium should be given with great caution, especially during the violence of the morbid action. When the skin is hot and dry, the mercurial should either be entirely withheld until further depletion has been accomplished, or it should be combined with some diaphoretic, as tartar emetic, ipecacuanha, or Dover's powder. Griping, which is so liable to occur during the progress of the treatment, should be counteracted by carminatives and the use of laxatives, as oil, salts, or magnesia.

It need hardly be said that the administration of so potent a remedy as mercury should be most faithfully watched. No honest or judicious practitioner uses it heedlessly or sakelessly. He knows that it is a remedy for good or for evil, and he therefore employs it wisely and properly; opportunely, not out of time. As soon as he discovers, by the fetid state of the breath, the red and tumid appearance of the gums, the metallic taste, and the increased flow of saliva, that the object of its exhibition has been attained, he either omits it altogether, or gives it only in very small quantity, and at long intervals. He does not persist in its administration, as was the custom with our silly forefathers, until the tongue is too big for the mouth, the teeth drop from their sockets, articulation, deglutition, and even breathing, are almost impossible, and the countenance presents a distorted and hideous aspect; but he simply touches the gums, maintaining the impression thus made, if necessary, on account of the continuance of the morbid action, or letting it die out, if the disease has been arrested.

There are certain individuals who, in consequence of idiosyncrasy, or the former use of mercury, cannot take this medicine, even in the smallest quantity, without being violently salivated. To avoid such an occurrence, which

is always exceedingly disagreeable both to patient and practitioner, inquiry should always be made with a view to the ascertainment of this fact, in every case, previous to the administration of the medicine. On the other hand, there are persons who cannot be constitutionally impressed with mercury, however largely it may be used, under any circumstances. They are completely mercury proof. It fails to enter the system in any form, combination, or mode of exhibition. In such cases, and also when the system is not as prompt in responding to the use of the medicine as is desirable, the article should be conjoined with some nauseant, as ipecacuanha or tartar emetic, with a view to more thorough relaxation of the system. The operation of the medicine may also be aided with frictions of mercurial ointment upon the groin, the inside of the thighs, the arm, and axilla, thrice in the twenty-four hours, for fifteen minutes at a time, the inunction being performed near a fire with the hand well protected with a pair of gloves, otherwise the assistant may salivate himself long before he succeeds in affecting the patient. From one to two drachms of the ointment will suffice at each application. Employed in this way, the effect is sometimes more rapid than when the medicine is given internally, though the constitutional impression is more mild and evanescent. The practice, however, is a very filthy one, and on that account is seldom resorted to by the modern practitioner.

There are circumstances which altogether contra-indicate the use of mercurials in almost any form. Most of the horrible effects which are so often witnessed in this country, especially in the southwest, where this medicine is more liberally administered than in any other section of the United States, are, I am satisfied, entirely attributable to the reckless and indiscriminate manner in which the article is given in all states of the system, and in every possible variety of circumstance. Persons of a strumous habit of body, the old, the infirm, the ill-fed, the badly-clothed, and the anemic, are particularly prone to suffer from the use of mercury, even when exhibited only in small quantity. It is in subjects of this description, more especially, that we so frequently witness those frightful ravages of the mouth, teeth, jaws, and cheeks, that have almost led to the creation of a new department of surgery for their relief, and which have thrown so much discredit upon the profession in certain regions of the United States.

Finally, when salivation sets in, the best remedies are astringent gargles, cooling laxatives, emollient applications to the face and neck, and the liberal use of anodynes, to allay pain and nervous irritation. The lotion that I have found to answer better than any other is a solution of Goulard's extract, in the proportion of one drachm to eight ounces of water, used every hour or two, the only objection to it being that it discolours the teeth, an effect which, however, soon disappears of its own accord. Gargles of alum, tannin, copper, zinc, and other astringent substances also prove beneficial, especially if not employed too strong. When the inflammation runs very high, leeches to the throat and jaws may become necessary; and it may even be required to scarify the tongue, to prevent suffocation.

The best internal corrective of salivation is the chlorate of potassa, administered in doses of from fifteen to thirty grains three or four times a day, in a large quantity of sweetened gum-water, or lemonade, to render it more soluble. This medicine seems to act with peculiar efficacy upon the digestive organs, and may often be advantageously resorted to as a prophylactic during the exhibition of mercury. It may also be beneficially employed as a gargle, from one to two drachms being dissolved in a pint of water, and the solution used every two or three hours. In very intractable cases of ptyalism, an emetic of ipecacuanha, morning and evening, will often answer when almost everything else has failed.

4. *Emetics*.—Emetics are not as often used now as they were formerly in the treatment of inflammation, their employment having been, in great measure, superseded by cathartics and other evacuants. Their exhibition, at the present day, is limited almost exclusively to cases in which there is marked gastric and biliary derangement, as denoted by the nausea and vomiting, the headache, lassitude, and aching of the back and limbs which sometimes so greatly oppress the patient in the earlier stages of his illness. When these symptoms are present, and there is no contra-indication, an emetic often acts like a charm, not only ridding the stomach of irritating matter, but allaying vascular excitement, promoting perspiration, and, in fact, unlocking all the secretions. Emetics are, of course, not used in the phlegmasias of the sub-diaphragmatic organs, as gastritis, enteritis, peritonitis, hepatitis, and cystitis, for the reason that the concussion caused by their action would inevitably prove injurious. For the same reason they are withheld in wounds of the intestines, hernia, fractures, and dislocations. In cephalic and cardiac affections they should also be carefully avoided.

The best forms of administration are tartar emetic, and ipecacuanha; common salt, alum, and ground mustard, also occasionally answer a good purpose, their effect being generally prompt and efficient. Whatever substance be employed, its use should always be followed by large draughts of tepid water, chamomile tea, or infusion of valerian, the latter being particularly beneficial in nervous and hysterical subjects. As a general rule, tartar emetic should never be given, on account of its sedative and irritating effects, to very young children and to persons who have become enfeebled by age and disease.

5. *Depressants*.—Depressants, or nauseants, are justly entitled to a high position in the scale of antiphlogistic agents. As their name implies, they are remedies which, by lowering the action of the heart, lessen the momentum of the circulation, and diminish the flow of blood to the affected tissues. This, however, is not the only good which they are capable of doing; by the impression which they make upon the nervous and sanguiferous systems, they become instrumental in re-establishing and improving the secretions, and in thus indirectly controlling the morbid action. There is, in fact, not a single organ which does not feel, to a greater or less extent, their influence, or which is not brought, more or less, under their dominion. The effect of this operation is often witnessed during the exhibition of tartar emetic in nauseating doses, in the relaxed skin, the softened pulse, the moistened tongue, and the pallid countenance, all bearing testimony to the universal impression of the remedy. Judiciously employed, depressants are among the most valuable and efficient antiphlogistic means that we possess, and they have the advantage that they may often be used without any preliminary depletion of any kind. Their beneficial effects are particularly conspicuous in inflammation of the respiratory organs, of the eye, the joints, and fibrous structures; also in certain forms of inflammation of the skin and cellular tissue. In many of these affections, if not in all, they have almost entirely superseded the use of the lancet and other evacuants, their controlling influence over the morbid action being generally most striking and satisfactory. Their efficacy is hardly less apparent in many of the diseases of the sub-diaphragmatic viscera; but their exhibition here demands greater care and vigilance, as their emetic effects could not fail to prove prejudicial. Their employment is particularly adapted to the treatment of acute inflammation of young, robust subjects, whose systems require to be rapidly impressed in order to arrest the progress of their diseases. Infants and children, the old, infirm, and decrepit, bear their use badly, and often sink under their injudicious administration.

The most trustworthy depressants are tartar emetic and ipecacuanha, to which may be added aconite, veratrum viride, and digitalis, which, however, hold a subordinate rank. Of the depressing effects of bleeding I have already spoken, and pointed out the circumstances under which they may be most readily produced.

Tartar emetic, as a depressant, may be administered in doses varying from the eighth to the fourth of a grain, repeated every two, three, or four hours, according to their impression, which should be steadily maintained until the object of the administration of the remedy has been fully attained. It will generally be safest to begin with a small quantity, and to increase it gradually if it be found to be borne well by the stomach. Sometimes the first few doses, even if small, will produce pretty active emesis, but this, so far from being injurious, will commonly be highly beneficial, by relaxing the system and opening the emunctories. By and by, gastric tolerance will be established, and then the remedy will often be borne in extraordinary quantities, though we never employ it in the enormous doses recommended by Rasori, Thomasoni, and other disciples of the Italian school. In this country, indeed, we seldom give as much at a single dose as half a grain, the average quantity rarely exceeding one-half or one-third of that amount. The Italian practitioners, on the contrary, often gave five, ten, and even fifteen grains at a dose.

The beneficial effects of tartar emetic, as a depressant, may often be greatly enhanced by the addition to each dose of a small quantity of the salts of morphia, just enough to produce a calming and diaphoretic impression. Such a combination is particularly serviceable in nervous, irritable persons, and in subjects who have been debilitated by intemperance and other causes of exhaustion. When the article, given by itself, is productive of vomiting, it should never be used in any other way. In children, too, such a mode of exhibition is, as a general rule, indispensable. Sometimes the article may be advantageously administered along with the neutral mixture.

The dose of *ipecacuanha*, as a depressant, varies from a fourth of a grain to a grain, and may be used alone or in combination with an anodyne, as, indeed, is usually found best. A nauseant effect may be kept up in this manner almost as long as may be desired, but the impression is less pervasive and far inferior, in every respect, to that produced by tartar emetic. On this account, however, the medicine is peculiarly adapted to the treatment of inflammatory affections of children, who, as already stated, usually bear the operation of antimony very badly.

Whichever of these two articles be employed, it will be well to withhold all drinks for from fifteen minutes to half an hour after the exhibition, as, when this precaution is neglected, they are very apt to cause vomiting. At the end of this time, however, diluents, cool or tepid, may be used with the greatest benefit, from their tendency to promote relaxation and secretion.

Of *digitalis* I have not been led to form a very favorable estimate as a depressant or sedative. I was formerly in the habit of employing it a great deal in various forms and combinations, as well as in various forms and stages of inflammatory disease, and yet it would be difficult for me to recall a solitary case in which I derived any appreciable benefit from it. I have, therefore, of late years altogether abandoned its use.

Modern materia medica has gained an important accession in the addition of *aconite* as an antiphlogistic agent. The form in which it is usually exhibited is the saturated alcoholic tincture of the root, prepared according to Fleming's formula, the dose of which is from one to five drops repeated every two, three, or four hours, until it has produced its peculiar depressing effect. The best, because the safest, plan is to begin with a small quantity, and to increase it gradually and cautiously until it brings down the pulse,

which, in the course of a few hours, often descends from ninety-five or one hundred to sixty-five or even fifty, the surface at the same time becoming bathed with perspiration. In large doses, it is powerfully sedative and anodyne, but it should never be given in this way on account of its prostrating influence. It is particularly adapted to neuralgic, gouty, and rheumatic affections, and to the higher grades of traumatic fever; and my practice generally is to combine it with tartar emetic and sulphate of morphia, as this insures a more prompt and beneficial action than when given by itself.

Veratrum viride is an American remedy, introduced to the notice of the profession by Dr. Osgood, of Providence. Its properties were subsequently investigated by Dr. Norwood, of South Carolina, who found it to exert a powerful influence upon the action of the heart and pulse, very similar to that of aconite, only, if possible, still more certain. The dose of the saturated alcoholic tincture of the root, the form of the medicine most generally employed, is from five to eight drops, repeated every two, three, or four hours, until it has sensibly reduced the force and frequency of the pulse, when it is either suspended or given in smaller quantity. As *veratrum viride* is an article of great potency, it is impossible to be too careful in its use. If carried too far, it causes nausea and vomiting, excessive prostration, faintness, vertigo, dimness of sight, and other dangerous symptoms. It is applicable to the same class of cases as aconite, and may be exhibited either by itself or in union with morphia and tartar emetic. The best means for overcoming the nauseating and depressing effects of this medicine, are opiates and alcoholic stimulants.

6. *Diaphoretics*.—Diaphoretics, in their mode of action, bear the same relation to the skin that cathartics do to the bowels. They constitute, therefore, a highly important class of remedies in inflammation, from the faculty which they possess of restoring and modifying the cutaneous perspiration, the suppression of which is a frequent source of disease. The quantity of perspiration daily thrown off by the skin, in the normal state, varies from twelve to sixteen ounces, and the retention of such an amount of material in the system must necessarily exert a most prejudicial influence upon the suffering organ. The importance of a critical sweat, as it was called by the ancient physicians, in putting a stop to disease, has long been familiar to the practitioner, and the employment of diaphoretics is only an attempt to imitate nature's efforts, in removing a cause of morbid action, or restoring a secretion which has been suppressed in consequence of the changes which that action has induced in the general system. As in the case of purgatives, depletion should always precede the employment of the remedy, so should it in the case of diaphoretics, a relaxed condition of the body always powerfully predisposing to a favorable action of the medicine.

The class of diaphoretics is very large, but there are only a few that are really at all reliable, or that are much employed by the experienced practitioner. These are tartar emetic, ipecacuanha, and Dover's powder, aided, if necessary, by tepid drinks, and sponging of the surface with tepid water. The spirit of Mindererus, in combination with a small quantity of spirit of nitric ether, makes a mild diaphoretic, and is often used in low states of the system. The efficacy of antimony, which deserves the highest rank in this class of remedies, will be greatly increased if given in union with morphia, the two articles thus counteracting the bad effects which they would produce if exhibited singly, at the same time that they subdue the heart's action, relax the skin, relieve pain, and induce sleep. The best form of exhibition is a watery solution, each dose containing from the sixth to the tenth of a grain of antimony, with from one-fourth to one-eighth of a grain of morphia, repeated every two, three, or four hours. Ipecacuanha is adapted chiefly to

children and old persons, and to the latter stages of the disease, and may be given alone, or, what is preferable, with some of the salts of opium. The ordinary dose of Dover's powder, for an adult, is ten grains, but in my own practice I seldom use less than fifteen, and frequently as many as twenty, repeated every eight, ten, or twelve hours. The action of these remedies should always be aided by tepid drinks, and, if there be much dryness of the surface, by frequent sponging of the body with tepid water. During very hot weather, and in high states of inflammation, cool ablutions are often more efficient, as well as more grateful, than warm.

Bathing is not often employed in the treatment of acute inflammation, on account, chiefly, of the inconvenience and fatigue attending its use. In the chronic form of the disease, however, it is a remedy often of great value, especially in affections of the skin, joints, and abdominal viscera. The water, which may be simple or medicated, is used at various degrees of temperature, the tepid bath ranging from 85 to 92 degrees of Fahrenheit, the warm from 92 to 96, and the hot from 96 to 112. A very excellent and convenient mode of conveying moist and heated air to the patient's body, as he lies in bed, consists in attaching one end of a tin tube, from three to four feet in length, to a teakettle filled with hot water, the other end being placed under the bedclothes. Copious perspiration usually promptly follows the application, which may be maintained for any desirable period. The foot-bath is occasionally used with advantage, but to derive full benefit from it the patient should be well covered up in bed, his feet hanging in the water placed in a suitable tub upon a chair, the immersion being continued from thirty to sixty minutes. The hip-bath is employed chiefly in affections of the genito-urinary organs.

7. *Diuretics*.—Diuretics are medicines intended to restore and modify the renal secretion, which is almost invariably more or less changed in inflammatory affections. Their employment is always, as a general principle, preceded by various depletory measures, and they are never given in inflammation of the kidneys and bladder. Their administration is usually accompanied by mucilaginous drinks, but these are not at all necessary to their beneficial effects, ordinary fluids answering quite as well. They may be conveniently arranged under three distinct heads: The first includes those articles which, when received into the system, depurate the blood, and increase the quantity of solid matter of the urine, as the nitrate, acetate, and bitartrate of potassa. The second class comprises colchicum, squills, and other vegetable diuretics, which carry off the watery portions of the blood; and the third consists principally of copaiba and cubebs, which not only augment the renal secretion, but exert a peculiar influence upon the mucous membrane of the bladder and urethra, as is shown in cystitis and gonorrhœa. Of these various articles, the most important, in the treatment of acute inflammation, are nitrate of potassa and colchicum. The former may be exhibited in doses of from fifteen to thirty grains every three, four, five, or six hours, in a large quantity of water. Colchicum is generally given in the form of the vinous tincture of the seed, in doses varying from ten to fifty drops, several times in the day and night. My own practice usually is to employ one drachm along with half a grain to a grain of sulphate of morphia every evening at bedtime. In this way the medicine produces a much more decided impression upon the system, as well as upon the renal secretion, increasing its quantity, and freeing it of lithic acid, and probably, also, of other nitrogenized elements. Moreover, it usually acts upon the bowels, bringing away thin watery evacuations, especially when employed by itself; and in large quantities, it often vomits. One full dose, administered in this manner at bedtime, is far superior to three or four small ones, which often only fret and irritate the

kidneys and bowels, placing them in a condition ill calculated to correct morbid action.

8. *Anodynes*.—There is no class of remedies which require a greater amount of nice judgment and correct discrimination in respect to their selection, mode of combination, and time of administration than that of anodynes. The subject, therefore, is one that should be carefully studied with reference to these particular points, by every one desirous of acquiring correct views of the practical application of anodynes to the treatment of inflammatory affections. My conviction is that these remedies are used much less freely than they should be, and that they are capable, if properly exhibited, of affording an immense amount of benefit, not only in allaying pain and inducing sleep, but frequently also in controlling morbid action, and, consequently, in abridging its course and preventing its ravages. Want of space will not permit me to enter fully into this subject, and I shall, therefore, confine myself to a brief statement of a few of the leading facts, giving them as practical a bearing as possible.

The same rules, as respects the premising of depletory measures, are applicable to anodynes as to cathartics. Thus, first, whenever there is plethora, fecal distension, or disorder of the secretions, their correction should, if possible, precede the exhibition of the opiate. Sometimes a full dose of morphia is made to succeed a large bleeding, or an active purgative, the medicine then exercising a decidedly sedative and soothing influence. Administered before the system has been properly relaxed, it rarely fails to increase the vascular action, to lock up the secretions, produce headache, prevent sleep, and augment thirst and restlessness.

Secondly, the medicine should always be exhibited in full doses, experience having shown that it makes a much stronger, as well as a much more soothing, impression in this way than when it is taken in small, and frequently repeated doses. With the precautions pointed out, an adult will bear, when the symptoms are at all urgent, from two to four grains of opium, or its equivalent of morphia, every twelve or twenty-four hours. The effects of the remedy must be steadily watched, especially if the patient be a child, or if there be any undue cerebral excitement. Should the pulse increase in fullness and vigor under its influence, the skin become more hot and dry, or the vigilance and restlessness augment, repetition is temporarily suspended, until, by farther depletion, the system is placed in a more favorable condition for its reception.

Thirdly, the best period for the exhibition of the medicine, when there is no immediate necessity for its use, is towards bedtime, the patient being thus more likely to obtain quiet and refreshing sleep after the removal of the light and other external stimulants.

Fourthly, when there is excessive pain along with great dryness of surface, and the depletion has been already carried to a sufficient extent, the anodyne should be combined with a diaphoretic, as ipecacuanha, or, what is better, tartar emetic, or, instead of this, a full dose of Dover's powder is given.

Anodynes are particularly beneficial in all cases of inflammation attended with violent pain, which, by its persistence, might rapidly wear out the powers of life. Their value cannot be too highly appreciated in the phlegmasias of the skin and cellular tissue, the joints, the sub-diaphragmatic viscera, the eye, ear, pleura, heart, and respiratory organs. Within the last few years enormous doses of opium have been given by Professor Clark and others in peritonitis with the most happy results, and I am sure that the same mode of treatment might be advantageously extended to inflammation of many of the other parts of the body. The importance of absolute rest to the affected organ is universally conceded, and is daily witnessed in the

management of external inflammation. Instinct alone is often sufficient to secure it, but where this fails the surgeon endeavors to procure it by means of various mechanical appliances. In the internal phlegmasias no such means are applicable, but here the object may be readily attained by opiates, given in full and sustained doses to control the movements of the suffering structures. In gastritis nothing so promptly and effectually quiets the muscular fibres of the stomach as a suitable quantity of morphine, and the same treatment has long been successfully employed in dysentery, or inflammation of the lower bowel. In cystitis nothing affords relief so speedily and permanently as a full anodyne. In pleuritis and pneumonia, how is it possible to give rest to the lungs and respiratory muscles, except by the same means? The more quietly the parts are kept while laboring under disease, the sooner, other things being equal, will the patient recover from its effects, and the less pain he will have to endure from the constant and rude contact of the affected surfaces upon each other. Even in inflammation of the brain and its meninges, after proper depletion has been practised, anodynes are frequently indispensable, not only to allay pain and induce sleep, but to control the morbid action. And how do they do this? Simply, in the first place, by subduing the action of the heart, and thus preventing it from sending out to the brain its accustomed quantity of blood; and, secondly, by making a direct impression upon the brain itself, thereby, in some degree, controlling its movements, so injurious both to its own substance and to its coverings, when thus affected. Anodynes, in most of these cases, as well as in many others, literally constitute nature's splint.

The best anodynes are opium and its different preparations, as the salts of morphia and laudanum. These may be given either by the mouth or rectum, double the quantity being usually required to produce the same effect in the latter as in the former case. Sometimes the remedy is employed endermically or subcutaneously, in the form of injection. There are some persons who cannot bear opium in any form. When this is the case a substitute should be sought in lupuline, hyoseyamus, Indian hemp, and other kindred articles; or, in what I have generally found to answer very well under such circumstances, a union of morphia with tartrate of antimony and potassa.

9. *Combination of Remedies.*—There are few acute surgical diseases or severe accidents in which a combination of several of the remedies now described may not be advantageously employed. In nearly every case of the kind the patient will be found to be oppressed with fever, thirst, pain, and restlessness; or, in other words, to labor under incited action of the heart and arteries, attended with diminished, if not suspended secretion, and all the evils consequent upon such a state of the system. To meet the indications of treatment, under such circumstances, there is no prescription which, according to my experience, is capable of conferring greater benefit than the saline and antimonial mixture, as it is termed, consisting of the following ingredients:—

R. Antimonii et potassæ tart. gr. iij.
 Magnesiae sulph. ℥ij.
 Morphiæ sulph. gr. j½.
 Aquæ destil. ℥x.
 Syr. zingiber. vel simplicis ℥ij.
 Acid. sulph. aromat. ℥ss.
 Tinct. veratr. virid. ℥iss.

M.

Of this combination the proper average dose is half an ounce, repeated every two, three, four, or six hours, according to the exigencies of the case. Should it produce emesis, or distressing nausea, the dose must be diminished.

Properly administered, it rarely fails rapidly to subdue vascular excitement, to cause copious perspiration, to allay pain, thirst, and restlessness, to maintain the bowels in a soluble condition, and to induce sleep and general tranquillity. Instead of the veratrum aconite may be used; but in general I give the former the preference. Colchicum may be added when there is a rheumatic or gouty state of the system, and quinine when there is a tendency to periodicity. The quantity of morphia may be increased when there is much pain.

10. *Antiphlogistic Regimen.*—Under this head are comprised the patient's diet, and the care which he may require during his confinement. The subject is one which rarely receives the attention its importance demands.

Few persons, fortunately, have any appetite during the height of an inflammatory attack, and hence the surgeon seldom experiences any difficulty in regard to the regulation of the diet. The stomach being oppressed with nausea, or a sense of uneasiness, either loathes food, or rejects it almost the moment it is swallowed. It is well it should be so; for any ingesta, however mild, taken at this period, would only become a source of further trouble, by increasing the morbid action, perhaps already progressing at a furious rate. When the appetite remains, it must be repressed, steadily and courageously, until all danger from over-excitement from its indulgence has been safely passed. The mildest and least nutritious articles only are admissible in the earlier stages of the disease; such as panado, gruel, arrowroot, sago, and tapioca. Not even the lightest animal broth is permissible, unless there is decided tendency to prostration, or an irritable state of the system, clearly dependent upon the want of proper nourishment, as occasionally happens in persons of a nervous, irritable temperament, or who are habitually huge feeders. The drinks should be cooling, consisting of iced water, gum-water, linseed tea, or barley-water, either simple, or slightly acidulated with lemon-juice, tamarind, or any of the subacid fruits; care being taken that, while they are used freely, they are not employed in such quantity as to produce gastric and intestinal oppression.

The promptings of nature should not be disregarded during the progress of recovery; for their tendencies are generally wholesome, and should therefore be gratified to at least a reasonable extent, unless there are well-marked contra-indications. Acid drinks and food are particularly apt to be craved, and a moderate use of them is often eminently beneficial, not only in whetting the appetite, but in promoting the digestion, by supplying the exhausted stomach with substances calculated to atone for the want of a due amount of gastric juice, so essential to healthy chymification. Improper indulgence should, of course, be avoided, and care must also be taken that the articles are of such a character as to prevent acidity and flatulence.

Rest of mind and body must be carefully observed. The importance of this is so self-evident that it would be folly to attempt to enforce it by any labored argument. Whatever has a tendency to excite the heart's action must necessarily increase the momentum of the circulation, and, through it, the inflammation. In all severe attacks the patient must keep his bed, from which he must not rise even to answer nature's calls; light and noise are carefully excluded from his apartment, especially if he is suffering from inflammation of the eye, brain, or ear; and no persons should be permitted to be about him, except such as are absolutely necessary to nurse him. Many a patient is killed by the kindness of his friends and relatives.

Attention must be paid to the temperature of the patient's room, this being regulated, not by his feelings, which are often deceptive, but by the thermometer. On an average, it should not exceed 65°, but in some cases it may range as high as 70°, and in others as low as 60°. The apartment

should be frequently ventilated. When it is recollected how soon the air becomes vitiated during sickness, and how important a due supply of oxygen is to the proper maintenance of the health, the importance of attention to this subject will not be doubted. Cleanliness of the body, and of the bed-clothes, is another subject of vital importance in the treatment of inflammation, and one to which, I am sure, few practitioners pay sufficient attention. To medicate the inside of a patient while we neglect the outside is one of those singular inconsistencies of which we see daily proofs in the sick chamber. I would not insist upon too frequent ablutions and changes of the body and bedclothes, but they should certainly, in ordinary cases, be effected at least once in the twenty-four hours; care being taken to avoid unnecessary exposure and fatigue during their performance. Even the arrangement of the furniture should be attended to, on the principle that an agreeable impression, of whatever kind, is more conducive to comfort and recovery than one of an opposite character.

II. LOCAL TREATMENT.—The local remedies of inflammation consist of rest and elevation of the affected part, the abstraction of blood, cold and warm applications, compression, destructives, and counter-irritation.

1. *Rest and Position*.—Without rest, steady and persistent, of the affected part, little progress can be made toward the cure of inflammation. The practitioner who neglects attention to this important circumstance, performs only half his duty. The patient, ignorant of its advantages, often continues to exercise the affected organ long after it has become unfitted for the discharge of its functions, much to his present discomfort and ultimate detriment. A simple conjunctivitis, that might be cured in a few hours, is often urged, for the want of a little rest of the eye, into a violent and protracted ophthalmia, perhaps, at length, eventuating in total loss of vision. An inflamed joint is frequently, for the same reason, rendered permanently stiff and useless. Hence, rest is universally considered as one of the most essential elements of the local treatment of inflammation. In general, it is easily procured, simply by the patient's own efforts; but where this is not the case, it must be insured by appropriate splints, and other means, applied so as not to interfere with the other treatment. In inflammation of some of the internal organs, as the heart, stomach, peritoneum, bowels, and urinary bladder, the object is sought to be obtained by the liberal use of anodynes, which, by temporarily paralyzing the muscular fibres of the affected structures, effectually prevent peristaltic motion, and thus place them in a better condition for speedy recovery.

But there is a period when rest must not be enforced too rigidly, for when it is continued too long, it may be productive of much harm. Its great utility is in the earlier stages of inflammation, when morbid action is grave-scent, and for some time after it has reached its culminating point. As soon as recedence has fairly begun, motion, gently and cautiously conducted, is often of great utility.

Not only should the part be kept at rest, but it should also be maintained in an elevated position, the success of the treatment being thereby greatly enhanced. The importance of attention to this point is well exemplified in many familiar diseases. The patient himself is often conscious of it, and, therefore, resorts to it, as it were, instinctively. Who that has ever had an attack of whitlow, does not remember the great relief which he experienced from carrying his hand in an elevated position? The effect of position is nowhere more strikingly evinced than in odontalgia. During the day, the patient, while attending to business, is, perhaps, hardly sensible of suffering, but, at night, no sooner does his head touch the pillow than the tooth begins to ache and throb, compelling him to get up and pace his room. In orchitis,

the beneficial effects of our remedies are always greatly aided by elevation conjoined with rest of the affected organ. It is quite easy to understand why this should be so. In inflammation, the vessels carry an extraordinary quantity of blood, which is still further increased when the suffering structures are placed in a dependent position, because the flow, not being opposed by gravity, has then free scope, thus crowding the already distended capillaries to the very utmost, and proportionably aggravating the morbid action.

Finally, the inflamed part should also be maintained in as easy a position as possible, mere rest and elevation not sufficing to insure comfort. All restraint must be taken off; all muscular contraction counteracted. Thus, in inflammation of the knee-joint, the limb should recline upon its outer surface, a pillow being placed in the ham, this being the best position for preventing tension. In synovitis of the elbow-joint, the forearm is bent at a right angle with the arm; and in hip-joint disease, the thigh is slightly flexed upon the pelvis, and turned towards the sound one.

2. *Local Bleeding.*—Blood may be abstracted locally by scarification, puncture, leeching, and cupping, each being more or less serviceable, in its own way, in particular cases and under particular circumstances.

The manner in which topical bleeding affords relief is sufficiently evident in some of these forms of depletion, but not very apparent in others. Thus, in scarifying and puncturing a part, the blood is taken directly from the engorged vessels, which are thus drained of their altered and vitiated contents. If the operation be carried to any considerable extent, as it often may be, especially in the former of these procedures, we may, at the same time, make a powerful impression upon the general system, nearly as rapidly and quite as effectually as when blood is drawn from a vein at the bend of the arm, although, in general, such an effect is neither aimed at nor desired. A similar influence is exerted by leeching and cupping, provided the operation is performed upon the inflamed surface, or in its immediate vicinity. Frequently, however, it is performed at a remote point, and then its mode of action is rendered more difficult of comprehension. Thus, in inflammation of the brain, it is difficult to determine how leeches and cups, applied to the nape of the neck, the temples, or back of the ear, afford relief to the affected organ. It is certainly not possible, in such a case, to make any direct impression upon the seat of the disease; whatever influence is exerted, must be exerted through the general system. This is a self-evident proposition. The vessels of the neck and scalp have no direct communication with the vessels of the brain; and hence, in leeching and cupping these parts, we can no more drain the cerebral capillaries than we can drain those of the hand, chest, or any other distant part. We may assume, then, that, when topical bleeding is practised by either of the latter methods, its beneficial effects are due not to any direct drainage of the suffering structures, but indirectly to the depressing influence which it exerts upon the heart and nervous system, and, through them, upon the morbid action, diminishing the momentum of the circulation, and, consequently, the flow of blood in the capillaries at the seat of the inflammation.

But whatever may be its mode of action; whether it affords relief in the manner in which we have attempted to explain, or by some revulsive agency, so much insisted upon by some of the older practitioners, and which it is so difficult to comprehend, topical bleeding, to be efficient, should always, if possible, be preceded by general depletion. When the force of the morbid action has thus been broken, the rest of the malady is often well dealt with by local abstraction of blood. It is only when the disease is very mild, or when there is no marked constitutional disorder, that this rule should be disregarded. Under such circumstances, the treatment may occasionally be

very properly commenced with the application of leeches, cups, or scarification, followed or not, as the exigencies of the particular case may seem to require, by other measures. The manner of taking blood topically will be pointed out in the chapter on Minor Surgery.

3. *Cold and Warm Applications.*—These remedies, which are more particularly adapted to external inflammations, comprise a great number of articles, in the form of water dressings and cataplasms, with the character of which every practitioner should be perfectly familiar. Both classes of remedies may be simple or medicated, according to the tolerance of the part and system, and the nature of the morbid action.

(1.) *Cold water* has been employed in the treatment of inflammation almost from time immemorial; but its beneficial effects were almost forgotten, until attention was recalled to it by some of the military surgeons of Europe, early in the present century. In this country, the subject has hardly yet received the consideration it deserves, the use of the article having hitherto been confined chiefly to hospital practice. From its value, however, as a topical application, it must soon find its way to general favor, and take its place among the great remedies for the cure of inflammation, especially as it occurs in the external parts of the body.

It is not difficult to conceive how cold operates in subduing morbid action. Its chief effect is evidently that of a sedative, lowering the temperature of the part, and causing contraction of the vessels, thereby relieving pain, swelling, and tension. It is particularly applicable to inflammation in its incipient and gravescent stages, while there is, as yet, little effusion, and no serious structural lesion. When the action has reached its acme, threatening supuration, or, what is worse, tending to gangrene, it is usually hurtful both to part and system, and must be promptly discontinued. Besides, it should not be forgotten that cold, when intense, or protracted, may of itself cause gangrene. Young and robust persons usually tolerate such applications much better than the aged and feeble; they are also better borne in summer than in winter. As it is impossible always to determine beforehand, in any given case, what their effects will be, their action should be carefully watched, in order that, if they should become a source of annoyance, they may either be entirely dispensed with, or employed in a modified form.

The water may be rendered anodyne, astringent, or antiseptic, according to circumstances, by the addition of opium, acetate of lead, or some of the chlorides. The best way to use it is to cover the affected part with a piece of old porous linen, and to direct upon it a constant flow of water from a basin with a stop-cock, slung to the top of the bedstead, the limb lying on an oil-cloth trough, from which the fluid is conducted into another vessel standing near the bed. Or the part may be covered with a wide, thin piece of sponge, spongio-piline, or common linen, over which is placed a bladder partially filled with pounded ice. Or the water may be conveyed from a basin by means of a candle wick to a layer of lint upon the inflamed surface, the wick acting on the principle of a syphon. Finally, when ice cannot be obtained, the water may be rendered cold by means of alcohol, in the proportion of one part to six of the fluid; by pyroligneous acid and alcohol; or by the admixture of a strong solution of hydrochlorate of ammonia and nitrate of potassa. In whatever manner the fluid is employed, the part to which it is applied should be constantly exposed to the air, to favor evaporation.

(2.) The use of *warm water* is also of great antiquity, having been employed by Hippocrates and other practitioners in gangrene and various cutaneous affections. It has, however, only been within the last fifteen years that it has assumed anything like the rank to which its importance as an antiphlogistic remedy entitles it. In my own practice, I generally give a

decided preference to warm water over cold, the impression made by it upon the part and system being usually more agreeable and soothing, while there is much less danger of metastasis, or of a sudden transfer of disease from the external to the internal parts of the body. It is particularly adapted to nervous, irritable individuals, who are easily chilled by cold applications, and to cases in which the inflammation has already made considerable progress, where there is much tension and swelling, or where suppuration is impending, or has already taken place. A good rule, both in regard to warm and cold applications, is to consult the feelings of the patient, using one or the other according to the tolerance of the part and system, or simply so long as they seem to be beneficial. When a change becomes requisite, care must be taken that it is not too sudden, lest it produce harm. Thus, hot applications should be succeeded first by warm, then by tepid, afterwards by cool, and finally, if necessary, by cold, the transition being gradual and wary, not great and sudden, so as to shock the part and system, and thus cause undue reaction.

Warm water may generally be advantageously combined with opium, or with opium and acetate of lead, or with opium and hydrochlorate of ammonia. The latter is the preparation which I generally prefer, the opium and ammonia being dissolved in hot water, in the proportion of about two drachms of the former and an ounce and a half of the latter to the gallon of fluid. A piece of old flannel of suitable size, and arranged in several thicknesses, is then wrung out of the solution, and laid upon the inflamed surface, a covering of oiled skin being spread over the cloth, to confine the heat and moisture. As the cloth becomes dry, it is wet, from time to time, not by re-immersion, but simply by pressing the solution upon it from a sponge; dressing by substitution being necessary only in the event of the flannel becoming soiled and offensive by the discharges. The only objection to the hydrochlorate of ammonia is its liability to cause slight pustulation, especially in persons of a delicate skin; when this happens, its use must be suspended. In the employment of cold water, the part is exposed; in the use of warm, it is covered. The former does good by constringing the inflamed tissues, and opposing effusion; the latter by relaxing them, and favoring effusion.

(3.) *Fomentations*, which may be considered as a species of local bathing, are often beneficially employed in inflammation of the joints and of some of the internal viscera, being particularly calculated to relieve pain, tension, and spasm. In cystitis, gastritis, enteritis, and peritonitis, as well as in wounds and other injuries of the pelvic and abdominal organs, their employment can rarely be dispensed with in any case. The most simple fomentation consists of a large, thick flannel cloth, wrung out of hot water, or water near the boiling point, by means of two sticks turned in opposite directions, and applied lightly to the part as hot as it can be borne. If a soothing narcotic, or sedative influence is required, chamomile flowers, poppies, hops, or what is much better, laudanum, or laudanum and brandy, will be found to form valuable additions. In whatever manner they are used, they should be frequently renewed, care also being taken that there are two cloths, so that, while one is taken off, the other may be immediately applied, all danger of shock and reaction from exposure to the air being thus avoided.

(4.) *Stuping* is a variety of fomentation serviceable in many cases, but particularly in affections of the eye, nose, ear, mouth, and throat. It is conducted with a piece of flannel, rolled into a kind of ball, which the patient holds in a small pitcher, at such a distance from the affected surface that the vapor may ascend to it, care being taken to wet the cloth as often as it becomes cool. The remedy may be medicated, if desired, with laudanum, camphor, belladonna, hemlock, or any other article, anodyne, astringent, or sorbefacient.

When it is desirable to apply steam more directly, a funnel may be inverted

over the hot fluid, and the tube held towards the affected surface at a suitable distance. Steam may be conveyed to any part of the patient's body, under the bedclothes, by means of a large gutta-percha tube, attached to a small tin boiler, placed upon a table, and heated by a spirit lamp.

(5.) *Poultices*, technically called cataplasms, are an important class of remedies, intended for external application in inflammation, wounds, ulcers, abscesses, and other affections. They are modifications of fomentations, and are made of various substances, either simple or medicated, according to the object they are intended to fulfil. They should be of such consistence as to accommodate themselves accurately to the surface to which they are applied, without being so tenacious as to adhere firmly to the skin, or so thin as to spread over the neighboring parts. They should never be heavy nor bulky, and they should be renewed as often as they become dry and cold; otherwise they lose their good effects and are converted into irritants. In general, it is sufficient to change them thrice a day; but in warm weather, or when there is much discharge, it may be necessary to reapply them every four, five, or six hours. Their temperature should be about the same as that of the body, that is, from 85 to 92 degrees of Fahrenheit, and they should be placed directly upon the affected surface in a uniform layer of from three to four lines in thickness, a piece of bobbinet, gauze, or thin netting being interposed to prevent sticking and facilitate removal.

The action of a poultice is usually limited to the skin, or, at all events, to the parts to which it is immediately applied; it is only when it is composed of very strong materials that its influence is more deeply felt. In using medicated cataplasms, it is necessary, especially when there is ulceration or abrasion of the skin, to be aware that the active ingredient may be absorbed, and thus produce the same effects as when introduced directly into the stomach. Poultices differ very much in their mode of action; thus, some are altogether emollient, that is, they soften and relax the parts to which they are applied, at the same time that they promote exhalation and absorption; some are anodyne; some astringent; some antiseptic.

The following list comprises nearly all that are now in use, with brief directions for their preparation:—

a. The *bread* poultice is made by pouring boiling water upon the crumbs of stale wheat bread and stirring the mixture in a basin with the back of a spoon until it is of a thick, mushy consistence. It is then spread upon a piece of folded cloth large enough to cover not only the affected surface, but to extend a short distance beyond it. Milk may be used as a substitute for the water, but when thus prepared the poultice requires to be more frequently changed, as it soon becomes sour and offensive.

b. The *arrowroot* poultice is prepared in the same manner as when that article is used for food, only that it is rendered more consistent; it is mixed at first with cold water, and then with a sufficient quantity of boiling water to convert it into a thick, gelatinous paste. This poultice is admirably adapted for irritable sores, and deserves to be more frequently employed than it is.

c. The *slippery-elm* poultice is prepared from the powdered bark of the slippery-elm, moistened with hot water. It is very light and demulcent, and, therefore, well adapted for burns, excoriations, and irritable sores.

d. The *linseed* poultice, perhaps the best and most convenient of all, from its emollient properties, is made of ground linseed mixed with boiling water, and stirred until it is converted into a thick, cohesive mass. This poultice is always very easily prepared, retains its heat for a long time, and has a sufficiency of oil to keep it soft and prevent it from adhering.

Excellent emollient poultices may be prepared from apples, carrots, turnips, or any of the more tender culinary roots, by boiling them, after having re-

moved the skin, and mashing them into a soft pulp. They possess, however, no peculiar virtues, and are therefore seldom used.

A poultice may be variously medicated. Thus it may be rendered astringent by the admixture of acetate of lead, Goulard's extract, alum, or a decoction of oak bark; anodyne, by laudanum, opium, morphia, poppy-heads, or hemlock; stimulating, by chloride of sodium, vinegar, or port wine; absorbent, by iodine and other articles.

The *fermenting* poultice, used in foul, fetid, and painful ulcers, in hospital gangrene, and in mortification, is prepared by incorporating a pound of wheat flour with half that quantity of yeast, the mixture being afterwards exposed to a gentle heat until it swells. The port-wine poultice, which belongs to the same class as the fermenting, is made in a similar manner, except that it is not boiled.

The charcoal poultice, also a good antiseptic application, though now rarely used, is prepared from recently burned charcoal, reduced to a very fine powder, and mixed with bread, oatmeal, or ground flaxseed. The objection to this poultice is its liability to discolor the affected parts, so as to prevent us from observing their real condition. This, may, however, be obviated, in great measure, by the interposition of a thin linen cloth.

A poultice may be rendered refrigerant by means of a freezing mixture, or a bladder partially filled with pounded ice and spread over its surface. Such an application, however, for reasons already stated, requires great care.

4. *Nitrate of Silver.*—There is no article which enjoys a higher reputation, as a local antiphlogistic agent, than nitrate of silver; certainly none that is more frequently employed. Without understanding its precise mode of action, experience has taught us its great value in the treatment of a large number of inflammatory affections, some of which it would be exceedingly difficult to cure without it, while nearly all are more or less benefited by it. Ever since its introduction into practice by Mr. Higginbottom, of England, as a topical antiphlogistic, it has been employed in almost every form of external inflammation, both in a solid and a fluid state. Indeed, very recently it has been employed, in the latter form, in cases of laryngitis, and one gentleman, Dr. Horace Green, of New York, has gone so far as to assert that he has even mopped the trachea and bronchial tubes with it. Its beneficial effects in diseases of the eye, throat, and genito-urinary organs have long been acknowledged by practitioners. In cutaneous affections, too, it enjoys a high and well-deserved reputation. In erysipelas it is perhaps more frequently used than any other single remedy, iodine alone excepted. Its value in the treatment of this disease, so common in this and other countries, is fully established, both in a curative and prophylactic point of view. In inflammation of the tonsils and fauces, whether the result of ordinary causes, of a strumous diathesis, or a syphilitic state of the system, no article is so generally employed, or enjoys so great a reputation, as the nitrate of silver. In gonorrhœa and gleet, in strictures and morbid sensibility of the urethra, in spermatorrhœa, in vaginitis, and metritis, nitrate of silver has become an indispensable means of cure. Indeed, it would be difficult to find an accessible disease, attended with preternatural vascularity and disordered structure, in which its application would not be productive of benefit.

Nitrate of silver may be used as a vesicant, as when it is applied to the skin, or simply as an alterant, or modifier of diseased action; for, as already stated, nothing definite is known of its mode of operation. When employed for blistering purposes, the solid form is usually preferred, the stick being passed lightly but efficiently over the surface, previously a little moistened with soft water, until there is evidence of slight coagulation of the albuminoid matter of the epidermis. A cloth, pressed out of warm water, is then applied, when

vesication will soon follow. The same result may easily be produced by a saturated solution of nitrate of silver; but, as the remedy is less manageable, it is not often employed with that view. Unless applied in a very concentrated form, and for an unusual length of time, nitrate of silver never acts as an escharotic, or as a destroyer of the tissues.

The solid nitrate of silver is often used with great advantage in ulceration of the mouth and throat, the cornea, the skin, vagina, and uterus, the application being usually made very lightly, and repeated not oftener than once every third, fifth, or eighth day. Employed too frequently or too abundantly, it often does immense harm, not only occasioning severe pain, but sometimes seriously aggravating the morbid action. These effects may be produced equally by a strong solution as by the solid stick. A strong collyrium of nitrate of silver has destroyed many an eye, or urged on an inflammation, perhaps on the very verge of resolution, to a most distressing extent. Urethritis is often aggravated, and greatly protracted, by a strong injection of this description. Much judgment, then, it will be perceived, is requisite in the local use of this remedy, not only as it respects its strength, but also the mode and time of its application. Carefully adapted to the exigencies of each particular case, it exerts a powerful impression upon the diseased structures, diminishing vascular action, relieving pain, and destroying morbid sensibility, often so conspicuous in inflammation of the eye and throat, and which nothing else can so well control.

5. *Iodine*.—Hardly less valuable than nitrate of silver, as a topical remedy in inflammation, is iodine, first introduced to the notice of the profession, in this relation, by Mr. Davis, an English surgeon. It is generally used in the form of the officinal tincture, either pure or diluted with alcohol. Its great value seems to consist in its alterant and sorbefacient properties, changing the action of the capillary vessels, and promoting the removal of effused fluids. That this is the case is sufficiently apparent from what takes place in erysipelas of the skin, where the effects of the remedy may always be easily watched. Within a few hours after the application has been made the swelling is usually observed to be so much diminished as to cause a marked corrugation of the surface, attended with a diminution of pain and hardness; circumstances plainly denotive of lessened vascular activity, and progressive absorption. Similar effects are witnessed when the application is made to an œdematous uvula, scrotum, or eyelid, there being not only no further effusion afterwards, but a removal of what was previously deposited. From these facts, it may be inferred that iodine, locally applied, is not merely, as has sometimes been asserted, a sorbefacient, but also an alterant, or modifier of secretory action.

Although exceedingly valuable as an antiphlogistic, it is questionable whether iodine has received the attention it really deserves, or whether we are sufficiently acquainted with the class of cases to which it is more particularly applicable. Its reputation in erysipelas seems to be fully established, and I have certainly myself found no article at all comparable to it in that affection as an endermic remedy. It is also of great service in boils, carbuncle, whitlow, corns, bunions, and inflamed, irritable ulcers of the extremities. Its beneficial effects are hardly less conspicuous in active œdema of the uvula and tonsils, the legs, scrotum, prepuce, and pudendum, a single application often sufficing to produce the most marked change in the condition of the part. As a collyrium and an injection, the value of iodine has not been sufficiently tested to enable us to form any definite opinion, but the trials that have been made with it, in this respect, are encouraging, and deserving of repetition.

For external use, I generally employ the tincture of iodine with an equal

amount of alcohol, applying the mixture by means of a camel-hair pencil until the skin becomes of a deep yellowish color. The application may be repeated once every eight, twelve, or twenty-four hours, according to the exigencies of each particular case. If the remedy be used stronger than this it will be very apt to produce severe pain and to excite capillary action; two circumstances concerning which it is impossible to exercise too much caution. When intended for the tonsils, uvula, and other delicate parts, the dilution should, for the reason just mentioned, be still greater.

6. *Compression*.—Compression, as an antiphlogistic agent, has been too much neglected, nor has it always been judiciously used when resorted to. That it is capable of doing an immense deal of good, when employed with proper care, and under suitable circumstances, my experience fully justifies me in asserting. Why it is so rarely used, it is difficult to determine, unless it is that practitioners do not possess the requisite skill in its application and mode of management. Very little, certainly, is said about it in surgical treatises; and, as to our teachers, few seem to be aware that there is such an agent. My space will not permit me to enter as fully into the subject as I would desire; a mere outline of a few of the more important facts connected with it must, therefore, suffice.

Compression, although more particularly applicable to the latter stages of inflammation, is yet not without its value in the incipient and gravescent periods of the disease. Affording support to the affected structures, it is well calculated, when early employed, to give tone to the distended capillaries, enabling them to urge on their sluggish contents, and, consequently, to prevent their effusion into the surrounding cellular tissue. Immense good is often done in this way, as every one knows who has ever treated erysipelas, wounds, fractures, and dislocations, by compression. If two cases of any one of these affections, of precisely the same character, could be treated, one with the bandage, and the other without the bandage, simply by the ordinary topical remedies, the difference would be most striking. The compressed limb would be comparatively free both from pain and swelling, whereas the other would be highly sensitive and greatly enlarged, from inflammatory deposits. We see, in such circumstances, how, in the one limb, action is controlled, and how, in the other, it pursues its wayward course. But this is not the only benefit which systematic compression is capable of affording. When judiciously employed, it controls muscular contraction, and thus prevents spasm, both of which are frequently so annoying in fractures, dislocations, amputations, and various affections of the joints. Another effect, and that by no means the least striking and important, is the sorbefacient influence which it exerts, rousing the absorbent vessels, and compelling them to remove the fluids that were deposited prior to the employment of the remedy. It is for this reason that compression may be so advantageously used in the latter stages of most of the external inflammations, attended with effusions of serum and fibrin, there being no means known to the surgeon so well calculated to effect this important object, and to assist in restoring the functions of the suffering parts. The treatment of orchitis by compression affords a beautiful and satisfactory illustration of the mode of action of the remedy under such circumstances. When this disease has been shorn of its violence by depletion, the swelling and induration, consequent upon the morbid action, often promptly disappear under the influence of systematic compression; generally, indeed, in one-fifth of the time in which they disappear under the use of mercury and ordinary sorbefacients. The absorption is frequently so rapid as to render it necessary to change the dressings twice in the twenty-four hours. Similar effects are sometimes observed in inflamed and enlarged joints.

The means of compression are the common bandage and adhesive plaster, applied in such a manner as to make gentle and equable pressure over the whole of the affected structures. Whenever the part admits of it, the bandage deserves the preference, as it is more easily managed, and equally efficient; but there are certain organs, as the testicle and mamma, where adhesive strips alone can be used. When an additional sorbefacient effect is desired, strips of gum ammoniac and mercurial plaster may be substituted for the ordinary plaster.

7. *Destructives.*—Destructives are remedies which the surgeon employs to destroy the germs of certain diseases, as that of chancre, hydrophobia, and malignant pustule; and to neutralize certain poisons, as that of the snake, and the dead subject. Their action is either curative or prophylactic; most generally the latter.

The most speedy and effectual remedy that can be used in the incipient stage of chancre is excision with the knife, or the destruction of the affected structures with some escharotic substance, as nitric acid, bichloride of mercury, or the acid nitrate of mercury. This plan should always be adopted whenever it is found that the poison has not yet had a chance of diffusing itself among the surrounding parts, inasmuch as it not only at once removes the local disease, but protects the system effectually from contamination, the little sore left by the knife or escharotic generally healing in a few days. The parts inoculated by the poison of hydrophobia and malignant pustule should be treated in a similar manner. When the knife is not admissible, on account of the timidity of the patient, the best remedy, according to my observation, is the acid nitrate of mercury, in the form of Bennett's formula, applied by means of a soft piece of wood, as a common match, or the point of a probe, inserted, if possible, into the part, and held there until the tainted structures are deprived of vitality. The same remedy, either pure, or properly diluted, is admirably adapted to the treatment of phagedenic ulcers and spreading gangrene, by whatever cause induced. It should not, however, be used without due precaution, as it is an agent of great power, and may extend its destructive influence much beyond the diseased limits. The ordinary nitric acid is less manageable than the acid nitrate of mercury from its liability to spread over the adjacent parts, and is now seldom used as an escharotic. Bichloride of mercury, dissolved in alcohol, in the proportion of two scruples to the ounce, is a most efficient caustic, producing a thin, soft, grayish eschar, which separates in a few days. It is used chiefly in venereal buboes, and always acts more promptly when its application is preceded by a blister. A powerful escharotic effect may be produced by a combination of three parts of bichloride of mercury with one of opium, made into a thick paste with concentrated sulphuric acid. The only objection to these preparations is the excessive pain they occasion, which is sometimes almost insupportable.

Similar means may be employed for neutralizing the poison of the rattlesnake and of other venomous reptiles, and for destroying the virus of wounds received in the dissection of dead bodies. In the former case, free excision is practised, followed by the use of the hot iron, or some escharotic substance; in the latter, the part is held for a considerable time under a stream of cold water, then well sucked, and next thoroughly cauterized with acid nitrate of mercury.

8. *Counter-Irritants.*—Counter-irritants are remedies which, when applied to the surface of the body, excite a new disease, or a new action, in a part more or less remote from the one originally affected. They are never used, or at least not as a general rule, until after pretty thorough depletion has

been practised, by which the inflammation has been robbed of its violence, their effect being always more prompt and decisive under these circumstances. The new disease is generally established close to the original one, but occasionally at some distance from it. Thus, in inflammation of the hip-joint, the counter-irritant is usually applied as near as possible over the acetabulum and head of the thigh-bone, the immediate seat of the morbid action, and so with the other articulations. In disease of the neck of the bladder and prostate gland, it is applied to the perineum; of the pleura and lungs, over the nearest point of the chest. In inflammation of the eye, on the contrary, the irritation is established on the nape of the neck, behind the ear, or on the arm, and not in the immediate vicinity of the suffering organ. Great judgment is often required to determine the precise point where, as well as the precise time when, the new action ought to be instituted. If it be too near the original affection, it may run, as it were, into it, and thus cause an aggravation, instead of a mitigation of the mischief; if, on the other hand, it be too remote, it may entirely fail of the object for which it was employed. Counter-irritation, as already stated, is never resorted to until the system has been relieved of plethora, and the morbid action weakened by other remedies. Used in the height of the morbid action, it can scarcely fail to be productive of local and constitutional disturbance, calculated to exercise a prejudicial influence upon the progress and termination of the case.

Although the class of counter-irritants comprises a large number of articles of a very diversified character, they may with great propriety be arranged under two heads, according to their mode of action, as vesicants, and suppurants.

(1.) *Vesicants* are remedies which, when applied to the skin, elevate the epidermis in the form of blisters filled with serum. They are of great value in the treatment of inflammation, both acute and chronic, and are applicable to a great variety of circumstances, with which the practitioner should be fully acquainted. The articles commonly used for this purpose are cantharides, either in powder or in the form of collodion-liquid, ammonia, and hot fluids. In acute disease these means, especially the first, are always preceded by active depletory measures, it being well known that, if they are employed before there has been a proper reduction of the system, they are liable to do mischief by increasing the local and general excitement. In chronic inflammation, however, they may often be advantageously used at the very commencement of the treatment. The vesicating agent is generally placed as near the affected part as possible; sometimes, indeed, directly over it.

Blisters, properly so called, are prepared with the common fly ointment of the shops, and vary in shape and size according to the object they are intended to fulfil, or the region to which they are applied. The part, if covered with hair, is previously shaved, and the plaster is confined with a compress and roller, or, what is better, with a few adhesive strips. To prevent strangury, an object of great importance in all cases, but particularly in persons of a nervous temperament and in young children, the surface of the blister should always be sprinkled with a few grains of morphia and camphor. The same end may be obtained, though less certainly, by the interposition of a piece of tissue paper, steeped in spirits of camphor. In addition to these precautions, the patient should be requested to make free use of some mucilaginous drink, as flaxseed tea, or gum Arabic water, either alone or combined with a little spirit of nitric ether. If strangury should occur, prompt relief may usually be afforded by a laudanum enema, and hot fomentations to the genitals and hypogastric region, aided, if necessary, by a dose of morphia by the mouth.

A blister should, on an average, remain upon the part from six to eight hours, unless the skin is very delicate and sensitive, when a shorter period

will suffice. In children, the desired effect is usually produced in from two to four hours, and it is necessary in them to be very careful, otherwise violent inflammation and even gangrene may be the result. I have seen horrible suffering, and, in two instances, death, follow the application of a small blister in children. In the very aged and infirm, similar accidents occasionally happen. Parts affected with paralysis often suffer severely from the protracted use of blisters. The plaster need not, in general, be kept on until there is thorough vesication; it is sufficient if the skin is quite red, or if there be here and there a little vesicle, the process being speedily completed by the warm-water dressing, or an emollient poultice, which are always the most suitable applications after the fly has been taken off. It is of great consequence to remove every bit of the salve, and also not to break the epidermis, but simply to puncture it with a large needle or small bistoury, to admit of the necessary drainage, it being a matter of great moment to exclude the atmosphere from the raw surface beneath. The dressings already mentioned may be continued until new skin has formed. Should the surface, however, become red, inflamed, and irritable, bleeding upon the slightest touch, and rendering the patient feverish and restless, recourse must be had to the starch, arrowroot, or slippery-elm poultice, or to the common white lead paint, than which nothing is generally more soothing. It should be put on in a thick layer, which is then to be covered with a sheet of cotton, the whole being supported by a roller. Pencilling the part with a weak solution of nitrate of silver has sometimes a good effect, and so has also the dilute ointment of the oxide of zinc, especially when the surface is studded with large irritable granulations.

Cantharidal collodion is a more elegant preparation than the common fly plaster, and may therefore advantageously take its place. It is best applied by means of a camel-hair brush, the surface to be vesicated being thoroughly covered with it, and the evaporation of the ether restrained by a piece of oiled silk, placed immediately upon the part. Unless this precaution be used, the article will require nearly as long a time to produce its specific effect as an ordinary blister. The principal advantages of cantharidal collodion are, that it can be more evenly applied to the skin, that it does not shift its position, that it is more rapid in its action, and that it is less liable to produce strangury, especially if it contain morphia in solution, an addition I would always advise.

Cantharidine blistering tissue is another elegant preparation for vesicating purposes; easily applied and removed, producing its effects promptly without strangury, and leaving no sores.

Ammonia is used only when the effect is desired to be strong and immediate, as, for example, in croup, where the inflammation, if not promptly checked, may speedily destroy life. Equal parts of lard and powdered harts-horn will produce small vesicles in five or six minutes; and similar effects will follow the application of Granville's lotion or liquid ammonia. Boiling water, the concentrated mineral acids, and the heated iron, cause rapid vesication. All these applications, however, are very painful, and they can never take the place of cantharides. Perhaps the least exceptionable article of this class of vesicants is the nitrate of silver, which often blisters the skin in a few minutes, especially when it is rather delicate, and has been previously well cleansed. The remedy is particularly well adapted to infants and children, as it is never followed by sloughing and other ill effects.

(2.) *Suppurants* are the most powerful counter-irritants we possess. They are much more permanent in their character than vesicants, and are therefore more serviceable in eradicating chronic disease. As their name implies, the discharge which they produce is of a purulent nature, and hence they are sometimes described under the name of pyogenic counter-irritants. The

class comprises permanent blisters, setons, and issues, which will receive particular attention in the chapter on Minor Surgery.

SECT. III.—CHRONIC INFLAMMATION.

Chronic inflammation is distinguished from acute by a variety of circumstances, which it is of the greatest importance to be able thoroughly to appreciate and understand. Its study, in fact, is of paramount consequence, and I am sure it is not placing too high an estimate upon its value when it is asserted that there is much greater merit in being able to diagnosticate a chronic disease, than to determine the nature and seat of an acute one. When a lesion declares itself, openly and boldly, by a well-marked train of symptoms, the practitioner must indeed be ignorant, if not positively stupid, if he cannot discriminate with tolerable accuracy between it and other affections which may simulate it, or bear some resemblance to it; but it is very different when the malady is of an obscure, chronic character, lurking in the system, no one, perhaps, knowing where, even after the closest and most patient scrutiny. It is under such circumstances that the intelligent pathologist and observant practitioner often appears to the greatest advantage, by turning his knowledge to the best account for his patient.

It does not comport with the design or scope of this work to enter into any of the more minute details of this subject; a large volume might be written upon it, and even then it would not be exhausted. A mere sketch of its more prominent features is all that I shall attempt.

Chronic inflammation is of great frequency, and is liable to appear in all organs and tissues of the body; it is generally a consequence or sequela of the acute form, but cases occasionally arise in which it would seem to be a primary affection. Strictly speaking, such an occurrence is of course impossible; all that we mean, when we use the word in this sense, is that the disease which it serves to designate is of so stealthy and insidious a character as to escape, for a considerable time, the attention both of the patient and his physician; the person is unwell, perhaps occasionally a little feverish, or the subject of headache, want of appetite, or a sallow complexion and constipated bowels; or, it may be, he has a cough, and a pain in his side; or a joint becomes sore and stiff; and still he is able to go about, and attend to business, although he is soon fatigued, and rendered uncomfortable by it. Thus a week, a fortnight, or a month may be passed, when, a careful examination being instituted, the discovery is made that there is grave disease in some important organ, and that it has perhaps already gone so far as to render recovery absolutely impossible, however skilfully the case may now be treated. The disease has been latent, or nearly so; it has failed to make itself known by any distinctive train of phenomena, and the result has been that both patient and practitioner have been lulled into fatal security. The morbid action has been lying all this time in ambush, and is now, in the true sense of the term, chronic. Such cases are by no means unfrequent, and they should serve to admonish us never to neglect any symptoms, however trivial, in our clinical investigations. A pain, a soreness, a cough, a halt in the gait, may, if properly interpreted, afford useful information in regard to the diagnosis of chronic disease, and should teach us the value and importance of patience and caution in the examination of the sick. The slightest neglect may be fatal; a little spark may kindle a devouring flame.

Chronic inflammation, however provoked, is generally tardy and sluggish in its movements, creating little constitutional disturbance, but not, on this account, the less surely and effectually undermining the part and system. In the acute variety, the action is rapid, bold, daring; suffering is severe; and constitutional response loud and unmistakable. In chronic inflammation, on

the other hand, the symptoms are, as already stated, often obscure, if not absolutely masked, and the embers of disease never break out into open flame. The disease may continue for weeks and months; now stationary, smothered, or apparently receding, and now advancing, and seemingly almost ready to assume the acute type.

The origin of chronic inflammation is often, if not generally, intimately connected with disorder of the digestive apparatus; seemingly, at all events, the first link in the chain of morbid action is frequently referable to the state of the stomach and bowels, especially to the effects of dyspepsia or constipation. Idiopathic inflammation of the eye and other organs often owes its origin to gastro-intestinal irritation. At other times the disease is awakened by derangement of the menses, defective action of the kidneys, suppression of the cutaneous perspiration, or disorder of the biliary secretion. Anxiety of mind, grief, anger, fatigue, intemperance in eating and drinking, and inordinate sexual indulgence are all so many predisposing and exciting causes of chronic inflammation.

The effects of this form of disease are various; if not closely watched and soon checked it may prove fatal, by the induction of serious structural changes, which neither nature nor art may be able to repair. The most common and important of these changes are suppuration, ulceration, softening, adhesion, contraction, induration, and enlargement, according to the intensity of the morbid action, the texture and situation of the affected organ, and the condition of the general system. The formation of pus and molecular disintegration, whether by softening or ulceration, are exceedingly common attendants upon this variety of inflammation, and often proceed to a most destructive extent. Adhesion is most liable to occur in the serous tissues; contraction in the bloodvessels and excretory tubes. Induration and enlargement usually coexist, although occasionally they occur independently of each other. Examples of these two changes are constantly met with in surgical practice, especially in the lymphatic ganglions of the neck, axilla, and groin, in chronic disease in and around the joints, in various affections of the skin, cellular tissue, and bones, and in inflammatory hypertrophy of the tonsils, testicle, mamma, and prostate gland. When existing in a high degree, they lead to serious functional embarrassment of the affected parts, growing out of alterations of structure, which the best directed efforts of the surgeon often fail to relieve.

Gangrene, as an effect of chronic inflammation, is rare; nevertheless it is occasionally met with, as is witnessed, for instance, in the mortification of the toes and feet, so graphically described by Pott, and dependent upon ossification and inflammation of the arteries. In most cases, when the disease passes into gangrene, it first assumes the acute type, which renders the transition much easier, and, in some degree, a necessary preliminary.

The symptoms of chronic inflammation are generally much less prominent than those of the acute variety; the pain is less, and usually also more dull or obtuse; the discoloration is dusky, livid, or purple; the swelling, often considerable, is characterized by unusual hardness, or by hardness and œdema; and the heat is nearly always less conspicuous than in acute inflammation. Functional disturbance is variable, being extensive at one time, and slight at another. Symptomatic fever may be entirely wanting, and it is this circumstance which so frequently causes this variety of inflammation to be overlooked, especially when it is of idiopathic origin. In time, the fever may assume a hectic type, or it may be of this character almost from the commencement. When the disease is extensive, or seated in an important organ, adynamic fever generally exists.

The vessels of the affected parts are generally very much dilated and distended with red and white globules, on which account the blood is propelled

through them in a very tardy and sluggish manner, strikingly contrasting with the force and rapidity with which it is transmitted in the acute form of the disease, where all is power and activity, especially in its earlier stages. When the inflammation is very protracted, many of the smaller vessels have a varicose, tortuous appearance, and are so crippled as to be almost unable to send on their contents at all. Hence, congestion, often deep and extensive, is generally present, both at the focus of the morbid action and for a considerable distance around.

Treatment.—In the treatment of chronic inflammation, the indications are, first, to remove the exciting cause of the disease; secondly, to correct constitutional disorder; and lastly, to promote the absorption of effused fluids and restore the tone of the crippled and dilated vessels.

The removal of the exciting cause of the disease obviously demands the same attention here as in the acute variety of inflammation; whenever it is accessible it should be promptly disposed of. All officious interference must of course be avoided.

Restoration of the secretions constitutes a most important indication, as it is upon their derangement or suppression that the morbid action in chronic inflammation so often depends. The remedies that are chiefly to be relied upon, for this purpose, are mercury, tartrate of antimony and potassa, iodine, bromine, nitro-muriatic acid, purgatives, and a judiciously regulated diet.

In placing mercury at the head of this list of remedial agents, I am only endeavoring to show the high estimate that is so justly attached to it in the treatment of chronic inflammation. If its administration is of doubtful propriety in many cases in the acute variety of the disease, there are few instances of the chronic in which it may not be beneficially exhibited, and yet, in making this remark, it must not be understood that I would give mercury indiscriminately or sakelessly. Its value is unquestionable, but, still, there are cases and circumstances in which it is utterly inadmissible; this is especially true of those cases of chronic inflammation which are so often met with in scrofulous children, and in persons of enfeebled and broken-down constitution, where mercury, in almost any form, is generally most pernicious, the smallest quantity sometimes producing profuse ptyalism, or gangrene of the mouth.

In administering this remedy for the cure of chronic inflammation, the surgeon has it in his power to make choice of a much greater number and variety of articles than in acute inflammation, in which he is obliged to restrict himself chiefly to calomel and blue mass. In the chronic form of the disease, he has, in addition, the bichloride, the protoiodide, cyanuret, and phosphate, which exert a most salutary influence in changing the capillary action of the part, and promoting the removal of effused fluids. Whatever substance be selected, the dose should be very small, and not repeated oftener, on an average, than twice or thrice in the twenty-four hours. The object is to produce a slow and gradual effect, and for this purpose it will generally be necessary to continue the remedy for several successive weeks. Active ptyalism is carefully avoided; it will be quite sufficient if we succeed in obtaining slight soreness of the gums. If calomel be used, a good average dose will be from one-sixth to one-half of a grain.

In children, the most suitable mercurials are blue mass, corrosive sublimate, and the hydrargyrum cum cretâ, or gray powder, given either alone or in union with soda, soda and columba, quinine, or Huxham's tincture of bark.

Iodine and its various preparations, as iodide of potassium, iodide of iron, iodide of cadmium, and Lugol's solution; bromide of potassium; barium; and tartar emetic; often exert a most salutary influence over chronic inflammation, and are particularly indicated where a slow, alterant effect is required. With

the exception of mercury, I know of no article of the *materia medica* which produces so powerful an effect as tartar emetic in controlling chronic inflammation, and favoring the absorption of effused fluids. My practice is to give it in small doses, as the eighth, tenth, or twelfth of a grain, in combination with a little morphine, three times in the twenty-four hours.

The different acids are sometimes administered with advantage, especially the dilute nitro-muriatic, which was formerly so much employed in the treatment of hepatic affections. They are particularly indicated in chronic syphilitic and scrofulous inflammations, attended with impaired digestive powers.

The bowels must be kept in a soluble condition, the nature and dose of the purgative being regulated by the exigencies of each particular case. The compound calomel pill, which, while it operates on the bowels, also excites the action of the liver and skin, constitutes one of the most eligible cathartics we possess in the treatment of chronic inflammation, accompanied with visceral obstruction.

Particular attention should be paid to the skin. This will appear the more necessary, when we consider that, in most cases of chronic disease, the perspiration is either entirely suppressed, or greatly changed in its properties. Frequent ablutions with cool, tepid or warm water, impregnated with common salt, soap, mustard, or potash, and followed by dry frictions, will often prove eminently serviceable. The renal secretion should also receive proper attention; sometimes elaborate chemical and microscopical examinations will be required to determine its character, and enable us to direct a suitable plan of treatment.

Exercise in the open air, either on foot, in a carriage, or on horseback, will often effect a wonderful improvement in cases of chronic inflammation, especially when of long standing, and attended with great debility. At other times, nothing but the most perfect rest will answer the purpose; as, for example, in serious disease of the brain, bones, and joints.

The subject of diet must claim special attention in the treatment of chronic inflammation. The indiscriminate use of food in this form of disease cannot be too severely reprehended. Too great abstinence, however, is often as injurious as too great indulgence. As a general rule, it may be stated that all stimulating and indigestible articles should be avoided, as being calculated to increase the local disease, and exercise a prejudicial effect upon the patient's recovery. If the system be inclined to plethora, the diet should be of a strictly farinaceous character, and daily be limited to a few articles, which may be varied from time to time as they become disagreeable to the palate, or offensive to the stomach. If, on the other hand, the patient is pale and feeble, it should be partly farinaceous, and partly animal, the meat being taken at breakfast and dinner, and its effects carefully watched. The different kinds of animal and vegetable broths, beef-essence, milk, arrowroot, rice, sago, and tapioca, are all eligible articles in chronic inflammation, and often prove of the greatest service in nourishing and sustaining the system. Their flavor and efficacy may be improved by the addition of spices, wine, and brandy, as may be deemed proper. When the patient is much exhausted, the use of brandy, wine, ale or porter, will often be indispensable to recovery. When marked debility exists along with emaciation, recourse may be had to cod-liver oil; rather, however, as an article of nourishment than with a view to the attainment of any alterant effect it may be supposed to possess from the presence of iodine and bromine. The dose should then be as large as may be consistent with gastric tolerance.

Finally, in the female, proper regard must be had to the state of the menstrual function; prompt measures being adopted for its improvement, or, in the event of its suppression, for its restoration. There are numerous com-

plaints which owe their origin, either directly or indirectly, to disorder of the uterine functions.

The local treatment of chronic inflammation is often a matter of paramount importance. It comprises, first, rest and elevation of the parts, the same as in acute disease; secondly, leeching, scarification, blistering, iodine, and nitrate of silver, especially in the earlier stages; thirdly, counter-irritation by croton oil, tartar emetic, issues, setons, and the actual cautery; and, lastly, sorbefe- cients, such as stimulating liniments, embrocations, and unguents, the cold douche, compression with the bandage, or adhesive strips, electricity, and dry friction.

CHAPTER IV.

TERMINATIONS AND RESULTS OF INFLAMMATION.

SECT. I.—DELITESCENCE AND RESOLUTION.

THESE terms are used to denote the restoration of the inflamed structures to their normal condition. The word *delitescence* is of Latin derivation, and literally signifies to abscond; it was introduced into surgical nomenclature by the French writers, and is employed to designate the sudden disappearance of inflammation, before it has passed through its different stages, and, consequently, before it has occasioned any serious structural changes. It is unquestionably the most desirable mode of termination, and may occur either spontaneously, or from the slightest treatment. A catarrh, caused by exposure to cold, and perhaps threatening to be quite severe, often aborts during a profound sleep induced by a warm bed, or a hot foot-bath and a grain of opium. An inflammation of a lymphatic ganglion of the neck, coming on late in the evening, and attended with great tenderness on motion and pressure, together with considerable swelling, often rapidly disappears under similar measures. An incipient gonorrhœa frequently aborts under the use of a mild injection of nitrate of silver or acetate of lead; and who has not seen a bubo promptly vanish under steady, systematic compression, aided by the application of a solution of iodine? Inflammation produced by the presence of a foreign body generally rapidly disappears after the removal of the exciting cause of the morbid action.

The above facts, with many others that might be brought forward, if it were deemed necessary for my purpose, teach us two most important lessons: the first, is always to remove as early as possible the exciting cause of the inflammation; and the second, to enter upon the treatment of every case of the disease without the least delay. The object, invariably, should be to save structure, and the best way to do this is to make the disease abscond, or *delitescere*. Such an event, however, is only desirable when the inflammation can be dislodged more or less completely without the risk of throwing it upon some other and, perhaps, more important organ. Thus an attack of gout in the great toe would be a trifling affair in comparison with an attack of gout in the heart, brain, or stomach; and hence it would be far better, where there is danger of such a translation of irritation, to let the original disease pursue its course than to attempt to arrest it by means calculated to favor such a result. A severe injection may suddenly arrest an incipient gonorrhœa, but it may do infinite harm by the rapid induction of orchitis, which perhaps no treatment, however judiciously conducted, may be able to dispel completely under several weeks, if, indeed, under several months.

The sudden disappearance of inflammation from one structure, or set of structures, and its invasion of another, usually known by the term *metastasis*, suggests the importance of proper watchfulness on the part of the surgeon to prevent such an occurrence; or, if it have already taken place, to employ such means as shall be calculated to recall the morbid action as speedily and as effectually as possible to its original situation. For this purpose free use should be made of counter-irritation, in the form of stimulating embrocations,

sinapisms, and blisters, aided, if the organ affected be one of great importance to life, by the abstraction of blood and full doses of opiates. If, in this way, the disease cannot be recalled, the treatment will go far to put a speedy stop to its violence and its tendency to extension.

The term resolution denotes the gradual dissipation of inflammation after the disease has made some progress and done some mischief, but before it has reached the suppurative crisis, or committed such ravages as to prevent the affected tissues from regaining their original properties. With such an issue effusion of serum and lymph is not at all incompatible, as these fluids may be entirely absorbed; a similar remark is applicable to pus, provided it exist in small quantity, and not in the form of an abscess, in which there is always more or less waste of tissue; and even to pure blood, which, if not too abundantly effused, or deprived of its vitality, is generally readily amenable to the action of the absorbents.

When resolution is about to occur there is a gradual and steady subsidence of the morbid action, as denoted by the changes in the local and constitutional symptoms. The discoloration, heat, pain, and swelling become less and less in consequence of the contraction of the vessels and the absorption of the effused fluids; the febrile disturbance goes off; and the part and system, no longer feeling the effects of the disease, at length regain their former condition. Often many weeks, and even several months, elapse before the restoration is finally completed. The absorbent vessels, kept in abeyance by the vascular action and the effused fluids, are slow to resume their functions; they act at first hesitatingly, as if afraid to enter upon their labor, but as the work progresses they acquire confidence, and, at length, setting about it in good earnest, they ere long finish their task, drinking in, as it were, all that their oppressors, the secernents, had previously poured out, and thus leaving the parts in a condition to regain their primitive characters. The bloodvessels usually remain dilated, feeble, and sluggish for some time after the complete subsidence of the disease, and there is also frequently more or less perversion of special sensation.

SECT. II.—DEPOSITION OF SERUM.

A deposition of serum, or of the watery elements of the blood, is a common attendant upon inflammation, and in some cases constitutes the principal, if not the only evidence of its presence. The structures which supply it in greatest abundance, when thus affected, are the cellular and serous, the secernent vessels of which are generally extremely active, even when the disease is comparatively mild. Large quantities of serum are also occasionally poured out by the mucous membrane of the alimentary canal, especially by that of the colon and rectum, as is observed in certain forms of diarrhoea and infantile cholera. Inflammation of the skin, unless produced by scalds, blisters, erysipelas, and the various bullar diseases, yields this fluid generally very sparingly. Very little is also effused in inflammation of the muscles and fibrous membranes, the nerves and vessels; while tendon, cartilage, and bone do not afford any, however severe the lesion. A similar remark is applicable to inflammation of the parenchymatous and glandular organs, as the lung and liver. In the cellular tissue serous accumulations are particularly liable to occur wherever this substance is most loose and abundant; hence they are very common in the eyelids, scrotum, prepuce, labia, nymphæ, legs, and feet, which are often enormously distended in consequence. Œdema of the glottis is an example of watery deposit in the submucous cellular substance of the edges of the windpipe. In the splanchnic cavities and the movable joints serum often collects in immense quantities; sometimes as an effect of acute, but more frequently as a result of chronic inflammation.

Particular epithets are employed to designate certain collections of serum, based either upon the appearance of the part, or the anatomical name of the cavity which serves to receive the fluid. Thus we are in the habit of speaking of œdema of the glottis, œdema of the eyelids, and œdema of the legs, simply because these structures, when thus affected, have a swollen, glossy aspect. The older writers applied the word anasarca to all aqueous accumulations of the inferior extremities, as the appearance thereby produced bears some fancied resemblance to a mass of flesh. Dropsy of the legs is another familiar expression intended to designate the same thing. The latter term, however, is generally restricted to the collections of serum in the various cavities of the body. Thus, when we speak of water in the peritoneum, we say that the individual has dropsy of the abdomen, and so of the chest, head, pericardium, joints, and vaginal tunic of the testicle. Or, instead of this term, we use a Greek one, either simple or compound, as being somewhat more classical. In this manner a dropsy of the abdomen becomes an ascites; of the chest, a hydrothorax; of the head, a hydrocephalus; and of the vaginal tunic, a hydrocele.

The appearance of the serum is generally limpid, but cases occur in which, from the admixture of extraneous matter, or hematin, it is yellowish, milky, or even quite dark. The latter appearance is generally present in the peritoneum in strangulated hernia, and is to be viewed as an evidence of intense inflammation. A similar phenomenon is witnessed in the blebs of incipient gangrene, and in the enormous serous accumulations which occasionally occur in the limbs in consequence of snake-bite and other severe injuries.

The fluid occasionally contains flakes of lymph, pus, and pure blood, although the latter is uncommon. It is often quite unctuous to the touch, is saline in its taste, but free from odor, and is readily coagulable by alcohol, acids, and corrosive sublimate; circumstances which show that it is composed principally of albumen, in combination with some of the earthy salts, especially the sulphates. Its quantity in acute inflammation is usually small, except in the splanchnic cavities, where it is sometimes immense, amounting to many quarts, or even several gallons. Under such circumstances, too, it always contains more or less fibrin.

Much diversity of sentiment has been expressed in relation to the kind of action by which this fluid is produced; some declaring that it may be deposited without the aid of inflammation, while others maintain that it is invariably the result of this morbid process. I have long been impressed with the truth of the latter doctrine, and have strenuously advocated it in my writings, as well as in the lecture-room, for the last twenty-five years. I cannot, indeed, see how it is possible to reach any other conclusion, unless we assume, which, however, I am not inclined to do, with certain pathologists, that there is no real or genuine inflammation without suppurative action, or, at all events, plastic exudation. Such a doctrine as this would, of course, be fatal to the idea that serous effusion is a result of inflammation. But these pathologists, notwithstanding their attempts at theorizing, are well aware that inflammation often, if, indeed, not generally, proves fatal long before it reaches this height. There is, therefore, but one alternative in regard to this question; we must assume either that there may be inflammation without exudation of fibrin and the formation of pus, or that thousands of persons daily perish without any disease whatever, simply from perverted nutrition, or functional disorder. To entertain such an opinion would be absurd, and we are therefore forced to the conclusion that, whenever there is an effusion of serum, such an effusion is denotive of the existence of inflammation, even when there has been no tangible evidence of the ordinary phenomena of the disease, as heat, pain, and discoloration. We have an illustration of this fact in chronic dropsies, where the inflammation is often so extremely mild

that, save the mechanical inconvenience which the fluid occasions, the patient is hardly conscious of any suffering whatever. Yet even in such cases it will generally be found, on dissection, that the serous membrane which furnished the water, exhibits sufficient indication of the lesion, as afforded by the opaque and thickened condition of its substance. It may be questioned whether mere congestion is capable of producing serous effusion. At first sight such an occurrence would seem to be quite probable; but a careful examination of the subject soon dispels the illusion. Permanent obstruction of the abdominal cava will cause ascites; not from congestion of the vessels of the peritoneum, but as a consequence of its inflammation, the result of the previous vascular engorgement. It is easy to see that vessels habitually distended must soon take on incited action, followed by abnormal deposits. A familiar illustration of this is afforded in the conjunctiva, where, if the vessels are at all engorged even for a short time, inflammation is sure to follow, unless the exciting cause of the determination be removed. If this mode of reasoning be correct, it follows that obstruction of the circulation, however induced, will, if permitted to continue, be soon succeeded by inflammation, of a grade and character sufficient to cause at least an effusion of serum, if not also of other fluids.

Of the nature of the morbid action, when serum is rapidly supplied, or when it is associated with other deposits, as lymph or pus, there can be no doubt; it is eminently inflammatory, and nothing else. The concomitant symptoms, and dissection after death, clearly establish the fact. The rapid and profuse serous exhalations which occur in acute pleurisy, peritonitis, and arachnitis admit of explanation in no other way; they are the appropriate products of these structures, and hence they are generally poured out quite early in the disease.

Effusion of serum is often associated with, if not remotely dependent upon, an impoverished and watery condition of the blood, accompanied by a marked decrease of fibrin and red particles. If, under such circumstances, inflammation be lighted up in almost any of the tissues, especially the cellular and serous, serum cannot fail to be supplied in large quantities, since, in consequence of the diminution of the plastic properties of the blood, there is nothing to restrain its exudation. Hence such action is very prone to be followed, externally, by anasarca, or œdema, and internally by dropsy.

The *symptoms* produced by this deposit are such, mainly, as are denotive of mechanical obstruction. In the eyelids, scrotum, prepuce, vulva, glottis, and legs, it is marked by a soft, inelastic swelling, which pits on pressure, and imparts a peculiar glossy appearance to the affected surface; attended, especially in the inferior extremities, with pain, heat, and more or less discoloration, usually of a pale dusky hue. A sense of distension is also commonly a prominent symptom. In œdema of the glottis there is serious impediment in the respiratory function, while in accumulations of water in the splanchnic cavities there must necessarily be more or less oppression, with displacement of the contained viscera. A large collection of water in the chest may not only cause collapse of the lung on one side, but greatly encroach upon the opposite one, and at the same time throw the heart completely out of its natural position, depress the diaphragm, and tilt up the intercostal spaces so as to give the thorax a vaulted configuration. In infiltration of the cellular tissue of the legs, feet, scrotum, and vulva, the fluid may, by its pressure upon the capillary vessels, cut off the supply of blood from the skin, and thus become a source of mortification, as we see exemplified in erysipelas and anasarca.

Treatment.—In the treatment of serous effusions, the main indication is to promote the absorption of the offending fluids by the use of hydragogue cathartics, diuretics, and mercurials; followed, when these means fail, by a

puncture for their efficient evacuation. The most important cathartics, after thorough purgation, are jalap and bitartrate of potassa, citrate of magnesia, and elaterium, given in doses proportioned to the strength of the patient and the tolerance of the stomach and bowels. These remedies, as well as others of a kindred nature, produce their beneficial effects by establishing a drain upon the serous capillaries of the alimentary canal, which leads indirectly to the absorption of the serous accumulation. When mercurials are required, as they will be when there is obstruction of the portal circle, with deficiency of the biliary secretion, the most eligible articles will be calomel, blue mass, or corrosive sublimate, either alone or in union with elaterium, squills, digitalis, or antimony, according to the nature of the collateral disorder. Deficiency of the renal secretion must be met by suitable diuretics.

When the accumulation of serum is very great, as in cases of dropsy of the chest, abdomen, or pericardium, all internal treatment will be likely to prove abortive, from the fact that it is generally impossible, under such circumstances, to arouse the absorbents to a sense of their duty; the pressure of the fluid keeps them in a crippled and paralyzed condition, altogether incompatible with the healthy exercise of their functions. Hence, instead of wasting our time and the strength of our patient, as is unfortunately too often done in such cases, early recourse should be had to an operation with a view of affording vent to the pent-up matter. I am certain, from frequent observation, that serious and even fatal errors are constantly committed by practitioners from their indisposition to early interference with the trocar in these accumulations. They forget that their purgative, diuretic, and alterative remedies, if available at all, can prove beneficial only at the expense of much distress and exhaustion of the system, which too often leave the sufferer, in the event of his recovery from the disease, with shattered and broken health for years afterwards, if not during the remainder of his life. An operation, on the other hand, generally affords prompt and efficient relief to the urgent symptoms, and places the part in a condition to be influenced by sorbefacient measures.

Local remedies are available chiefly in serous effusions in the external parts of the body. In œdema of the extremities vast benefit is often derived from steady and persistent elevation, and regular, equable compression with the bandage, extending upwards from the distal portion of the limb. In this way support is given to the capillaries, while a salutary stimulus is imparted to the absorbents, well adapted to rouse them into action. This treatment often derives important aid from frictions with sorbefacient unguents, liniments, and embrocations, and the application of the dilute tincture of iodine. When the distension is inordinate, or threatens to eventuate in gangrene, early punctures and even free incisions are called for. In œdema of the glottis nothing short of prompt and decisive scarification will prevent suffocation.

SECT. III.—LYMPHIZATION, OR FIBRINOUS EXUDATION.

Lymphization is the act of separating lymph from the blood and depositing it into the organs and tissues, or upon their free surfaces. The term, which I was the first to introduce into science, has been objected to, on the ground, as is alleged, that it is not well chosen, because the word lymph is given to the fluid contained in the lymphatic vessels. I can perceive no reason, however, why it should not be retained and generally adopted, for it is certainly quite as appropriate and classical, in reference to the substance which it serves to designate, as the word suppuration is in relation to pus, which is the product of that act. I am the more inclined to this view, seeing that the word "lymph" is still in general use, notwithstanding the attempts that have recently been made to discard it by substituting the term "plasma," which is,

if possible, still more objectionable. Perhaps the least obnoxious term is "fibrin," which is now also much in vogue, and which is expressive of at least one of the most important attributes of that substance, namely, its chemical constitution. The phrase "plastic matter" would be very appropriate, were it not that it is too circuitous for easy use.

There is rarely any inflammation, however slight, in which there is not some deposit of lymph. Indeed, in many cases, and in certain situations, it constitutes almost the only product of the morbid action. Thus, in croup and peritonitis, the chief evidence of the existence of these diseases, after death, is the presence of lymph; in general, however, it is associated with other deposits, especially serum, which is often poured out along with it in large quantities. When the inflammation is at all severe, and particularly if it has already made considerable progress, there may be, in addition, puriform matter, pus, and even pure blood. Its presence, whether occurring singly or combinedly, is always, as a general rule, denotive of a higher grade of action than the mere effusion of serum.

The capacity of furnishing lymph, in inflammation, is possessed in different degrees by different organs and textures, depending upon the peculiarities of their organization. It is always, other things being equal, poured out most freely by the serous membranes, especially the pleura and peritoneum, by the cellular tissue, and by certain portions of the mucous system, as the faucial, laryngeal, intestinal, and uterine. Very little is effused, under any circumstances, by the fibrous membranes, the muscles and their tendons, the vessels, nerves, cartilages, and bones, except in cases of fracture and other injuries, when it is sometimes thrown out in great abundance. In the parenchymatous organs, the same diversity obtains in respect to this deposit as in the tissues, properly so called. In some, as in the brain, liver, and kidneys, it is usually supplied very sparingly, whereas, in inflammation of the lungs and spleen, it is often effused quite freely, leading to rapid solidification of their proper structure. Large quantities of lymph are sometimes exhaled during the progress of abscesses, many of which it serves to inclose in a distinct cyst, known as the pyogenic membrane.

The deposit of lymph generally begins soon after the inflammatory action, and often continues for an indefinite period, increasing and declining with the disease. It is surprising how soon it sometimes shows itself. From my experiments upon inferior animals, as well as from my observations upon the human subject, I have been led to believe that it generally begins much sooner than is commonly supposed. In 1841, I had occasion to see repeated proofs of this fact, while engaged in an elaborate series of experiments upon dogs, with a view of elucidating the nature and treatment of wounds of the intestines. I found, in many of these animals, that the bowels had become extensively adherent, not only to each other, but likewise to the walls of the abdomen, within the space of a very few hours after the operation. In the case of a gentleman whose abdomen I opened some years ago, on account of a twist in the small intestine, I ascertained that, although death happened at the end of four hours, nearly the whole peritoneum, visceral and parietal, was coated with a thin film of fibrin, of which hardly any traces existed anywhere at the time of the operation. In another case, that of a young lad, who died within nine hours after he had been shot in the side, the ball wounding the abdomen, diaphragm, and chest, large quantities of lymph were seen both upon the peritoneum and pleura. The flaps made in amputation become speedily glazed with fibrin, and a similar phenomenon is often witnessed upon incised wounds, the edges of which frequently adhere quite firmly within a very short time after the application of the dressings.

From the preceding facts, it may be concluded that the process of lymphization generally begins at an early period of the inflammation, and that, if

the circumstances are at all favorable, it proceeds with great vigor. If the reverse, however, be the case, then it goes on comparatively slowly, or it may even fail entirely. Such an event will be most likely to happen in low and depraved states of the system, attended with an impoverished condition of the blood, and consequent lesion of the innervation.

Lymph, plasma, or fibrin, considered as an effect of disease, is a direct product of the vessels of the affected structures, the process by which it is elaborated being one of a vital character, analogous to, if not actually identical with secretion. No one, so far as I know, doubts this opinion, except Virchow, who maintains that this substance has an extra-vascular origin, or, in other words, that it is a local product of the tissues, on and in which it is found, being essentially composed of the material generated in the inflamed part itself through the changes in its condition. He denies that there is, in the usual acceptation of the term, any inflammatory exudation whatever; or, what is the same thing, he insists upon it that there is no real transudation from the blood-liquor. Time will prove whether this opinion is true or erroneous.

Lymph exhibits, when first effused, a whitish, pale straw, or opaline appearance, though occasionally it is somewhat reddish, from the admixture of hematin. In cases of protracted jaundice, I have occasionally found it of a pale-orange hue. It is of a soft, unctuous consistence, like hot glue, or a thin solution of starch, without smell, and of a faint saline taste. Its chemical constitution is fibrin, in union with albumen and serum. Immersion in alcohol renders it tough, and changes its color from white to buff.

Examined *microscopically*, lymph is seen to consist of numerous globules, of a spherical shape, nearly homogeneous, and about the $\frac{1}{2500}$ of an inch in diameter. Delicate fibrils, straight, parallel, and interspersed with innumerable granules, are also visible in it. It is derived directly from the blood by a process of secretion, and is identical with the buffy coat and the blood-liquor; possessing vital and organizable properties, and therefore capable of performing important duties in the economy. Being always deposited in a fluid state, it soon arranges itself in various forms; now as an amorphous mass; now as a tube, as in the larynx, and bowel; at one time as a lamella, and at another as a distinct band; its conformation being materially influenced by that of the organ, tissue, or cavity in which it is effused.

Lymph does not always exhibit the same appearances under the microscope any more than it does under the naked eye. In this respect it shares the same fate as other morbid products. I cannot, therefore, recognize the doctrine of an essential difference in the character of the effused substance, so strenuously maintained by some recent pathologists, believing, as I do, that this difference is entirely due to a difference in the state of the part and system in different individuals, localities, and grades of the morbid action. Corpuscular lymph, as it has been termed, differs from ordinary lymph only, or chiefly, in having a greater number of exudation globules, and less of healthy fibrin. Hence, it is generally met with in persons of deficient vital powers, with an impoverished state of the blood, and usually manifests a disposition to break down and become effete.

Fig. 7 displays a portion of recently-effused lymph, opaque, white-colored, friable, and magnified about 380 diameters, from an inflamed pleura. It is composed of globules, smaller molecules, and granular matter in a hyaline matrix. In the lower part of the figure the granules and molecules are shown as floating in serous fluid. In fig. 8, the structure of the effused matter is somewhat different. It forms, in fact, a sort of false membrane, magnified 800 diameters. Numerous corpuscles are seen, more or less globular, and having the character of primary cells; the intervening texture is formed of

most delicate fibrils. A few minute granules are interspersed through the tissue.

Fig. 7.

Fig. 7. Plastic corpuscles and filaments in recent lymph exuded on the pleura. *a*. The corpuscles, unchanged by acetic acid.

Fig. 8. Recent lymph, forming false membrane.

The period at which the organization of this substance takes place varies with a number of circumstances, of which the most important are, the plasticity of the effused matter, the nature of the affected tissue, and the state of the general system. To enable it to attain this point at all it is necessary that it should have a strong cell-life, or cell-force; for when this is wanting the development of cytoblasts and nuclei is either impracticable, or it occurs so imperfectly as to be soon arrested, or, at all events, very much impaired. When everything is favorable, the development proceeds very rapidly; cells and nuclei are formed in great numbers, and these, connecting themselves with each other, are gradually spread out into fibres, lying, for the most part, in straight, parallel lines, and profusely inlaid with granules, as in fig. 9. Soon after this process has begun, vessels show themselves in the new product, either as an offspring of a new epigenesis, or as an extension from the neighboring structures, the latter being by far the more common source of the supply. The walls of the vessels are, at first, very frail and yielding, so

Fig. 9.

Fig. 10.

Fig. 11.

Figs. 9 and 10, from Bennett, show nuclei and cells developing themselves into fibres: whilst fig. 11 exhibits a perfect fibrous tissue.

that the least pressure is sufficient to rupture them and cause an extravasation of their contents. Gradually, however, as they increase in age, they become better qualified for the discharge of their functions, and in time acquire all the properties of the natural vessels. When fully developed, they can be easily discovered with the naked eye, and readily admit fine injecting matter. The veins are usually disproportionably large to the arteries, but this defect also ultimately disappears. Nerves and absorbents likewise exist,

but whether they are supplied by the surrounding tissues, or by the inherent powers of the effused matter is undetermined.

The arrangement of the newly-formed vessels is represented in the annexed sketches. Fig. 12 is a portion of coagulating lymph attached by a narrow neck to the peritoneal coat of an inflamed intestine. The vessels have a ramiform disposition, and freely anastomose with each other. Fig. 13 is a

Fig. 12.

Newly-formed vessels in plastic lymph.

Fig. 13.

Vessels in false membrane of the pleura.

piece of false membrane of the pleura. The vessels are large, numerous, and farther advanced than in the other sketch.

There are some situations where fibrin is never organized, however strong its vitality may be at the moment of its deposition. Such an occurrence, for example, is nearly always impossible in the alimentary canal and urinary bladder, for the reason that the irritating and heterogeneous contents of these reservoirs speedily deprive the lymph of its organizable properties. Site, then, exercises an important influence upon the process, which, it may be added, is also materially affected by the state of the blood and solids; the more feeble and impoverished these are the less likely will the effused substance be to form cells and nuclei, vessels, nerves, and absorbents.

Lymph is susceptible of absorption both in its fluid state and after it has been changed into blastema and fibro-cellular tissue. This, however, does not occur, at least not to any extent, during the height of the inflammation, by which it has been produced; on the contrary, there must always be a marked reduction of the morbid action before the absorbent vessels can be induced to take hold of it; but when this point has once been reached, the process often goes on very rapidly, as is witnessed in fractures, dislocations, wounds, and other injuries, in which the swelling, chiefly caused by fibrinous deposits, occasionally completely vanishes in a few days. The absorption will of course be more difficult when the lymph has become organized, when, in fact, it not unfrequently effectually resists all the efforts that the surgeon can employ to get rid of it. The opaque spot on the cornea often remains despite of the most protracted treatment. It is probable that lymph, before it can undergo absorption, even in its liquid state, is broken up and dissolved in the fluids of the affected parts; being thus brought more readily under the influence of the vessels.

Moreover, lymph is susceptible of various kinds of degeneration, both in its early and in its more advanced stages, just like other deposits and formations. When recently effused, it may be converted into pus, especially when it is aplastic and exposed to the air; under which circumstances it also frequently becomes hard, dry, and shrivelled, losing its vitality, and assuming the character of an effete substance. It also undergoes fatty degeneration, both before and after vascularization; and, finally, there are cases in which it becomes the seat of pigmentary deposits.

1. USES OF PLASTIC MATTER.

The uses of coagulating lymph in the repair of disease and injury were very imperfectly understood by the older surgeons, and hence it is not difficult to account for their erroneous principles of treatment. A few only had any correct notions on the subject, which, however, strange as it may appear, they rarely applied in practice. Taliacotius, although he knew how to reconstruct mutilated parts, by the transplantation of integument from one region of the body to another, seems never to have thought of applying the knowledge thus acquired to the reunion of accidental wounds. Instead of approximating their edges and keeping them together for a certain period, to insure their adhesion, the older surgeons not only allowed them to gape, but took great pains to irritate and inflame them, thinking thereby to rid the part and system of noxious humors. No person with such an injury was deemed safe until the parts had passed through a process of mundification, suppuration, and incarnation. To treat them otherwise would, in their judgment, have subjected them to great hazard, on account of the supposed retention of peccant matter. An opportunity must be afforded for the escape of this matter, and the period consumed in this delusive treatment often extended through several months even in the most insignificant cases. Wounds which, if properly managed, would have healed in a few days, were thus often kept open for an incredible length of time. This practice, so prejudicial to the true progress of surgery, and so utterly at variance with the best interests of humanity, continued in vogue until the time of John Hunter, towards the close of the last century. It remained for this illustrious man to point out the properties of plastic lymph, and to describe its many surgical uses. Through his influence a happy revolution has been effected in the treatment of wounds and other injuries, as well as in the various plastic operations, the beneficial effects of which cannot even yet be fully estimated.

The modern practice in the treatment of wounds is, as soon as all oozing of blood has ceased, to approximate their edges by appropriate dressings, and to retain them in this position for a sufficient length of time to insure their reunion by the organization of the plasma that is effused between them. But little inflammation is required for the process, and hence the chief duty of the surgeon consists in keeping the parts cool, elevated, and at rest. The great danger is in doing too much, thereby thwarting nature's efforts at repair. All heating and stimulating applications are out of the question, as so many impediments to the desired action; the mind and body are kept free from excitement, and the strictest attention is paid to the bowels, diet, and secretions; under this management the wound generally heals in a few days, the bond of union becoming hourly firmer and firmer until it is as perfect as nature can make it by the conversion of the plasma into fibro-cellular matter, of which, however, very little is ordinarily left when the process is completed.

Parts completely separated from each other, and immediately replaced, will, if judiciously managed, often reunite, and be nearly, if not quite, as useful as before. * Numerous cases, of a well-authenticated character, are upon record of bits of fingers, the nose, and the ear having been successfully treated in this wise.

It was upon a knowledge of the plastic properties of coagulating lymph that Taliacotius founded his world renowned operation, which is now universally known by his name, of repairing mutilated noses, lips, and ears. His attention was originally directed to the subject by watching the effects of the grafting of trees; he observed that the transplanted portion not only contracted firm adhesions in its new situation, but that it generally grew with

great vigor, and ere long produced most excellent fruit, altogether superior to, and different from that of the parent stock. Possessed of a profoundly inventive genius, he was led to believe that a similar operation might be performed upon man, and it was not long before he put his reasoning to the test of experiment. His success was complete, and the result was that he became the great rhinoplastic surgeon of his day. His method consisted in raising a flap of integument from the arm, and after having thoroughly pared the mutilated organ, in sewing the raw edges accurately together, care being afterwards taken to maintain the parts in contact with each other until they had become closely and inseparably united. The Indian method, as it is termed, differs from that of Taliacotius mainly in this, that the flap of skin is generally borrowed from the immediate vicinity of the deformed organ, its pedicle being twisted upon itself in such a manner as not to interfere injuriously with its circulation.

Du Hamel, near the middle of the eighteenth century, executed some curious experiments, which, as having a direct bearing upon the present subject, deserve passing notice, notwithstanding they are old and trite. They consisted in ingrafting the spur of a cock upon the comb of the same animal, where, especially if the spur was a young one, it generally promptly united. In one instance he found that the spur, although not larger than a hemp-seed when the operation was performed, acquired in the course of from three to four years a length of several inches. The experiment was subsequently repeated by John Hunter with similar results. He ascertained not only that what Du Hamel had said was perfectly true, but that, if the testicle of a cock be transplanted into the abdomen of a hen, such complete union will occur between them as to permit minute injecting matter readily to pass from the vessels of the one into those of the other.

The fact that a tooth, extracted by mistake, will, if immediately replaced in its socket, speedily reunite, and ultimately regain its former hold, has long been familiar to dentists. It was formerly supposed that the adhesion was always imperfect, but that this is not so is shown by the circumstance that the vascular connection between the tooth and the socket may be demonstrated by injection. The knowledge of this fact led to the painful and disgusting practice, so much in vogue in the last century, of transplanting teeth from the mouth of one person into that of another, and which was finally abolished only when it was discovered that it was fraught with danger, on account of its liability to transmit disease.

Finally, there is, as an additional illustration of this interesting subject, the singular experiment of John Hunter of inserting a fresh human tooth into the comb of a cock, where it took root, and became firmly fixed, new vessels extending up into the cavity of the fang, as was ascertained by injection after the death of the animal.

Curious and instructive as the above experiments are, they hardly equal, in point of interest, many of those that have been performed by the modern surgeon upon the human subject for the relief of mutilated structures. Whether science has attained its highest triumphs in the department of plastic surgery, or whether it is capable of still further achievements, time alone can determine.

The good effects of plasma are exhibited in various other processes, as in the suppression of hemorrhage, and the radical cure of hernia. In the former, the patient would inevitably bleed to death if it were not for the agency of lymph in sealing up the mouth of the vessel by attaching the internal clot firmly to its surface. In hernia a radical cure can only be effected through the intervention of plastic matter, thrown out in consequence either of the pressure of a well-adjusted truss, or the injection of some irritating fluid, causing inflammatory action in the parts around.

Plastic matter is often of service in circumscribing morbid action, and in inclosing foreign bodies. In abscess a wall of lymph is generally formed around the pus, effectually preventing its diffusion among the surrounding tissues. Occasionally the fluid is inclosed by a distinct membrane, derived from the fibrin of the blood, and possessed of a high degree of organization. In carbuncle and erysipelas the lymph is usually of an aplastic nature, and therefore incompetent to prevent the extension of the disease. Balls, needles, pins, and various other foreign bodies are occasionally inclosed in a manner similar to pus, and, in consequence, often remain harmless tenants of the body for many years.

Again, plasma is of service in obviating accidents. Thus, in abscess of the lung, if it were not for the intervention of the fibrin of the blood, the matter would often break into the cavity of the chest, and destroy life in a few days, if not in a few hours. How then is this untoward occurrence prevented? Simply by the development of inflammation in the pulmonary pleura, followed by a deposit of lymph, which thus becomes the bond of adhesion between this membrane and the costal pleura; so that by the time the matter reaches the surface an effectual barrier is opposed to its effusion, in consequence of which it generally discharges itself through a contiguous bronchial tube. A similar occurrence takes place in abscess of the liver in relation to the peritoneum and intestinal tube. In typhoid fever the glands of Peyer are often perforated, and yet it seldom happens that the contents of the bowel escape into the abdominal cavity, simply because of this wise provision of nature in gluing together the contiguous serous surfaces.

Finally, lymph is of use in obliterating serous cavities. In the radical cure of hydrocele, a disease which has its seat in the vaginal tunic of the testicle, an operation is performed which has for its object the establishment of a certain degree of inflammation, followed by a deposit of fibrin, just sufficient to cover the opposing surfaces, and to insure their permanent agglutination. Serous cysts are treated upon similar principles; and modern surgery has been emboldened to inject even some of the movable joints, the abdomen, and ovarian tumors with irritating fluids, for the radical cure of dropsical diseases of these parts.

2. INJURIOUS EFFECTS OF PLASTIC MATTER.

But lymph is capable of producing injurious effects as well as beneficial; nature's operations cannot always be controlled by art, and it is therefore not surprising that she should often overleap the bounds of discretion when she is depleting the inflamed structures by effusion of plastic matter. Immense mischief is frequently done in this manner, within a few hours after the commencement of the morbid action; mischief which it may require months of the most judicious and persevering efforts of the surgeon to eradicate. Examples of this occurrence are daily met with in practice, and serve as mortifying illustrations of the impotency and imperfection of our art, as well as of the perverseness of disease.

Among the more common and obvious effects of this description are the following: 1. Mechanical obstruction of the natural outlets of the body. 2. Change of structure by interstitial deposits. 3. Abnormal adhesions. 4. Induration and enlargement.

a. An example of *mechanical obstruction* from a deposit of lymph is afforded by what occurs in the windpipe in plastic croup, the principal anatomical character of which is the formation of a false membrane, which often moulds itself accurately to the shape of the tube, and which, especially when it extends high up into the larynx, may become a source of suffocation by impeding the entrance of the air into the lungs. In rare cases the membrane is

detached and expectorated; but generally it remains in spite of our remedies, and speedily destroys the patient. Not even an artificial opening into the trachea will usually avert this event.

In some of the mucous canals this matter is poured out beneath the lining membrane instead of upon its free surface, where, becoming organized, it leads to permanent contraction of the tube. It is in this manner that stricture is formed; when the case is a very bad one, lymph may also be effused into the substance of the lining membrane, and even upon its free surface, as is seen in what is called the bridle-stricture of the urethra, which, however, is exceedingly rare.

b. Change of structure by *interstitial deposit* of lymph occurs in almost all cases of inflammation, however slight or however situated. In pneumonitis, it closes up the air-cells and minute bronchial tubes, as well as the cells of the connective areolar tissue, producing what is called hepatization of the lungs. Opacity of the cornea, acting obstructingly to the rays of light, is the invariable result of a deposit of plastic matter either beneath its conjunctival covering or in its inter-lamellar structure.

c. *Abnormal adhesions*, wherever found, are occasioned by this substance, thrown out as a consequence of inflammatory action. The effects of such adhesions are always more or less prejudicial. In the thoracic cavity, they confine and restrain the play of the heart and lungs; in the abdomen, they often become a source of internal strangulation; in the mucous outlets, as in the vagina and uterus, they may produce complete occlusion of their orifices; and in the vessels, especially the arteries, they sometimes induce obliteration of the largest sized trunks. Abnormal adhesions between the bowel and the sac in hernia are sometimes a cause of its irreducibility.

Great mischief is often done by deposits of lymph into the joints. If the matter be not promptly removed by the absorbents, nature makes an effort to organize it, and to convert it into an adventitious structure, which, undergoing various mutations, at length assumes the properties of the osseous tissue, at the same time that it effectually destroys the motions of the articulation. The case, in fact, is one of bony ankylosis, and no treatment that can be brought to bear upon it will be of any avail in regaining the functions of the part.

d. Among the more frequent and distressing evils of plastic deposits are *induration and enlargement*, or hardening and thickening of the organs and tissues. Such occurrences are generally exceedingly annoying, often severely taxing the patience of the sufferer and the skill of the professional attendant. They are the direct result of interstitial deposits, which often manifest an early tendency to organization and transformation, and which none but the most determined perseverance in the use of remedies can enable us ultimately to overcome. The stiff and thickened joint, the indurated and enlarged testicle, the hypertrophied spleen, liver, and lymphatic gland, the hardened and enlarged tonsil, are literally living witnesses to the truth of this statement.

TREATMENT.

The treatment of lymphization is to be conducted upon general antiphlogistic principles; undue action is to be repressed, and the absorption of effused matter is to be promoted. To accomplish the first of these objects, the ordinary local and constitutional measures are employed; for the second, sorbefacients are necessary, as mercury and iodide of potassium internally, and the tincture of iodine, liniments, and embrocations externally. In the acute stage of the disease, while secretion is still active, purgatives and antimonials, with the liberal exhibition of calomel, constitute the chief means of

relief; but the tendency to deposit having ceased, their use is dispensed with, all except the mercury, which is now given in minute doses, and with a view strictly to its alterative effect; it is often carried to slight ptyalism, the mouth and gums being maintained in a tender condition for perhaps several weeks consecutively; or, with an occasional interval, for even a much longer period. In the latter event, the bichloride frequently, if not generally, forms a valuable substitute for the calomel; less likely to act hurtfully, and yet, at the same time, very effectually stimulating the absorbents. In such cases, too, small doses of tartar emetic often produce a most salutary influence; its action being hardly inferior to that of mercury itself, with which it may frequently be advantageously combined. When the inflammatory action has pretty much subsided, its products, especially the serous and plastic, are generally easily gotten rid of by hydrochlorate of ammonia, or iodide of potassium, administered in doses varying from three to twenty grains, in aqueous solution, three times in the twenty-four hours; strict attention being paid, meanwhile, to the diet and bowels. When the case is obstinate, an occasional mercurial will constitute a valuable addition.

Among the more beneficial topical means are, the dilute tincture of iodine, applied twice in the twenty-four hours; inunctions with mercurial and other unguents, particularly that of the iodide of lead; stimulating embrocations; and steady, uniform support with the bandage. Various kinds of plasters, as the common mercurial, the compound galbanum, and others of a kindred nature, are also frequently serviceable. Washing the part well, when accessible, twice a day with hot water and Castile soap, and then using dry friction upon it, often do more good than anything else. In some cases, again, cold, especially in the form of the douche, acts very beneficially, affording relief when everything else seems to fail. In the case of the joints passive motion must be carefully performed, at first once, and then twice a day, to prevent ankylosis from the organization of the fibrinous bands which are so liable to form during the progress of synovitis.

When the object is simply to assist nature in her efforts at repairing injury, as a wound or fracture, care should be taken, on the one hand, that the attendant action is not too low, and, on the other, that it does not transcend the fibrinizing limits. By over-officiousness the system may be so exhausted as to render the proper supply of lymph in the part a matter of impossibility, or such a state of the constitution may be brought about by the effects of previous disease, intemperance, or inadequate nutrition from the want of proper food. However induced, it should claim prompt attention, every effort being made, by the use of tonics, stimulants, and other invigorating measures, to supply the blood with the requisite material for the deposition of fibrin; all debilitating topical applications being at the same time discontinued. Over-action, on the contrary, is met by the usual antiphlogistic means, carefully and warily applied, lest harm should result from the too rapid reduction of the vital powers. The management of the reparative process always demands great judgment and vigilance.

SECT. IV.—SUPPURATION AND ABSCESS.

Suppuration is the process by which pus is formed, and is one of the most frequent, as it is certainly one of the most important, of the results, events, or conditions of inflammation. Its presence, as a general rule, is denotive of a higher grade of excitement than a mere deposition of serum and plastic matter, which, however, are nearly always associated with it. But it must not be supposed that the reverse of this proposition is true; for inflammation often exists in a severe degree, with an abundant effusion of the watery and

fibrinous elements of the blood, and yet there is not the slightest evidence of suppuration.

It was formerly supposed that suppuration might occur without the agency of inflammation, and there seems to be still a lingering disposition on the part of some pathologists to adhere to this doctrine, if not by direct advocacy, at least by implication. The opinion doubtless had its origin in the fact that there are occasionally cases of suppuration in which large quantities of pus are thrown off, without any evidence of the ordinary phenomena of inflammation, such, especially, as pain, heat, and discoloration of the structures in which the matter is formed, or any constitutional disorder; the whole process being apparently conducted as if both the part and system were unconscious of what is going on. Such cases are by no means infrequent, and yet if they be carefully investigated, or traced through the various stages of their progress up to the dissection of the affected tissues, the most satisfactory proof will be afforded of their phlogistic nature. In a cold, strumous or scrofulous abscess, for example, which has so often served as the basis for this, now nearly exploded idea, and the formation of which is sometimes the work of several months, inflammation is just as much concerned in the production of its contents, as in a phlegmonous boil that is developed in three or four days. The only difference is, that in the one the morbid process moves on slowly and almost imperceptibly, while in the other it proceeds very rapidly, and is accompanied by such well-marked symptoms as to render it impossible to mistake their character.

Pus may be formed, as is well known, without any breach of continuity of the affected parts. This mode of suppuration is, in fact, very common, not only in the serous cavities, but throughout nearly the whole of the mucous system. It is not, however, confined to these textures. In the cellular substance, lungs, brain, liver, and other viscera, nothing is more frequent than suppuration, without any ulceration whatever in the inceptive stages of the morbid action.

The formation of purulent matter does not take place with equal facility in all the organs and textures. Of the viscera, those which are most prone to take on suppurative action are the liver, lungs, and brain; of the tissues, the cellular, cutaneous, mucous, and serous. In the fibrous, cartilaginous, tendinous, and osseous textures, this fluid forms with difficulty, and is seldom of a thick, consistent nature. Of the mucous system some portions are more liable to be affected with suppuration than others. Thus, it is much more common to find pus in the colon than in the stomach or ileum, in the vagina than in the uterus, in the urethra than in the urinary bladder, in the nose than in the mouth, in the fauces than in the œsophagus, in the bronchia than in the larynx. So, likewise, in the serous system, suppuration is more frequent in some situations than in others; as, for example, in the pleura, the vaginal tunic of the testicle, and the lining membrane of the larger joints. In the subcutaneous cellular texture, pus is most readily formed in those parts which are remote from the central organ of the circulation. The blood-vessels do not often suppurate, except when wounded; and the same, so far as we know, is the case with the absorbents. The lymphatic ganglions, however, are very frequently affected in this way, especially those of the axilla, the groin, the mesentery, and the base of the lower-jaw, particularly in persons who are predisposed to scrofulous disease. The nervous tissue seldom suppurates, and the muscular still more rarely. From all these facts we may deduce the axiom, that those structures are most prone to form matter which contain the largest amount of loose cellular substance, and, conversely, that those which possess this tissue sparingly always suppurate with difficulty, requiring in general a much longer period, and elaborating a less perfect fluid.

The period at which suppuration may occur after the establishment of inflammation varies, on an average, from twenty-four hours to three or four days, depending upon the nature and situation of the affected tissues, the intensity of the morbid action, and also, and that in a material manner, upon the condition of the system, and the character of the exciting cause. Mucous membranes, especially if exposed to the air, generally suppurate very readily, having, as it were, a predisposition to take on this kind of action; serous membranes, on the contrary, suppurate with difficulty, one reason of which is that, being arranged in the form of shut sacs, they do not feel the stimulus of the atmosphere; another, doubtless, is the fact that such structures, when irritated, are naturally inclined to furnish lymph rather than pus, their organization peculiarly fitting them for that office. The same difference exists between the veins and arteries, and it is practically fortunate that it does; otherwise the danger of wounds, whether the result of accident or design, requiring the ligation of the principal arteries, would be much greater than experience has shown it to be. No surgeon likes to tie a large vein, well knowing that the operation may be followed by fatal suppuration of its lining membrane. In some of the internal viscera, as the brain and liver, pus sometimes forms with great rapidity, as is seen in cases of injuries of these organs. Matter, other things being equal, forms more rapidly when the inflammation is very intense than when it is comparatively mild. A wound inflicted upon an unhealthy or intemperate person will be more likely to run speedily into suppuration than one of a similar character occurring in an individual of sound constitution and regular habits. A phlegmonous boil will usually begin to deposit pus in from twenty-four to thirty-six hours, whereas a chancre does not furnish any, so far as we are able to judge, until the beginning of the fourth day. In variola, the suppurative process is generally not fully established until about the ninth day.

Exposure of an inflamed surface to the air greatly promotes suppurative action, and is, consequently, directly hostile to adhesion. The more nicely the edges of a wound are approximated, the greater, all other things being equal, will be the probability of speedy and permanent reunion, and conversely. Serous membranes, as already stated, have naturally a disposition, when inflamed, to pour out lymph, and become glued together; but whenever they lose the character of closed sacs, as they necessarily do when they are accidentally opened, the morbid action, consequent upon the injury, is certain to be followed by the formation of pus, especially if the air is permitted to have free access to them for any length of time.

Pus originally appears in the form of distinct globules, which are dispersed through the affected structures, and can be easily recognized by their pale yellowish color. As the purulent particles increase in number, they gradually become confluent by the removal of the parts concerned, and in this way the matter is at length collected into an abscess.

The symptoms which characterize the suppurative process will claim special attention when we come to speak of abscesses. Meanwhile, it will suffice to observe, in general terms, that they are such as denote the existence of ordinary inflammation, with an increase, more or less considerable, of the local and constitutional disturbance.

Pus, the product of suppuration, has been an object of anxious study from the earliest ages of the profession down to the present time; but it has only been within a comparatively recent period that any real and reliable light has been thrown upon its physical, chemical, and microscopical properties.

When genuine, or, as it is not unaptly termed, good, healthy, or laudable, pus is of a white, yellowish tint, opaque, homogeneous, of a sweetish taste, without any particular smell, and of the consistence of thin cream. It is heavier than water, in which it is partly dissolved, emits a faint, mawkish odor

on being heated to the natural temperature of the body, resists putrefaction with remarkable pertinacity, and is coagulated by heat, alcohol, and hydrochlorate of ammonia. Pus freezes less rapidly than water, and when thawed does not regain its original properties.

The specific gravity of pus is liable to considerable variation. It is less than that of blood, and greater than that of serum. According to Gueterbock, it ranges from 1030 to 1033. In seven distinct examinations of pus, taken from abscesses in different situations—as the thigh, arm, axilla, back, pleura, and the lung in pulmonary phthisis—Dr. John Davy found the specific gravity as low in one as 1021, and in another as high as 1042. This great disparity is mainly attributable to two circumstances, the unusual quantity of the solid ingredients, and the variable density of the liquid part.

The *chemical* constitution of pus has been examined by a great number of experimentalists, and the results of their investigations tend to show that it contains most of the elements of the blood. The following analysis is by Gueterbock, from the pus of an abscess in the human breast.

Water	86.1
Fat, soluble only in boiling alcohol	1.6
Fat and osmazome, soluble in cold alcohol	4.3
Albumen, pyine, pus globules and granules, soluble neither in hot nor in cold alcohol	7.4
Loss	0.6
	<hr/> 100.0

Lehmann has investigated the chemical composition of the different elements of pus with great care. Normal pus he found to contain from 14 to 16% of solid constituents, of which from 5–6% belonged to mineral or inorganic substances. The most usual insoluble salts of pus are the phosphates of lime and magnesia, and the sulphate of lime; the principal part of the soluble salts is furnished by chloride of sodium. The quantity of fat was found to vary from 2–6%; the quantity of albumen in the serum from 1.2 to 3.7%. Casein and the coloring matter of the blood do not occur in normal pus. A substance which usually enters into the composition of pus is *pyine*. Gueterbock, who discovered it, considers it as a peculiar animal principle. Its exact nature is not understood. It is supposed by some to be an oxide of protein, by others a form of fibrin. It can be precipitated from pus by acetic acid, or by alum. It is soluble in water, but insoluble in alcohol.

Pus occasionally contains a peculiar substance, denominated *pyocyamine*; it imparts a bluish or greenish hue to the contents of certain abscesses, and to the discharges of certain ulcers, but its real nature is not well understood.

With regard to the composition of the compound part of the pus globules we possess no positive knowledge. The cell walls, contents, and nuclei, react like protein bodies, and are probably of an albuminous nature. The cell walls are dissolved by acids, but resist the action of alkalies.

Pus, *microscopically* examined, is found to be composed of numerous small corpuscles suspended in a thin, transparent fluid, called the pus-liquor. These little bodies, which have received the name of pus globules, are generally of a spherical form, and vary in size from the $\frac{1}{2000}$ th to the $\frac{1}{3000}$ th of an inch in diameter. They are mostly very granular, and possess a delicate cell wall, which becomes distinct on the addition of water. They

Fig. 14.

a. Natural appearance of pus corpuscles. b. Appearance after the application of acetic acid.

are nucleated; some containing one well-defined nucleus, others two, three, or more small nuclear bodies. Acetic acid has the effect of rendering them apparent; the cell-contents and wall becoming transparent under its influence, especially if the acid be undiluted. Fig. 14 exhibits pus corpuscles in their natural state as well as their appearance when acted upon by acetic acid.

These corpuscles float in the pus-liquor, and are intermixed with various other solid elements, as granules, shreds of fibrin, and exudation corpuscles; also, at times, with small homogeneous, non-nucleated corpuscles, termed pyoid.

Pus is liable to be modified in its properties by the presence of extraneous substances, such as grumous blood, fibrin, cholesterine, and the debris of the organs and textures in which it is formed. In common phlegmon, it often contains shreds of cellular tissue, of a dirty grayish color, not unlike wet tow. The brownish matter found in certain abscesses of the liver probably derives its color and consistence from the intermixture of the softened and broken-down hepatic parenchyma. In suppuration of the different glands, the pus is not unfrequently mingled with the product of their secretion. Thus, in the kidney, it may blend itself with the urine, in the liver with the bile, in the mamma with the milk, in the testicle with the semen. Purulent matter is sometimes very fetid, probably from the extrication of sulphuretted hydrogen.

The different varieties of pus have received different names. When the fluid is of a whitish color, creamy in its consistence, and composed of a great number of globules, it is said to be *healthy*, pure, or laudable, in reference to the process by which it is produced, which is of a healthy, sanative, or restorative nature. It is usually met with in suppurating wounds, in healing ulcers, and in phlegmonous abscesses. Its properties have already been sufficiently described.

Sanious, serous, ichorous, or sanguinolent pus is thin, almost transparent, of a yellowish, oily, or reddish color, and generally so acrid as to erode the parts with which it comes in contact. It is a product of unhealthy inflammation, and is principally observed in caries of the bones, in irritable ulcers, and in open cancer. This variety of pus is frequently blended with grumous blood, flakes of fibrin, and the debris of the affected tissues.

Fibrinous pus consists of common pus in combination with lymph. It is of a whitish, grayish, or cineritious color, and of a semi-liquid, concrete, or lardaceous consistence. Under the microscope, it displays the globules of healthy pus, with numerous other cells and fibres of irregular shape. It is commonly found in the joints, the splanchnic cavities, in metastatic abscesses, and in carbuncular inflammation. Its presence denotes a high degree of morbid action.

Scrofulous pus is mostly seen in pulmonary caverns, cold abscesses, scrofulous disease of the joints, and chronic inflammation of the lymphatic ganglions. After standing a little while, it usually separates into two parts, of which one is thick, straw-colored, and inodorous; the other, which rests on the surface, thin, ropy, and mixed with small, opaque, curdy flakes. When scrofulous pus is long retained it may acquire a disagreeable, nauseous smell, not unlike the pollen of the chestnut; at other times it is excessively fetid. The attendant action is usually very languid.

There is a variety of pus to which, from its admixture with mucus, the term *muco-purulent* is applied. It is usually a product of a high degree of inflammation of the various outlets of the body, particularly the nose, eye, bronchial tubes, and genito-urinary apparatus. The mucus which proceeds from these surfaces in the healthy state is composed of a transparent fluid, and of abraded epithelial cells, flat, and irregularly sided with a central nucleus. In addition to these, the microscope detects numerous granular

masses and spherical globules, similar to those of pus; the whole being suspended in a viscid, transparent, ductile fluid. Under inflammation, the epithelial cells are cast off so quickly that they have not time to become flattened out, and the globules are not only greatly augmented in number, but they acquire somewhat the character of those of pus.

Finally, there is what is called *puriform* matter, a substance which, as the name implies, is not true pus, but an imperfect liquid bearing some resemblance to it. It is found chiefly in bad forms of inflammation, as erysipelas, carbuncle, and pyemia, and consists essentially of broken-up lymph and shreds of tissue, interspersed with fatty substance, granules, abortive cells, and a few globules, smaller than those of pus, and not affording the usual reaction under acetic acid.

Certain kinds of pus, as those, for example, of smallpox, varioloid, gonorrhœa, and chancre, are *contagious*. In what particular element of the fluid the virus or specific secretion is contained, or whether it exists as an entity, is undetermined. The vitality of the organ by which it is elaborated is not necessary for the preservation of its peculiar effects. Once formed, it becomes independent of its source, and retains, for a considerable period, the power of contaminating the parts to which it is applied, producing a disease of the same character. Various chemical agents, however, as the alkalies and acids, have the property of neutralizing or destroying it, so that, if inoculation be afterwards attempted, no effects will follow. If the pus of a chancre be examined with the microscope, it will often be found to contain animalcules, particularly the *vibrio lineola*.

Pus was formerly supposed to be a product of secretion, an operation similar, in principle, to the secretion of bile and other fluids. This opinion, however, is no longer tenable, modern researches having shown that it is merely altered coagulating lymph, fibrin, or plasma, so abundantly effused during the inflammatory process, especially at the focus of the morbid action. In what manner, or by what agency, the change is effected, is not determined. All that is certainly known concerning it is that the pus corpuscles resemble, in their size, shape, and structure, the corpuscles in the effused lymph, and that the former always contain more or less oily matter, which thus constitutes one of their characteristic features. Leaving, then, out of the question any speculation in regard to the subject, it is evident that the fluid, called pus, is formed externally to the vessels by a species of disintegration and decay of the plastic elements of the blood, thrown off as an effect of inflammation, and that, consequently, secretion has no agency whatever in its production.

Pus globules are, as has already been seen, nucleated cells which have their origin in germs that pre-exist in the effused lymph, but which are not fully developed until they have been subjected to a species of metamorphosis, the precise nature of which has not been explained. The change is probably partly of a vital, partly of a chemical nature; or, possibly, it may be mainly of the latter description, the peculiar color, form and size of the pus globules being dependent upon transformation effected in the exudation. Rokitansky has advanced the idea that the pus corpuscles may change, by a kind of exogenous process, if not also by an endogenous one, into granule cells; a view which seems to me neither plausible nor consistent with the established doctrine of ordinary cell formation. No development of this kind can occur without the agency of the vital principle, and it is hardly possible to conceive that a pus globule should be so endowed after it has attained its full growth. Rokitansky also supposes that the fluid in which the corpuscles are suspended may give rise to a large amount of oily matter.

The more aplastic or degraded lymph is, at the moment of its deposition, the more likely will it be to be transformed into pus; hence what has been called corpuscular or croupous lymph is much more prone to assume this character

than the fibrinous, or more organizable variety of this product. The degeneration is also, no doubt, materially influenced by the softened and disintegrated condition of the affected tissues, in the meshes of which the lymph is situated, such a change being highly favorable to the development of pus germs, or, what is the same thing, inimical to the production of healthy blastema.

Pus is susceptible of absorption, probably in all its varieties, as well as in almost every locality. Satisfactory proof of this fact is afforded by what occurs in abscesses in the different external parts of the body; and it is therefore analogically reasonable to infer that it may also take place in the internal organs and cavities. Great doubt has recently been expressed, especially by some of the French pathologists, respecting the possibility of pus being taken up in this manner, on the ground, chiefly, that the accumulations which occasionally disappear, both spontaneously and under treatment, are really not abscesses, but collections of plastic matter. Every surgeon, however, of experience knows that pus, or puriform fluid, is sometimes removed by the agency of the absorbents, after its existence has been satisfactorily tested by the exploring needle. Particular remedies are often employed for the attainment of this object, and our efforts are certainly not unfrequently crowned with success, although probably not as often as is generally supposed.

Pus, as pus, is never absorbed. It is extremely probable that the thinner parts are at once carried into the system, without any previous change; whereas, the pus globules are no doubt obliged to undergo a species of degeneration and disintegration, before they can be acted upon by the absorbent vessels. Whether the fatty matter remains, or whether it, also, is removed, has not been determined. How pus is disposed of, after it has reached the circulation, is likewise unknown; but the most reasonable conclusion is that it undergoes oxidation, and is excreted by the liver and kidneys, if not, also, by some of the other emunctories.

ABSCESSSES.

An abscess is a circumscribed cavity of abnormal formation, containing pus. When the matter is poured out into a natural cavity, as the chest, or within a joint, the collection constitutes what is called a purulent effusion. An abscess may be superficial or deep, acute or chronic, common or specific. An abscess is said to be superficial when it is immediately beneath the common integuments or in the cellular substance among the superficial muscles. The word deep, on the contrary, is used when the matter is lodged in an internal organ, in the substance of a bone, or among muscles, bound down by a large quantity of tissue. The terms acute and chronic have reference merely to the time occupied in the formation of the abscess. A common abscess is one produced by ordinary inflammation; while the specific abscess is the result of the operation of some particular poison, as the virus of chancre, smallpox, or glanders. Finally, an abscess is circumscribed, as when it is bounded by plastic matter; or diffuse, as when its contents are sent abroad through the connecting areolar tissue.

The most philosophical division of abscesses is into phlegmonous, scrofulous, and metastatic, the first being incident to all persons, while the second is capable of occurring only in certain classes of individuals, or such as are affected with a strumous taint of the system. The term "metastatic," formerly so much in vogue, is employed to designate those collections of pus which are consequent upon severe injuries, operations, and diseases, and might be advantageously abolished, as it is only calculated to convey false impressions respecting a form of suppuration which properly comes within the definition of phlegmonous, although, as will be shown by and by, it is generally supposed to have its origin in a toxical condition of the blood. It has recently

been described under the term "multiple," and will claim particular attention under the head of pyemia. It is not easy, in the present state of the science, to assign an appropriate place to the diffuse abscess, as it is often impossible to determine its real character. The specific abscess will not require any special consideration, since, apart from its exciting cause, its mode of formation does not, so far as we are able to comprehend it, differ at all from that of the common phlegmonous abscess.

1. PHLEGMONOUS ABSCESS.

A phlegmonous abscess is one which runs its course with unusual rapidity, and which is always accompanied by well-marked inflammatory symptoms. The part feels, as the name implies, as if it were on fire, being hot, tender, and exquisitely painful. A tensive, throbbing sensation is generally present; it is synchronous with the contraction of the left ventricle of the heart, and is always greatly aggravated by dependent position; it is particularly severe at the focus of the morbid action, and is a valuable diagnostic symptom, as it is generally denotive of suppuration. Its immediate cause, as explained elsewhere, is obstructed circulation, and consequent pressure upon the nerves of the affected structures.

If we examine the *anatomy* of a phlegmonous abscess, we shall find it to be a very curious structure, growing out of several highly interesting pathological changes. In the first place, the matter is obliged to have a receptacle for its accommodation. This is usually furnished by the cells of the connecting areolar tissue of the part; but as the accumulation, which is at first drop-like, progresses, this substance is destroyed by ulcerative action, and in this way a cavity is gradually formed, often capable, in the end, of holding an immense quantity of fluid. While the process of deposition is going on, plastic matter is poured out at the periphery of the cavity, gluing up the cellular tissue, and forming thus a kind of boundary line around the pus, by which its diffusion among the surrounding structures is effectually guarded against. No distinct cyst is built up, for nature has not time for such an enterprise, nor is she at all in need of it, although the occurrence is not impossible even in acute abscess, especially in one of the liver. The next circumstance to be observed is the effort which the matter makes to reach the nearest surface, for this is one of the laws of interstitial suppuration. To this object the matter itself is eminently contributory, the pressure which it exerts upon the superimposed parts greatly promoting and expediting the ulcerative action, by whose agency evacuation is finally attained. Thus, at least three separate and distinct processes are going on during the formation of an abscess; a deposit of pus, an effusion of lymph, and ulceration. The importance of an effusion of plastic matter is shown by the fact that, when it fails to be furnished, the contents of the abscess are widely diffused among the surrounding structures, committing extensive havoc in the connective tissues, and causing frightful separation of the muscles. These evil effects are often witnessed in phlegmonous erysipelas, where, in consequence of the cacoplastic character of the lymph, the matter occasionally burrows to a great distance, destroying everything within its reach.

The great law which presides over the evacuation of abscesses, by which their contents are enabled to reach the nearest surface, is attended with the most fortunate results, for it not only abridges suffering, but also saves structure. Thus, in abscess of the liver, a long time would elapse, and an immense amount of pain and constitutional disorder would be caused, if the matter, instead of emptying itself, as it usually does, into an adjoining coil of intestine, were compelled to travel across the walls of the abdomen.

The *contents* of the phlegmonous abscess usually partake strongly of the

nature of well-elaborated pus, being of a whitish, or pale straw color, and of a thick, cream-like consistence, with an abundance of large and well-matured pus corpuscles. Intermixed with them are often flakes of lymph, and the debris of the affected structures. Thus, in abscess of the external parts of the body, it is not uncommon to meet with shreds of areolar tissue; in abscess of the liver, with broken-down hepatic substance. Occasionally, again, the pus is blended with the peculiar secretion of the part, as semen in abscess of the testicle, bile in abscess of the liver, milk in abscess of the mamma. A knowledge of these facts is of great practical value, as a means of diagnosis, the nature of the adventitious matter often pointing directly to the seat of the disease. Some forms of acute abscess, as those more particularly which follow severe accidents and capital operations, and to which the term metastatic is sometimes applied, are made up almost entirely of fibrinous matter, the quantity of pus corpuscles being extremely small. The contents of certain abscesses are excessively fetid. This is especially true of abscesses around the anus from the proximity of the pus to the bowel, or from the actual intermixture of fecal matter. The same circumstance occasionally obtains, although generally in a less degree, in abscesses in some other situations, as of the tonsils, bones, and lymphatic ganglions.

Abscesses sometimes contain air, the fluid resting upon the top of the matter. Such an occurrence is most liable to happen in the perineum, about the sacrum, in the ileo-lumbar region, and in front of the abdomen, in consequence of the existence of a communication with the intestinal tube. A similar phenomenon is occasionally witnessed in suppuration of the chest, when the matter contained in that cavity makes an effort to escape externally through one of the intercostal spaces, after an opening has been made into a bronchial tube. In general, the pus, when thus admixed, is excessively fetid, and the abscess is distinctly emphysematous, crepitating under pressure, and often emitting a peculiar gurgling noise.

Phlegmonous abscesses are liable to occur at all periods of life, and in all classes of individuals. We occasionally meet with them within a few weeks after birth, especially in the mamma and in the lymphatic ganglions about the neck, and in the axilla. They may be traumatic, or idiopathic; or, in other words, dependent upon external injury, or constitutional causes, as derangement of the digestive organs, or the suppression of some important secretion, as that of the liver, kidney, or uterus. Abscesses are sometimes of a secondary character, one forming after another, as if there existed a species of pyogenic diathesis. Such an occurrence often proves exceedingly untoward, sadly interfering with recovery, especially when it manifests itself during the progress of convalescence after protracted fevers and severe injuries.

Abscesses of this kind may form in any part of the body; but they are most commonly observed in the areolar tissue, beneath the skin, among the muscles, and around the lymphatic ganglions, as well as in the substance of these bodies, especially in those of the neck, axilla, and groin. Among the internal organs, those that are most liable to suffer are the liver, lungs, and brain, but even here phlegmonous abscesses, except as a result of external injury, are extremely rare.

The number of abscesses varies from one to a great many; being generally in an inverse ratio to their size. Two or three large ones occasionally exist simultaneously in different parts of the body, and, on the other hand, the whole surface is sometimes, as in variola, literally covered with small ones. The size of a phlegmonous abscess ranges from that of a mustard seed up to that of an adult's head.

The *symptoms* which precede and accompany the formation of a phlegmonous abscess are subject to much variety. In general, they are such as

characterize ordinary inflammation. The part, when open to inspection, is found to be red, hot, swollen, and painful, beating and throbbing synchronously with the contraction of the left ventricle of the heart. As the matter accumulates, all these symptoms augment in severity, especially if the fluid be bound down by hard, unyielding structures, interfering with its extension. Under opposite circumstances, however, the pain often diminishes, the part feeling relieved almost as soon as the deposition of pus has fairly begun. However this may be, the discoloration of the skin always increases as the matter approaches the surface, and generally assumes a dusky, purple, or livid aspect, particularly at the focus of the abscess. The swelling also augments, and the part often pits on pressure, more or less serum being effused into the subcutaneous cellular substance. The heat is much greater than it is in the surrounding structures, and there is always serious functional disorder.

The morbid action continuing, the centre of the abscess becomes acuminated, and the matter, in surgical language, is said to point. The skin here is not only greatly discolored, but thin and impoverished; and giving way at the most prominent part of the tumor, allows its contents to escape, generally by a small orifice, which is often entirely inadequate to thorough clearance. The period which intervenes between the commencement of the inflammation that leads to the formation of the abscess, and the evacuation of the pus, varies from a few days to several weeks.

When an abscess of this kind is small, or situated in a comparatively unimportant part, the constitution may fail to take any cognizance of it whatever. But this is rather the exception than the rule; for, in the majority of cases, the system warmly sympathizes with the local trouble, and manifests the interest it feels in it by well-marked inflammatory symptoms. If an abscess is about to form in an internal organ, the patient will be seized with rigors, often violent and long continued, alternating with flushes of heat, and generally followed by copious sweats. This frequently happens even when the abscess is of very trivial size; the importance of the affected structures giving proportionate force to the morbid action. Rigors also generally occur in abscess of the bones and joints, but comparatively seldom when the disease is seated in the subcutaneous cellular substance. Abscess of the ear, parotid gland, tonsils, anus, and perineum are nearly always attended with high constitutional excitement. If the case is at all severe, delirium will be apt to be present, lasting either until the part is relieved, or until the disease proves fatal. The countenance is generally flushed, the eyes are suffused, and there is frequently a hectic spot upon the cheek, especially in internal suppuration. The pulse is full, strong, and frequent; the skin hot and dry; the urine scanty, high colored, and loaded with uric acid. Great thirst and restlessness usually exist. When the abscess is fully formed, the constitutional symptoms, as well, indeed, as the local, often greatly abate, comparative comfort succeeding the violent perturbation. The pulse becomes soft and calm, the surface is bathed with perspiration, the renal secretion increases in quantity and improves in quality, and the patient falls into a tranquil sleep, grateful for the happy change.

Diagnosis.—Notwithstanding that the symptoms of phlegmonous abscess are usually well marked, cases now and then arise where the diagnosis is so obscure as to cause serious doubt respecting their true character. Indeed, there is probably no department of surgery where so many mistakes are constantly committed as in this. If the records of the science could be thoroughly explored, they would, I am sure, be found to abound in blunders of diagnosis in this kind of abscess. As it is, we frequently hear of encephaloid tumors, aneurism, and hernia being opened for abscesses, and life either destroyed upon the instant, or placed in great ultimate jeopardy, by the operation.

Such mistakes are hardly less injurious to the surgeon than to the poor patient; for they but too certainly ruin his prospects and reputation as a practitioner. Attention to the following circumstances will, I trust, enable the reader to steer clear of difficulty: 1. The history of the case; 2. Pointing; 3. Fluctuation; 4. Œdema; 5. The use of the exploring needle.

1. The first object that claims attention is the *history* of the case. Upon inquiry, it will usually be found that the disease has been of short standing; having commenced with the ordinary symptoms of inflammation, and gradually increased until the suppurative point was attained, the fever being high, and the local distress often extreme. Rigors are looked for if the abscess be deep seated, extensive, or among important structures; the pain is tensive and throbbing, steady and persistent, not intermittent, or severe at one time, and absent at another. If the abscess be lodged externally, the swelling is observed to be gravescent, unnaturally hot, excessively tender, intolerant of manipulation, and of a dusky reddish color, especially at its most prominent point. Its career is comparatively brief, a few days, a week, or, at most, a fortnight, sufficing to reach its acme. Then comes the period of dissidence, if the matter is not evacuated; the symptoms abating in severity, the pulse and skin becoming soft, and the pain losing its throbbing character.

2. *Pointing* is a symptom of great importance in the diagnosis of phlegmonous abscess. It is always most conspicuous where there are, or were, most pain and discoloration. The skin looks dusky or livid, and feels thin and attenuated as if it were ready to give way, which, in fact, it generally is. A tumor, benign or malignant, may also point, but a careful consideration of the history of the case will commonly suffice to show the difference.

3. An abscess, near the surface, always *fluctuates*, that is, its contents permit themselves to be displaced on one side, and to be rendered correspondingly prominent upon the opposite. Two methods may be adopted in conducting the examination. In one, alternate pressure is made with the hands or fingers resting upon opposite sides of the abscess. As one hand or finger sinks in the other is elevated, and whenever this is the case there can be no question about the existence of fluid, although the fluid may not be purulent. The other method consists in percussing the tumor with one hand, the other hand being placed upon the opposite side. If matter be present, an undulatory motion will be imparted, one of the surest signs of the occurrence of suppuration. This method, however, is less delicate than the other, and is applicable only to abscesses of unusual volume. Finally, when the matter is seated superficially, its presence may often be detected by passing the finger over the most prominent part of the swelling, when, if there be pus, it will generally sink in a little, in consequence of the skin at that part being less resistant than at the periphery of the tumor. This method of examination is particularly valuable in small superficial abscesses of the scalp, perineum, tibia, clavicle, fingers, and other superficial portions of the skeleton.

4. Valuable information is often obtained from the appearance of the *swelling*. Thus, when the matter is very deep seated, as in abscess of the thigh, the existence of œdema is nearly always decisive of the nature of the case, especially when it is conjoined with a hard, brawny state of the parts. The fluid cannot reach the surface on account of the manner in which it is bound down, but its presence causes inflammation in the skin and subjacent cellular substance, leading to an effusion of serum, and consequently to more or less pitting under the pressure of the finger. In empyema, or purulent collections in the pleura, œdema of the chest, directly over the seat of the fluid, is usually a prominent, and, indeed, in many instances, a characteristic symptom. A puffy and œdematous state of the scalp is often denotive of abscess of the brain and dura mater, in cases of injury of the skull.

5. The *affections* which are most liable to be mistaken for abscess are ence-

phaloid, aneurism, and hernia. From the first of these the history alone of the case will generally suffice for a correct diagnosis. Encephaloid is a chronic affection; a phlegmonous abscess, an acute one; the first is attended with little or no pain until ulceration sets in; the latter is attended with a great deal, generally from the moment it begins until it is evacuated. An abscess may be mistaken for an aneurism, especially if it be seated over a tolerably large artery, which communicates to it its impulse. I recollect a notable case of this kind which occurred, many years ago, in the Louisville Hospital, and which created quite a sensation at the time. The patient, a young English sailor, had a globular tumor, the volume of a foetal head, in the epigastric region. It had existed there, in a marked degree, for upwards of a month, and as it received a distinct impulse from the aorta, it was believed by the surgeons in attendance to be an aneurism of that vessel. The patient was apprised of the supposed nature of his disease, and his only regret was that he should never be able to reach his native country. The man soon after this fell into the hands of Dr. Donne and myself, when, upon introducing an exploring needle, we found that the tumor was not an aneurism, but an abscess seated deeply in the wall of the abdomen.

A strangulated hernia of the groin, abdomen, or upper part of the thigh might be mistaken for an abscess, but such an accident could hardly happen in the hands of an experienced surgeon. The history of the case, the peculiar character of the swelling, and the existence of symptoms of strangulation will always be sufficient to clear up any doubt that may arise respecting the nature of the case.

6. When, notwithstanding the most thorough scrutiny of the case, its nature remains undetermined, recourse must be had to the exploring needle, which often decides the question in a moment. The instrument which I usually prefer is an ordinary cataract needle, introduced at the most prominent part of the swelling down to its very centre, and freely rotated upon its axis, in order to condense the walls of the puncture, and thereby facilitate the flow of fluid. If the contents be purulent, the circumstance will be revealed by the appearance of a drop of pus at the orifice; whereas if the swelling be an aneurism the discharge will be sanguineous. If the tumor be encephaloid, probably nothing will appear, except a little blood consequent upon the penetration of the instrument.

Prognosis.—The prognosis of this disease is influenced by a variety of circumstances, of which the most important are the size, number, and seat of the abscesses, and the age, habits, and constitution of the patient.

A large accumulation of pus is, other things being equal, more dangerous than a small one, because it not only produces more havoc among the tissues, but it exerts more severe pressure upon the surrounding parts, and establishes a greater drain upon the system. Number has an important bearing upon the prognosis. A man may struggle through several abscesses, even when of considerable bulk, but when he is laboring under a great many he must be extremely fortunate, indeed, if he do not sink under them. Smallpox is always a dangerous disease, chiefly on account of the enormous number of abscesses which attend its progress; few patients being capable of withstanding the irritation and consequent prostration occasioned by their development. The situation of the matter is an object of importance. Thus a small abscess of the perineum may cause fatal retention of urine, as a small abscess of the fauces may induce death by compression of the glottis. Importance of structure is another circumstance which influences the issue of the case. An abscess of an internal organ, as the liver, is more dangerous, and more likely to prove fatal, than an abscess of an external part of the body, as a lymphatic ganglion.

The recovery of a person laboring under phlegmonous abscess is often materially influenced by his age, habits, and state of constitution. Young adults and middle-aged subjects usually get on better than children and very old persons, who often meet such attacks very poorly, making a very feeble show at resistance. The intemperate man has a worse chance than one of good habits, and the man of bad previous health than one who has always had an excellent constitution.

Treatment.—The treatment of phlegmonous abscess is conducted upon general antiphlogistic principles; by depletion, purgatives, antimonials, and the ordinary topical means, to limit deposit and save structure, and afterwards by the lancet to favor evacuation and reparation. Sometimes spontaneous removal is looked for, as when the abscess is seated just beneath the periosteum, as an effect of tertiary syphilis, or when it occupies a lymphatic ganglion, and has yet made little progress; favored, if necessary, by the administration of mercury and iodide of potassium, and the application of iodine, blisters, and other sorbefacients. But such cases are exceptional, and do not affect the general rule of practice, which always seeks an early outlet for the pent-up fluid. In some situations we do not even wait for well-marked pointing, much less distinct fluctuation; but, assured that matter is present, make an early and free incision, thus abridging suffering and saving structure. The beneficial effects of this practice are strikingly illustrated in abscesses in various parts of the body. Thus, in purulent collections around the anus, an early outlet is indispensable to prevent the matter from burrowing along

the side of the rectum and perforating its walls, thereby forming an anal fistule.

Abscess of the perineum requires prompt interference to prevent retention of urine and the establishment of urethral fistule; of the fingers, to prevent the matter from travelling along the sheaths of the tendons and so producing extensive sloughing and necrosis; of the fauces and tonsils, to prevent suffocation by the pressure of the swelling upon the glottis. The torturing pain of a gum-boil, an abscess of a tooth, bone, and periosteum, is often instantly relieved by an early and free incision. The same procedure in deep-seated abscess of the extremities not only relieves pain and constitutional irritation, but prevents the pus from burrowing among the muscles, and thus causing extensive destruction of the connecting cellular tissue.

An abscess should be opened early when, from its proximity to a large vessel, there is danger that, if neglected, a communication will be established between them, thus leading to fatal hemorrhage. Such an event will be particularly liable to occur in delicate children laboring under the effects of scarlatina, measles or smallpox, and in elderly subjects worn out by long suffering and an impoverished state of the blood. The arteries most subject to this danger are those about the neck. In Mr. Liston's celebrated case, the abscess

Mr. Liston's case. *b.* The external opening of what was an abscess. *a.* The ulcerated communication between the cyst and the carotid artery; the latter has been sliced open. *c.* The par vagum.

measles or smallpox, and in elderly subjects worn out by long suffering and an impoverished state of the blood. The arteries most subject to this danger are those about the neck. In Mr. Liston's celebrated case, the abscess

opened into the external carotid; it was punctured, and the patient perished from hemorrhage. The parts are represented in fig. 15.

Artificial evacuation may be effected with the knife or with caustic. The latter, at one time so much in vogue, is now seldom employed by any one, and it would be difficult to conceive what possible advantage it can possess over the former, which is incomparably more expeditious, less painful, and more certain. I would not so far humor a patient as to use caustic when my judgment plainly condemned it, simply because he was foolishly timid, especially now that we can so readily prevent all apprehension and suffering by the administration of anæsthetics; nor would I, on the other hand, resort to caustic with the view of promoting suppurative action, since we have always at our command articles infinitely more desirable and efficacious. If, however, such a remedy should be called for, the best one is the Vienna paste, applied as in making an ordinary issue, the eschar being afterwards penetrated, if need be, by the bistoury, now no longer dreaded by the patient.

Various instruments are employed for opening abscesses. The awkward, clumsy thumb lancet, which formerly figured so conspicuously in every pocket case, is now seldom used, having been advantageously superseded by the scalpel and bistoury. The scalpel is, however, rarely employed, except in very large abscesses, where it is necessary to make a very free division of the overlying structures. By far the neatest contrivance for the purpose is the little bistoury, represented in fig. 16, which I have used, almost exclusively, for many years. It consists of two very narrow, sharp-pointed blades, one straight, and the other slightly curved, short, yet long enough to reach to the desired depth in almost any case likely to fall under the observation of the practitioner. Selecting the most prominent, and, if possible, also the most dependent, portion of the abscess, the instrument is plunged perpendicularly through the skin, into the very midst of the matter, its arrival there being indicated by a want of resistance and probably also by an escape of a few drops of fluid, especially if this be rather thin. The puncture thus made is then converted into an incision, by depressing the handle of the bistoury, and cutting from within outwards, the length of the opening varying, on an average, from a third of an inch to an inch, according to the volume of the abscess. In general, it is better that the opening should be too large than too small, as the object always is to afford free vent to the pent-up fluid. Care, of course, is taken, in introducing the bistoury, not to interfere with any important vessels and nerves, or to perforate any important cavity.

When the abscess is very deep seated, as, for instance, when it occupies the muscles of the thigh, the walls of the abdomen, the groin or axilla, the safest plan will be to divide the skin and fascia freely with the knife, and then to push, very cautiously, as has been suggested by Mr. Hilton, a grooved director or pair of forceps into its interior.

Penetration having been effected, the matter usually escapes of its own accord, simply by the pressure of the atmosphere; but the evacuation may be aided, if necessary, by the hand or finger, used, however, with the greatest

Fig. 16.

Bistoury.

gentleness, otherwise it may not only cause severe pain but an aggravation of the inflammatory action. Too much caution, indeed, cannot be observed in this particular. Nothing can be more reprehensible than the rude manipulations which we so often see practised after this operation, even by surgeons otherwise well educated. To prevent the incision from healing by the first intention, and the necessity of the repeated use of the knife, a small tent, well oiled, made of old linen, is interposed between its edges, one extremity being carried a short distance into the now empty sac, and the other left slightly pendent externally, substitution being effected once in the twenty-four hours. The best application for the surface of the abscess is an emollient cataplasm or the warm water-dressing; but this should not be made until bleeding has ceased, otherwise a troublesome hemorrhage might ensue. As soon as the parts have become perfectly comfortable, the warm dressing is discontinued, on account of its relaxing tendency, a piece of lint, spread with simple cerate, or wet with olive oil, being used in its stead.

When the abscess is seated in a bone, evacuation must be sought with the trephine; but the operation is not always certain of success, owing to the difficulty of the diagnosis.

When the abscess is of large size, or when it has been productive of extreme separation of the muscles, its sides should be approximated, after evacuation, by means of a thick and well-adjusted compress, secured by adhesive strips, or, in the event of the abscess being seated in an extremity, by the common roller, extending upwards from the distal part of the limb; care being taken not to interfere with the artificial opening. In this way a cavity that would not otherwise close under several weeks, will often be effectually obliterated in a few days.

An abscess is sometimes prevented from healing by the unfavorable position of its opening, whether natural or artificial, the matter accumulating in a kind of sac, situated between the orifice and the bottom of the swelling. Such a state of things calls for what is termed a *counter-opening*, which is easily established by making an incision at the most dependent part of the sac, upon the end of a grooved director, introduced through the previous and now useless aperture. Counter-puncture is often necessary in abscess of the neck and parotid region, from the gravitating tendency of the matter in these situations. Sometimes, again, an opening of this kind is called for on account of the change in the position of the part after the first operation, performed perhaps well enough at the time. Whatever may be the circumstances demanding it, patency is maintained with more care, if possible, than under ordinary circumstances.

Again, reparation may be rendered tedious, if not impracticable, by the existence of a *sinus*, extending, perhaps, deeply among the surrounding parts, or, it may be, communicating with some natural cavity. When this is the case, the most speedy and effectual remedy is incision with a bistoury upon a grooved director, inserted into the bottom of the track, the parts being thus laid into one, and permitted to heal by granulation, readhesion being prevented by the constant interposition of a piece of lint. In the milder cases, steady and systematic compression sometimes succeeds in obliterating the abnormal channel; sometimes, again, gently stimulating injections are useful; and, finally, there is a class of cases where the seton is worthy of trial. In general, however, these means only serve to amuse the patient, and annoy the surgeon, who is at last compelled to have recourse to the remedy which his judgment tells him he should have employed in the first instance.

Hemorrhage is not common after this operation, but it may take place in spite of the utmost precaution on the part of the surgeon, and may prove quite troublesome from the difficulty of finding its source. The proper remedy is the ligature, the vessel being seized and drawn out with the tena-

culum, or surrounded with a curved needle. Gentle compression sometimes answers the purpose, especially if the bleeding be venous, or if it proceed from a number of small points. If a considerable sized artery has been laid open, and cannot be easily reached, the incision should be dilated to effect the necessary exposure.

The *healing* of an abscess, whatever may be the manner of its evacuation, is effected by the contraction and approximation of its walls, which generally begin the moment the matter has escaped, and steadily progress until the sac is completely obliterated. The raw state of the opposed surfaces strongly predisposes them to unite with each other; an occurrence which is always favored by an effusion of plastic substance. If the cavity of the abscess were obliterated, as was formerly supposed, by granulations, the part would remain hard and prominent for a long time; but this is not the fact. On the contrary, it soon shrinks, becomes soft, and drops down to a level with the surrounding surface. The opening alone unites in this way; but even this is not always so, for cases constantly occur where it closes by the first intention.

Although, as a general rule, the outer wall of the abscess soon recovers its pristine softness and pliancy, yet occasionally the reverse is true, the parts remaining hard, tender, and enlarged, being seemingly reluctant to throw off their inflammatory burden. To expedite resolution, the affected surface may be covered with a gum ammoniac and mercurial plaster, probably the very best remedy that can be used for the purpose; or rubbed several times a day with some sorbefacient liniment, unguent, or embrocation, aided, perhaps, by the bandage and a few alterative doses of mercury.

2. DIFFUSE ABSCESS, OR PURULENT INFILTRATION.

The above is one variety of phlegmonous abscess; the circumscribed, in which, united with rapidity and severity of action, the matter is bounded by a distinct wall of fibrin, serving the purpose of a cyst, although in reality there is no such formation. In the present variety, already incidentally adverted to, there is no connective exudation, and the consequence is that the pus is widely diffused among the surrounding structures, dissecting and separating them from each other in the most frightful manner. Such collections, which are generally attended with intense suffering, are often described under the appropriate and expressive appellation of purulent infiltration.

The diffuse form of abscess is met with under a great variety of circumstances, both as it respects the nature of the exciting *cause* and the condition of the general system. It is most common in persons whose constitution has been dilapidated by intemperance in eating and drinking, by want and exposure, and by organic affections of the heart, lungs, liver, bowels, and kidneys, leading to anemia, obstructed circulation, and exhaustion of the vital powers. When such persons meet with a serious accident, or suffer from a prolonged attack of fever, suppuration is extremely prone to take on this kind of action, often sadly complicating the original disease. Diffuse abscesses are also sufficiently common after severe injuries, as compound fractures and dislocations, lacerated, railway, gunshot, and dissection wounds, and capital operations, especially amputations of the larger limbs and resections of the bones and joints. Persons of a scrofulous constitution are, on the whole, more liable to suffer from diffuse suppuration than any other class of individuals, their vital powers being too feeble to enable them to furnish a sufficiency of fibrin to limit the purulent matter that is so often effused under the above circumstances.

Diffuse abscesses may occur independently of any other appreciable disease, or they may take place in conjunction with erysipelas, pyemia, or phlebitis,

which they resemble very much both in their mode of origin and in the character of their symptoms. Their presence, in fact, is always denotive of a bad or depraved state of the system; in some cases the fault apparently lies in the blood, either in a defect of some of its more important constituents, or in the ingress of some morbid poison; in others, again, it seems to depend upon imperfect action of the skin and kidneys, excess of food and drink, the respiration of impure air, over-action of the brain, or exhaustion of the nervous system.

The *symptoms* of this variety of abscess are ordinarily bold and well defined. In general, the disease is ushered in by considerable shivering, if not by a severe rigor, followed by heat and perspiration; the pulse soon becomes small, quick, frequent, and irritable, the extremities are cold, the urine is scanty and high-colored, the appetite is destroyed, the tongue is covered with a brownish fur, the strength rapidly fails, and the patient soon sinks into a state of delirium. Great irritability of the system exists; the pain is often excessive, sleep is interrupted, and the mind is peevish and fretful. Frequently the symptoms are of a typhoid character from the beginning; if not, they are sure soon to become so; and yet not merely typhoid, but typhoid and irritative, the two classes being generally well balanced throughout.

The local symptoms are those of ordinary inflammation, only that they are more severe, especially when the matter is deep seated. The discoloration is of an erysipelatous nature, the parts are swollen and pit on pressure, the pain is smarting and pulsatile, and the skin feels hot, stiff, and numb. If the matter lies immediately beneath the surface, or among the more superficial muscles, a boggy sensation will be imparted to the hand of the examiner, and a little pressure will be sufficient to push the fluid about from one place to another, sometimes to a distance of many inches. When, on the contrary, the pus lies far below the surface, being bound down by muscles and aponeuroses, its early detection will generally be very difficult; under such circumstances, the best guide to its situation will be the history of the case, the deep-seated pain, the presence of œdema of the skin and areolar tissue, and the character of the constitutional phenomena. If any wounds or sores exist, they speedily dry up, and assume an unhealthy appearance.

Any part of the body may become the *seat* of diffuse abscesses, but their most common situations are the limbs, in which the matter often burrows to a great extent, both beneath the integuments and among the muscles; in some of the worst forms that I have ever seen, it lay in immediate contact with the bones, separating them from the soft structures, and even from the periosteum. In a case, which was under my observation some years ago, the purulent fluid had spread along the posterior surface of the lower extremity, in close contact with the femur and the bones of the leg, from the hip as far down nearly as the heel.

The *matter* which accompanies this variety of abscess is always of an unhealthy character; it is generally thin, sanious, irritating, acrid, and excessively offensive, often tainting the atmosphere of the apartment for many feet around, and fastening itself upon the hands and clothes so as to be perceptible for hours afterwards, notwithstanding perhaps the liberal use of the chlorides. In fact, the stench is usually of the most disgusting character. In some cases the fluid approaches more nearly to the properties of ordinary pus, but this is uncommon. Occasionally extensive sloughs form, especially in the cellular tissue; so that the disease may be said to partake of the character both of suppuration and of gangrene.

The *prognosis* of this form of abscess is generally most unfavorable, there being few constitutions that can withstand its depressing effects. The very fact that such a disease is in operation shows, as already stated, that the system is in a depraved condition; and when it is recollected that some of

this foul matter must necessarily find its way into the circulation, contaminating everything with which it comes in contact, it is not difficult to anticipate what the result will be likely to be, even when the purulent collection is not very extensive, especially in persons already exhausted by shock, loss of blood, or lesion of some important organ.

The *treatment* of diffuse abscess is sufficiently obvious. The leading indications are to evacuate the matter, and to support the system. The first is fulfilled by early and free incisions, practised at the most favorable site for ready drainage, with the precaution of avoiding hemorrhage, the smallest quantity of which is sometimes sufficient, under such circumstances, when life is, as it were, quivering in the balance, to bring on fatal exhaustion. Counter-openings are often necessary. After the fluid has been thoroughly evacuated, recourse is had to the bandage, for the purpose of effecting approximation of the sides of the abscess; a means of support which is frequently of the greatest consequence, not only in preventing the extension of the matter, but in promoting the healing of the parts. When the fluid is excessively offensive, the cavity of the abscess should be well syringed several times a day with tepid water, charged with a suitable quantity of liquid chlorinate of soda, which, while it will allay fetor, will be instrumental in imparting a healthy action to the disabled structures. If sloughs form, they should be speedily removed, the knife being used, if necessary, to effect their separation. The parts are placed in a proper position for facilitating drainage; and are enveloped in warm water-dressings, or emollient poultices, medicated with acetate of lead and opium.

Among the more important internal remedies are anodynes, quinine, ammonia, iron, and brandy, with animal broths and soups, and a pure atmosphere, which is of paramount importance to the recovery of the sufferer. For this purpose, the windows and doors of the apartment should be frequently thrown open, the dressings changed, and disinfecting agents used. Anodynes are indispensable to allay pain and induce sleep, and should be administered in full doses, either in the form of morphia, opium, or black drop. The best tonics are quinine and brandy, given in the same manner as in typhoid fever; the tincture of the chloride of iron, in doses of from fifteen to twenty drops, every three or four hours, will also be of service; and, in many cases, ammonia, in camphor mixture, will meet the exigencies of the case better than almost any other remedy, especially when there is hiccough with twitching of the tendons.

3. SCROFULOUS ABSCESS.

The scrofulous abscess is of such frequent occurrence, and possesses, withal, such distinctive features, as to entitle it to separate consideration. It is known by various names, some of which have reference to its progress, some to its symptoms, some to the nature of its contents, or to the state of the constitution which precedes and accompanies its formation. Thus, it is often described as the chronic abscess, tardy development being one of its characteristic features; the word cold is frequently employed on account of the absence of inflammatory symptoms; but scrofulous is the appellation by which it is generally known at the present day. As implying the same thing, the terms strumous and tubercular are much in vogue. There is a form of this abscess to which the name *congestive* has been applied, from its tendency to change its position, although it is impossible to discover any etymological fitness in the expression.

The scrofulous abscess is altogether a singular production; singular in its origin and progress, and singular in respect to its treatment. It is never met with, except in the strumous constitution. The phlegmonous abscess is

common to all persons, of every age, grade, and condition in life; the scrofulous, on the contrary, can occur only in persons who have a predisposition to scrofulous affections, whom nature has stamped, so to speak, with a peculiar diathesis, or state of the system, rendering them prone to phthisis, coxalgia, caries of the spine, and other kindred maladies. Its sphere of action is, therefore, comparatively limited, a hundred cases of phlegmonous abscess occurring to one of a scrofulous character.

The progress of scrofulous abscess is peculiar. It is always slow, weeks and months often elapsing before it acquires any considerable bulk. Hence the term chronic, by which it is so frequently designated. Phlegmonous abscess, on the contrary, is always rapid in its progress, generally attaining its full development in a very short time. Another peculiar feature of the strumous abscess is the absence of the ordinary inflammatory symptoms. There is neither heat nor redness of the skin; instead of this, the surface is cold and blanched, the part feeling and looking as if there were great deficiency in its circulation. Hence this variety of abscess is often termed cold, especially by the German surgeons, who were the first to describe it. Pain, too, is absent, or, if it exist, it is so slight as hardly to attract attention. Functional disorder also is very slight, especially in the earlier stages of the disease. Looking at the constitution, we find the same uncommon train of phenomena. The general health may be somewhat impaired; the strength may slowly and almost imperceptibly decline; and the countenance may have a pale, sallow appearance; but there are none of the open and well-marked inflammatory symptoms which attend the march of a phlegmonous abscess, and which, especially when the disease is located in an important internal organ, suggest the idea of great and immediate danger. Thus, as far as appearances are concerned, the affection is one seemingly of little moment; its discovery is often purely accidental, and, for a while, both patient and surgeon may be wholly unconscious of its true character. It is, indeed, as completely different from the ordinary abscess as it is possible for one disease to be from another. Scarlatina and measles are not more unlike each other.

The strumous abscess is very frequent in the lymphatic ganglions, subcutaneous cellular tissue, and dorso-lumbar region. The testicle and liver are also sometimes its seat. In the lungs, however, it is more common than anywhere else, being the immediate product of the softening of tubercular matter, eventuating generally in the formation of what are termed vomicae, or pulmonary caverns. In the external parts of the body it is usually situated in the neck, on the chest, in the axilla, on the loins, in the groin, or upon the superior portion of the thigh. Large strumous accumulations sometimes form in connection with the movable joints.

Some diversity obtains in regard to the size and number of this abscess. In certain situations, as in the lungs, they are always small, but at the same time often quite numerous; while in others, as in the cervical glands, on the chest, in the groin, and on the back, they are usually single, and from the volume of an orange to that of a foetal head.

The strumous abscess is nearly always furnished with a distinct cyst, bag, or capsule, technically called the *pyogenic* membrane, which, while it serves to individualize it, separates it effectually from the surrounding parts. At what period of the suppurative process the membrane begins to be formed is not determined, but that it is developed at an early stage is unquestionable. It has been supposed, singularly enough, that its formation, at times, precedes the deposition of the pus; but for such an opinion there is not, so far as I can perceive, any well-founded reason. The subject, however, does not admit of easy demonstration; for it is seldom that we have an opportunity of inspecting an abscess of this description until after it has attained consider-

able bulk, and the membrane has acquired some degree of development. The most plausible conjecture that can be framed respecting it is, that the membrane is formed out of the necessity of the case, nature intending it as a means of limiting the diffusion of the pus, which would otherwise inevitably happen in consequence of its tardy but steady deposition. To accomplish this object she sets up around the purulent depot, at an early period of the morbid action, a species of adhesive inflammation, by which, in the first place, the cells of the neighboring tissues are effectually occluded, the process being precisely similar to that which occurs in an ordinary phlegmonous abscess. Thus, the secretion is temporarily circumscribed, but, as may readily be perceived, the barrier thus opposed would soon yield before the accumulating burden, and thus thwart nature's intentions. To prevent this a wall of plastic matter is next constructed, which no amount of pus, however great, can, for a time, break down or destroy. The thickness of this wall varies from the eighth of a line to the eighth of an inch; its density steadily increases with its age, and hence it is often found to be of a fibrous consistence, with here and there a semi-cartilaginous patch. Its outer surface is rough and intimately united with the surrounding structures; the inner, on the contrary, is either perfectly smooth, or studded with minute granulations, not unlike the villi of the small intestines, only not so regular and numerous. Its vascularity, which is always considerable, is easily distinguishable by the naked eye, as well as by minute injection. It also, no doubt, contains nerves and absorbents, although none have yet been demonstrated.

No one can reflect upon the structure of this membrane without being impressed with the conviction that it is invested with important functions. In the first place, as has already been stated, it protects the tissues in the immediate neighborhood of the abscess from the diffusion of its contents; a circumstance which could not fail to be productive of great injury, inasmuch as the matter, burrowing about in different directions, might occasion extensive separation of the muscles, which it would afterwards be extremely difficult to remedy. Secondly, the membrane is an important secreting structure, since it furnishes the matter which it incloses, not directly, but through the agency of lymph, which is speedily transformed into pus. Thirdly, it is also an absorbing structure, as is proved by the fact that the matter which it contains occasionally entirely disappears, either spontaneously, or under the influence of treatment. Finally, the membrane possesses important sympathies with the rest of the system. Let alone, it silently enjoys its parasitic existence, preying upon the parts around without any serious general detriment, but the moment it is opened or disturbed by rough manipulation, it resents the aggression, and is sure to give rise to severe constitutional derangement.

The pus of the strumous abscess is generally of a whitish or yellowish cast, slightly inclining to greenish, of a tolerably thick consistence, free from odor, and intermixed with caseous particles, looking and feeling very much like pieces of soft-boiled rice. Instances occur, especially in scrofulous disease of the lymphatic ganglions of the neck, where it is very thin, pale, and full of curdy substance, consisting apparently of imperfectly broken-down tubercular matter. When long retained, or situated near the ano-rectal region, scrofulous pus is sometimes excessively fetid, either from actual decomposition, or the presence of sulphuretted hydrogen. If it be permitted to stand for some time, it separates into two parts, one of which is thin, whey-like, or sero-oleaginous in its appearance, the other thick and curdy, the former being always upon the top of the latter. Like the pus of the phlegmonous abscess, it occasionally, although rarely, contains the debris of the organs in which it is formed, and also some of their peculiar secretion. Thus, a strumous

abscess of the liver occasionally contains bile; of the breast, milk; of the spine, osseous particles.

In regard to quantity, there is much variety in the pus of this form of abscess. In psoas abscess, which is one of the best examples of the disease, the accumulation is sometimes enormous, reaching several quarts, or, perhaps, even a gallon. In scrofulous abscess in the glands of the neck, there is also occasionally a good deal of pus, although, in general, it is small. Large collections of strumous matter are sometimes seen in chronic abscess beneath the skin, especially in the lower extremity. A young woman, a patient at the College Clinic, had an abscess of this kind on the left thigh, containing nearly a gallon of pus.

The diagnosis of this form of abscess may be gathered from the remarks which have been made respecting that of phlegmonous abscess. The only two affections with which it is at all likely to be confounded are encephaloid and aneurism; but from these it may usually be easily distinguished by the history of the case, the fluctuating character of the swelling, and, if necessary, the use of the exploring needle.

Treatment.—The treatment of this abscess differs essentially from that of the phlegmonous. In the latter, the system often bears energetic measures; in the former, seldom, if ever; in the one, the surgeon does not hesitate to make an early and free incision into the swelling, with a view to the early evacuation of its contents; in the other, he waits and hesitates, well knowing that such an operation is often the prelude to serious constitutional disturbance, if not death. The one is the work of a few days, or, at most, of a few weeks, taking the part and system, as it were, by surprise, and, therefore, requiring prompt interference; the other is the work of time, affording the part and system an opportunity of accommodating themselves to its presence, and, therefore, often intolerant of interference. When the quantity of matter is small, removal is occasionally effected by absorption, the process being sometimes advantageously aided by internal and external remedies, particularly the iodide of potassium and the bichloride of mercury, together with sorbefacient plasters, unguents, and embrocations. These means are more particularly available in chronic abscesses of the glands of the neck, groin, and axilla, and in those of the mamma and subcutaneous cellular tissue. In psoas and lumbar abscesses, on the contrary, little or no benefit usually results from their employment, beyond the influence they may exert in improving the general health, and removing the strumous diathesis. When general debility exists, relief should be attempted with tonics, as quinine and iron, along with milk punch, and change of air.

Concerning the evacuation of strumous abscess, no one hesitates to interfere, when the disease is seated in the external parts of the body, as the mammary gland, the lymphatic ganglions of the neck, or the subcutaneous cellular tissue. In such cases, indeed, we can hardly make too early or too free an incision; for, not only is there, as a general rule, no danger of causing constitutional disturbance, but the procedure is eminently calculated to save structure and promote recovery. The matter being evacuated, the cavity usually at once contracts, and the tendency to secretion gradually diminishing, the part finally heals by granulation or adhesion. Besides, such a procedure always enables the surgeon to watch the morbid action, and apply his remedies directly to the affected surface.

The best local applications, after the abscess has been punctured, are emollient poultices, rendered slightly stimulating by the addition of a little common salt; or tincture of iodine, spirituous lotions, or some sorbefacient plaster, as the gum ammoniac and mercurial, soap, compound galbanum, or iodine plaster, care being taken to leave an appropriate opening for the discharge of matter. I can speak with great confidence of the beneficial effects

of these plasters, especially the first, having used them for a long time in the treatment of strumous abscess of the neck, mamma, and subcutaneous cellular tissue. When the cavity of the abscess is slow in healing, in consequence of the torpor of its vessels, or the existence of a strong pyogenic membrane, nitrate of silver, nitric acid, or acid nitrate of mercury may be employed, in the form of weak injection, as local stimulants until there is a disposition to the formation of healthy granulations. Sometimes, as in the case of the subcutaneous abscess, a seton may be advantageously introduced, retention being maintained until the sac has become obliterated by inflammation. Or, instead of this, a counter-opening may be made, and a tent inserted.

When the abscess is connected with disease of the bones, as it always is when it takes the name of psoas or lumbar abscess, the treatment usually followed is that originally suggested by Mr. Abernethy, and which consists in making a valve-like opening in the most prominent and dependent portion of the swelling. The object of this procedure is to exclude the atmosphere, not that this is of itself at all injurious, as was at one time erroneously supposed, but because its contact with the purulent matter has a tendency to cause decomposition; an occurrence which cannot fail to be succeeded by bad consequences, by awakening all the constitutional sympathies of which such a disease is capable. Educated in a school in which this practice was strongly inculcated, and warmly prepossessed in its favor, on account of the high authority of its originator, I was led to expect from it all that the most sanguine feeling could anticipate; but, after an experience of upwards of twenty-five years, I am compelled to say that it has utterly disappointed me, in the only class of cases to which, in my judgment, it is at all applicable. I cannot, in truth, recall to my mind a solitary instance in which I have found it productive of the least permanent benefit. My experience is that the opening, however judiciously made, will, at no distant day, be followed by ulcerative action, leading thus to all the bad effects that are usually caused by making a free incision in the first instance. I believe that this generally occurs, whatever may be the amount of matter evacuated, whether small or large, and whether the operation be repeated at long or short intervals. It has appeared to me that any interference, however trivial, is always sure to be resented, and that, instead of benefiting the case, we only render it worse. Hence, I am satisfied that, when the pain from the pressure of the accumulated fluid is not so great as imperatively to demand its withdrawal, it is best, as a general rule, to let the part alone, patiently waiting for spontaneous evacuation, and the accommodation of the part and system to the approaching event.

When artificial evacuation becomes necessary, it may be effected simply with the knife, the trocar, or the knife and trocar together. Whatever instrument is employed, care is taken to carry the point some distance between the skin and sac, before the latter is penetrated, so as to give it the valvular form so much insisted upon by the advocates of this mode of treatment. From two-thirds to four-fifths of the matter having been withdrawn, the orifice is accurately closed with two broad strips of adhesive plaster, arranged crucially, and supported by a compress and bandage. Care is also taken to prevent the orifice from being pressed upon by the reaccumulating fluid, lest it should reopen spontaneously. The operation is repeated from time to time as the matter collects, an opportunity being thus afforded to the abscess to contract, and finally to become obliterated; an event, however, that is certainly extremely rare.

It was proposed, some years ago, to open these abscesses while the patient's body is immersed in water, on the ground that there would thus be less likelihood of the introduction of air; but we may well ask whether the ingress of the former fluid would not be quite as injurious as that of the latter? The truth

is, it is hardly possible to perform the operation without some risk of this kind; still, if proper care be taken, the quantity will be so small as not to produce any serious mischief.

As to iodine injections, which have been recommended for the radical cure of this form of abscess, the experience of the profession has nothing to offer in their favor. The practice, considered in a purely theoretical point of view, is sufficiently plausible, since its object is to change the character of the secerning surface of the pyogenic membrane, by inviting an effusion of plastic matter, which shall lead to the obliteration of its cavity. It was evidently suggested by the beneficial effects which are known to follow the use of iodine injections in hydrocele and other kindred affections, but to insist upon a similarity of structure of the sac of a chronic abscess to that of the vaginal tunic of the testicle certainly displays a very limited and imperfect knowledge of morbid anatomy. It is not surprising, therefore, that the practice should have failed, and that its employment should have been attended, in most cases, with considerable risk, from the tendency which it has to create undue irritation both in the part and system.

Whatever mode of treatment be employed, it is of paramount importance to sustain the system by tonics and to allay pain by anodynes.

4. MULTIPLE ABSCESS, OR PYEMIA.

The fact that some injuries and operations are occasionally followed by the development of abscesses in some of the internal organs of the body did not escape the attention of some of the older surgeons. Ambrose Paré makes distinct mention of the occurrence; and Pignai, about the same period, had an opportunity of noticing that, during one particular year, nearly every person who was so unfortunate as to have a wound of the head died of supuration of the liver. These observations were afterwards confirmed by Morgagni, Bertrandi, and Andouillé; and, more recently, by Schmucker, Kern, Klein, Hennen, Larrey, Guthrie, and other military surgeons, as well as by many hospital and private practitioners. Mons. Velpeau, however, was the first to investigate the lesion in a really scientific manner, and to institute a thorough and elaborate examination into its etiology, pathology, and treatment.

The name pyemia, by which this affection is now generally known, literally signifies an alteration of the blood by pus, or, perhaps, more properly speaking, an admixture of the two fluids, giving rise to what has been called septicemia, or purulent infection. It is a corruption of pyohemia, first applied to this disease by Piorry, and is synonymous with ichorhemia, a term recently introduced into pathology.

The exciting causes of pyemia, or blood-poisoning, are not only numerous but of a highly diversified character; they may be stated, in general terms, to be such as are productive of great shock to the system, loss of blood, or depression of the vital powers. As following severe injuries of the head, it was, as already stated, long ago noticed by many of the older pathologists and surgeons, although they failed to offer any correct or even plausible theory of its occurrence. Since attention was first prominently called to it, in 1823, by Velpeau, it has been much oftener noticed after compound fractures and dislocations, lacerated, contused, and gunshot wounds, and amputation of the larger limbs, than after any other accidents. In lying-in females it is also sufficiently frequent, and is, in fact, a considerable source of the mortality consequent upon the puerperal state. It has been known to supervene upon erysipelas, carbuncle, smallpox, scarlatina, and typhoid fever. One of the first cases of the disease I ever saw occurred, many years ago, in a young woman who had an attack, apparently not a severe one, of erysipelas

of the leg. On dissection, I found a sufficient cause for death in a pyemic abscess in the left lung, about the volume of a large almond, filled with plastic matter, and surrounded by highly inflamed and softened pulmonary tissue. No appreciable disease existed in any other part of the body. The secondary purulent collections so often met with in glanders and dissection wounds evidently belong to this class of affections. Pyemia occasionally succeeds to the use of the trephine, the extirpation of tumors, lithotomy, lithotripsy, the perineal section for the cure of stricture of the urethra, and the operation for aneurism. Sometimes, indeed, apparently the most trifling operation is followed by it. In 1831, I attended, in consultation, a man who lost his life by blood-poisoning consequent upon bleeding at the bend of the arm; and a similar case occurred a number of years ago in my own practice at the Louisville Marine Hospital. The patient, a colored woman, laboring under chronic disease of the wrist-joint, was bled, at my request, by the resident physician, at the median basilic vein. In a few days violent phlebitis supervened, followed by large purulent collections in nearly all the great joints, as well as among the muscles of the arm and shoulder, terminating in death in less than a week. The injury inflicted in the removal of a small piece of dead bone has been known to cause death by ichorhemia. In 1848, I lost a young man, twenty-eight years of age, from pyemia, brought on by tying three hemorrhoidal tumors. Death occurred on the eighth day; and, on dissection, I found the cellular tissue of the meso-rectum studded with hundreds of abscesses, from the size of a currant to that of a small pea.

Pyemia occasionally follows the suppurative inflammation consequent upon a badly-healed stump, perhaps weeks and even months after the amputation, and long after the patient is apparently out of all danger. The discharge, perhaps never entirely arrested, suddenly increases in quantity, the parts become tender and irritable, the constitution is seriously affected, rigors soon set in, and, in short, all the symptoms of blood-poisoning are fully declared.

No period of life is probably entirely exempt from the attacks of this disease. It has been met with even in children at the breast. A case has been reported of an infant, only ten days old, in whose body, affected by erysipelas, not less than nine large abscesses of this kind had formed, causing death in a short time. On the other hand, it occasionally appears at a very advanced age. Young and robust subjects, however, have appeared to me to be most liable to it, especially after severe railway and other accidents, attended with severe shock and a good deal of loss of blood. Wounds of, and operations upon, the veins are very prone to be followed by blood-poisoning. There can be no doubt also that pyemia is more common among the inhabitants of crowded cities than among those who enjoy the benefits of pure country air, good wholesome food, and an abundance of exercise and sleep; it is likewise more frequent in hospitals, almshouses, and other receptacles for the poor than in private practice; circumstances of no little interest both in an etiological and therapeutic point of view.

Such being some of the remote causes of pyemia, the question may now be asked, What are the immediate causes of the disease, or the circumstances whose operations are more directly concerned in its production? This subject has led to much speculation; and, although it has been ably discussed by a number of enlightened pathologists, yet it must be confessed that our knowledge respecting it is still extremely meagre and unsatisfactory.

The old notion that pyemia is the product of metastasis; or, in other words, that it is due to the absorption of pus from the part originally affected, and to the transportation of this fluid to some other, more or less remote situation, where it is collected into a focus, and thus becomes a source of new irritation and disease, has still its advocates and adherents. It rests upon the supposition that the pus corpuscles are admitted, unchanged, into

the open mouths of the veins at the seat of the wound, as, for example, the surface of the stump, and that, being so introduced into the circulation, and pushed onward by the blood, they are finally arrested in the minute capillaries, which are unable to transmit them, as they do the red particles of the blood, in consequence of their larger size. The mechanical obstruction thus caused forms, it is alleged, a new cause of morbid action, which is soon followed by the development of an abscess, or a deposition of pus, and, if the new dépôts be numerous, by purulent infection. In opposition to this doctrine, it has been contended that pus corpuscles never gain access in this way into the circulation, and that those who profess to have seen them there were deceived by the resemblance which these corpuscles bear to the colorless globules of the blood. Moreover, it is asserted that there is nothing in the corpuscles of healthy, laudable pus of an irritating nature, and that, even supposing they got into the veins, it would not be possible for them to occasion multiple abscesses.

Cruveilhier, from some experiments which he performed on the inferior animals, as dogs, came to the conclusion that pyemia and multiple abscesses might be induced by any irritating fluid, accidentally introduced into the system, and incapable of spontaneous elimination. On injecting ink, mercury, and other substances into the blood, he found that purulent dépôts occurred wherever the extraneous substance became impacted in the minute vessels. Granting that these experiments caused precisely what has been alleged of them, it is difficult to see why they should have been brought forward as a proof of the manner in which pyemia is developed in the human subject. There is certainly no similarity, hardly, indeed, any analogy, between the substances used by Cruveilhier in his experiments upon dogs and those that are formed in a suppurating wound, or on the surface of a stump after amputation.

Mr. Henry Lee, of London, in a small treatise on the origin of Inflammation of the Veins, published in 1850, advanced the ingenious, and, at first sight, very plausible, idea, that these purulent deposits are essentially due to the coagulation of the blood in consequence of the admixture of pus within the veins. He found that when healthy, recently-drawn blood was mingled with pus, it solidified more rapidly and more firmly than under ordinary circumstances; and, coupling this occurrence with the well-known fact that the veins are often obstructed by large clots in phlebitis, he concluded that coagulation must be the first link in the chain of morbid action. The inspissated blood, unable to make its way through the living body, would, Mr. Lee thinks, soon adhere to the sides of the vessels, which would thus become so many centres of inflammation and purulent deposits. It will be perceived that this theory, like that of the older pathologists, previously adverted to, rests essentially upon the idea that pus may pass bodily into the veins, or, in other words, without any change in its composition, and that it differs from it only in assuming, what is doubtless true, that it possesses the power of coagulating the blood with which it comes in contact.

Finally, there is another class of pathologists who attempt to account for the formation of purulent deposits by supposing that they are caused by the development of a peculiar poison, derived from certain kinds of pus, which, entering the circulation, contaminates the blood and solids, and thus brings about that adynamic and atonic state of the system so characteristic of pyemia. According to this doctrine, which has found one of its ablest advocates in Professor Bennett, of Edinburgh, pus corpuscles do not enter and mingle with the blood, what have been taken for these bodies by various observers being merely so many colorless cells of the blood, the distinction between the two being often extremely difficult, if not impracticable.

Of the foregoing explanations the last, it seems to me, is not only the most

plausible, but also the most consistent with facts. Agreeing with its advocates that it is impossible for pus corpuscles to enter the circulation, except in the case of open-mouthed veins communicating with a suppurating surface, it is unquestionable that the more attenuated and watery parts of pus; or, perhaps, more correctly speaking, the more ichorous, sanious, or sanguinolent varieties of this fluid, frequently become commingled with the blood in suppurating wounds and in the stumps of amputated limbs, thereby speedily and thoroughly contaminating both solids and fluids, and, consequently, effectually undermining the constitution. It is not improbable that this poisonous matter, soon after its admission into the circulation, excites inflammation in the capillary vessels, as well as in some of the larger veins, rapidly followed by deposits of fibrin and pus, or the development of purulent collections. The coagula, so often met with in the veins of those who die of this disease, are a direct result of this inflammation, their formation being favored by the plasma thrown out by the inner surface of the affected vessels. The occurrence, in fact, is similar to what takes place, at times, in inflammation of varicose veins in the lower extremities of laboring people, which are occasionally completely clogged up in this way. Thus, it is not unlikely that the first link in the chain of morbid action in this affection is a poisoned and disorganized state of the blood; the second, the development of inflammation in the capillaries and veins; the third the formation of adherent coagula, clots, or concretions; and the last, as the necessary and inevitable effect of the others, a deposition of pus, or pus and fibrin.

Is pyemia always, as the name denotes, a result of the admission of vitiated secretions, or putrescent matter into the circulation? Instances occur, as when the disease complicates typhoid fever, scarlatina, and asthenic and other affections, where the reverse would seem to be the case, and yet, it must be confessed, it is not always possible, even here, to determine whether the individual is entirely free from antecedent suppurative action. It is probable that, under such circumstances, a mere disordered state of the blood, such as undoubtedly attends the worst forms of these maladies, may be quite adequate to the production of secondary abscesses of a very bad character.

The period of latency of pyemia is often, if not generally, very short, frequently not exceeding a few days from the time of the accident or operation giving rise to it. There are cases, however, in which a much longer time elapses, although they are uncommon. As a general rule, it may be assumed that the briefness of the period of latency will be in proportion to the shock of the system, the amount of hemorrhage, and the ill state of the patient's health prior to the injury. The period is usually shorter in traumatic than in idiopathic affections, in the latter of which the secondary lesion occasionally does not come on until near the time of apparent convalescence.

The approaches of pyemia are generally very stealthy and insidious; hence it often happens that the young and inexperienced practitioner is thrown completely off his guard in respect to the nature of the formidable disease with which he has to grapple. If the case is one, for instance, consequent upon an amputation, he probably feels concerned to find that the stump gives evidence of being in an unhealthy condition; that it is unusually tender and painful, that it manifests no disposition to heal, and that the discharge is not only profuse but of a thin, sanious, bloody, or ichorous nature. The patient, although not inclined to complain much, is restless and ill at ease, looking pale, sallow, and anxious, as if some serious evil were impending. His pulse is irritable and too frequent, the cheek is marked by a sinister flush, the appetite is impaired, and the secretions are deranged. This prodroma is of short duration; often hardly lasting twenty-four hours. Violent rigors now set in, which, after having continued for a period varying from fifteen minutes to half an hour, an hour, or even two hours, are succeeded by violent reaction,

and this, in its turn, by profuse sweats, often completely drenching the surface and even the body clothes. These rigors may return several times in the twenty-four hours, or they may come on at regular periods, not unlike the paroxysms of an intermittent fever, for which the unwary sometimes mistake them. Their severity is not always the same; cases occur in which they are replaced, as it were, by chilly sensations, alternating with flushes of heat, and not unfrequently lasting for several days together. In whatever manner this outbreak of the disease is displayed, the case at once assumes a more bold and decisive character. The conjunctiva and skin exhibit a well-marked icterode appearance; the features are shrunken and withered, the nose being pinched and the eye sunk in its socket; the pulse is small, frequent, and feeble; the breathing is accelerated and performed with unusual effort; the tongue is dry and clammy; the thirst is urgent; the sleep and appetite are interrupted; the bowels are irregular, being at one time relaxed, and at another constipated; the stomach is irritable and nauseated; the urine is high-colored and scanty; the extremities are cold; the mind wanders; and the body is often racked with excruciating pain, especially in the joints and muscles, which are not unfrequently exquisitely sensitive to the slightest touch. Occasionally the patient complains of severe pain in some internal organ, to which he refers all his principal suffering. Cough is sometimes present, and when this is the case an examination of the chest generally reveals the existence of more or less serious lesion of the pulmonary tissues, or of the lung and pleura. As the disease progresses, red blotches, swollen, and excessively painful, appear over the larger joints, and serve as the forerunners of approaching suppuration in their interior, as well as in the tissues immediately around them. Similar marks occasionally show themselves in the course of the principal veins and in the situation of some of the muscles, particularly the deltoid and pectoral.

The symptoms, long before the disease has reached this crisis, are of a typhoid character, the whole system seemingly laboring under the depressing influence of a deadly poison. The downward tendency is rapidly progressive; the machinery of life moves alternately forward and backward; the pulse becomes more and more feeble; the respiration is frightfully oppressed; the body is remarkably emaciated; and the patient lies in a comatose condition, from which he is destined never to awake. This, however, is not uniformly the case; for the instances are not infrequent, where the mind retains its consciousness almost to the last. The period at which death occurs, after the disease has once fairly commenced, varies from three to ten days, or a fortnight, the average being about one week, or perhaps a little under.

Although there are, strictly speaking, no pathognomonic symptoms of pyemia, yet it is seldom that any one who has ever seen a case of this disease, or who has made himself thoroughly familiar with its history and progress, can possibly confound it with any other complaint. Its very mode of invasion generally sufficiently stamps its true character. The sudden, violent, and unexpected rigor; the unhealthy character of the suppurating sore or wound, if any exist; the icterode and shrunken state of the features; the rapid supervention of typhoid symptoms; the great mental anxiety and excessive restlessness; the horrible aching pains in the joints, limbs, and other regions; and, lastly, the rapid abduction of the fat, leaving the body in a wasted and emaciated condition, far beyond what occurs in almost any other affection, excepting, perhaps, cholera; are signs which, if they do not unerringly mark the nature of pyemia, will always excite the serious suspicion of the attendant, and induce him to scrutinize his case in the most careful and thorough manner. The only disease with which blood-poisoning is liable to be confounded is intermittent fever; but here the distinction is so easily drawn as to render mistake impossible, unless the most stupid carelessness is evinced by the practitioner. The diagnosis of traumatic pyemia will, in

general, be less difficult than that of the idiopathic variety, or that arising from internal causes; for the violent rigor, the icterode countenance, and the rapid prostration and emaciation will usually afford sufficient characteristic evidence of the nature of the complaint to prevent mistake.

The dissection of patients dead of pyemia reveals, as might be supposed, important and interesting changes both in the solids and in the fluids. Of those affecting the solids, the most constant are abscesses and purulent depôts in various organs, cavities, and tissues. The former, generally known under the name of *metastatic*, or multiple abscesses, are most common in the lungs and liver, then in the spleen, and, lastly, in the brain, heart, and kidneys. They sometimes occur in the subcutaneous cellular substance, and beneath the peritoneum. In one instance, previously referred to, I found an immense number in the areolar tissue of the meso-rectum. Their presence has also been detected in the prostate gland.

In regard to their number, metastatic abscesses vary in different instances. It is seldom that we find only one; most generally there are as many as twenty, thirty, fifty, or even a hundred. Sometimes, indeed, the surface of the affected organ is completely studded with them, more than a thousand having been observed in a single case, principally in the deep-seated viscera. The size of this abscess is also very variable. Some do not exceed that of a hemp-seed or garden pea; while others are as large as a hazelnut, a marble, a pigeon's egg, or an orange. When very numerous, they are usually proportionably small. In their figure they are generally oval, spherical, or angular; sometimes remarkably irregular. When seated near each other, they occasionally become confluent, like the pustules of smallpox.

The contents of a metastatic abscess are seldom of the nature of well-elaborated pus; on the contrary, they are almost always of a semi-concrete consistence, of a dirty grayish, cineritious, or drab color, and composed mainly of aplastic lymph. This is particularly true of recent cases; in those of longer standing, the contents are more decidedly purulent, but even then they are often blended with grumous blood and flakes of fibrin.

The textures immediately around the abscess may be natural, or variously altered in their appearance and consistence. In most cases they are engorged with blood, heightened in color, softened, or converted into a pulpy diffuent substance. The coats of the vessels are inflamed, thickened, and infiltrated with serosity, while their canals are filled with pus, semi-fluid blood, or fibrinous concretions. The capillary veins usually participate in the inflammation.

Purulent collections, as a consequence of ichorhemia, are most frequently met with in the chest, being rare in the peritoneal cavity, the arachnoid, and pericardium. The reason of this difference seems to be due to the fact that the lungs nearly always suffer whenever there is serious involvement of the system, whereas the abdominal viscera, heart, and brain, commonly escape in this case.

Professor Sédillot, of Strasbourg, who has studied this disease with great care, and who has combined the results of his observation in a highly instructive and interesting monograph, published in 1849, remarks that in 100 cases of pyemia, we should find the lungs affected in 99; the liver and spleen in 1 of 12, the muscles in 1 of 15, and the heart and peripheric cellular tissue in 1 of 20: the brain and kidneys suffering comparatively seldom.

The joints often suffer very severely. In some of the cases which I have had an opportunity of examining after death, matter was found in nearly all the larger articulations, and also in quite a number of the smaller ones. In many cases the pus is situated on the outside of the joints, as well as within.

Large collections of purulent fluid are sometimes discovered in the subcutaneous and intermuscular areolar tissue; the veins also occasionally contain

a considerable quantity, either lying free in their cavities, or, as is more common, commingled with the blood in the interior of fibrinous concretions.

The pus which occurs in these various localities is of the same nature as that which is contained in metastatic abscesses, properly so termed, that is, it is ill-elaborated, and intermixed with a large proportion of aplastic material. Both in the veins and in the intermuscular areolar tissue, it is generally, as just stated, interspersed through fibrinous concretions, coagula, or blood-clots, giving the latter a peculiar appearance, as if they were pervaded by small specks of lymph, or lymph and pus.

The prognosis of pyemia is most unfavorable; few patients recover, and these, for the most part, remain for a long time in a debilitated and crippled condition, liable to other attacks of disease from the slightest causes. As already stated, death usually occurs within the first week after the commencement of the malady, being apparently dependent upon the severe exhaustion consequent upon the excessive pain and obstructed circulation, which form such conspicuous features in the progress of this affection. In most cases a return to health is announced by the appearance in the urine of an unusual quantity of lithic acid.

Treatment.—In the treatment of ichorhemia two indications present themselves to the practitioner, and these should, throughout, receive his most earnest and faithful attention. These are, first, the removal of the exciting cause of the disease; and, secondly, the support of the system, in order to enable it, if possible, to shake off the toxical influence under which it is so plainly laboring.

If the disease has been induced by an accident or operation, attended with an open, suppurating surface, much may be done, in many cases, by the promotion of cleanliness, to prevent further mischief from the ingress of purulent fluid. This object is best attained by diligent, almost incessant attention to the dressings and position of the part, the former being frequently changed, and the latter so arranged as to favor the escape of the secretions as fast as they take place. Detergent lotions are often serviceable, especially if they contain chlorinate of soda, but care must be taken that they are not so strong as to irritate, and it will be well, particularly if we have to deal with a foul stump, to throw them freely upon the parts with a large syringe, as this exerts a much better and wider influence than mere irrigation with a sponge. It will also be advantageous to keep the dressing constantly sprinkled with the chlorides, both with a view to allay feter and to purify the air of the apartment, which must be frequently renewed by opening the doors and windows.

To prevent the further ingress of purulent fluid into the system, is not so easily accomplished, if, indeed, it can be accomplished at all. If the surface is not too extensive, I should strongly advise the free use of a mixture of one part of the solution of acid nitrate of mercury and two parts of water, applied rapidly with a mop, the intention being not so much to produce an escharotic as an alterant effect, thereby inviting a rapid change in the action of the capillary vessels and an abundance of exudation matter, so as to close up the mouths of the vessels, and cause consolidation of the affected tissues generally. When the vessels are large and patulous, they may sometimes be closed by well-regulated methodical compression, care being taken that this is applied in as gentle and uniform a manner as possible. The actual cautery, recommended by the French surgeons, for sealing the suppurating surface, has met with few advocates anywhere, and should never, I conceive, be employed for this purpose, unless it is drawn over the parts in the most careful and considerate manner, the surface being previously well wiped with soft linen to divest it of its moisture.

The second indication is best fulfilled by stimulants and tonics, as brandy,

wine, ammonia, camphor, iron, and quinine, with animal broths, and other suitable means of support. Opiates should be given freely to allay pain and induce sleep. The recurrence of rigors, or chilly sensations, is usually easiest prevented by quinine and morphia, the dose of the former being not less than ten grains to one grain of the latter, every four or six hours, until a decided impression has been made upon the system. No benefit can accrue, under such desperate circumstances, from administering these articles in smaller quantity, as they only serve to tease the system, and permit the play of morbid affinities. The irritability of the stomach, so often present in pyemia, is generally best controlled by sinapisms, abstinence from drink, the use of ice, and the exhibition of aromatic tincture of ammonia. When dependent upon the presence of bile, or vitiated ingesta, a gentle emetic may be of service.

Inflammation of the joints and muscles must be treated by soothing measures, as warm medicated dressings, aided by the frequent application of iodine. If abscesses form, evacuation must be afforded by early and free incisions, the openings being made in such a manner as to prevent accumulation and bagging of fluids. Determinations to internal organs, as the lungs, heart, spleen, or liver, must be counteracted by dry cupping and blistering. The secretions, generally so much disordered in ichorhemia, should be corrected with blue mass or calomel, but care should be taken not to carry these medicines so far as to excite ptyalism, which could hardly fail to produce a prejudicial effect upon the progress of the case.

Bleeding, both local and general, is invariably inadmissible in all diseases attended with blood-poisoning. The system, oppressed and borne down by the toxical influence, needs all the support it can derive from this fluid; the whole current, it is true, is vitiated, and its life-power greatly impaired, but, although this is the case, no sensible practitioner would attempt to improve the condition of the affected part by such a procedure. Good nourishing food and drink, with supporting medicines, alone can be confided in under such circumstances, when the loss even of a small quantity of blood would inevitably hasten the fatal crisis.

When marked tendency to hemorrhage exists, in consequence of a dissolved and broken-down state of the blood, recourse must be had to some of the preparations of iron, especially the tannate and tincture of the chloride; the former being given in doses of from five to ten grains, and the latter of from fifteen to twenty drops, in a suitable quantity of water, every three or four hours. The same remedies will generally answer excellently well for suppressing the copious sweats so often present in the different stages of pyemia. Sometimes acids, as the nitric and sulphuric, may be advantageously exhibited, both with a view to their tonic and their anti-diaphoretic effects.

Throughout the whole treatment, great attention should be paid to cleanliness; the bed and body clothes should be frequently changed, the surface of the patient sponged with tepid salt water, or weak chlorinated washes, and the apartment constantly ventilated. Should recovery take place, a change of air and a rigid observance of hygienic measures will be required to insure ultimate restoration. The convalescence will always be tardy, and the slightest exposure or irregularity of diet will be certain to endanger life.

5. HECTIC FEVER.

Hectic fever, although not necessarily dependent upon suppuration, is yet so closely connected with it, as a common result of that process, that it may very properly be described under the same head. Its existence is nearly always indicative of serious organic lesion, of which it, therefore, constitutes merely the general expression. The word *hectic*, literally signifying a bad

habit of body, was originally employed to designate the peculiar train of phenomena attendant upon pulmonary phthisis, of which it forms so remarkable an attribute as to have attracted the attention of practitioners in all ages. It is, however, no longer restricted to such narrow limits; for the group of symptoms which it serves to characterize follows a great number of diseases, accidents, and operations, and, therefore, claims the special consideration alike of the surgeon and the physician.

Hectic fever never occurs, as was once supposed, as an idiopathic affection; on the contrary, it is always symptomatic of some particular disease, generally of the presence of profuse discharge, as of pus or blood, or the development of an abscess in some important structure, as the brain, lung, or liver. One of the most remarkable circumstances connected with its history is, that it rarely, if ever, appears until the malady which it serves to represent has made considerable progress, or induced serious structural changes, along with grave inroads upon the constitution. Thus, in phthisis, it is seldom witnessed until softening of the tubercular matter is about to take place, sometimes, indeed, not until pretty large cavities have formed; on the other hand, there are cases, as in psoas abscess, where pus frequently exists in large quantity, perhaps, for several months, and yet none of the ordinary signs of hectic fever arise. Serious as the local disease apparently is, the general system does not seem to be disposed to take any particular notice of it; the pulse, sleep, appetite, bowels, and secretions all go on in nearly their accustomed manner; and, if there be any loss of flesh and strength, the alteration is so gradual and imperceptible as almost to elude the attention even of the patient himself. But sudden and often most alarming changes occur in the constitution if, in consequence of a large opening, air is freely admitted into the cavity of such an abscess, causing decomposition of its contents. The shock is violent, and resentment of the injury is close at hand; soon a severe rigor comes on, lasting, it may be, several hours, when it is succeeded by violent fever, as this, in its turn, is followed by copious sweat. Such is not unfrequently the commencement of an attack of hectic fever, a bad habit of body, which often ceases only with the patient's life. Thus, it will be perceived that hectic fever, like every other form of fever, at least so far as we can comprehend its nature and type, is not a disease, but a symptom of disease, an expression of general suffering, dependent upon some special local lesion, not always, perhaps, appreciable by our senses, yet, nevertheless, in active operation, and effectually accomplishing its work.

In traumatic affections, hectic fever often sets in at an early period after the accident; perhaps there may have been grave shock, and profuse hemorrhage, and the two are soon followed by copious suppuration, which thus still further undermines and exhausts the vital powers; or it may be that more or less of the pus has been carried into the circulation, and that the whole system has become poisoned by the unfortunate admixture, every blood cell and every fibre and atom of solid matter feeling the baneful influence. The brief struggle which ensues may be characterized by the inflammatory type; but this is evanescent, hectic soon taking its place, and thence on steadily maintaining the ascendancy, no intercurrent circumstances ever changing its real character, although they may temporarily disguise it, or for a time keep it in abeyance.

Hectic, then, is a continued, remittent fever, lasting generally as long as the cause which induced it lasts; subject to distinct paroxysms of exacerbation and remission, but at no time, perhaps, completely absent, although apparently it may be. Its outbreak is often sudden and violent, sweeping over the system with the fury of a hurricane; at other times, and more generally, it creeps on gradually and stealthily; in the former case, it is marked by severe rigors, in the latter merely by a sense of chilliness, or slight horri-

pilations. Whatever may be its mode of attack, its actual invasion is always preceded by more or less indisposition, amounting ordinarily to a mere state of malaise, or a feeling of lassitude and discomfort, which the patient struggles in vain to throw off. His appetite and sleep are impaired; his tongue is inclined to be dry, perhaps somewhat coated; more or less thirst exists; and there is often considerable fever, either of the inflammatory, irritative, or typhoid type. In short, hectic, like every other fever, passes through a stage of incubation, brief in one case, protracted in another. The crisis being attained, the chill appears, and thus the disease is fairly inaugurated; taking its position in the system, which, as already stated, it never abandons until the removal of the exciting cause, and often not then.

The febrile exacerbation is usually vesperal, coming on late in the afternoon, or early in the evening; lasting, on an average, from six to nine hours, and then gradually going off, to reappear, in a similar manner, about the same time the next day, thus giving the disease a distinct periodical character, not unlike that of an ordinary intermittent. Not unfrequently there are two paroxysms in the twenty-four hours; one in the evening, and the other perhaps late at night, or during the course of the morning; the latter being generally much the milder of the two. The chill ushering in the fever is often very long and severe, the patient occasionally shivering for several hours, his teeth chattering violently, and the whole body feeling as if it were wrapped in ice; at other times, as already intimated, the sensation of cold is very slight, and perhaps perceived chiefly along the spine, shoulders, and lower extremities, its duration being variable, now short, now quite protracted. The chill passing off, reaction succeeds, usually violent in proportion to the previous depression, and gradually, sometimes suddenly, merging into a profuse sweat, the harbinger of returning ease and comfort. All the secretions are again unlocked; the mouth regains its moisture; the urine is poured out in increased quantity; the thirst rapidly subsides; the pulse becomes soft and comparatively calm; and ere long the poor patient, tortured and racked with suffering, sinks into a tranquil and refreshing sleep.

In the interval of the paroxysms, the patient, although comparatively comfortable, is by no means entirely free from excitement. The pulse, in particular, is always preternaturally frequent, often even quick and small; seldom entirely normal in any case or at any time; easily disturbed by exercise and mental emotion. The countenance exhibits well-marked evidence of the inward trouble; in the morning it is pale, shrunk, and careworn; in the afternoon, on the contrary, it has generally a somewhat full appearance, and a circumscribed blush, too plainly denotive of the vital decay, rests upon the cheeks in striking and often mournful contrast with the surrounding pallor. The eyes have a peculiar lustrous expression, and gradually retreat more and more within their sockets. Emaciation begins early, and is steadily progressive, proceeding from bad to worse, until the body is literally wasted away to a skeleton. Amidst all these evidences of decay, it is remarkable how well the appetite frequently sustains itself; the patient often eats voraciously in the intervals of his paroxysms, and digestion goes on with little or no interruption, assimilation alone being at fault. The tongue is variously affected; in general, however, it is clean, or nearly clean, but, perhaps, a little too red at the tip and edges. At times it is remarkably smooth and glossy; and cases occur in which it appears to be glazed, as if it were coated with a thin layer of mucus. A foul tongue is a rare phenomenon in this form of fever. Hectic patients are usually easily impressed by atmospheric vicissitudes; the slightest exposure produces chilliness, and hence they always require an unusual amount of clothing. The feet and legs, in particular, are nearly incessantly cold; the hands, on the contrary, are generally dry, hot, and burning.

As the disease occasioning the hectic progresses, the symptoms gradually manifest more and more of a downward tendency; the appetite fails, the sleep is interrupted, the perspiration becomes more profuse and exhausting, aphthæ make their appearance upon the tongue and fauces, and the bowels are constantly harassed with diarrhœa, the discharges being thin, watery, and excessively fetid. Thus, the case goes on, steadily but almost imperceptibly, from bad to worse, until the patient dies literally exhausted from the want of nourishment, and perhaps also in consequence of the severity of his bodily pains. During all this struggle, it is astonishing to see how the mind, rising above the mortal decay around, maintains its supremacy; being not only clear and strong, but hopeful and often even sanguine to the last.

The prognosis of hectic fever is influenced by such a variety of circumstances as to defy anything like a definite statement. In general it promptly disappears with the removal of the exciting cause, provided the inroads made by that cause have not been productive of any serious disorganization; should this have happened, the case will probably have an unfavorable issue, the hectic continuing in a modified form down to the fatal crisis. The fortunate manner in which hectic disappears after the removal of the disease that occasioned it, is much more frequently witnessed by the surgeon than the physician, whose practice more generally brings him in contact with all kinds of incurable organic maladies. I have repeatedly seen a severe and protracted hectic, consequent upon the disorganization of a tuberculosed joint, completely vanish in less than twenty-four hours after the removal of the limb, and the system rapidly recover from the effects of the previous disturbance.

The indications in the treatment of hectic fever plainly are, first, to remove the exciting cause, and, secondly, to support the system until time is afforded to it to shake off the effects of the morbid action.

The first of these objects is frequently best accomplished by the knife, as when the disease depends upon, and has been kept up by, a tuberculosed joint, or a suppurating compound fracture, the removal of which often promptly restores health and tone to the prostrate system. If the cause be inaccessible, the case must be treated upon general principles, in the hope that, by and by, as the strength improves, the patient will have sufficient recuperative power to dislodge the source of irritation, and so rid himself of his malady.

The second indication is to be fulfilled by tonics, nutritious food, anodynes, the suppression of unnatural discharges, change of air, and attention to cleanliness.

The use of tonics is generally indispensable in almost every case of hectic, however induced, particularly in its more advanced stages, when there is a wretchedly impoverished condition both of the blood and solids. The articles most to be relied upon are quinine, Huxham's tincture of bark, and the different preparations of iron, of which, according to my experience, the sulphate and the tincture of the chloride deserve the preference. Whatever substance be selected, its operation should be aided by a nutritious diet, consisting of the richer kinds of animal broths, jelly, tapioca, arrowroot, and milk, with brandy toddy, wine whey, ale, or porter. When the emaciation is steadily progressive, and dependent upon a tubercular diathesis, the use of cod-liver oil is indicated, and should be given in as large doses as may be consistent with the tolerance of the stomach.

Anodynes are among our most valuable agents in the treatment of hectic, as they serve to allay the inordinate action of the heart, to relieve pain and irritation, and to procure sleep, which is generally so much impaired in cases of this kind. They should be given in full doses, not too often repeated; and the best period for their exhibition is usually towards bedtime, so that their appropriate effects may be realized during the night in refreshing tran-

quillity. Morphine will generally be found to be borne better than opium, but when there is much sweat or diarrhœa it may often be advantageously replaced by the latter, as more likely to produce an astringent influence.

The exhausting effects of diarrhœa and perspiration, especially when they are of a colliquative character, must be promptly counteracted by suitable remedies, of which opium, as just stated, is one of the best. When the diarrhœa is dependent upon vitiated fecal matter, a mild laxative should be given, and blue mass, or calomel, in minute doses, if it has been caused by derangement of the biliary secretion. Sometimes it is most readily checked by astringents, as rhatany, prepared chalk, or tannin, in union with an anodyne.

Night sweats, which are often a source of so much prostration, will be best met by the free use of aromatic sulphuric acid, tannate of iron, or oxide of zinc, with frequent ablutions of the surface with tepid alum water. Sometimes they may be effectually prevented by a full opiate administered a short time before the expected rigors.

Whenever the local disease, inducing the hectic, will admit of it, exercise should be taken in the open air, which frequently conduces more to the restoration of the patient's appetite and strength, and the relief of the colliquative diarrhœa and sweats, than all other means combined. Children may be carried about in their nurses' arms, or in hand cars, while adults may ride about in a carriage, or walk, as may be most agreeable and convenient. Occasionally a residence at the seaside will be found to be eminently beneficial.

Finally, the greatest attention should be paid to cleanliness; the body should be frequently washed and rubbed; the excretions carefully and promptly removed; and the apartment thoroughly ventilated at least twice a day.

SECT. V.—HEMORRHAGE.

A discharge of blood, as an effect of inflammation, is, on the whole, an uncommon occurrence. It may take place in the interstices of the organs and tissues, or upon their free surfaces, and is generally a result of the rupture of some of the vessels of the part, in consequence of the manner in which the blood is sent into them by the heart, at a time when their walls, weakened by the morbid action, are incapable of offering much resistance. It is probable that, when the blood is in a dissolved condition, as occasionally happens in scurvy, typhoid fever, and other low states of the system, the hemorrhage may occur as a product of secretion, or, perhaps, rather as a mechanical transudation, the fluid percolating through the coats of the vessels as water does through a bladder, the globules passing off in an altered and disintegrated form.

The fluid may present itself in a pure state; but, in general, it is mixed with other morbid products, as serum, lymph, pus, and mucus, which may thus essentially modify its properties, if not, in a great degree, mask its character. The quantity of the effused blood varies, in different cases and under different circumstances, from a few drops to a number of ounces. The largest hemorrhages of this kind commonly occur in connection with the serous and mucous surfaces, and the subcutaneous and intermuscular cellular tissue, especially in diffuse erysipelas, and in inflammation consequent upon snake-bite, in the latter of which the dissolved state of the blood powerfully predisposes to the extravasation. In scorbutic affections, where a somewhat similar condition of the fluid exists, inflammatory hemorrhages are by no means infrequent. Considerable effusions of blood occasionally take place in the air-cells of the lungs and the minute bronchial tubes in pneumonitis.

In dysentery, a discharge of blood and mucus is one of the characteristic symptoms of that disease.

Inflammatory hemorrhage rarely comes on until the action of which it is a product has made considerable progress; hence its appearance may generally be regarded as denotive of a higher grade of excitement than a mere deposit of serum, plasma, or even pus. When the discharge is copious, it may, provided it do not go too far, prove serviceable in the way of depletion, answering pretty much the same purpose as local bleeding by leeching, scarification, or puncture. In general, however, it is too small to confer any substantial benefit in this way; while, on the other hand, if it be very copious, it may speedily lead to fatal exhaustion, or, at all events, to such a degree of depression as to interfere materially with recovery. Besides, it may cause serious mechanical obstruction, as when it is effused into the interstices of organs, thus sadly impeding their functions.

In the treatment of inflammatory hemorrhage our reliance is to be placed mainly upon the ordinary antiphlogistic measures, employed more or less vigorously according to the exigencies of each particular case. If the discharge be at all copious, so as to threaten exhaustion, recourse may be had to the administration of acetate of lead in union with opium, and injections of the same article, or, what will be better, of the perchloride of iron, a substance which possesses a remarkable controlling influence over all kinds of capillary bleeding, whether inflammatory or otherwise. They must, however, be used with great caution, otherwise they may do harm by their irritating nature, thus adding fuel to the flame. Sometimes the discharge may be readily arrested by cold applications, as cloths wrung out of ice water, and frequently renewed, or by the steady employment of a bladder partially filled with pounded ice, or some refrigerating lotion. When the blood has been poured out into the cellular tissue beneath the skin, or among the muscles, and acts injuriously by compressing the capillary vessels, nothing short of early and free incisions will be likely to avail. When the hemorrhage is internal, proceeding from a serous membrane, as the pleura, or peritoneum, sorbefacient remedies are indicated; but, these failing, as they will be likely to do, when the deposit is uncommonly large, evacuation must be attempted with the trocar, although such a proceeding will generally be extremely hazardous, to say nothing of its inefficacy in case the effused blood has undergone coagulation, rendering its escape impracticable.

SECT. VI.—MORTIFICATION.

Mortification may be defined to be the death of a part, the rest of the organism retaining its vitality. The word, as usually employed in this and other countries, is synonymous with gangrene, so much in vogue among French writers. Formerly the term gangrene was used to denote that state of a part which immediately precedes its dissolution, while sphacelus was employed to signify the complete extinction of life, without any possibility of its recovery. When we speak of the death of a bone, necrosis is the expression generally used. It would save much trouble, and prevent confusion, if all these terms, excepting the first, were abolished.

Mortification may be acute or chronic, moist or dry, common or specific, according to the rapidity of its progress, the condition of the dead part, or the nature of the exciting cause. There is really no material difference between acute and moist mortification, or between dry and chronic, and hence these terms may very properly be employed in a convertible sense. The word specific implies the operation of a peculiar virus in the production of

the death of a part, as the poison of the rattlesnake, of chancre, or of malignant pustule.

1. ACUTE MORTIFICATION.

Acute mortification, whether the result of traumatic or idiopathic causes, is liable to occur in all parts of the body, with, perhaps, the sole exception of the heart. There are some organs and tissues, however, which possess this tendency in a much greater degree than others, or which, more properly speaking, are better adapted to withstand its assaults. As a general rule, it may be stated that those textures are most prone to perish from the effects of inflammation which stand lowest in the scale of organization, and which, consequently, have naturally a feeble life. Hence the fibrous membranes, tendons, ligaments, cartilages, and bones, generally perish very readily, and often to a great extent. The cellular tissue is also very liable to suffer, its areolar structure adapting it in a very special manner for the reception of morbid products, the pressure of which, inducing mechanical obstruction in its vessels, is a frequent cause of mortification in erysipelatous and other forms of inflammation. When the supply of blood is cut off from the skin, in consequence of infiltration of the cellular substance beneath, this structure also dies very readily, notwithstanding its wonderful nervous and vascular endowments. Next in order come the mucous and serous membranes, the lymphatic ganglions, muscles, nerves, and bloodvessels, the latter of which, especially the larger trunks and branches, generally die with great reluctance, as is proved by the fact that we often find them retaining their vitality in the midst of the sphacelated parts, as occasionally happens, for example, in malignant scarlatina, attended with mortification of the glands and cellular tissue of the neck.

Mortification of the internal organs is extremely rare. In the lungs such an event occasionally occurs as a consequence of pneumonia, but it forms the exception, not the rule. It is likewise noticed, but still more rarely, in the liver, spleen, kidneys, uterus, and ovaries. The testicle, mamma, tonsils, and salivary glands sometimes perish from the effects of erysipelas, and the prostate from urinary infiltration. Of mortification of the heart I am not acquainted with a solitary well-authenticated instance. Gangrene of the brain, from wounds of its substance, although infrequent, is occasionally witnessed.

In regard to the *causes* of acute mortification, they are the same as those of acute inflammation; whatever has a tendency to produce the one may occasion the other. It is not necessary, therefore, to enter into any minute discussion respecting them, although it must be apparent that the subject is too important to be passed over entirely in silence. They may be divided, in reference to their character, into five distinct classes: 1. Intensity of inflammatory action. 2. Mechanical obstruction of the circulation. 3. Chemical agents. 4. Defect of nervous energy. 5. Constitutional debility.

I. It has already been seen how *intensity* of inflammation acts in producing obstruction in the capillary vessels of the affected part; how the blood, rendered adhesive by the increase of fibrin and white globules, becomes attached to their walls, and how these walls, softened and dilated, at length yield under the pressure of their contents, which are often, in consequence, extensively effused through the surrounding tissues, thus materially aggravating the local trouble. As the disease progresses, the capillary engorgement rapidly augments, the blood becoming more and more stagnant, and there is almost a complete suspension of the nervous fluid. In short, the utmost perversion of structure and function exists, the part is in an utterly helpless condition, circulation and innervation are entirely at fault,

and death, already actively engaged at the focus of the inflammation, soon accomplishes its work.

Mortification from intensity of action is generally very rapid in its progress, a large amount of tissue, and sometimes even an entire limb, perishing in the course of twenty-four hours from the commencement of the process. Some of the most characteristic forms of this species of gangrene are met with in compound fractures and dislocations, in lacerated, contused, railway, gunshot, and poisoned wounds, in burns and scalds, in carbuncle, and in erysipelas, in which the tissues often succumb under the resulting inflammation with amazing rapidity. Hence, such cases, of which fig. 17 affords an

Fig. 17.

Acute mortification, rapid in its progress, and attended with much swelling and moisture.

excellent illustration, are generally said to be acute; and, as the parts are always infiltrated with an abundance of fluids, the term "moist" is also often used to designate them.

II. Mortification from *mechanical obstruction* of the circulation may be caused by direct injury to the arteries, or indirectly through disease of the heart, interrupting the flow of blood to the part. The operation of tying the femoral artery for the cure of aneurism of the popliteal, is occasionally followed by mortification of the foot and leg; and the same accident sometimes happens from the pressure which a tumor of this kind exerts upon the terminal branches of this vessel. The circulation being thus impeded, inflammation, generally of a very active kind, is liable to be awakened, which soon overpowers the affected tissues. Laceration of the principal artery of a limb often results in the death of the structures which it supplies with blood. Disease of the valves of the heart, leading to vascular engorgement of the feet and legs, along with œdema of the subcutaneous cellular tissue, not unfrequently produces similar effects. Tight bandaging, pressure of the body from protracted decubitus, and inordinate constriction of the bowel, in strangulated hernia, are so many causes of mortification from interruption of the circulation.

III. The influence of *chemical agents* in producing inflammation and mortification is exemplified in various ways. The contact of the alkalies and acids, if very slight, will, in general, cause merely a rubefacient effect; if more severe, it will induce vesication; while, in its worst form, it will occasion instantaneous destruction of the tissues. The application of heat and cold acts very much in the same manner. In all these cases life is destroyed, either by the primary impression of the chemical agent, or as a consequence of the violence of the resulting inflammation. In persons of feeble organization, especially in young children impoverished by starvation and disease, the application of a common blister is often followed by extensive sloughing; and a similar effect is occasionally witnessed as a result simply of the protracted use of a mustard plaster. The infiltration of urine in the cellular tissue of the perineum often produces wide-spread gangrene

of the scrotum ; and portions of peritoneum sometimes perish from the contact of bile and feces.

Although we know nothing of a definite character of the nature of animal poisons, yet it is highly probable that they induce inflammation and gangrene very much in the same way as the acids and alkalies. Some of these poisons are the product of a peculiar secretion with which the animal is provided, as a means of defence ; others, on the contrary, appear to be developed in consequence of a peculiar septic action, which is particularly strong during the last moments of life, and for a short time afterwards, before the tissues have undergone much decomposition. However generated, their insertion into the living structures usually awakens a peculiar form of inflammation, which not unfrequently terminates in the death of the affected structures ; often with extreme rapidity, as, for instance, in snake-bite, chancre, and malignant pustule.

IV. Defect of *nervous energy* is an occasional cause of mortification. Observation long ago showed that a palsied limb is much less capable of resisting the influence of ordinary physical agents than a sound one, and that, when inflamed, the morbid action is much more liable to terminate in mortification than under ordinary circumstances. In apoplexy and injury of the spinal cord, attended with lesion of innervation, the most trifling puncture, and even the application of a blister will sometimes be followed by the death of the part. The occurrence of bad bed-sores, from the same cause, is a matter of daily observation. The division of the peroneal nerve in the removal of a tumor of the leg has been succeeded by mortification of the small toes ; and Magendie ascertained, many years ago, that if the ophthalmic branch of the fifth pair of nerves be cut, the resulting inflammation will end in sloughing of the cornea.

V. The occurrence of mortification from *general debility* is well illustrated in typhoid fever, scarlatina, measles, smallpox, and scurvy, as well as in other states of the system, attended with loss of innervation, and an impoverished condition of the blood. During the progress of these diseases, local inflammation, however induced, is extremely liable to assume a bad type, and to terminate finally in mortification. In typhoid fever, extensive sloughs often form upon the hips and sacrum, despite of all the attention we can bestow upon the patient, in the way of warding off pressure ; and in scarlatina, and other eruptive maladies, mortification of the neck and throat is by no means uncommon from an inflammation, which, under ordinary circumstances, would readily resolve itself in a few days, but which, now that the system is exhausted by the operation of the peculiar poisons of these affections, is promptly followed by the death of the part. Inflammation of an organ, lighted up immediately after the occurrence of profuse and debilitating hemorrhages, is very liable to eventuate in the same disastrous manner. Mercury given in low states of the system, to the induction of ptyalism, often leads to violent sloughing of the gums and cheeks, and to necrosis of the jaw and teeth, followed by the most horrible disfigurement of the features.

In Germany, a form of mortification of the lower jaw has long been known among the operatives engaged in the manufacture of lucifer matches, in consequence of the pernicious effects of phosphorus ; and within the last few years several cases of a similar nature have occurred in this country. What the mode of action of the article is in producing this result, is still a mystery. It is supposed by some that it makes its impression locally ; but, if this were so, it is reasonable to presume that it would also injure the soft parts, which, however, is not the fact. We may therefore conclude, in the absence of reliable information, that it acts through the constitution, but why it should affect the lower jaw-bone, in preference to other portions of the skeleton, is not known. Possibly its operation may be similar to that of mercury.

When acute inflammation is about to terminate in mortification, there is, in general, a sudden aggravation of all the previous *symptoms*, both local and constitutional. The pain and sensibility become more keen and intolerable, the redness assumes a more vivid aspect, the swelling and tension materially increase, effusion is unusually active, and functional disorder is at its maximum. If sores or wounds exist, all discharge generally ceases. Along with these local phenomena, there is marked augmentation of the constitutional trouble; the fever is excessive, the pulse is frequent, and often quite strong, the thirst is intense, and there is great restlessness, commonly with more or less delirium. The type of the constitutional symptoms exhibits much diversity. In young and robust individuals it is generally of a sthenic character, or denotive of strength; but, when the disease has been unusually violent, or the system has sustained a serious shock, whether from the present attack, or from previous suffering, it is commonly indicative of prostration, the tongue and mouth being dry, the pulse frequent and feeble, the stomach irritable, and the surface bathed with cold perspiration.

The complete cessation of vitality is denoted by the livid, black, or mottled discoloration of the part, supposing that the mortification is external; by all absence of heat and sensibility; by a peculiar fetid, or cadaverous odor; and by more or less crepitation, in consequence of incipient decomposition. Immediately beyond the seat of the mortification the ordinary phenomena of inflammation are still visible; the surface being of a scarlet hue, hot, dry, tumid, and painful, the dead and suffering parts being usually insensibly blended or marked off by a faint, indistinct line.

The part having actually died, the general symptoms are no longer of an equivocal character, whatever they may have been during the previous struggle. They are clearly of a typhoid nature, and, consequently, fully denotive of the exhausted condition of the system. The pulse is small and feeble, and from one hundred and forty to one hundred and sixty a minute; the surface, bathed with a cold clammy sweat, has a yellowish, withered appearance, and exhales a peculiarly disagreeable odor, not unlike that of moist earth; the respiration is short, hurried, and difficult; the countenance is pale and shrunk; the eyes are devoid of lustre and sunk in their sockets; the nose has a singularly pinched appearance; the lips are incrustated with dark scabs; the tongue is dry, contracted, and covered with a thick blackish fur; the abdomen is tympanitic; and there are frequent twitchings of the tendons, with hiccough, and low, muttering delirium. The strength is so much exhausted that the patient cannot sustain himself upon his pillow, but constantly sinks down in the bed; the stomach is harassed with nausea, and occasionally with bilious vomiting; and, towards the last, there are often involuntary discharges from the bowels, with retention of urine.

The cause of this depressed condition of the system is probably twofold. In the first place, it may be supposed to depend upon the shock which such an occurrence must necessarily inflict upon the great nervous centres; and, secondly, upon the absorption of vitiated matter, which, by its union with the blood, contaminates both solids and fluids, rendering them thereby incompetent for the discharge of their appropriate functions.

The *color* of the mortified parts varies in the different organs and tissues. The skin, as already remarked, is usually purple, black, or mottled, while the cellular tissue beneath it generally retains, in great measure, its normal complexion, unless, as sometimes happens, it has been infiltrated with bloody matter, when it will, of course, be of a reddish or modena color. The aponeuroses, muscles, tendons, nerves, vessels, cartilages, and bones, undergo very little change in this respect. In mortification of the lungs, the color is black; of the brain, grayish or ashy; of the liver, reddish or yellowish. The serous membranes are commonly of a purple tint, and the mucous of a

black, brownish, or claret, with almost every possible intermediate shade. As a general rule, it may be assumed that the depth of the color of the sphacelated structures is in direct ratio to their vascularity and the violence of the antecedent action.

The *consistence* of the dead part is also variable; but in general it is quite soft, and, as it were, broken down, from the infiltrated condition of the cellular tissue and of the intermolecular spaces of the proper structure of the affected organ. In mortification of the limbs, involving all the component tissues, the part feels swollen, soft, and crepitant, because it contains both gas and different kinds of fluids, as serum, pus, and blood; but if we examine the individual textures, they will all be found, with the exception of the areolar, to be very nearly of their normal consistence, particularly if there be as yet but little decomposition. In the parenchymatous organs, as the brain and lungs, the loss of cohesion is always very great, the mortified mass being of a soft, pap-like consistence.

The *fetor* in mortification is peculiar and characteristic. It evidently depends upon the extrication of sulphuretted hydrogen gas, and is sometimes, as in mortification of the lungs, almost insupportable.

The *effects* of mortification upon the general system vary with many circumstances; they may be so severe as to destroy life in a few hours, or, at most, in a few days, as occasionally happens in the traumatic form of the lesion; or, on the other hand, so slight as to be hardly felt even as a serious inconvenience. In the latter case, an attempt is generally made, after some time, to detach the dead parts from the living, by the establishment of ulcerative action, the first evidence of which is exhibited in the formation of a circle of vesicles, usually filled with a sero-sanguinolent fluid. Presently these vesicles burst, and then a faint reddish line is observable, technically called the line of demarcation, which, as it is denotive of the cessation of the gangrene, is always looked

for with great anxiety by the attendant. The process, which constitutes a species of natural amputation seen in fig. 18, often proceeds with considerable rapidity, one part separating after another, generally skin and cellular tissue first, then muscle, next tendon and aponeurosis, then vessels and nerves, and lastly, cartilage and bone; the latter being always detached with extreme difficulty, on ac-

count of the large quantity of earthy matter which it contains. It is owing to this circumstance that several months commonly elapse before the connection is finally severed, and then the proceeding is often anything but surgical, the stump thus made being rarely well covered with integument, a matter of so much consequence in the subsequent progress of the case, and the ultimate well-being of the patient.

The separation of the dead parts is always accompanied with more or less pain, discharge, and fetor, adding still farther to the prostration of the system, and the danger of constitutional contamination. The pain is sometimes excessive; at other times it is insignificant, depending upon the extent of the morbid action, and the state of the constitution. In general, it is sharp, smarting, or burning. The discharge, which is often quite profuse, is always,

Fig. 18.

Mortification of the foot and leg, with an appearance of the sloughing process, the soft parts being extensively separated from the bone.

at first, unhealthy, ichorous, or sanguinolent, and irritating; by degrees, however, it assumes a more favorable character, and at length acquires all the properties of laudable pus. The fœtor is generally most horrible, sickening, and overpowering; tainting the atmosphere of the apartment, and exerting a most prejudicial effect upon the patient, unless prompt and effectual measures are adopted for its correction. The emanation is, of course, rather from the dead parts, now called a slough, than from the gap, or trough, which lies between them and the living. As the separation progresses, granulations gradually spring up along the raw border, exhibiting the usual appearances of healthy bodies of this kind in other situations, and furnishing an abundance of thick, yellowish pus, which, while it serves to shield them from the rude contact of the air, affords the surgeon an excellent opportunity of judging of the nature of the ulcerative action, or, in other words, of the state of the part and system.

While these changes are going on between the dead and living parts, for the riddance of the former, and the benefit of the latter, all the ordinary phenomena of inflammation are plainly visible in the structures above the breach, nature being busy in throwing up her walls of defence by pouring out a liberal supply of plastic matter into the meshes of the cellular tissue. In this way, the surviving structures are solidified and fortified against the ingress of air, and also, at least in some degree, against the absorption of pus.

The manner in which the vessels are closed during the progress of mortification, so as to prevent them from parting with their contents during the act of sloughing, is curiously interesting, and well calculated to elicit admiration. As was before stated, both the arteries and veins possess a wonderful conservative power, by which, at least in many cases, they are enabled to maintain their vitality in the midst of the dead and perishing structures. At length, however, they also yield to the devastating influence, but before this is fully accomplished their contents coagulate, and becoming firmly adherent to their inner walls, the vessels are thus, as it were, hermetically sealed. Hence, during the sloughing process it is impossible that there should be any bleeding; and for the same reason there is often no hemorrhage whatever during the artificial section of the part, inasmuch as the clots of blood frequently extend many inches beyond the line of demarcation.

Treatment.—The treatment of acute mortification is to be conducted upon the general principles applicable to that of inflammation. When this event is about to occur in a person of strong, robust habit, with a vigorous pulse, and a red, fiery, and painful condition of the part, the indication is to draw blood by venesection and leeching, to make free use of the antimonial and saline mixture, along with a sufficiency of morphia to allay pain and quiet the heart's action, and to cover the affected surface with a large blister, to paint it with iodine, or to keep it constantly wet with saturnine and anodyne lotions, either tepid or cold, as may be most agreeable. When the local action is accompanied with severe swelling, punctures, scarifications, or incisions should be made, freely and early, in order to afford vent to effused fluids, to relieve congestion, and to moderate pain and tension. The approach of gangrene may often be averted, or, at all events, materially checked, by the timely use of a blister, large enough to cover in not only the whole of the inflamed part, but also a portion of the healthy skin, and retained sufficiently long to effect thorough vesication. I am satisfied, from observation, that there is, in general, no more efficient remedy, and I therefore rarely ever omit its employment. It is particularly valuable in the idiopathic form of the disease, although it is not without its benefit in the traumatic. I was first led to use it from its great efficacy in erysipelas, where it unquestionably very frequently averts the occurrence of gangrene altogether, and it is well known

to the American surgeon that it was a favorite means, in this affection, in the hands of Physick.

When mortification has actually occurred, our line of conduct must of course be different from what it is when we are watching its approaches. The symptoms may still be of a sthenic nature, as will probably be the case when the patient is young and robust, and the part invaded is of trifling importance in the scale of organic life. Nevertheless, it would hardly be proper, even then, to indulge in farther depletion, certainly not in depletion of a general character; leeching may be admissible, and we may perhaps continue, in a moderate degree, the internal use of antiphlogistics; cautiously and warily, however, lest they be instrumental in bringing on premature exhaustion, and thus placing life in jeopardy. When, on the contrary, the patient is feeble, the pulse small and frequent, and the tongue already covered with a brownish fur, clearly denotive of an asthenic state of the system, stimulants and tonics must be employed, and, in fact, every means taken to husband the remaining powers of the constitution. The best remedies, under such circumstances, are quinine, carbonate of ammonia, camphor, and opium, alone or variously combined, together with wine-whey, pure wine, or, what is far better than either, brandy, gin, or whiskey. The diet must be as nourishing and concentrated as possible, that, while it affords the greatest amount of sustenance in the smallest space, it shall not oppress by its weight and bulk. The most suitable articles, generally, are the different animal broths, jelly, arrowroot, tapioca, and sago, which are commonly well borne by the stomach, especially if they be properly seasoned. In most cases the best treatment will be found to consist of quinine, given freely in camphor mixture; of full doses of opium, to allay pain and procure sleep; and of brandy, in the form of milk punch. Little, if any, confidence is to be placed in carbonate of ammonia, musk, castor, and valerian, so much vaunted by some of the older writers, and still occasionally exhibited by modern practitioners; these articles possess no blood-generating power, and rarely do much good even as nervines. The system, in such a state, requires something more active and permanent, and there are no means so well calculated to fulfil this indication as those just indicated.

Whatever measures, of a general nature, be adopted, the utmost attention must be paid to cleanliness and to the renewal of the air in the patient's apartment. Sponging the surface several times a day with tepid salt-water, or, if there be much perspiration, with a strong solution of alum, will be highly beneficial, especially if care be taken not to carry it to fatigue; the body and bedclothes must be frequently changed; and the windows must be raised several times during the twenty-four hours; for nothing is more conducive, under such circumstances, to the healthful reaction of the system than a pure atmosphere.

The object of the local treatment is to allay fetor, which is generally so excessive in acute gangrene, and to promote the separation of the sloughs in the most prompt and easy manner. The first of these measures is best accomplished by the liberal use of the chlorides, the hypermanganate of potassa, or Labarraque's disinfecting liquid, sprinkled freely upon the parts, as well as upon the body and bedclothes; and the second by the steady application of fermenting cataplasms, or the warm water-dressing, simple or medicated. The charcoal poultice, formerly so much in vogue in such cases, is now seldom employed, on account of the manner in which it discolours and obscures the inflamed surface, thereby preventing a proper examination of its true condition. The ordinary yeast poultice is, on the whole, as eligible an application as can well be made; where an additional stimulant is required, recourse may be had to the nitric acid lotion, camphor water, pyroligneous

acid, or the solution of the chlorinate of soda; pieces of lint wet with any of these substances being laid in the gap, and kept in place by the cataplasm.

When the sloughs are tardy in separating, advantage may be derived from the use of the knife, but care must be taken, in making the dissection, not to interfere with the living tissues, much less to lay open any important vessels. For want of due precaution in performing this little operation, much suffering is sometimes entailed, and I have witnessed several cases where the patient was absolutely destroyed by it; for, when the powers of life are greatly reduced by the effects of the gangrene, the most insignificant bleeding and the most trifling shock may prove fatal.

Clearance having been effected of the dead and putrid mass, the next object is to promote the granulating process, by the steady use of emollient and soothing dressings; aided, if necessary, by the nitric acid lotion, the nitrate of silver, solutions of copper, lead, or zinc, the balsam of Peru, the tincture of benzoin, and similar articles. Proper attention must also be paid to the state of the system, every effort being made to rebuild it by the judicious administration of tonics; along with nourishing food and change of air. As soon as the granulations begin to assume a healthy aspect, as indicated by their florid color, and the thick, yellowish character of the discharges, the healing process will generally progress best under the most simple dressings, serving merely as protectives against friction and rude exposure; as, simple cerate, or a light linseed poultice. If the sore be large, cicatrization may be promoted by touching its edges lightly once a day with solid nitrate of silver, and drawing them gently together with adhesive strips.

In connection with this subject the question of *amputation* necessarily arises. Under what circumstances is this operation necessary or proper? Should it be performed while the mortification is still in progress, or should it be postponed until it is completely arrested, and a line of demarcation is formed? These are important points, and they should therefore receive due consideration in every case; for it is the solemn duty of the surgeon not only to save the life, but also, if possible, the limbs of his patient. His object should ever be to preserve, and not to mutilate; for it is a thousand times more creditable to his skill and judgment to save one extremity than to lop off a hundred, however adroitly it may be done.

In attempting to settle this question special reference must be had to the nature of the mortification, or the causes under whose influence it is developed; for experience has shown that the two forms of the disease generally require different treatment. Thus, in idiopathic gangrene the rule now is never to amputate until the surgeon is assured, by the establishment of a circle of demarcation, that both the part and system are in a condition to bear the shock of the operation, and that death has been completely arrested. Even further delay may be demanded, if, upon careful investigation, it be found that the patient is still feeble from the effects of the mortification; that he looks pale and wan; that he has a weak and shattered pulse; in short, that everything is denotive of a broken state of his constitution. To amputate under such circumstances would greatly endanger the result, if not positively destroy the patient; proper allowance must also be made for the loss of blood and the shock which must of necessity follow the use of the knife, both of which, even when the greatest care is taken in performing the operation, are often most serious. If, on the other hand, the powers of the system are sufficiently active, if there is no apparent contamination of the fluids and solids, and, above all, if nature is making a vigorous effort to arrest the extension of the malady, there is no reason for delay, and hence the sooner the offensive parts are removed the more likely will the case be to have a favorable termination; the system is prepared for the emergency, and will soon react from any depression that may ensue from the employment of the knife.

Longer delay, in truth, should not be thought of, seeing what pernicious influence the retention of the dead structures must, by their putrid and fetid condition, exercise upon the system, already weakened to an unreasonable extent by the disease before the tissues were fully deprived of vitality.

From this treatment that of traumatic gangrene is altogether different; here the extinction of vitality is usually more rapid and extensive, and hence to wait always, or even generally, for the appearance of a line of demarcation would be virtually, in many cases, to consign the patient to the grave without making an effort to rescue him from the impending danger. Where injury of an important artery, nerve, or joint is the cause of the mortification, amputation can hardly be performed too soon; nothing, certainly, can be gained by delay, which, even in a few hours, may put the case beyond our reach, such, not unfrequently, is the swiftness with which the lesion travels along the affected limb. This is particularly liable to happen in railroad, factory, and steamboat accidents, which are so common in this country, and which are often of the most frightful nature, pulpifying the soft parts, laying open large vessels and joints, and literally crushing the bones into atoms. Under such circumstances the judicious surgeon will of course amputate at once, the very moment sufficient reaction has taken place to enable the system to bear the operation; but instances often occur where the case has been neglected, or ill managed, and where death of the parts has already set in before we are consulted. Now it is precisely in such a case as this that the question will arise in regard to the propriety of immediate action, and much judgment and experience are frequently required to enable us to come to a correct decision. The proper procedure, I think, is not to hesitate, if the state of the system is such as to warrant the belief that it will be able to bear up under the shock of the operation; but I should certainly refrain from it if the patient was so far exhausted as to render it probable that he would sink under it. I should, under such circumstances, endeavor to make his system rally, if possible, by the free use of cordials, as wine, brandy, and quinine, and use the knife as soon as a favorable change occurred. If this did not arise, I should prefer to let him perish from the effects of his injury rather than become his executioner.

2. CHRONIC MORTIFICATION.

There is a form of mortification, the very opposite, in many respects, to the one just described, and to which, therefore, the term chronic, or dry, may very properly be applied. The affection, which may be induced by various causes, is characterized by the remarkable tardiness of its progress, by the absence of humidity, and by the great blackness of the skin, which, when the loss of vitality is complete, looks very much like a piece of charcoal.

One of the best types of this variety of mortification is what is now generally known as senile gangrene, from the fact that it is most common in elderly subjects. It is the same disease which was so admirably portrayed, for the first time, by Percivall Pott, of London, under the appellation of mortification of the "toes and feet," and which, for this reason, was formerly known by his name. It generally begins as a little bluish or purple speck, not larger, perhaps, than a mustard-seed, upon the inside of one of the small toes, which is soon succeeded by a minute vesicle, filled with a serous ichorous, or sanguinolent fluid, and which, bursting, exposes a black surface beneath, perfectly cold and insensible. This spot gradually spreads in different directions until it involves the whole foot, as in fig. 19, as high up, in many instances, as the ankle, or even the middle of the leg, although, in general, the patient dies long before it reaches that situation. Occasionally, the mortifi-

cation begins at several toes simultaneously, or in pretty rapid succession; and I have met with several cases where it first showed itself upon the heel

Fig. 19.

Chronic gangrene of the feet, the disease being arrested, and the parts undergoing separation.

and instep. However this may be, the part always exhibits a characteristic appearance; it is perfectly dry and withered, cold, insensible, odorless, or nearly so, and as black as charcoal, the limb looking as if it were unnaturally small, as, in fact, it generally is. During the progress of the mortification, especially if this be somewhat rapid, the skin

has occasionally a mottled, purplish aspect, owing to the coagulation of the blood in the superficial veins.

The disease is usually preceded and accompanied by pains in the toes and foot, darting about in different directions, and liable to nocturnal exacerbations, preventing sleep, and rapidly undermining the general health. These pains, which are of a burning, scalding, or stinging character, are often referred by the patient to the effects of gout or rheumatism, particularly if he was formerly subject to attacks of that nature; they always increase with the spread of the malady, and demand the free use of anodynes for their suppression. The dependent posture commonly aggravates them, but, in a case which I saw not long ago with Dr. Levis, of this city, the suffering was immensely increased whenever the limb was elevated even for a few moments, and where, consequently, the patient, an old man of eighty-three, was constantly obliged, during the day as well as the night, to let his foot hang down. In some instances, the attendant pain is extremely slight. Considerable swelling is sometimes present in the part, above the site of the mortification; and cases occur, although they are rare, in which the whole extremity is oppressed with œdema, being exquisitely sore, of a pale rose color, and pitting deeply under pressure.

Well-marked *constitutional symptoms* attend this complaint, usually from the very first, and sometimes even before there is any local evidence of its presence. They are either of an asthenic type from the beginning, or they soon become so. The pulse is feeble and upwards of one hundred and twenty in the minute, quick, sharp, and irritable. The tongue is coated with a brownish fur, dry, and more or less tremulous; the appetite is impaired; the bowels are costive; the alvine evacuations are fetid; the urine is scanty and high-colored; the sleep is interrupted by pain and frightful dreams; the strength rapidly declines; and the patient gradually dies from sheer exhaustion, the period between this event and the commencement of the attack varying from six weeks to three or four months.

This form of gangrene occurs in both sexes, and probably with nearly equal frequency, although it was formerly supposed to be more common in men than in women. It is observed in all classes of individuals, the rich and the poor, the idle and the industrious, the temperate and the dissipated. Nearly all the cases, probably about thirty, that have come under my notice occurred among the middle and poorer orders of the community. Mr. Pott was of

opinion that the disease was peculiar to the old, but subsequent experience has shown that it may take place at different periods of life; and within the last fifteen years a number of cases have been reported where it occurred in children under ten years of age. It has been conjectured that a gouty and rheumatic temperament predisposes to the development of the affection, and there are numerous facts upon record which would seem to countenance such an idea. Again, it has been asserted that particular modes of life, as indolence and huge feeding, powerfully contribute to its production.

From the form of chronic mortification which we are now considering few patients recover. If occasionally one escapes, it only forms an exception to the rule. In most cases, the disease proceeds steadily, or, with an occasional temporary interruption, to a fatal termination. Now and then, when the powers of life are not too much exhausted, nature makes an effort to arrest the morbid action by the formation of a line of demarcation, and, this succeeding, a kind of amputation takes place, followed, after long suffering, by recovery. The event is denoted by the establishment of ulcerative action at the limits of the dead parts, immediately above which the surface exhibits a dusky, erysipelatous blush, very different from what usually occurs in ordinary gangrene. The sloughing process is generally attended with severe pain and the most offensive smell.

The *cause* of senile mortification was not, until recently, at all understood. Mr. Cowper, the anatomist, had, it is true, advanced the idea, now become general, that it was owing to ossification of the arteries, but his researches had not been conducted upon a sufficiently extensive scale to justify the positive conclusions which modern observation has so fully established. The result of my own dissections is very decidedly in favor of this view. Ossification of the arteries, however, is merely a predisposing, and not the immediate cause of the lesion, which consists in the formation of fibrinous clots closing up the calibre of the arteries, and thus mechanically intercepting the passage of the blood. I have ascertained that the principal obstruction occasionally exists at a considerable distance from the seat of the disease. Thus, I have found the occlusion limited altogether to the femoral artery, the popliteal, or the commencement of the tibial and fibular. In most cases, however, it affects also the smaller branches. The concretions generally exist in various degrees of development, from recent coagulation of the blood to complete organization; hence, while some can be easily detached, others are firmly adherent to the sides of the vessels.

What the immediate cause of these clot formations is has not been determined. It has been alleged that it is owing to the interception of the fibrin of the blood by the roughened walls of the arteries consequent upon their calcification; but my own view is that it is due to an effusion of plastic matter, the result of chronic inflammation of the serous membrane, thereby favoring the adhesion of the blood and its conversion into clots.

A very remarkable form of chronic gangrene is sometimes produced by the inordinate use of *ergot* or *spurred rye*, the *secale cornutum* of botanists. The affection, which has occasionally prevailed endemically, has hitherto been observed chiefly among the inhabitants of France, Germany, and Switzerland, in certain districts of which rye bread forms a principal article of diet. When the seasons are very wet an unusual quantity of ergot is generated, and this entering largely into the composition of the flour has the effect, when used for any length of time, of giving rise to mortification in the remote parts of the body. The attention of the profession was first directed to the subject in a prominent manner in 1676, by Mons. Dodard, a French physician, and since then it has been frequently noticed by other writers. For a long time doubts were entertained respecting the power of ergot to produce this effect, and in order to solve these Mons. Tessier, of Paris, was commissioned, many

years ago, by the Royal Academy of Medicine to investigate the matter experimentally. For this purpose he selected various animals, especially pigs, ducks, and turkeys, which he fed exclusively upon ergot; he found that most of them died between the tenth and twenty-fourth day, and that distinct marks of mortification existed in the bodies of all, both externally and internally. Since the poisonous effects of this substance have become so well understood the disease has almost entirely disappeared, and in this country I am not aware that it has ever been noticed in the human subject. It is said, however, to have prevailed extensively among the horned cattle of Chester County, in this State, in 1819, and in the following year in Orange County, New York, in consequence, as was supposed, of the free use of the green grass, the *poa viridis*, the seeds of which were affected with ergot.

The manner in which ergot acts in producing this disastrous effect has not been explained. It is very singular that its virulence should explode upon those parts of the body which are most remote from the heart, as the feet and legs, and the corresponding portions of the upper extremities, along with the nose, chin, and ears. I am myself inclined to believe that the primary impression of the poison is upon the blood, rendering it abnormally stimulant and plastic; and the secondary upon the inner coat of the arteries, which, becoming inflamed, thereby intercepts the liquid, and thus leads to the formation of fibrinous clots. In a word, there is reason to believe that mechanical obstruction of the vessels is the direct and immediate cause of the gangrene, and if this idea be correct, we cannot fail to discover the closest analogy between this form of the disease and senile mortification described in a previous page. It is much to be regretted that Dodard, Noel, Bossau, Gassoud, and others, who have left such admirable descriptions of the external characters of this strange affection, should not have given us any account of its pathological anatomy.

Mortification from ergotism has been observed at all periods of life; it is usually preceded by discoloration, pain, and burning heat, which, subsiding in the course of four or five days, leave the parts cold, dry, hard, insensible, of a uniform black color, and free from feter. It generally begins in the toes, whence it gradually extends over the foot and leg, until, in some cases, which, however, are rare, it reaches as high up as the hip. Occasionally it appears simultaneously both in the lower and upper extremities, as well as in the nose and ears. Sometimes the disease is accompanied by considerable swelling and by the most excruciating pain, which allows the patient no rest day or night. The constitutional symptoms vary, being at one time very slight, at another excessive; in general, however, the patient is tormented with fever, thirst, restlessness, and high delirium. Under favorable circumstances ulcerative action is set up, and this, gradually progressing, at length eventuates in spontaneous amputation of the sphacelated structures.

Anomalous cases of chronic mortification occasionally occur, so obscure in their character as to render it impossible to refer them to any particular division of the disease. To this variety belongs the extraordinary instance, published a few years ago, in the Philadelphia Medical Examiner, by Dr. Bernard Henry, of this city, of a female, aged forty-two, who suffered from gangrene of all the extremities, from the effects of which she finally died. She was the mother of nine children, of intemperate habits, and formerly affected with syphilis. The malady was preceded by stinging and burning pains in the hands and feet, which, together with the top of the nose and the skin of the knees, were gradually transformed into black, dry, and shrivelled bodies, the gangrene finally extending beyond the middle of the arms and legs. The only lesion revealed on dissection was some contraction of the left auriculo-ventricular orifice, which seemed to have obstructed the flow of blood into the aorta. The arteries were free from ossification.

This disease sometimes appears at a very early age. An instance, the particulars of which were related to me by the late Dr. Leonard, of New Albany, Indiana, occurred, some years ago, in the vicinity of that city, in a little girl only six years old, who, while seemingly in tolerably good health, was suddenly seized with excessive prostration, accompanied with delirium, unconsciousness, and great depression of the temperature of the whole body. In a short time the left lower extremity became livid, and by next morning the foot was found to be dead as high up as the ankle, the surface being black, dry, cold, and insensible. At the end of about a week a line of demarcation began to appear, and amputation being performed below the knee, the case resulted in a good recovery. It is worthy of remark that the little patient experienced at no time any considerable pain or constitutional disturbance.

Treatment.—Much diversity still exists among authors respecting the proper method of treatment in chronic mortification; some favoring stimulating measures, while others are the warm and avowed advocates of depletion, just as if it were possible in a disease which exhibits such a protean character to lay down any one plan that shall be applicable to all cases. When a writer recommends an exclusive system of treatment, and especially when he inculcates the adoption of that treatment with extraordinary enthusiasm, tinctured, perhaps, with a sense of bitterness which neither the subject nor the occasion demands, his views may well be received with some degree of allowance; and to no surgical topic is this remark more justly applicable than to that under consideration. If the reader will take the trouble to peruse the literature of the profession upon this subject from the time of Mr. Pott down to our own, he cannot fail to be struck with the truth of this remark, nor fail to lament the uncertainty of medical doctrine and practice. How are we to reconcile such discrepancies? By supposing that different practitioners have had totally different and opposite classes of cases, or that the disease varies in different countries and at different seasons, being now attended with high excitement, and now with great depression? Such occurrences are possible, but not probable, unless we conclude that there has been an extraordinary concurrence of events, or that the views of these opposite partisans are founded upon the most limited personal experience. A more plausible conjecture is that these notions are incorrect, from having been deduced from an insufficient number of facts, or that they are the offspring of preconceived hypotheses. However this may be, it is certain that no one method of treatment is applicable to chronic gangrene, although, as a general rule, the stimulant will be found to be the most reliable. I have seen cases where, from the robust state of the individual, and the character of the pulse, no doubt could be entertained about the propriety of the employment, at least, to a moderate extent, of antiphlogistic measures, where, indeed, even the lancet and antimony were admissible; but I am quite sure that such instances are comparatively few, and that, even in them, too much caution cannot be used in their adoption. Nine patients out of ten would be injured by this course. The symptoms are generally of a typhoid character from the very beginning of the malady, and not only so, but the disease nearly always occurs in old, worn-out subjects, or in persons who have long labored under depression of the nervous, vascular, and muscular powers, and who are therefore ill-prepared to undergo such a plan of treatment with impunity. Tonics and stimulants, judiciously administered, and aided by appropriate local measures, constitute the proper means in such cases. Sometimes a "masterly inactivity" is more effective than anything else, the surgeon doing little more than watching the case, and attending to his patient's diet, bowels, and secretions. But, in general, it will be found that a supporting plan of treatment is absolutely necessary, to prevent the system from falling into a hopeless state of

exhaustion. Quinine, carbonate of ammonia, and the tincture of the chloride of iron, with wine-whey, or milk punch, and opium, are the articles most to be relied upon, and they should be given in such doses as shall be calculated to meet the exigencies of each particular case.

Locally the best remedies are the dilute tincture of iodine, brushed very thoroughly twice a day over the whole of the affected part, and the use of the bandage, applied with moderate force, and kept constantly wet with a strong solution of opium and acetate of lead, Goulard's extract, or hydrochlorate of ammonia. Leeches are usually objectionable, as their bites are sometimes provocative of gangrene, and the same remark is applicable to punctures and incisions. By these means the inflammation of the obstructed vessels may now and then be promptly arrested, and the further extension of the mortification prevented.

When the sloughing process has commenced, the treatment must be conducted upon the same general principles as in the acute form of the malady, only that the local applications should, if possible, be still more mild and soothing. The most eligible remedies are, according to my experience, the nitric acid lotion, in the proportion of from two to six drops to the ounce of mucilage of gum arabic, or the opiate cerate, for the ulcerated surface, and cloths constantly wet with a solution of chloride of lime for the dead, especially if there be much feter. As the parts become detached they may be removed with the scissors, but this must be done with the greatest possible gentleness, as the slightest injury inflicted upon the living tissues is sure to be productive of mischief.

In regard to the question of amputation, it is extremely difficult to give any satisfactory statement. My belief, founded upon considerable experience, is that we ought scrupulously to follow the practice long ago laid down by surgeons not to interfere until there is a well-marked line of demarcation; and, indeed, not even then unless it is perfectly evident that there is sufficient strength of the system to bear the shock of the operation. I have, however, seen several cases where amputation was succeeded by the most happy results before nature had made any attempt to cast off the slough, and that too under circumstances apparently not at all promising as it respected the powers of the constitution. Whenever surgical interference is deemed advisable no means should be spared to support the patient with tonics and stimulants, as upon their judicious use the chances of his recovery will, in great degree, depend. When the operation is performed prematurely, or before the system has sufficiently recovered from the exhausted condition consequent upon the gangrenous action, the disease will generally reappear within a few days after upon the stump, or death will follow from sheer prostration.

In regard to chronic mortification from the use of ergot, we have no positive knowledge to guide us in our treatment. There is no remedy, so far as is at present known, the employment of which exerts the slightest counteracting influence upon the deleterious effects of this substance upon the system. Hence the only proper plan of procedure is to treat all such cases upon the general principles just laid down in respect to the management of the ordinary form of chronic gangrene.

SECT. VII.—HOSPITAL GANGRENE.

Under this name may be described a variety of mortification, or of mortification and ulceration, which often commits great ravages among the wounded in crowded hospitals, in camps and on board of vessels of war. The disease appears to be much more common in Europe and in the East than in this country, where, judging from the silence of the profession respecting it, it is exceedingly infrequent, a case being rarely met with even in our larger elee-

mosynary institutions, while in private practice it is almost unheard of. I place this affection between mortification and ulceration, as it evidently, in many cases, if not in all, strongly partakes of the nature of both.

Although it is extremely probable that hospital gangrene has existed from time immemorial, yet no distinct and satisfactory account of it appeared until 1783, when an admirable description of it was published in the posthumous works of Pouteau, of Lyons, who had himself suffered from a severe attack of it while resident pupil of the Hôtel Dieu of that city. Soon afterwards attention was directed to it by Dussasoy, whose treatise was rapidly followed by the tracts of Moreau, Burdin, Gillespie, Leslie, Blackadder, Brauer, and Boggie, to whose joint labors we are mainly indebted for our present knowledge of this curious disease.

Various names, more or less expressive of the nature of this disease, have been employed to designate it by different authors. Thus, by Pouteau and some of the earlier writers upon the subject, it was denominated hospital gangrene, evidently in reference to the frequency of its occurrence in this class of public institutions, of which it was at one time the great scourge, both in military and civil practice, particularly the former. Subsequently it was described under the appellations of contagious gangrene, gangrenous phagedena, putrid degeneration, malignant sloughing, or putrid ulcer, camp gangrene, and humid hospital gangrene.

Sporadic cases of this variety of gangrene, more or less severe, are occasionally met with in all large hospitals and other places crowded with sick and wounded, but we no longer hear of that frightful devastation which used to characterize its existence in former times. This happy change is no doubt due to the great attention which the modern practitioner bestows upon ventilation and cleanliness, and the prompt segregation of his patients on the appearance of the malady. According to Mr. Macleod, hospital gangrene was not at all common among the English during the late war in the Crimea; it prevailed during the first winter in a mild form at Scutari, but it never became either general or severe, although the barrack hospital of that city was, during the early occupation of the troops, in a very filthy and uncomfortable condition. Whenever any cases broke out, the patients were at once isolated, and sent into wards especially set apart for the treatment of the disease. The French, on the other hand, suffered most severely, owing, as was supposed, to the injury which they sustained during their removal immediately after being wounded to the hospitals on the Bosphorus, and to the manner in which they were crowded together in the wards of those institutions.

Formerly hospital gangrene often prevailed as an *endemic*, attacking almost every one that was brought within its baneful influence, and thus causing the most horrible mortality. In the Hôtel Dieu, at Lyons, in the time of Pouteau, several frightful outbreaks of this sort appeared, and such were their ravages that this distinguished surgeon was induced to ask the question, whether hospitals were not an evil instead of a blessing. In 1780, the disease prevailed extensively among the inmates of the naval hospital at New York, some of whom had been sent thither from the American squadron, then in port on account of stress of weather, others from the West Indies. Upwards of two hundred cases occurred, and of these many died; quite a number from the recurrence of gangrene upon the stump after they had suffered amputation. In 1781, the malady committed terrible ravages at the naval hospital on Pigeon Island, St. Lucia. In 1800, it prevailed extensively on board the Prince of Wales, on her homeward passage from Martinique to England; the suffering is described as having been excessive, and it is stated that every little scratch or injury, in whatever manner inflicted, speedily degenerated into a bad gangrenous ulcer. A short time before this, the disease

existed, in a very severe form, at the Cape of Good Hope. At the hospital at Bilbao, after the battle of Vittoria, the mortality from this source was excessive. In the Parisian hospitals, the disease has prevailed, off and on, for many years, often sadly interfering with the results of surgical accidents and operations. In 1847, it appeared in some of the London hospitals, and nearly at the same time in some of those at Edinburgh; in both cities, however, in a mild and transient manner.

I have adduced these references with a view of showing the occasional epidemic tendency of this disease, and the consequent absolute importance of avoiding the huddling and crowding together indiscriminately of the sick and wounded in large hospitals, camps, and other places, often selected with little judgment, for the accommodation of the poor. There can be no doubt whatever that much, if not the whole, of the immunity enjoyed by the hospitals, infirmaries, and almshouses of this country is due to the vigilance that is exercised in the sequestration of their inmates and the great attention that is paid to the cleanliness and ventilation of these establishments; circumstances which can never fail to exercise a powerful prophylactic influence upon this and other diseases whose origin and propagation are so closely connected with a vitiated state of the atmosphere and a disordered condition of the blood.

Hospital gangrene shows itself in one of two ways: either as an original affection, upon an unbroken surface, or in connection with an open wound, ulcer, or abrasion; more frequently in the latter than in the former. When the tendency to the disease is very strong, the slightest scratch, or the most trivial sore or wound may become the means of propagating it, and of producing the most frightful ravages. Several instances have been recorded of the most horrible sloughing occasioned by the accidental inoculation of the bite of the mosquito. When the disease prevails endemically, or even when there is merely some tendency to its outbreak, no operation, however insignificant, can be performed with any certainty that it will not be followed by hospital gangrene. The stripes inflicted in flogging soldiers have frequently been known to become the seat of the disease in its very worst forms. Boils, abscesses, sinuses, fistules, and cicatrices generally, under such circumstances, share a similar fate. It has been noticed, what is certainly very singular, that, when hospital gangrene exists as an endemic, it manifests but little disposition to seize upon ulcers of a specific nature, as chancres, syphilitic buboes, and cancerous sores. In its sporadic form, on the contrary, these are the parts which seem to be particularly liable to suffer, the disease often attacking them, apparently, in preference to simple ulcers.

The distinction, which has been made by some authorities, of this disease into sloughing and phagedenic, seems to me to be improper, since it is evident that the two affections are merely different grades of the same disorder, the one destroying the tissues in large masses, the other on a small scale, the action by which this is done being strictly identical in both cases. A much more important division is that into idiopathic and traumatic, the origin of the former depending upon constitutional causes, that of the latter upon external injury.

If we inquire into the *causes* of this variety of gangrene, we shall find little to reward our labor. While some regard it as a strictly local affection, others are disposed to consider it as having a constitutional origin; and in this opinion I am strongly inclined to concur, from a careful study of the history of the disease, both from what I have seen of it myself, and from the accounts given of it by different writers. Possessing many features in common with erysipelas, it is highly probable that, like that disease, it owes its origin to a species of blood-poisoning, depending upon a foul, infected atmosphere, operating upon a depraved and enfeebled constitution. It is very

certain that the strong and robust are much less liable to suffer from it than those of an opposite state of the system, or who have become exhausted by intemperance, disease, exposure, or want of proper food; and it is often easy to determine, beforehand, when a great many persons are crowded together in the wards of an infected hospital, which will be likely to be attacked and which to escape, simply from the differences in their appearances. Whether the subjects of hospital gangrene are capable of generating a poison which, in its turn, can impart the disease to others, by its operation upon the system, is a point for whose solution we possess no reliable data; but that this is the case, seems to be extremely probable. However this may be, the fact that the malady may be communicated by actual contact of the secretions of a gangrenous sore with a sore of a healthy character, seems to be well established; at all events, the theory is constantly acted upon in institutions where the disease is prevalent, in the care which is taken to prevent sponges and other articles used in cleansing and dressing affected persons, from being employed upon healthy ones. A very striking circumstance, bearing strongly upon the question of the existence of a distinct poison elaborated during the progress of this malady, has been recorded by Sir George Ballingall, in his *Outlines of Military Surgery*. Referring to this disease as it prevailed in a regimental hospital at Feversham, in 1806, he states that, after the endemic had been going on for some time, it was discovered that all the ulcers in the establishment had been washed with one sponge. A different mode of cleansing the sores was immediately adopted, and the consequence was that not a single case of the disease appeared afterwards. When to this circumstance is added the result of the experiment of Ollivier, who produced the disease in his own person, by inserting matter, taken from an ulcer of the very worst description, into the arm just below the attachment of the deltoid muscle, it is impossible to withhold our belief in the contagious property of traumatic hospital gangrene. The case of Blackadder, who suffered severely from a puncture accidentally inflicted upon one of his fingers in dissecting the stump of a man dead of this affection, is equally strong and convincing.

A scorbutic state of the system, severe shock, loss of blood, and, in short, all depressing influences whatever, probably act as so many predisposing causes of this disease, by lowering the powers of the heart and nervous system, and thereby favoring the operation of the septic poison, if such a poison really exist. Protracted courses of mercury, or exposure to wet and cold during salivation, have often been observed to be followed by the disease during its endemic prevalence. In private as well as in hospital practice, it is particularly liable to be induced in young, unhealthy, scrofulous persons, affected with syphilitic ulcers, and weakened by all kinds of privation, especially the effects of cold, and the excessive use of ardent spirits. In the army and naval service of Europe, it formerly often supervened upon severe and exhausting attacks of dysentery, scurvy, and typhoid fever.

The time that the poison of hospital gangrene lies *latent* in the system has not been determined. It probably varies in different persons and in different cases, depending upon the previous state of the general health, and the peculiar mode of the infection. In most cases it is short, not exceeding thirty-six or forty-eight hours before it shows its specific effect. When the infection is indirect, a longer time is probably required for the development of the disease than when it is direct, or effected by actual contact of the secretions.

The disease occurs at all periods of life, and the only reason, probably, why children do not suffer more frequently, is that they are so seldom subjected to the influence of its exciting causes. Both sexes are obnoxious to it; but, for the reason just mentioned, men suffer much oftener than women. No season of the year is exempt from its attacks, but it is most common, as well as most virulent, in hot weather.

The *symptoms* which characterize this affection are partly of a local, partly of a constitutional nature, the order of their priority being not always easily determined. When it supervenes upon an ulcer or abrasion, the appearance of the pre-existing affection undergoes at once a series of the most important changes, completely modifying its whole aspect. The discharge is sensibly diminished, or, perhaps, entirely dried up; the granulations, if any exist, assume a dark, foul appearance, and are rapidly destroyed; a large quantity of aplastic lymph, of a dirty grayish color, soon covers the bottom of the sore, the edges of which at the same time become jagged and everted; the adjacent parts are of a deep purple or livid hue, and the seat of numerous vesicles, filled with a sanious or bloody serum; the pain is constant and excessive, being sharp, biting, or stinging; the affected structures exhale a horrible odor; and swelling is both great and threatening. Sloughing now takes place, skin, cellular tissue, fascia, and muscle often dropping off in large, livid, putrescent masses, thoroughly impregnated with the most horribly offensive secretions. In the more severe forms of the lesion, the ravages are not limited to the soft parts, but often extend to the bones and even to the joints; the affection, perhaps, rapidly travelling up a limb until it is completely destroyed, the patient literally dying, as it were, by inches. Long before this crisis has been attained, indeed, generally at an early period, glandular swellings are observed in the groin or axilla, possessing many of the features of pestilential buboes; they usually involve a number of ganglions, and are always exquisitely tender and painful, thus greatly aggravating the local and constitutional distress. When suppuration occurs, which, however, is not invariably the case, the discharge is generally abundant and highly fetid, and the resulting ulcer speedily exhibits all the characteristics of the parent sore.

When the disease appears on an unbroken surface, which, however, it rarely does, its advent is announced by the formation of one or more little vesicles, or blebs, filled with ichorous fluid, and surrounded by a reddish areola; both gradually extending, the former soon bursts, and thus reveals a dirty, foul slough, which, dropping off, exposes a filthy looking, excavated cavity, incrustated with a thick layer of adherent, grayish, unorganizable lymph. The parts feel hot and stinging; there is great swelling, with livid discoloration, of the adjacent surface, and a tendency to rapid extension and destruction, the different tissues dying either together or successively, in the same manner as when the disease is ingrafted upon an ulcer or open sore.

The constitutional symptoms of hospital gangrene are generally well marked, their severity being usually in proportion to the violence of the local disturbance. If the patient, prior to the attack, was tolerably strong and robust, they will probably be of a strictly inflammatory nature, but in any event they will soon lose this type, and assume the asthenic form, which will become more and more distinct as the disease pursues its downward tendency. The pulse will be found to be unusually frequent, quick, and irritable; the mind is peevish, fretful, and desponding; the tongue is dry, and covered with a brownish fur; the strength is much impaired; and the pain is so excessive that the patient is completely deprived both of appetite and sleep. Delirium often sets in at an early period, forming one of the most prominent symptoms.

The *diagnosis* of hospital gangrene is generally not difficult, for there are few diseases with which it can be confounded. Almost the only affection, indeed, for which it is in danger of being mistaken is scurvy, but a little attention will usually serve to render the distinction between them very evident. The scorbutic ulcer, as it has been named by Lynd and other writers, is remarkable for its fungous, livid, bloody, and fetid character; the granulations are of enormous size, very soft and spongy, growing with great rapidity,

and bleeding copiously upon the slightest touch. The discharge is profuse, and the blood often lies in cakes upon the surface of the sore, from which it is wiped with difficulty; the pain is trivial, and if the granulations are cut away they are speedily reproduced, generally in the course of a single night. Ulcers of this kind are nearly always attended by serious disease of the gums, which are fungous, and extremely vascular, and by hemorrhagic spots in different regions of the body. There is also, as another striking diagnostic circumstance, an absence of fever, and, generally, also of vesication. In hospital gangrene, on the contrary, there is always grave constitutional disorder, and the local phenomena are such as denote the existence of high vascular action. The ulcer is foul, exquisitely painful, deeply incrustated with lymph, and surrounded by a livid, vesicated surface. The granulating process is speedily arrested, and sloughing extends in every direction.

The *prognosis* of this disease varies with many circumstances, a few only of which it will be necessary to specify. Thus, it is always, other things being equal, more unfavorable when the attack is of an epidemic character than when it is sporadic, and in persons who have been exhausted by previous suffering, privation, or intemperance, than in such as are young and robust. The extent of the disease must also necessarily exert a material influence upon the progress of the case, the danger being less when this is slight than when it is considerable, and conversely. Serious involvement of the brain, the early occurrence of delirium, or the development of secondary disease in some internal organ, as the lung or liver, always portends evil, and should induce a guarded prognosis. Formerly, hospital gangrene was an extremely fatal disease, the mortality being often in the proportion of one to three of those attacked. In some instances, indeed, nearly one-half perished. Since the pathology of the disorder, however, has come to be better understood, very few cases are found to prove fatal.

Death may be caused by mere exhaustion of the vital powers, in consequence of the extreme violence of the morbid action; or from the occurrence of repeated hemorrhages, as when an important vessel is laid open during the sloughing process. In general, the arteries and veins are among the last structures that yield to the devastating influence of the disease, and it seldom happens that they are not protected by a provisional clot; now and then, however, this is not the case, and under such circumstances the hemorrhage is sometimes not only profuse but fatal. Finally, there is a class of cases, by no means an uncommon one, in which, although the suffering is very great, death is apparently occasioned by an empoisoned state of the system, induced by purulent infection, or the formation of secondary abscesses. The time at which death occurs varies from a few days to several weeks from the commencement of the attack.

Treatment.—The treatment of hospital gangrene was, until lately, but little understood, and the consequence was that an immense number of persons were lost by it. The indiscriminate use of bark and other stimulants, so much in vogue among the army and naval surgeons of Europe, especially those of Great Britain, even down to the time of the late Mr. Hennan and his colleagues in the Peninsular wars, exercised, there is reason to believe, a most destructive influence upon the subjects of this disease. No judgment seems to have been employed by these practitioners in adapting their remedies to the exigencies of their cases; all were treated alike, and the result was an amount of mortality that was often truly appalling. Dr. Boggie did much to reform this vicious system, by substituting the use of the lancet; but it is questionable whether he did not err by carrying his measures to the opposite extreme. However this may be, it is certain that neither plan is applicable to all cases; but that the management of each one must depend upon its own contingencies. The abstraction of blood can, as a general rule, be required

only in persons of a comparatively robust constitution, and in the earlier stages of the disease; but even then it should be practised with much caution, lest it should lead to fatal exhaustion, or so far damage the system as to prevent it from shaking off, without great difficulty, the morbid influence. The disease, it must be recollected, has an asthenic tendency, often from the very start, especially when it is of an endemic character; and hence any measures calculated to favor this tendency must necessarily exercise a pernicious influence.

Purgings and attention to the diet and secretions constitute important elements in the treatment, and must on no account be neglected. A good dose of calomel and rhubarb, or of equal parts of blue mass, jalap, and compound extract of colocynth, given so as to induce two or three large, consistent, alvine evacuations, will often be more beneficial in arresting the morbid action than almost everything else of which we have any knowledge. Subsequently the bowels should be constantly maintained in a soluble condition, without establishing any decided drain upon them, and the utmost care should be taken to restore the secretions, which are always so much disordered in hospital gangrene. Mercury, as a salivant, is to be avoided as a poison.

When the system begins to flag, whether from the overwhelming influence of the attack, or from the neglect of the proper treatment, prompt recourse must be had to quinine, iron, wine, brandy, and nutritious broths. The best preparation of iron is the tincture of the chloride, given in doses of from fifteen to twenty-five drops, every three or four hours, in some mucilaginous fluid. Quinine is often extremely serviceable, and there are few cases, when this stage has been attained, which will not be immensely benefited by brandy, or some other form of alcohol, either alone or combined with milk.

But the great constitutional remedy in hospital gangrene is opium, either in substance, or in the form of the salts of morphia. It should be given in large doses, generally not less than from four to six grains, every four, six, or eight hours, in union with a diaphoretic, as ipecacuanha, tartar emetic, or the neutral mixture. When we reflect upon the excessive pain, irritability, and sleeplessness which so generally attend the severer grades of this disease, it is impossible to place too high an estimate upon the value of anodynes as means not only of insuring comfort to the patient, but of arresting the morbid action.

The diet, especially in the latter stages of the disease, should be highly nutritious, and given in as concentrated a form as possible. The patient's apartment should be consequently ventilated, the bed and body clothes should be daily changed, and the surface should be frequently sponged with tepid salt water, or weak alkaline solutions. Free use should be made of the chlorides, sprinkled about the room. If the disease manifests an endemic tendency, as when it breaks out on board ship, or in the crowded wards of a hospital, the patients should be promptly sequestered, and the apartments whitewashed and thoroughly cleansed.

When the disease is obviously connected with a scorbutic state of the system, the best internal remedies will be potassa, in union with lemon-juice, potatoes, water cresses, oranges, and other fresh fruits and vegetables.

The *local treatment* should be of the most gentle and soothing character. Any vesicles that may exist should be promptly opened, and the whole surface pencilled over with a weak solution of iodine, followed by the warm or cold water-dressing, containing a large supply of acetate of lead and opium, a cloth dipped in the solution being kept constantly upon the part. If an eschar has formed, the adjacent structures should be freely rubbed with the solid nitrate of silver, and as soon as the slough has dropped off, the bottom of the sore should be thoroughly touched with a solution of acid nitrate of mer-

cury, with a view of changing its action. If the tendency to spread is very great, and if there is, at the same time, excessive pain with a feeling of tension, scarifications and incisions must be practised, in the same manner and with the same object as in erysipelas. During the sloughing process a port wine poultice, the weak nitric acid lotion, and the liquid chlorinate of soda will often be found extremely valuable in arresting morbid action, and allaying fetor. Another extremely useful remedy is pyroligneous acid, in the proportion of one part to six or eight of water, kept constantly upon the affected surface with a cloth. Dead structure should be removed with the knife and scissors. Should the mortification stop, amputation must not be thought of until there is a decided line of demarcation, with sufficient power in the constitution to bear the shock of the operation. During convalescence change of air generally proves an important auxiliary to recovery.

SECT. VIII.—ULCERATION AND ULCERS.

Ulceration is the molecular death of a part, as mortification is the destruction of a part upon a large scale: in a word, it is dissolution in miniature. At least three distinct acts are concerned in its production: these are, first, the softening of the affected tissues, secondly, their disintegration, and, lastly, their removal, as effete and extraneous matter. Antecedently, however, to these acts there is another in operation, paving the way for their advent; and this is inflammation, which is always an indispensable accompaniment of the process, whatever may be its situation, stage, or degree. It was supposed until lately, chiefly in consequence of the influence of the writings of Mr. John Hunter, that ulceration consisted essentially in the disintegration and absorption of the suffering textures; and hence the general use of the phrase "ulcerative absorption." According to this doctrine the substance of the affected part, after having been deprived of vitality, is taken up by the absorbent vessels, and carried by them into the circulating mass, to go the rounds of the body, and be finally cast off as excrementitious matter. There are numerous circumstances which, at first sight, would seem to favor such a view. Thus, large ulcers sometimes form in a very short time, and yet it is quite impossible, so far as we can determine by the most careful examination, to ascertain what has become of the tissues concerned in their development. If search be made for them in the discharges they cannot be discovered, since their quantity, however great, is frequently insufficient to account for the loss of solid substance. Similar phenomena are witnessed in abscesses of the brain, liver, and spleen, where enormous destruction of the proper structure of these organs often occurs in consequence of the accumulating pus, without our being able to explain what has become of it. We might naturally suppose that the lost tissues were contained, in an altered and disintegrated condition, in the pus, but that this is not the case, is proved by the fact that it is impossible to detect their presence by the most careful examination.

Ulceration manifests a remarkable proneness to invade some structures and to avoid others. Those which are most liable to its inroads are the dermoid and mucous tissues, the cartilages and bones, the lymphatic ganglions, the tonsils, uterus, lungs, and kidneys. The fibrous and serous membranes, the muscles, tendons, vessels, nerves, brain, heart, liver, and spleen, together with the salivary, prostate, and thyroid glands, seldom suffer in this way. Newly-formed parts, as cicatrices and the callus of broken bones, are easily affected by ulceration, especially when, from any cause, there is a depraved and impoverished condition of the system. It is worthy of remark, both in a pathological and practical sense, that this action is more prone to show itself in certain portions of the same structure than in others.

We have an illustration of this occurrence both in the skin and in the mucous membranes. Common ulceration of the skin is by far most frequent in the legs and feet, whether because these parts are in a state of habitual congestion, or because they are more exposed to fatigue and accident, is not determined; but that this is the fact daily observation abundantly attests. Ulceration is extremely rare in the œsophagus, but quite common in the pharynx, tonsils, tongue, cheeks, and lips. The same statement is true of ulceration of the stomach and small intestine as compared with ulceration of the colon and rectum. In the genito-urinary division of the mucous system the same law obtains. Thus, the disease is extremely infrequent in the urethra and bladder of the female, but common enough in the vulva, vagina, and uterus. The male, on the contrary, rarely suffers in any portion of the genito-urinary apparatus.

The terms common and specific, as applied to this disease, are sufficiently significant. By the former is meant an ulceration that is liable to occur in all persons, as well as in all parts of the body; one which is the result of ordinary inflammation. The word specific, on the other hand, is employed to denote an ulceration which is the product of some specific cause, which runs a peculiar course, and which, in its progress, furnishes a specific secretion, capable, by inoculation, of producing a similar action. To this category belong syphilitic ulceration and the ulceration which follows vaccination and smallpox. The ulceration which attends carcinoma is also specific, but the matter it yields is not, so far as we know, capable of propagating a similar disease.

Ulceration varies in its progress, being sometimes very rapid, at other times very tardy. The circumstances which determine this result are not always appreciable, but, in general, they may be considered as depending upon the nature of the exciting cause, the amount of the attending inflammation, and, above all, upon the state of the system. When the action is very rapid, an extent of surface may be destroyed in a few days which it will perhaps require several months to repair. The process often goes on simultaneously at several points in the same organ or tissue, and not unfrequently in structures of an entirely opposite character.

The *causes* of ulceration are such as produce inflammation, which, as has been already stated, always accompanies the process. They may be very properly divided into predisposing and exciting. The former comprise an impoverished state of the blood, however induced, and, in short, whatever has a tendency to impair the powers of the system. Experiments, performed long ago, by Magendie and others, have established the fact that the protracted and exclusive use of starch, sugar, and other non-azotized articles of food, will produce ulceration of the cornea; and it is well known that the poorer classes of people, who are ill fed and sometimes almost starved, are peculiarly subject to this disease in the skin and mucous membranes. Ulceration of a severe nature often follows upon various kinds of fever, especially typhoid, scarlet, and morbillous, from the exhausting influence which they exert upon the solids and fluids.

Of the exciting causes of ulceration, nothing need be said, except that they may be common or specific, the latter being such as act primarily upon a particular part, as the head of the penis in chancre, or secondarily, in the same disease, upon the constitution, in consequence of the absorption of the specific poison. Tubercular, scirrhus, encephaloid, and melanotic matter, having undergone a process of softening, always creates ulceration by its pressure upon the adjacent tissues, thereby favoring its elimination from the part and system.

The inflammation which precedes and accompanies ulceration varies much in its degree, as well as in its character. When acute, it is usually marked

by the phenomena which ordinarily distinguish it under other circumstances, as discoloration, heat, swelling, pain, and disordered function, and then often spreads with great rapidity, laying waste a large amount of tissue in an almost incredibly short time. When this is the case, the molecular structures perish, as it were, in mass, and not in the slow and gradual manner which characterizes the disease when the inflammation is of a more mild and simple grade. It is to this form of ulceration that the term *phagedenic* is commonly applied, from a Greek compound which literally signifies to eat, feed upon, or corrode, the parts around the breach made by the morbid action being rapidly disintegrated and cast off, as if they had been consumed by fire, their ashes alone being left as the evidence of their former existence. When the concomitant inflammation is chronic, the ulceration generally advances more tardily, and is also marked by milder symptoms; this rule, however, has many exceptions.

The pain of ulceration is sometimes peculiar, affording thus valuable diagnostic information. Thus, in ulceration of the joints and bones, it is usually heavy and aching, as if insects were feeding upon the part; in rupia, it is hot and burning; in scirrhus, sharp and lancinating, or like the pricking of a needle. Sometimes, again, there is a complete absence of pain, as in common ulceration of the skin, in ulceration of the glands of Peyer in typhoid fever, and in ulceration in tubercular disease of the large bowel. As a general rule, it may be stated that the pain is more severe in the acute than in the chronic form of the disease, and, under such circumstances, it is also more steady and persistent. In syphilitic ulceration of the bones and skin, the suffering is often of an intermittent character, the paroxysm usually coming on at night, and gradually disappearing towards morning. Finally, the pain may be of a neuralgic character, although this is rare.

Ulceration is always attended with more or less discharge of matter, the quality of which is greatly influenced by the nature of the case. Thus, when the attendant inflammation is unusually high, the matter is generally of a sanious, bloody, or ichorous character, corrosive and profuse; a similar fluid is always present in ulceration of carcinomatous growths. When the action is less severe, or tending to restoration, the discharge is commonly somewhat consistent and of a yellowish color, like laudable pus.

The tendency in ulceration is usually towards the nearest surface, a circumstance which is often of great service in the evacuation of abscesses and the discharge of foreign matter. It would seem as if nature availed herself of the operation of this law to economize time, to save structure, and prevent pain. Without its aid, abscesses would often, if, indeed, not generally, be emptied in the most tedious and circuitous manner, and at the expense of a vast amount of suffering, both local and constitutional. An illustration of the beneficial effects of this law is afforded in collections of pus in the liver, which, as a general rule, discharge themselves, not through the walls of the abdomen, which are thick, muscular, and resistant, but through a contiguous coil of intestine, which is thin, proximal, and yielding. In abscess of the lung, the matter usually escapes through a neighboring bronchial tube; when it makes an effort to empty itself externally, it either pours the fluid into the pleuritic cavity, thus speedily causing fatal inflammation, or it attains its object only after a long and tedious process of ulceration, generally accompanied by great pain and hectic irritation.

When ulceration has continued for some time, it manifests a disposition either to remain stationary, to cease altogether, or to continue in a modified form. Its conduct, in these various particulars, is greatly influenced by internal and external circumstances, as the state of the constitution, the amount of the local inflammation, the nature of the exciting cause, and the effects of remedies. In the skin of the lower extremities, in syphilitic rupia,

in the spongy structure of the bones, in the movable joints, and in malignant growths, it often continues for an almost indefinite period, being better at one time and worse at another. When it is about to cease, the accompanying inflammation gradually subsides, the discharges disappear, and, plastic matter being poured out, granulations are formed, by which the breach is finally closed up, the process of cicatrization generally, if not always, proceeding from the circumference towards the centre.

In the *treatment* of ulceration, the great and leading indication is to combat the concomitant inflammation, and thus place the part in a condition for the efficient development of granulations, as it is through their agency that the lost substance is to be repaired. For this purpose the ordinary antiphlogistic appliances are to be put in requisition and continued until the morbid action has been completely arrested, as will be denoted by the subsidence of the pain, heat, swelling, and redness by which it is usually characterized. When granulations begin to form, none but the most mild and soothing measures must be employed, and the sore carefully watched to keep it in a healthy condition until it is perfectly cicatrized. In specific disease, as chancre and malignant pustule, the most efficient treatment, provided the case can be seen in time, before the matter has been absorbed into the system, is to cut out the part or destroy it with the actual cautery, Vienna paste, or acid nitrate of mercury.

ULCERS.

An ulcer is a breach in the continuity of a surface, organ, or tissue, attended with inflammation, and a discharge of pus, ichor, or sanies. The disease is of frequent occurrence, being met with at all periods of life, in both sexes, and in all classes of persons, and is often a source of great suffering to the patient, as well as of immense trouble and vexation to the surgeon. Its very name carries with it an idea of loathsomeness, and it may well be imagined how much this feeling is increased when, as so often happens, the sore is the seat of foul and offensive discharges, rendering the patient disagreeable both to himself and to all around him.

It may confidently be asserted that there is not, in all surgery, a class of maladies whose pathology and treatment are less thoroughly understood, by the profession generally, than those of ulcers. It is amazing to find what an immense amount of confusion still exists upon the subject, at the present day, among many of the best and most experienced authors. In examining the various treatises on surgery, in the principal languages of Europe, the inquirer after truth has but little cause to congratulate himself upon the progress that has been effected in this department of the healing art. He looks almost in vain for any positive additions to his stock of knowledge since the latter part of the last century, when Mr. Benjamin Bell published his *Treatise on the Theory and Management of Ulcers*. The minute divisions and subdivisions, the refinements and absurdities, respecting the nature of these lesions, are, with little variation, substantially reproduced by most of the practical writers of the present day. In studying the literature upon the subject, one is almost forced to the conclusion that, while every other branch of surgery has experienced the benign influence of progress, this one alone has remained unimproved and uncared-for. I am, indeed, ready to admit that the nosography of ulcers is much more perfect now than it was in former times; but who can read their classification, as it appears in most of our modern treatises, and not be struck with its many absurdities and inconsistencies? The catalogue is absolutely appalling, and it must be apparent to the most superficial observer that it comprehends, under different names, diseases which are

absolutely and positively identical in their nature; not even constituting, strictly speaking, so many varieties, much less distinct species. Sir Astley Cooper, in his *Lectures on the Principles and Practice of Surgery*, describes not less than ten forms of ulcers, under the names, respectively, of healthy, languid, inflamed, gangrenous, irritable, sinuous, menstrual, varicose, ungual, and cutaneous, the latter including *noli me tangere*, and ulcers with thickened, inverted, and everted edges. A more recent foreign author, whose works are extensively circulated in this country, adopts a somewhat similar arrangement. Thus, he treats, under so many separate heads, of the simple purulent or healthy, the weak, scrofulous, cachectic, indolent, irritable, inflamed, sloughing, phagedenic, and sloughing-phagedenic ulcer. The same spirit of classification pervades the works of other writers. Why, then, should it be deemed strange that the student should take up the investigation of the subject with doubt and misgiving as to his ability to comprehend it, even in the most superficial manner? No one, however industrious and zealous, can possibly unravel the mysteries of divisions so minute, and, it may be added, so utterly meaningless and unphilosophical. It would puzzle the most profound pathological anatomist to discriminate between some of these classes of ulcers, as, for instance, between the irritable and inflamed, the sloughing and sloughing-phagedenic. To describe every sore that appears upon the body as a distinct ulcer because it happens to possess slight shades of differences, in its external characters, would be as absurd as to describe, in a work on anthropology, every human being as a separate variety of the race because he happens to be a little unlike his neighbor. All inflammatory affections resemble each other, some closely, others remotely, but yet always sufficiently so to enable the observer to trace out their relations and affinities. The same is strictly true of ulcers; we never meet with two cases which are precisely alike, and yet he who runs may see that they exhibit many traits in common, the one with the other; one may be undermined, incrustated with aplastic matter, and the seat of severe pain, with a foul, sanious discharge, and great discoloration, heat, and swelling of the surrounding integuments; another may have hard and elevated edges, and a glossy, granulated surface, with, perhaps, scarcely any secretion at all, and none of the ordinary evidences of inflammation; in a third case the ulcer may be disposed to spread, its tendency being essentially destructive; in another series, by no means uncommon, the sore has thickened and everted edges, with profuse ichorous discharge, and an inability to furnish reparative material; finally, there may be a varicose state of the veins of the part, a sinus, disease of the adjacent bone, or disorder of the general system, modifying the action of the ulcer, and interfering with its cure. These are, be sure, contrarieties, but contrarieties which are solely dependent upon local and constitutional causes, and which, consequently, are not entitled to be considered as distinct diseases. We might as well say that the varieties of color in ordinary inflammation constituted so many reasons for founding new species of morbid action; when it is obvious that in this as in the former case, the circumstance is entirely accidental. The tendency of this refinement, of this division and subdivision, is, as above stated, the cause why practitioners have so imperfect a knowledge of ulcers, and why every one complains of the great difficulties and embarrassments which still environ the subject in all its aspects and relations, notwithstanding the great advances of pathological science.

Assuming that all ulcers are but so many forms of inflammation with breach of texture and more or less discharge, the most rational classification, it seems to me, that can be adopted, is that of ulcers into acute and chronic, according to the intensity and rapidity of the morbid action. Such an arrangement will, I am satisfied, greatly simplify the subject and divest it of much of the mystery and perplexity that have hitherto enshrouded it.

There are two genera of ulcers, the common and the specific, just as there are two genera of inflammations. Common ulcers are such as are produced by ordinary causes, as common inflammations, abrasions, and wounds; specific ulcers, on the contrary, owe their origin to the operation of some peculiar virus, as the poison of syphilis, smallpox, glanders, malignant pustule, scirrhus, encephaloid, tubercle, or melanosis. Although the ensuing remarks are more particularly intended to illustrate the various forms of common ulcers, yet they are also, in some degree, applicable to the specific, which, however, will receive special attention in their proper place.

1. ACUTE ULCERS.

The acute ulcer is distinguished by the rapidity of its progress, and the severity of its symptoms, which are those very much of ordinary acute inflammation. The sore usually begins at a small point of skin, or skin and cellular tissue, from which it speedily spreads in different directions until it often covers a large extent of surface. In its form it is generally somewhat oval or circular, but it is frequently very irregular, and instances are met with in which it is of a serpiginous, creeping, or angular shape. When the ulcerative action commences simultaneously at several spots, as occasionally happens, the sore may have a peculiar sieve-like, or worm-eaten appearance, similar to that of the cover of an old book, or the bark of a tree. Its surface is red and angry-looking, either uniformly, or red at one point, and white at another, owing to a deposit of aplastic matter, which occasionally overspreads it completely. When the action is unusually severe the bottom of the ulcer generally exhibits a foul, greenish, brownish, or blackish appearance, and if, under such circumstances, any plasma is poured out, it is immediately spoiled or washed away by the discharges, which are always profuse, thin, sero-sanguinolent, and irritating, possessing none of the properties of laudable pus, such as is furnished by a granulating wound. In regard to the edges of this class of ulcer, they present the greatest possible variety; in general, however, they are thin, rather sharp, and somewhat undermined, or undermined at one place, straight at another, and perhaps everted at a third: in some cases they are very steep and ragged, notched or serrated. Extending from the sore in different directions are occasionally small sinuses or fistulous passages, which thus greatly complicate its character and protract the cure. The parts immediately around the ulcer exhibit all the phenomena of high inflammation, being of a deep red or purple color, preternaturally hot, painful, and more or less œdematous from sero-plastic effusions, and consequently pitting under pressure. The latter symptom is hardly ever entirely absent in any case of acute ulcer, and is therefore of great diagnostic value. The œdema often extends over a considerable surface, but is always most conspicuous in the immediate vicinity of the sore. The same remark is applicable to the other inflammatory phenomena.

The pain of the acute ulcer is frequently a prominent and absorbing symptom; it varies not only in degree but likewise in character, being at one time throbbing, or pulsatile, at another sharp or pricking, at another dull, heavy, and gnawing, as if insects were feeding upon the part. Its violence is often altogether disproportionate to the extent of the morbid action. I have seen cases where, although the ulcer was scarcely as large as a twenty-five cent piece, it was so excruciating as to deprive the patient of sleep for days and nights together, and bring on rapid emaciation and hectic irritation. It may be limited to the sore, but in general it is felt over the whole of the inflamed surface, and is usually worst at night and in damp states of the atmosphere. Posture also commonly aggravates it, being generally more severe when the part hangs down than when it is elevated,

although I have occasionally found the reverse to be true, even when the sore was quite large.

Along with these phenomena there is generally considerable constitutional derangement, manifesting itself, commonly not so much in febrile commotion, as in an irritable state of the system, and disorder of the digestive organs. The patient feels unwell rather than sick; his head troubles him; his appetite is vitiated, or temporarily arrested; the tongue is coated, and there is a bad taste in the mouth, especially in the morning; the bowels are inclined to be constipated; and the urine is scanty and high-colored. When the ulcerative action is rapid and extensive, there is frequently more or less fever, with thirst, restlessness, loss of sleep, and excitement of the pulse. Disorder of the secretions is generally a prominent symptom in these cases, especially of the liver, the uterus, and mucous follicles.

An impoverished state of the blood, however induced, habitual intemperance, excessive indulgence at table, mental anxiety, exposure to cold, and the various eruptive diseases may be enumerated as so many predisposing causes of the acute ulcer. Nervous, irritable, and plethoric persons, especially old dram drinkers, are its most frequent subjects. Both sexes are liable to it, but men suffer much more frequently than women. The malady is rarely met with in the higher circles of society, and it is also very uncommon in children.

The acute ulcer may be a primary affection, or an ulcer, after having been for some time in a dormant condition, may suddenly assume the acute character, either in consequence of local or constitutional causes, or of both combined; that is, the part becomes more or less severely inflamed, and manifests a tendency to extend its ravages. However this may be, the disease often spreads with great rapidity, eating away everything with which it comes in contact—skin, cellular tissue, fibrous membrane, muscle, and sometimes even bone—and often laying waste in a few days an extent of surface which it may take months, aided by the best skill, to repair. When this is the case, the action may be said to be truly phagedenic, or to consist in rapid mortification of the molecular structure of the suffering part, which is hot, œdematous, fiery red, exquisitely painful, and bathed with profuse, fetid discharges. Constitutional disturbance is great, and the tendency is usually decidedly typhoid, especially if the subject of the disease has been worn out by intemperance and other causes of depression. This form of ulcer is very prone to occur upon new and imperfectly organized skin, where it often commits the most terrible ravages, which, for a time, hardly anything can successfully resist.

Treatment.—The treatment of the acute ulcer must be conducted upon strictly antiphlogistic principles, modified, of course, by the peculiar exigencies of each particular case. When the symptoms are urgent, as denoted by the severity of the local and constitutional disorder, the indication obviously is to take blood from the arm, provided the patient is at all plethoric, or, this not being permissible, at all events to open his bowels freely with an active cathartic, containing from five to ten grains of calomel, and followed up, if necessary, in six or eight hours, by infusion of senna and sulphate of magnesia; recourse is then had to the antimonial and saline mixture, to subdue vascular action; and opium is administered in large doses to allay pain and induce sleep. The diet must be mild, and not too nutritious, and the patient must observe the most perfect rest in the recumbent posture. Active purgation will be found of the greatest value in this form of ulcer; in fact, it is difficult to imagine a case in which it could be entirely dispensed with. To render it promptly effective, however, I have long been in the habit of combining with it a certain quantity of mercury, either in the form of calomel, or blue mass, with a view of making a strong and rapid impression upon the

secretions, which, as before stated, are usually notably deranged, and which thus keep up a spreading tendency in the disease. Of the beneficial effects of anodynes in arresting acute ulceration no one can form any just conception, who has not witnessed them. That they exert any direct influence upon the part itself cannot be supposed; but that they produce a most salutary impression by tranquillizing the heart's action, and allaying nervous irritability, which is generally so prominent a symptom in this affection, is indisputable; hence the remedy should always be given in large and sustained doses from the very commencement of the malady.

It is not to be inferred from the remarks now made, that active depletion is suited to all cases of this disease; on the contrary, we are often obliged to use tonics and stimulants at the very beginning of the treatment, and to continue their exhibition until we have succeeded in building up the system, so as to enable it to oppose a successful barrier to the encroachment of the morbid action. The state of the pulse, skin, digestive organs, and muscular system will generally serve as a correct guide to the kind of treatment best adapted to meet the exigencies of this class of cases. Quinine and milk punch, with opium, or the salts of morphia, will usually constitute the most reliable means.

The local treatment will not differ, in its general principles, from that already described as applicable to acute inflammation, except as it respects the modifications arising from the presence of a broken surface. The part, as a primary and essential step, must be placed perfectly at rest in an easy and elevated position, to prevent arterial ingress and favor venous return; it will even be well, in many cases, to place the limb upon an inclined plane, so that the sore shall be higher than the rest of the body, and to confine it, if necessary, in this situation by means of a light roller, care being taken not to obstruct discharge or to make undue compression. If the part be filthy from want of cleanliness, or adherent dressings, ablution by immersion precedes direct medication. If the morbid action be high, the young practitioner might be induced to apply leeches, not to the sore, but in its immediate vicinity; but such a proceeding is objectionable, for the reason that the bites of these animals are liable to occasion excessive pain, and sometimes even an aggravation of the disease. A much better plan is to draw blood by scarification by means of a lancet, the limb, the while, standing in a tub of warm water, with a cord thrown firmly round its upper extremity, a few inches below the knee. From six to a dozen vertical incisions, not quite skin deep, are made over the inflamed surface around the sore, the blood being permitted to flow until the patient shows signs of approaching syncope, if he be at all plethoric, or, at all events, until the engorged vessels have been measurably deprived of their contents, as denoted by the comparative pallor of the part. I know of no method so well adapted as this to make a prompt and decisive impression upon an acute ulcer; it is a most potent alterant, and I rarely omit its employment whenever the case presents the slightest urgency. For the sore itself the best remedy is a weak solution of acid nitrate of mercury, in the proportion of one part of Bennett's formula to two, three, or four parts of water, according to the foulness of the affected surface. The application should be made lightly with a soft sponge or cloth mop, and may, if necessary, be repeated once in the twenty-four hours until there is a decided improvement in the condition of the ulcer, when it should be entirely dispensed with, or used more sparingly, and still weaker. As a constant cover for the part the most suitable remedy will be a light emollient cataplasm, sprinkled with morphia, laudanum, or powdered opium, or the warm water-dressing, simple or similarly medicated. Feter is allayed with the chlorides. In some instances yeast may advantageously be added to the poultice; but in general this may be dispensed with. Under this treatment rapid improve-

ment may usually be looked for; indeed, in many cases we have the satisfaction to find, within less than thirty-six hours after its commencement, already a decided change for the better; the ulceration evinces a disposition to cease, the discharges assume a more healthy aspect, and the surrounding parts lose their fiery red and œdematous character. By persevering in the treatment, in a modified form, the sore will soon begin to granulate, and to form new skin along the margin of the old, and this point being attained, none but the mildest applications will be required.

Such, in a few words, is an outline of the treatment which, when a choice of remedies is allowed, I usually adopt in this disease. But the patient will not always submit to scarification, nor is this always proper, owing to the exhausted condition of his system. Under such circumstances, our object may often be promptly attained by the free application of the dilute tincture of iodine to the parts around the sore, while the sore itself is lightly touched with the acid nitrate of mercury, as in the former case, or with a strong solution of nitrate of silver, or this article in substance, although both are decidedly inferior to the former remedy. In some instances I have succeeded in putting a prompt and permanent check to the ulcerative action by covering the sore and the inflamed surface with a blister, retained until thorough vesication was induced, and then using the ordinary dressings. Few cases of acute ulcers will, I am confident, be able to resist this remedy. Its beneficial effects are no doubt due to the drainage which it establishes and the consequent change in the action of the capillary vessels. The progress of the cure is sometimes embarrassed by dead matter, as shreds of cellular tissue or fibrous membrane, the removal of which should receive prompt attention.

Of creasote, sulphate of copper, acetate of lead, and other remedies so much lauded by some practitioners in the treatment of acute ulcers, little need be said. These articles undoubtedly possess some merit, and I have occasionally employed them with advantage, but as they are altogether of a subordinate character they should never take the place, in urgent cases, of those just mentioned. Acetic and nitric acid, the former in the proportion of one drachm, and the latter of eight or ten drops to the ounce of water, are excellent applications, in the milder varieties of the affection, allaying fetor and changing the action of the sore so as to promote the formation of healthy granulations and laudable discharge.

2. CHRONIC ULCERS.

While it is not always easy to determine when an ulcer becomes chronic, it is to be borne in mind, as was previously stated, that a chronic ulcer may, in consequence of local and constitutional causes, occasionally assume an acute character. In this respect the present disease does not differ from ordinary inflammation, unattended by breach of texture. Thus, an inflammation of the conjunctiva, after having pursued a chronic march, with but little pain and discoloration, perhaps suddenly, at the end of several months, breaks out with renewed vigor, characterized by all its primitive intensity, and now rapidly urging on the affected structures to permanent disorganization, rendered the more prone to this occurrence by their protracted suffering. Ulcers are not unfrequently subjected to similar hardships; not once only, but, perhaps, many times during their progress, and thus their career often becomes a most checkered one, defying alike our powers of diagnosis and treatment, and constituting at least one of the causes, previously adverted to, of the *outré* nomenclature which disfigures this branch of the art and science of surgery.

When does an ulcer become chronic? or, in other words, what time must

elapse before it can be said to possess this character? To this question it is impossible to give anything like a definite reply; in some instances the disease is chronic almost from the beginning; in others, it becomes so in a few weeks, and in others, again, perhaps several months intervene. The term chronic, as every one knows, has reference to time, and is employed to designate a class of affections which have passed through their acute stages, and which, consequently, have been deprived of their primitive characteristics; their action has been modified by treatment, or by the operation of time, or the joint influence of both. The inflammation now generally exists in a much milder form; there is less functional disturbance, while the constitutional derangement often entirely ceases, and the local phenomena of heat, redness, pain, and swelling are materially diminished. The part, however, is oppressed, if not overpowered, by effused fluids, its vessels are sluggish, dilated and engorged with dark blood; nervous sensibility is perverted, and the restorative tendency is either much enfeebled or else completely at a stand. Ulceration still goes on, and perhaps even serious havoc is committed by its action, but that action is tardy, and exhibits few, if any, of the phenomena which characterized it in the first instance. It would seem, at first sight, as if it were a paradox to say that a disease was chronic from its commencement, and yet such is, nevertheless, the fact, rather, however, in reference to its symptoms than in regard to the true and legitimate meaning of the word. But upon this subject I have already dwelt at some length in a former chapter, and I shall therefore not enter into any minutiae respecting it here.

Chronic ulcers often exist for many months and years together; at one time stationary, now receding, and now advancing; in one case exhibiting too much action, and in another too little, but rarely in a condition to furnish the requisite amount and quality of reparative material. Even if granulations occasionally do form, they are seldom of a healthy character, or, if they are, it is seldom that they long retain it; on the contrary, they soon languish for the want of proper support, or they perish from the violence of the attendant inflammation. These effects may be the result purely of local causes, or of causes exerting their influence indirectly through the constitution; but in the majority of cases they are, there is reason to believe, the consequence of the operation of both. If this statement be true, as multiplied observation proves it is, we cannot fail to deduce from it important principles of practice. It plainly suggests to us the necessity, in every instance, of instituting a careful inquiry into the nature of the exciting cause and the condition of the system, as well as the state of the part itself. To treat a chronic ulcer upon any other plan would be a palpable absurdity; and yet that this is generally the case my experience amply attests. Few practitioners look upon this class of diseases in the true light of philosophy; their ideas of their pathology are vague and indistinct; and it is therefore not surprising that they should find themselves completely baffled in their attempts at curing them. It is for this reason that chronic ulcers of the legs have so long been regarded as an opprobrium of surgery, and that so many patients are obliged to carry their malady with them to the grave, notwithstanding the numerous attempts that may have been made to get rid of it; all arising from the fact that its true nature was never properly understood.

The chronic ulcer is capable of assuming every possible variety of seat, number, form, size, color, condition of surface, and complication. In general, it is found to occupy the inner surface of the leg, a few inches above the ankle; but it is often situated higher up, and in rare cases it is placed directly over the joint itself. The outer surface of the limb is also liable to suffer, and we occasionally meet with instances of ulcers existing simultaneously upon both sides. In fact, no part of the leg is wholly exempt from the disease,

unless it be that just below the knee. Why this liability should exist to a greater extent at one point than at another is a circumstance which we are unable to explain. Is it owing to the fact that the inner surface of the limb is more liberally supplied with veins, and, consequently, more subject to habitual congestion of the skin and cellular tissue? Such an idea is not improbable, but whether it is correct, we have no means of determining.

The form of the ulcer is variable, being at one time circular, now oval, and then angular, or so irregular as to defy all attempts at accuracy of description. In some cases, it extends round the limb in the form of a belt nearly of equal width. In size it ranges from that of a five-cent piece to that of the palm of the hand, or even the entire hand, the destruction of substance being truly frightful. In its depth, it rarely reaches beyond the subcutaneous cellular tissue; in some cases, however, it involves the aponeuroses, the muscles, and even the bones and cartilages. Such ravages generally imply an unusual amount of antecedent inflammation, or the repeated intervention of acute action, although they are often produced by the steady progress of the chronic disease itself.

The chronic ulcer is often solitary; but it is not uncommon to meet with two, three, or even a larger number, situated either in close proximity with each other, or at different, and perhaps rather remote points of the limb. When the number is considerable, their size is usually proportionably small.

The color of the ulcer varies from light rose to deep purple, according to the intensity of the concomitant action and the congested condition of the cutaneous capillaries. The most common shades of color are the dusky, brownish, and light livid, but it is worthy of note that an ulcer which is of a rosy hue to-day may be of a deep purple to-morrow, simply in consequence of a change in the condition of the inflammatory action. The parts around the sore are often quite as high-colored as the sore itself; sometimes, indeed, much more so. In general, the discoloration, whatever may be its character, is lost by insensible gradations in the surrounding healthy hue, not abruptly, as in erysipelas and erythema.

In regard to the edges of the chronic ulcer, nothing can be more diversified; hence, some of the singular distinctions of Home, Astley Cooper, and others who have followed so closely in each other's footsteps. In general, the edges are hard or callous, elevated, rather broad, and so insensible as to admit of the rudest manipulation; in some cases, they are thin, ragged, almost serrated, and either everted or inverted, and perhaps exquisitely sensitive. In another class of cases, by no means infrequent, they are considerably undermined, or shelving at one point and everted at another. In fact, there is no end to the diversities presented by the boundaries of the sore; hence, all attempts at description must be futile.

The surface of the sore is generally more or less irregular, being deeper at one part than at another, although, as was before stated, it rarely extends

Fig. 20.

Chronic ulcer with deep edges, partially undermined, and a foul unhealthy bottom, studded with fungous granulations.

beneath the subcutaneous cellular tissue. Its real condition usually varies with the amount of inflammatory action. When this is considerable, there is often an entire absence of granulations, and then the bottom of the sore will generally be found to be in a foul, bloody, or phagedenic condition, or incrustated with a stratum of lymph too feeble to admit of organization; or, finally, granulations, sloughy matter, and vitiated plasma may all be present, in varying degrees, upon different parts of the exposed surface. The concomitant discharge is profuse, sanious, fetid, and irritating, possessing none of the properties of healthy pus. The sore, as well as the surface immediately around, is unusually sensitive, and often the seat of severe pain. It is to this form of ulcer that writers usually apply the term inflamed, or irritable, from its excess of vascular and nervous activity. It is most common in nervous, irritable subjects, and in persons who are habitually intemperate. It is of frequent occurrence.

When the inflammation is more moderate, granulations will seldom be wholly absent, and they may exist even in great abundance, although they may be altogether unhealthy in their character. When the action is somewhat less, but not too languid, they commonly exhibit a pale, reddish, flabby appearance; their surface is irregular or tuberculated, and they are much too large; in fact, they look as if they had been reared in a hot-bed, and had been too freely watered. Their reparative power is very feeble, and we are often obliged to get rid of them entirely before we can effect a cure. This state of granulation constitutes what is vulgarly called "proud flesh," and is often difficult to manage.

Again, the circulation may be inordinately languid, and then the granulations, if any be present at all, will generally be still larger than in the preceding case, totally insensible, and perhaps quite œdematous, a serous, or sero-sanguinolent fluid freely exuding from them if punctured, and readily pitting under pressure. Cacoplastic lymph is generally interspersed through the granulations, or adherent to the surface of the sore, the edges of which are hard and very prominent, so that the raw surface appears as if it were much below the level of the surrounding parts, which, however, is seldom the case. The accompanying discharge is slight, thin, and sero-sanguinolent; and the adjoining skin is œdematous and of a dusky-brownish hue.

Finally, cases occur where the granulations are very small, or apparently stunted in their growth, irregular in shape, of a fiery red color, and so exquisitely sensitive as to be a source of great suffering, the ulcer being intolerant of the slightest pressure, or manipulation; the discharge is sanious and irritating, although seldom very fetid or profuse; the edges of the sore are thin, irregular, everted, or inverted; and the surrounding skin is the seat of active inflammation.

The chronic ulcer is often complicated with other diseases, which tend to modify its action, and impede, if not entirely prevent, its restoration. Of these affections some are of a local, others of a general character. The former consist mainly in the involvement of the deep-seated structures, as the fibrous membranes, tendons, muscles, and bones; in the formation of sinuses; in a varicose state of the veins; and in the presence of foreign matter, under the influence of which the ulcer was, perhaps, originally induced. Among the constitutional complications the most common are, disorder of the secretions, especially of the liver and alimentary canal, anemia, dyspepsia, plethora, and habitual intemperance in eating and drinking. I have never seen what writers have called the menstrual ulcer, although it is not to be doubted that great uterine derangement, showing itself in deficiency of discharge, might seriously interfere with the healing of a sore on the leg, or, indeed, in any other part of the body.

Treatment.—In the management of chronic ulcers three leading indications

present themselves; first, to remove any complications that may exist; secondly, to regulate the inflammatory action; and thirdly, to produce healthy granulations. Keeping before him these important points, to the attainment of which all his energies should be steadily directed, the practitioner cannot fail to settle down upon a rational and philosophical plan of treatment, one which must, sooner or later, be crowned with success. Let him not lose sight of common sense, but proceed precisely as if the disease were one of ordinary inflammation, modified merely by accidental circumstances, and he will be sure to go right. His object should be, in every case, to bring the ulcer into a simple granulating condition, so as to give nature an opportunity of beginning and carrying on, without impediment, the healing process.

Ulcers sometimes refuse to heal in consequence of the partial destruction of aponeurotic, tendinous, or muscular tissue, or the manner in which the parts are compressed by overlying structures: in the former case, the dead substance is removed with the knife or scissors, while in the latter relief is afforded by adequate incisions, after which the malady is treated upon general principles. If necrosed bone exist, this must be extracted, while caries must be cut away with the chisel, saw, or scalpel.

Varicose veins are to be dealt with according to the rules laid down for the management of that disease in a subsequent chapter; the complication is often a serious one, and nothing short of the ligation of the vessels, or their destruction by the Vienna paste, will answer the purpose. When the malady is comparatively slight, amelioration may be afforded by wearing a laced stocking to give uniform support to the limb, and by the free use of spirituous lotions, with the occasional application along the track of the enlarged vessels of the dilute tincture of iodine. Hemorrhage sometimes attends this complication, from extension of the ulceration into a contiguous vein; I have seen cases where more than a quart of blood has been thus lost in a few minutes, and two instances have been reported to me where the bleeding was so copious as to prove fatal. The proper remedy is compression with the compress and bandage, followed, if need be, by a Vienna paste issue to produce permanent obliteration of the vessel at the seat of the ulceration.

Sinuses are to be laid open with the director and bistoury, their course being completely traced out, as no cure is to be expected so long as any portion remains concealed. Reunion of the incision is opposed by the tent and careful dressing.

Ulcers, consequent upon wounds, are frequently prevented from closing by the presence of foreign matter, as a pellet of paper, a piece of cloth, a ball, nail, or fragment of bone; when this is the case a careful search is made with the probe, and the substance extracted in the usual manner.

One of the worst complications in chronic ulcers occasionally arises from the edges of the sore being undermined, inverted, uncommonly ragged, or very callous. The best procedure is to use the knife, cutting off all that is spoiled, redundant, or irreclaimable. Exuberant granulations are dealt with in the same manner, excision here being far preferable to escharotics, which are always painful, tedious, and uncertain.

The second object is to reduce the concomitant inflammation so as to enable the sore to form healthy granulations, which it cannot possibly do so long as the morbid action is either very high or very low. One step towards accomplishing this end is the removal of complications, which, indeed, is frequently of itself sufficient to effect a cure. When this fails, the rest of the inflammation is often readily relieved by the use of the dilute tincture of iodine to the parts immediately around the ulcer, preceded, when the congestion and discoloration are unusually great, by free scarification; and by touching the sore itself very gently, once a day, with the solid nitrate of silver, or, what is better, the acid nitrate of mercury, either in its pure state

or variously weakened, according to the exigencies of each particular case. One application of the acid will usually suffice in the twenty-four hours, and in many instances the cure will progress more rapidly and satisfactorily if it be made less frequently. Other topical remedies may often be used with advantage, especially the nitric acid lotion, and weak solutions of sulphate of copper, acetate of lead and zinc, sulphate of zinc, creasote, and acetic acid. All these articles, however, are of a subordinate character, and hence I seldom have recourse to them. As a constant protection for the parts, nothing is more suitable than the elm or linseed cataplasm, which, notwithstanding the abuse that has been heaped upon it in certain quarters, is still, in most cases, one of our nicest and most reliable remedies. Or, instead of the poultice, the warm water-dressing may be used, although this is generally much less convenient in private practice, and not any better. When the pain is very great, the application should be medicated with solutions of morphia, or morphia may be sprinkled directly upon the surface of the ulcer.

During all this time proper attention is to be paid to the state of the system; the bowels are to be regularly moved with mild aperients, and care is taken that the diet is perfectly mild and not over nutritious. If the general health is much disordered, recourse is had to more active purgation, and free use is made of the antimonial and saline mixture, with a full opiate at night, if there be much pain, or inability to sleep. Bleeding at the arm will only be required in very plethoric subjects, in urgent cases. Absolute recumbency is observed, at least until the morbid action has been measurably subdued; and the affected part is placed at rest in an easy and elevated position, just as in ordinary cases of inflammation.

If the general health is much reduced by protracted suffering, or if the system is in an anemic condition, or, finally, if typhoid symptoms are present, stimulants and tonics will be indicated, especially quinine, with milk punch, and nutritious food.

If the measures now detailed be judiciously employed, the surgeon will

Fig. 21.

Granulating ulcer, beginning to cicatrize; the process extending from the periphery towards the centre.

soon be able to get the ulcer into a condition for the development of healthy granulations, fig. 21, and, as soon as this has been brought about, he will have little else to do than to watch the parts, with a view to the prevention of over-action. The mildest and most soothing applications will now generally suffice, the object being rather to protect the surface of the sore from the injurious contact of the atmosphere, than to promote its action by medicative agency. Among the best of these remedies are the cerates of opium, balsam of Peru, oxide of zinc, and, last, but not least, of the nitrate of mercury, which I prefer to all others, on account of its cicatrizing properties. It must, however, be employed with care, and in a very weak form, as in the proportion of six, eight, or ten grains to the drachm of simple ointment. The scabbing process may occa-

with care, and in a very weak form, as in the proportion of six, eight, or ten grains to the drachm of simple ointment. The scabbing process may occa-

sionally be expedited by touching the granulations along the edge of the sore, once a day, very lightly, and for the space of a line, with the solid nitrate of silver.

I consider rest, in the treatment of ulcers, as a matter of paramount importance in all cases where it is desirable to effect a rapid cure; I am certain, from much observation, that nothing else is at all comparable to it. Nevertheless, instances often occur where, either on account of the patient's condition in life, or the exhausted state of his health, exercise in the open air is absolutely indispensable; under these circumstances, the part should be as carefully protected as the exigencies of the case will admit of, fatigue and protracted dependency being especially guarded against. In such cases, the bandage becomes usually a powerful adjuvant both to comfort and cure; but it must be applied equably from the distal part of the limb upwards, and not in folds or creases, otherwise it will do infinite harm. It must be changed at least once a day, being replaced as soon as the extremity has been thoroughly cleansed and the sore properly dressed. In hot weather, it may occasionally be kept constantly wet, with good effect, with cold water, spirituous lotions, or weak solutions of lead and opium.

Many practitioners are fond of strapping the sore and the adjacent parts with adhesive plaster, cut into strips varying from an inch to an inch and a half in width, and long enough to extend about three-fourths around the limb, each band being so arranged as to overlap that which is below it, and drawn so firmly as to afford uniform support to the affected surface, as in fig. 22. This plan of treatment, however, which is known as that of Mr. Baynton, by whom it was first suggested, has many disadvantages, of which one of the most serious is the impossibility of watching its effects, the sore being too much concealed from view. The method of Mr. Crichtett, which has been recently brought under the notice of the profession, is, I conceive, still more objectionable; it consists in enveloping the entire foot and leg, for some distance above the ulcer, with adhesive plaster, a proceeding which, although it may answer very well in the hands of its ingenious originator, can hardly fail to prove mischievous in the practice of others less adroit and less experienced in the use of the remedy.

A few words may be added here respecting the proper method of dressing ulcers. To this subject usually too little attention is given, and the consequence is that the part often suffers great injury. All rude manipulation and protracted exposure must be avoided; the sore should never be wiped, or even touched with the finger, and, while the necessary ablutions are going on, the limb should be carefully supported over a basin or small tub, the water, which may be cold or tepid, being gently squeezed upon it from a sponge held several inches off. The secretions being thus disposed of, the surrounding surface is properly dried, and the dressing reapplied. If fetor be present, a little liquid chlorinate of soda may be mixed with the water employed in

Fig. 22.

Strapping of the indolent ulcer shown.

cleansing the sore, as well as sprinkled from time to time upon the poultice and bandage.

When a large extent of integument has been destroyed by the ulceration, or when the morbid action has a constant disposition to reappear, as so often happens, upon the imperfectly organized cicatrices of old sores, it has been proposed to cover the breach by borrowing the requisite amount of tissue from the immediate neighborhood, just as in the more ordinary plastic operations. The plan, which has been dignified with the name of *elkoplasty*, has been warmly advocated by Professor Hamilton, of Brooklyn, in a short article which he published upon the subject in the *New York Journal of Medicine*, for 1854, in which he describes several cases of its successful employment. Dr. John Watson, of New York, had previously applied the same principles of treatment in a case of syphilitic ulcer of the forehead, the particulars of which will be found in the *American Journal of the Medical Sciences*, for October, 1844, under the name of *mylopoplasty*. To insure the union of the edges of the wound, it is necessary that the part should be quite free from inflammation, and that the general health should be as nearly as possible at the natural standard. The flap should be much larger than the gap in the limb, and should be well secured in its new position by the interrupted suture.

Whatever mode of treatment be employed, it is of paramount importance, as it respects the prevention of relapse, that the patient should observe great care in regard to his diet and exercise, for a number of weeks after the ulcer has completely healed. If he indulges his appetite too soon, neglects his bowels, or allows his secretions to become disordered, he can hardly escape a new outbreak of the disease, especially if, at the same time, he fatigues his leg much, lets it hang down constantly, constricts it improperly with his garter, rubs it with his boot, or permits it to become covered with filth. Cleanliness, indeed, cannot be too rigidly insisted upon as a means of promoting a restoration of healthy action. The parts should be thoroughly washed at least once a day with soap and water, and then sponged with some alcoholic lotion, to revive and invigorate their exhausted powers.

In inveterate cases, extensively involving the osseous tissue, greatly impairing the general health, and resisting the best efforts of the surgeon for their relief, the only resource is amputation, performed through a sound portion of the limb. I believe, however, that such a procedure will rarely be demanded in these days of conservative surgery; for, unless the bone be almost entirely destroyed, it will be easy, in the majority of instances, to dispose of the diseased structures with the knife, gouge, and mallet; or by a resort to resection.

In conclusion, we may ask the question whether it is always safe and proper to heal old ulcers? Upon this subject, various opinions have been expressed by writers on surgery. Those who assert that it is not, assume that a sore of this kind acts, when it has existed for a great length of time, as an issue, which serves the purpose of a safety-valve to the system, by ridding it of redundant, if not positively peccant, humors. They allege that cases have occasionally been witnessed where attacks of cerebral apoplexy, and other serious diseases, have occurred as the direct and speedy consequence of the drying up of such sores. Those, on the contrary, who espouse the opposite side of the question, declare that such occurrences are mere accidental circumstances, readily explicable by the laws of coincidence; and such is the view which I am myself inclined to adopt. I do not believe that medical science possesses any well-authenticated facts by which this opinion can be sustained. I have often cured ulcers of five, ten, and even fifteen years' standing, constantly attended with more or less discharge and irritation, and yet it has never fallen to my lot to meet with a solitary instance to which such an event could justly be ascribed. Besides, the constitutional treatment

which is usually necessary in these cases to effect a cure, is, in itself, almost a guarantee against attacks of grave disease in other parts of the body. If, however, any one should feel inclined to adopt a different view, it would be easy, while the sore is being dried up, to protect the system against such assaults, by ordering a continuance of the constitutional remedies, especially a spare diet, and the occasional use of a purgative, conjoined with the employment of an issue in a remote part of the body, as the arm, chest, or neck.

SECT. IX.—GRANULATION.

Granulation is the means by which lost tissues are replaced and wounds healed when they refuse to unite by the first intention, or adhesive action. The process is one of great interest, whether it be viewed merely as a physiological phenomenon, or as an operation employed by the system to restore injured and mutilated structures. An intimate knowledge of its nature and habits is therefore of paramount importance to the surgeon.

It is chiefly upon the external surface of the body that we have an opportunity of examining the process in question with any degree of satisfaction. In the various mucous outlets it is more difficult to watch it, and to trace it through its different stages; while in the internal organs it either does not occur at all, or is observed only as a post-mortem appearance.

Before granulation can begin, it is necessary that there should be a reduction of the inflammation of the part, however it may have been induced; I do not mean to say by this remark that all the inflammation must be got rid of as an essential preliminary, for I believe that more or less of this action is absolutely necessary to its successful operation; I merely wish to declare that granulation cannot go on so long as there is any considerable degree of inflammation; or, what is the same thing, that high vascular excitement and repair are, as a general rule, incompatible with each other. The balance of action having thus been re-established, the breach soon becomes covered with a layer of lymph, which, undergoing organization, is rapidly converted into red, fleshy-looking bodies, technically denominated granulations. By a continuance of this action the process of repair steadily progresses until the gap is finally filled up and scabbed over.

A granulation is a curious and interesting body, as well as a body of great

Fig. 23.

Arrangement of the bloodvessels in a granulation.

consequence. It is highly organized, and therefore capable of executing very important functions. Under the microscope it is found to consist of

cells, without any very definite arrangement, and connected by a small quantity of intermediate substance, the precise nature of which is not understood. It is usually of a florid color, very vascular, extremely sensitive, and of a conical, rounded, or oval shape, its volume varying from that of a clover-seed to that of a large shot. Minutely studied, it is found to consist, as seen in fig. 23, of numerous vessels, which are evidently sent into it as outgrowths from those of the adjacent parts, being arranged in the form of beautiful loops and arches, closely interwoven with each other. As they are developed with great rapidity, their walls are at first so extremely delicate as to yield under the slightest pressure; hence there is generally more or less hemorrhage from whatever is brought into rude contact with them. The veins, which are very large, exhibit, when viewed with a magnifying lens, a remarkably tortuous and convoluted appearance. No nerves are demonstrable in this body, but that it receives an abundant supply of this kind is shown by the fact that it is often very sensitive, especially when it is in a state of disease. The existence of lymphatic vessels is also a matter rather of inference than of positive observation. Experience has proved that certain articles, placed in contact with a granulating ulcer, will be promptly taken up, and carried into the system, producing the same effect, and nearly in as short a time, as when introduced in the ordinary manner. Thus, morphia will readily allay pain and induce sleep; atropia, dilate the pupil; arsenic, irritate and inflame the stomach; strychnia, convulse the muscles. Moreover, a granulation is a secreting body, a kind of compound gland, capable of pouring out plasma and providing the elements of pus; the former for enlarging its own dimensions and multiplying itself, the latter as a means of defence from the atmosphere and from the surgeon's dressings.

Granulations form with various degrees of facility, depending mainly upon the structure of the part and the amount of inflammatory action. Ulcers of the skin and cellular tissue always, other things being equal, furnish them most readily, as well as in most abundance; a circumstance which is not surprising when we reflect upon their extreme vascularity and high nervous endowment. Bone, cartilage, tendon, and fibrous membrane, on the contrary, granulate more slowly, and hence their injuries are always repaired with more difficulty. The same remark applies, but in a more pointed manner, to scirrhus and other malignant ulcers.

Granulations are liable to disease. This often occurs from causes apparently the most insignificant; depending, perhaps, at one time upon the state of the part, at another upon the state of the constitution, or upon both combined, but more frequently upon the nature of the dressing, and the indiscretion of the patient. Hence, the appearance of these bodies usually serves as an index of the concomitant action, local and general, and affords useful indications of treatment. The most important alterations which they undergo are such as relate to their size, color, consistence, and sensibility. Healthy granulations are generally small, not exceeding the volume of a mustard-seed, but cases occur in which they are many times larger. Their natural color is a beautiful florid; when congested or inflamed they assume a livid aspect, while under opposite states they are occasionally quite pale, or even blanched. In their consistence these bodies also present much diversity, being sometimes very soft and lacerable, and at other times very firm, inelastic, and almost callous. Occasionally they have an infiltrated, œdematous, or dropsical appearance, serum escaping freely upon the slightest puncture. Their sensibility is usually very feeble, but in nervous, irritable persons they are sometimes exquisitely sensitive, particularly when they happen to be much inflamed. In ulcers from burns the granulations are always distinguished by their excessive tenderness.

The discharge furnished by these bodies is liable to vary in different cases

and under different circumstances. When they are in a perfectly normal condition, as is indicated by their florid aspect, small size, and steady development, it is usually of a thick, cream-like consistence, and of a pale yellowish color, or, in other words, of the nature of laudable pus; if, on the other hand, they are inflamed and irritable, it will generally be thin and sanious, with an inordinate quantity of earthy salts; when the excitement is very high, the matter is usually mixed with aplastic lymph; hard, callous granulations are often free from all discharge, being apparently incapable of furnishing purulent matter of any kind. In dropsical granulations the fluid is usually of a serous description.

The management of the granulating process must be conducted upon the same general principles as the ulcerative. The leading indication is to favor its development by protecting the raw surface from the atmosphere and from whatever else has a tendency to embarrass its progress. The most suitable applications, as a general rule, are water-dressing and emollient poultices, which should be employed in such a manner as, on the one hand, not to excite exuberant action by their warmth, and, on the other, not to repress growth by their refrigerant effect. Rude contact, protracted exposure to the air, and irritating applications must be carefully avoided.

SECT. X.—CICATRIZATION.

Cicatrization is the completion of the granulating process, the last act in the operation of repair, the hermetic sealing, as it were, of the breach left by the destruction of the tissues of the affected part. If we study this process with proper care, we shall find in it much that is calculated to arrest attention and elicit admiration at the wonderful resources of the animal economy.

When cicatrization is about to take place, there must necessarily be a subsidence of the inflammation of the part, just as in the development of granulations, only to a still greater extent. This may be regarded as an essential preliminary. The next step is a deposit of plasma upon the edges of the breach, followed by its rapid organization and conversion into epithelial scales, a thin, bluish, or whitish pellicle, which forms a striking contrast with the granulations and adjoining skin, indicating the progress of the change. The new substance may always be easily detached with the sponge or finger, for as yet its consistence is very slight. Gradually, however, it becomes more thick and firm, assimilating itself more and more closely to the pre-existing integument, the place of which it is intended to supply. The process thus begun continuing, the plastic, organizable film extends steadily onward until the exposed surface is finally completely covered in, the length of time necessary for this varying according to the size and shape of the breach, the absence or presence of complications, and the state of the system. Observation has shown that ovoidal ulcers, all other things being equal, heal more rapidly than circular, superficial than deep, common than specific. It is also well known that cicatrization is usually more easily accomplished in the upper extremities than in the inferior, and in the skin and cellular tissue than in the other structures. In the organs, properly so called, it generally takes place with difficulty, and only after a long interval.

It is a law of cicatrization that the process shall always begin, as the starting point, at the edges of the breach which it is designed to repair, and thence proceed towards the centre. So uniform is this occurrence that I have seen but few instances to the contrary, notwithstanding the numerous and diversified cases which have been thrown in my way. It would seem as if the aid of the pre-existing tissues were necessary in order to enable the

new substance to obtain a proper foothold. I am aware that a different doctrine has been promulgated by some, and there is, no doubt, occasionally an instance where the process proceeds in an opposite direction, after having commenced at a central point; but if this be so, it forms merely an exception to a general law, and not the law itself. Those who assert that this occurrence is rather frequent than otherwise may have been deceived by the existence of a small fragment of old tissue, with or without integument, which, standing like a little island in the midst of the ulcer, thus becomes the nucleus of the new structure. In this event, however, there is obviously no new law in force, but simply an application of the one already described.

Some time necessarily elapses, after the cicatrization is completed, before the new structure, now called a *cicatrice*, acquires much solidity and strength.

Fig. 24.

Structure of a cicatrice of the skin.

It is only by degrees that it loses its bluish appearance and assumes the properties of the pre-existing substance. Even then it is at best only a very imperfect copy of the original, although it is capable of supplying its place and of executing the functions which nature has allotted to it. Its vessels, which are, at first, remarkably large and tortuous, gradually dwindle down to a size approximating them to those in the adjacent sound parts, and, when fully formed, they generally exhibit a beautiful retiform arrangement, as is shown in the annexed sketch, fig. 24. The scar always remains tender for a considerable period after its formation,

and is usually very liable to break, crack, or ulcerate from very slight causes. Its tendency to contract or diminish also continues for a while longer.

What I have said respecting the imperfect reproduction of skin is equally applicable to the other textures. New bone comes perhaps nearer to the original structure than any other; but even this presents many peculiarities, and it is certain that it often acquires a degree of hardness and solidity far greater than the primitive substance. There are, moreover, some pieces of the skeleton which, when broken, never unite by osseous matter, but only through the medium of fibrous tissue, fibro-cartilage or cartilage. Fractures of the patella, the olecranon, the acromion process of the scapula, and the neck of the thigh-bone within the capsular ligament, are generally, if not always, repaired in this way, the parts not having the power of secreting phosphate and carbonate of lime, in consequence of their imperfect supply of blood and nervous influence, to say nothing of the difficulty of maintaining the ends of such fractures in contact for a sufficient length of time to afford them an opportunity of becoming consolidated. Cartilage is never perfectly reproduced after injuries; the new substitute is always very thin, hard, and of an unnaturally bluish tint. Tendon is renewed only in the case of subcutaneous section; never when it has been lost by disease. Muscles usually unite through the medium of fibro-cellular substance. In fracture of the costal cartilages the consolidation is effected by bone. Bloodvessels and nerves are never regenerated; the continuity of the former cannot be re-established after complete division, on account of the retraction of their extremities; if a small piece of the latter is excised, the gap is supplied by fibrous tissue, very different from the pre-existing one, but, nevertheless, often sufficient to transmit the nervous fluid with little or no impairment of its influence. The cerebral, pulmonary, hepatic, splenic, salivary, renal, and seminiferous structures are incapable of reproduction, the new substitute being always of a cellulo-fibrous, or fibro-cartilaginous nature. Serous, mucous, and fibrous membranes are repaired in a similar manner. Thus it will be seen that a tissue, when seriously mutilated, is seldom perfectly reproduced, whatever pains may be taken to assist its efforts.

It is not surprising that a substance so imperfectly organized as a cicatrice

should be liable to inflammation and its consequences, as well as to some of the heterologous formations. Its powers of resistance being naturally feeble, it yields, in general, more readily to disease, whether simple or malignant, than the original structures. It is for this reason that inflammation of the substitute-tissue is prone to pass into ulceration, and, if the morbid action be at all severe, even into mortification. In suppuration, the matter furnished by the part is nearly always of a thin, ichorous nature, a development of genuine pus being almost impossible under any circumstances.

The most common form of malignant disease liable to show itself in a scar is epithelial cancer or lupus; it may break out upon any part of the body, but is most prone to appear upon the face, hands, and feet, parts which are habitually exposed, or frequently subjected to pressure and friction. The diseased structure, almost of stone-like hardness, and the seat of sharp, pricking, or burning pains, soon ulcerates, and pours out a thin, sanious, and fetid fluid, highly irritating to the neighboring healthy surface. The edges of the sore are hard, steep, everted, or partially undermined, while the bottom is foul and slightly covered with spoiled lymph; occasionally the part has a worm-eaten appearance. However this may be, the ulcer is always intractable, and, going on steadily from bad to worse, is apt to be followed by the most serious consequences.

Keloid is another form of disease which is liable to appear upon cicatrices; this, as will be seen elsewhere, is a peculiar fibro-plastic growth, which often forms after burns and scalds, and which derives its name from the supposed resemblance which it bears, in its configuration, to a crab.

Finally, cicatrices sometimes manifest a remarkable disposition to contract, which often continues long after they have apparently attained their full development. This tendency is nowhere more conspicuous than in burns and scalds, where it is occasionally so great as to give rise to the most horrible deformity. Thus, a vicious scar may pinion the arm to the side, pull back the hand upon the wrist, and draw down the chin upon the chest. The new tissue, consequent upon the loss of substance caused by salivation, generally contracts in such a manner as to produce firm adhesion of the jaws, sadly interfering with eating and mastication.

In order to prevent degeneration of a cicatrice, it should be protected, especially if it be large, for a long time against rude manipulation, pressure, friction, and irritating applications. If there be any tendency to undue contraction, measures should be promptly adopted to counteract it, otherwise it may lead to great deformity and impairment of function.

CHAPTER V.

TEXTURAL CHANGES.

UNDER this head may be described those organic changes which are effected in the substance of the organs and tissues, as the result either of inflammation or of defective nutrition, consequent upon lesion in the circulatory and nervous systems. The most important of these alterations of texture are softening, induration, transformations, hypertrophy, atrophy, contraction, and fistule.

SECT. I.—SOFTENING.

Inflammation not unfrequently passes into softening, or what the French pathologists have denominated *ramollissement*. The event is characterized by a loss of cohesion of the affected textures, varying in degree from the slightest change of the natural consistence to almost complete pulpification. All parts of the body are liable to this occurrence, but those which are most apt to suffer are the lungs, brain, spleen, liver, and heart, together with the mucous membrane of the stomach and bowels, the articular cartilages, and the spongy structure of the bones. The subcutaneous and inter-muscular areolar tissue is occasionally softened to a great extent in rapidly progressive forms of inflammation, particularly in diffuse erysipelas. The vessels, nerves, muscles, and tendons, the fibrous and serous membranes, the lymphatic and salivary glands, the kidneys, the thyroid body, uterus, ovaries, testes, and prostate rarely experience this alteration under any circumstances, however violent the attendant action.

Softening sometimes takes place rapidly, at other times slowly; hence the distinction into acute and chronic. In the former case the affected tissues may be almost completely deprived of their natural consistence within the space of a very few days. Thus, in acute pneumonia the lungs are often so much softened at the end of three or four days as to be incapable of resisting the slightest pressure of the finger. In the brain and spleen the loss of cohesion sometimes proceeds even more rapidly than in the lungs. Chronic softening is most common in the cerebral substance and in the mucous membrane of the ileum and colon, where it is generally a most insidious disease, often involving a large extent of tissue, and yet unaccompanied by any characteristic symptoms.

The true nature of softening has not been explained. We can hardly, however, divest ourselves of the idea that it is not a species of molecular mortification, especially in its more advanced stages. Be this as it may, it is unquestionable that the loss of cohesion, under such circumstances, is entirely incompatible with the exercise of the functions of the part, or its restoration to health. Many of its smaller vessels are completely obliterated, while the remainder are so crippled and paralyzed as to be scarcely able to propel their contents. Changes not less conspicuous are observable in the proper parenchymatous structure, which not only loses its natural consistence, but also its natural color; its cells are infiltrated with serosity, or serosity, lymph, pus, and blood, and its minute texture is no longer distinguishable by the aid of

the most powerful microscope. If this is not death, or a condition closely approximating to it, what can it be? In the milder forms of mollescence the structure may still retain some vitality, and may, consequently, be able, in time, to regain its original characters; or, what is more probable, may be rebuilt by plastic matter, after the manner of other broken-down and mutilated tissues, the first step in the process being the removal of the effete substance.

There is a species of softening which is intimately connected with, if not dependent upon, obliteration of the vessels of the affected structures, with a consequent deficiency of blood and an impairment of nutrition. It is most frequently met with in the brain and spinal cord of old persons, and is generally supposed, although, as I think, erroneously, to be of a non-inflammatory character. If this opinion were correct, it is not probable that we should find, as we always do in this disease, more or less effusion of serum, plasma, and even pus. Wherever these fluids are deposited they afford indubitable evidence of incited action; hence it would be folly to conclude that they could be poured out here without inflammation.

This event of inflammation is interesting chiefly in a pathological point of view; for, as it is met with almost exclusively in the internal organs, and presents no characteristic symptoms, it is evident that treatment holds out little prospect of relief. When the true nature of the lesion is suspected, the proper remedies, in the acute form, will be such as are calculated to reduce inflammatory action and favor the removal of deposits; in the chronic variety a mildly alterative course, with tonics, embracing cod-liver oil, quinine, and iron, is indicated.

SECT. II.—INDURATION.

It has already been seen that a deposit of lymph, plasma, or plastic matter is common to nearly all inflammations, whatever may be their cause, site, or degree. When occurring upon the free surfaces of the organs, it usually presents itself in the form of a layer, which, escaping the influence of the absorbents, is ultimately converted into an analogous tissue, which often remains during the rest of the individual's life, being subject, in the meanwhile, to all the diseases and accidents incident to the pre-existing structures. When the deposit takes place in the substance of the organs, it fills up their cells, interstices, or molecular spaces, and thus increases their consistence, as well as their weight, the matter assuming the shape of the cavities in which it is lodged, and being liable, as in the former case, either to be absorbed or to become organized, according to the condition of the part and the vitality of the morbid product. A similar arrangement occurs when plasma is effused into the cellular tissue beneath the skin, among the muscles, and in other situations.

Induration is extremely common, and may occur in any organ and tissue of the body. It is most frequently met with, however, in the lungs, spleen, liver, thyroid gland, testicle, the lymphatic ganglions, the prostate gland, the mamma, ovaries, uterus, bones, and subcutaneous cellular structure.

Age exerts considerable influence upon the production of induration. In the great majority of the organs it may take place at any period of life, but in some, as in the thyroid gland, for example, it rarely occurs before the fourteenth year, while in the genital apparatus it is hardly ever observed until after puberty. Induration of the prostate gland, of the vessels, and of the brain and spinal cord is an affection of advanced life, as is also induration of the crystalline lens and its capsule.

The degree of induration varies from the slightest alteration of the natural consistence of the part to the solidity and density of concrete albumen, old

cheese, fibro-cartilage, cartilage, or bone. Much, in this respect, will depend upon the nature of the affected tissue, and the date of the lesion, or the degree of change which the deposit upon which the induration depends may have undergone. The color of the affected part may be normal, or variously altered, according to the amount of its vascularity and the presence or absence of effused blood. Much diversity also exists in regard to its volume, although in most cases this is considerably augmented, and sometimes even quite enormously, the bulk many times exceeding that which is natural to the organ in health. The weight of the part, too, is usually increased, and there is commonly more dryness, with a marked loss of elasticity.

The period required for the production of induration ranges from a few hours to several days, weeks, or months, depending upon the nature of the exciting cause and of the affected structures. In the testicle it often occurs in a very marked degree in less than twenty-four hours, and at the end of forty-eight hours the organ may be so hard as to be entirely incompressible. The induration accompanying the development of tonsillitis, adenitis, furuncle, carbuncle, and erysipelas generally occurs with extraordinary rapidity; and the same thing is frequently witnessed in the cellular tissue around the joints, especially in inflammation of a gouty or rheumatic character. In pneumonitis the parenchymatous substance of the lungs is often extensively solidified within a few days from the commencement of the morbid action. On the other hand, the induration may proceed very slowly, as in goitre, in chronic arteritis, hepatitis, and splenitis, and in certain affections of the uterus and prostate gland, where months, if not years, may elapse before it attains its full development.

The effect of induration upon the tissues in which it occurs is of the most prejudicial character, sadly impairing their structure and functions, and frequently leading to the worst results. Thus, when it affects both testicles it may become a cause of impotence; in the liver it may interfere with the secretion of bile; and in the lung it may produce death by offering a mechanical obstruction to the ingress of the air. In the arteries induration is frequently followed by rupture of their coats, leading to aneurism; while in the cellular tissue around the joints it always impedes the exercise of the articular surfaces.

The immediate cause of induration is a deposit of plastic matter into the cells of the affected structures, which it thus obliterates while it condenses the adjoining substance, and so renders it unfit, either temporarily or permanently, for the proper exercise of its functions. The fluid is generally associated with more or less serum, and not unfrequently also with pus, and even pure blood. When the circumstances under which it is deposited are favorable, it soon becomes organized, and may finally be converted into an analogous tissue, which often retains its parasitic connection during the remainder of life, although in most cases it ultimately disappears.

In the treatment of induration the leading object is to excite the absorbent vessels so as to induce them to remove the deposits upon the presence of which the lesion depends. It need hardly be said that the sooner this is done the better. The longer we wait, the greater will be the danger of a permanent change of structure, or, when the organ is one of great importance to life, of the death of the patient. When the deposit is recent, and action still high, our reliance is mainly upon the vigorous employment of antiphlogistics, such as bleeding, purging, and diaphoretics, with antimonials, light diet, and perfect rest in the recumbent posture. Inflammation having thus been moderated, the induration, already greatly reduced by the previous measures, may usually be promptly disposed of by alterative doses of mercury, carried, perhaps, to slight ptyalism; and, where the part is accessible, by sorbefacient liniments, embrocations, and unguents, aided by pressure with

the bandage. In the more chronic forms of the affection the different preparations of iodine must be brought in play, particularly Lugol's solution, Donovan's liquor, and the various forms of mercury, as the bichloride and biniodide; along with the topical applications just mentioned, if the induration be external. Friction and the cold douche will also prove serviceable under such circumstances.

SECT. III.—TRANSFORMATIONS.

The human body is in a state of constant mutation, of decay and renovation, commencing before birth, and continuing down to the last moments of existence. The Wolffian bodies and the gubernaculum of the testicle disappear during intra-uterine life; the thymus gland is gradually effaced during childhood; the arteries ossify in elderly persons; and at every period of life various states of the system, depending upon disease or accident, arise, in which there is a strong tendency to the deposition of oil globules, or the transformation of different organs and tissues into fatty matter.

The most important of these changes, surgically considered, are the cellular, mucous, cutaneous, fibrous, calcareous, and fatty; they are all connected with defective vitality, and with atrophy of some, if not all, of the constituent elements of the affected structures.

The cellular transformation is met with chiefly in parts that have been rendered useless, either from the natural cessation of their functions, or in consequence of accidental circumstances. Thus, the thymus gland, which is evidently connected with some important office in the fœtus, gradually decays during childhood, being converted into shreddy cellular substance, of which hardly a trace remains after the thirtieth year. The gubernaculum undergoes a similar change; the gall-bladder, occluded by biliary concretions, is occasionally completely transformed into this tissue; and the cellular adhesions so often seen between the costal and pulmonary pleuræ, consequent upon the degeneration of old adventitious membranes, are familiar to every pathologist. Various ligaments, especially the capsular, sometimes degenerate in this way; the metamorphosis is most marked in young subjects affected with unreduced dislocations of the hip and shoulder.

When skin is inverted for any length of time into one of the natural outlets of the body, as, for instance, the anal, it gradually undergoes a species of metamorphosis into mucous membrane. The first indication of the change is a softened condition of the cuticle and the disappearance of the hair; the epidermis scaling off, the surface beneath assumes a reddish, velvety aspect, becomes extremely vascular, and soon begins to secrete a thin, ropy, whitish fluid, not unlike mucus.

A change from mucous membrane to skin is sometimes observed, although the occurrence is uncommon. It is noticed chiefly in prolapse of the rectum, vagina, and uterus, the mucous investment of which, from long exposure to the atmosphere, becomes dry, rough, and insensible, and is ultimately converted into a tissue bearing a more close resemblance to the cutaneous than the mucous. The transformation, however, as in the case of the skin, is at best extremely imperfect, and it remains to be shown whether, in either instance, the old structures are so completely deprived of their identity as to justify the idea of a genuine transformation.

The *fibrous* transformation is most commonly met with in those parts of the body that have been deprived, either accidentally or otherwise, of their natural functions. Thus, in an artery that has been tied for the cure of aneurism or the arrest of hemorrhage the portion of the vessel included between the ligature and the first large collateral branch is gradually converted into

a solid cylinder, which, in its turn, is changed into a dense, fibrous structure, in which it is impossible to discern any trace whatever of the primitive tissues. Ligaments, serous membrane, and adventitious textures occasionally undergo similar changes. The cornea, in the withered and atrophied eye, the victim of destructive inflammation, seems, at times, to be almost completely transformed into a substance bearing the closest resemblance to the sclerotica, one of the best examples of the fibrous tissue. In some of these cases, as in that just mentioned, the change is accompanied by a deposit of oil globules. The whitish opaque bodies, so frequently observed in the coats of the spleen, in the placenta, and in the arteries of elderly subjects, are apparently essentially composed of fibrous substance, although in their outward characters they strikingly resemble fibro-cartilage.

The *calcareous* degeneration is most common in the arteries, but is also occasionally seen in other parts of the body, as in fibrous tumors, especially those of the uterus, in the articular cartilages, and in the concretions sometimes found in the larger joints, particularly that of the knee. In the arteries it generally begins in the form of little opaque patches, in the cellular substance between the inner and middle tunics, which, as they advance in age, assume a firm, solid consistence, and ultimately convert the vessels into rigid earthy cylinders. The deposit—for such is its nature, rather than a genuine degeneration—was formerly supposed to be of an osseous character, but recent researches have shown it to be altogether different, both in its chemical and physical properties. In the more matured specimens it is essentially composed of carbonate and phosphate of lime, in union with a minute portion of albumen; in recent cases, on the contrary, the animal matter exists in much greater quantity. It differs still further from bone in having no areolar structure, and in being destitute of vital properties. In fibrous tumors of the uterus large calcareous masses, weighing several pounds, are occasionally found.

The *fatty* degeneration, if not the most common of all, is the most universally distributed, since there is hardly any organ or tissue of the body in which, under favorable circumstances, it may not occur. Recent observation has demonstrated that it may take place in the lungs, in cartilage, in bone, the placenta, the cornea, and the crystalline lens. It is also met with in plastic exudations, tubercles, cancerous growths, and even, it is supposed, in pus globules. It has long been known to be of frequent occurrence in the muscles, and within the last fifteen years its presence has often been detected in the coats of the arteries, in connection with the atheromatous deposit. Thus it will be perceived that the fatty degeneration may take place both in natural and in adventitious formations; in the hard as well as in the soft, in the most humble as well as in the most exalted in point of organization and life-power. Of all the various structures, however, which are liable to suffer from this lesion, the liver and arteries are probably most frequently affected. The former may undergo the fatty degeneration at any period of life, even in young children, and is a very common consequence of habitual alcoholic stimulation; the latter, on the contrary, is usually restricted to elderly subjects. The senile arc of the cornea is most common in advanced life, and is supposed by some recent observers, amongst others by Mr. Canton, to be almost always coincident with fatty degeneration of the heart and other organs. Fatty degeneration of the muscles occurs both in the voluntary and involuntary classes, although it is by no means so common in the latter as in the former.

The fat in this degeneration occurs occasionally in a free state, in the form of oil globules, cholesterine, and amorphous fragments, and is then essentially a deposit occupying the intercellular structure of the tissues. Such a super-addition of fat is often observed in the liver, arteries, brain, and pancreas.

On the other hand, there is no doubt that the transformation is sometimes real, being the same in principle as the fibrous or calcareous; that is, the affected tissues are broken down, and converted into fatty matter, or, to express the idea more accurately, replaced by oil.

An organ that has undergone the fatty degeneration will generally be a few shades lighter than in the natural state, and diminished rather than increased in consistence, easily torn, greasy to the touch, and of lighter specific gravity than in health. The amount of oil which it contains often ranges from one-third to one-half of its own weight.

What is the essential cause of the fatty degeneration? In some cases it would seem to be connected with general hypertrophy of the adipose tissue, and, consequently, to be owing to a mere redundancy of oily matter dependent upon the use of an inordinate quantity of hydro-carburetted food, and imperfect assimilative power. In the liver of some of the inferior animals the fatty degeneration can often be produced at will, simply by subjecting them to rest, and constantly cramming the stomach with food, which, by creating obstruction in the portal circle, probably induces congestion and inflammation of the hepatic tissues, which thus favor the deposition of oily matter. The fatty transformation of the liver of drunkards is doubtless occasioned in a similar manner. In other cases the lesion appears to be essentially due to a want of exercise of the affected parts, conjoined with deficient nervous supply, as is so often witnessed in the muscles of the leg in paralysis of the inferior extremity. Under such circumstances, especially when the case is of long standing, the muscles generally assume a pale, yellowish, or brownish aspect, are remarkably soft and flaccid, and yield a clear oily fluid on pressure, their fibres, however, remaining perfectly distinct.

It is still a mooted question whether the fatty matter, in this transformation, be deposited directly from the blood, or whether it be the product of some chemical change in the affected tissues, or in these tissues and other consentaneous exudations. My own belief is that it is generally, if not invariably, derived from the former source; and my reason for this opinion is simply this, that the transformation in question, when at all extensive, is nearly always associated with defective vital power of the diseased textures, along with impaired assimilative action, and with a redundancy of the protein principles of the blood; circumstances eminently propitious to the formation and deposition of fatty matter. Besides, cases have recently been observed of fatty degeneration of the heart and other viscera in which oil existed in the blood. On the other hand, the researches of Quain, Bennett, and others go to prove that the change may be altogether the result of a chemical transformation, these pathologists having found that healthy muscular fibre may be rendered fatty artificially, simply by digesting it for several weeks in water.

Of the treatment of the fatty transformation the present state of the science does not enable us to offer any satisfactory account. The whole subject, in fact, is shrouded in mystery, and it would therefore be premature to attempt any discussion of it. When the patient's habits are at fault, they must of course be corrected; alcoholic stimulation must be abandoned, the diet must be changed, and a system of exercise must be instituted, to improve the state of the blood and the assimilative powers. Local treatment should not be neglected when the degeneration is suspected to be going on externally, as when the muscles of a limb begin to waste in case of paralysis, disease, or injury.

SECT. IV.—HYPERTROPHY.

The word hypertrophy is employed to designate the increased size and weight which an organ acquires in consequence of an augmentation of its nutrition or the deposit of plastic, organizable matter into its interstices. Its use was originally restricted to those preternatural enlargements which are so frequently met with in the heart and thyroid gland; but modern observation has shown that it is applicable to all organs and tissues characterized by an unusual development of their substance.

Hypertrophy may be general or local, and the latter may either occupy an entire organ or be limited to particular portions of it, or even to some of its component elements. It may exist alone or in association with other lesions, and is liable to occur at all periods of life; sometimes, as in the thymus gland and capillary vessels, apparently even before birth. No organ or structure is probably entirely exempt from it; but among those which are most frequently affected may be specified the lymphatic ganglions, the mamma, thyroid gland, spleen, liver, heart, prostate gland, tonsils, bones, vessels, adipose tissue, and skin. The best example of hypertrophy of the cutaneous textures is elephantiasis, in which the increase of weight and bulk is sometimes enormous.

The causes of hypertrophy are, first, inordinate exercise of an organ; secondly, mechanical obstruction; and, thirdly, chronic inflammation.

The most simple way, apparently, in which hypertrophy of an organ occurs is from an increase of its functional activity. Examples of this variety of the affection are found in various textures of the body, particularly in the muscles, lungs, and kidneys. In every part of the frame, the muscles are proportionate, in size and structure, to the efforts required from them; and it is a law of nature that, whenever they are frequently called into action, their fibres become considerably augmented in thickness, and capable, consequently of much greater exertion. Thus the blacksmith, who constantly uses his arms in striking with his hammer, has much larger and stronger muscles than the dancing-master, who merely employs his legs. The same is true with regard to the lungs and kidneys. When one of these organs is imperfectly developed, compressed by effused fluid, or destroyed by some morbid growth, the other is sure to become preternaturally expanded, thereby compensating for the deficiency. There are certain viscera which are subject to temporary hypertrophy. Of this description are the uterus and mammary gland. During pregnancy and lactation these organs increase very much in bulk, but again diminish soon after parturition and weaning.

Hypertrophy may be caused, secondly, by some mechanical impediment interfering with the due performance of the functions of an organ. This is frequently seen in the heart, where, in consequence of disease of the valves, preventing the easy passage of the blood, the viscus is obliged to undergo increased action, and so becomes more or less enlarged. In the muscular fibres of the stomach, the same change is often witnessed from obstruction at the pylorus, and in those of the urinary bladder, from stricture of the urethra, or hypertrophy of the prostate gland.

Hypertrophy from chronic irritation is of frequent occurrence, and is met with under a great variety of circumstances. Some of the best examples of this species of hypertrophy are seen in the lymphatic ganglions of the groin from chronic irritation of the head of the penis, of those of the mesentery from ulceration of the ileum, and of those of the bronchiæ from disease of the lungs. Enlargement of the liver and spleen, sometimes of enormous size, is unquestionably due to a similar cause. In chronic dysentery, not only the

mucous and submucous cellular textures become hypertrophied, but the affection often extends to the muscular tunic, which occasionally attains an extraordinary degree of development. The follicles and villousities, which, in the healthy state, are hardly perceptible to the naked eye, are also rendered extremely prominent, the former being sometimes of the size of a mustard-seed, the latter more than a line in length. A similar development is frequently observed in the coats of the urinary bladder, in consequence of chronic inflammation.

Encysted tumors of the skin, mucous membranes, ovaries, and some other parts of the body, are evidently mere enlargements of the glands, cysts, and cells which naturally exist in these structures in consequence of chronic irritation or inflammation. The manner in which some of these tumors are formed is easily understood. Thus, in the skin-follicle, the first step in the development of the morbid growth is an obstruction of its orifice, thereby interfering with the evacuation of its natural secretion. This being retained, becomes materially altered in its properties, at the same time that it presses everywhere upon its sides; thus two sources of irritation are set up—altered and retained secretion and constant pressure—under the influence of which the little follicle often expands into a considerable sized tumor. The mucous tumor is formed in the same manner. The enormous ovarian growths, so often seen in elderly women, are frequently, if not generally, mere enlargements of the so-called Graafian vesicles consequent upon chronic disease.

The color of the affected organ varies much in different cases and under different circumstances. In general, it is very much heightened, especially when the hypertrophy is wholly physiological; on the other hand, it is occasionally greatly diminished: and instances are often observed where it is apparently quite natural. The consistence may likewise be normal, diminished, or increased. These three conditions do not, however, occur with equal frequency. An increase of density is by far the most common, and is particularly conspicuous in hypertrophy of the heart, mammary gland, the muscular fibres of the stomach and colon, the lymphatic ganglions, cellular tissue, bones, liver, spleen, and kidneys. A diminution of consistence is extremely rare, and cannot be viewed as a necessary consequence of the lesion.

An increase of weight of the affected organ follows, as a necessary consequence, in all cases where the lesion is not conjoined with atrophy. An augmentation of volume is by no means constant. Thus, in hypertrophy of the heart and bladder, there may be great development of the muscular fibres, with marked diminution of the size of their cavities. A change of form always arises when the hypertrophy is partially circumscribed, or limited to a particular point, as in the bones, skin, heart, bronchial tubes, and blood-vessels.

Hypertrophy essentially consists in an augmentation of the nutritive function. When in a state of unusual activity, the quantity of blood which an organ receives is considerably increased, in consequence of which it assumes a deeper color than one that is less exercised, at the same time that it augments somewhat in density; its elementary particles are increased in number, or such as already exist are augmented in size. It is in this manner that the alteration under consideration is brought about. In that variety of it which results from chronic irritation, it is not unlikely that there is often superadded to the alteration just mentioned a deposit of new substance in the spaces of the connecting cellular tissue, leading thus to a real change of structure. The effects of hypertrophy on surrounding parts will be pointed out in connection with the different organs and textures of the body.

In regard to the treatment of hypertrophy, no definite rules can be laid down, as it must be regulated, in great degree, by the nature of the exciting cause, which should, therefore, always be a prominent object of inquiry.

Much benefit may, in general, be anticipated from the steady and persistent use of sorbefacients, locally and constitutionally applied, such as iodine, blisters, compression, mercury, iodide of potassium, and tartrate of antimony and potassa, aided by purgatives and attention to diet. In some cases, nothing short of the removal, partial or complete, of the affected organ will hold out any prospect of relief.

SECT. V.—ATROPHY.

Atrophy is the reverse of hypertrophy, consisting in a wasting of the substance of an organ, with a diminution of its weight and bulk. Occurring at all periods of life and in both sexes, it may affect a whole organ, or it may be limited to a part of an organ, or to some of its constituent elements.

Remarkable examples of general atrophy are occasionally met with, but such an occurrence is of no special surgical interest, and does not therefore demand any particular notice here. Cases of this kind are sometimes apparently of a congenital character; at other times they are the result of disease, and are either curable or otherwise, according to their extent and the nature of their exciting causes.

Local atrophy may be produced by a variety of causes, of which the principal are, first, cessation of the natural function of an organ; secondly, loss of nervous influence; thirdly, deficient supply of blood or nutritive matter; and lastly, inflammatory irritation.

It appears to be a law of the animal economy that an organ, when of no further use, gradually falls into a state of decay. Of this class of structures are the umbilical vesicle and the pupillary membrane of the fœtus, the former of which, after having subserved the purpose of its formation, disappears at the close of the third month, the latter between the seventh and eighth. The kidneys are preceded in the embryo by two jelly-like bodies, to which the term Wolffian has been applied; these bodies, which exist not only in the mammalia, but likewise in birds and amphibia, acquire their greatest bulk about the middle of utero-gestation, after which they gradually diminish by absorption, and at length entirely disappear. The gubernaculum, which is visible in the tenth week of embryotic life, is a thin membranous process, which guides the testicle to the internal ring, and is finally converted into cellular substance. These are instances of atrophy from the cessation of the functions of an organ in the fœtus. After birth changes not less remarkable are to be observed; such, for example, as the wasting of the thyroid body, the supra-renal capsules, and the thymus gland. From the same cause the alveolar processes of the jaws disappear after the removal of the teeth. The ovaries shrink after the decline of the menses; and, in conformity with a similar law, the testicles often diminish remarkably in size in monks, who lead a life of celibacy, in the strict observance of their vows.

Atrophy may result, secondly, from a diminution of nervous influence; a circumstance not surprising when it is recollected how much the action of the capillaries is under the control of the cerebro-spinal axis. Whole limbs sometimes waste from this cause; in other cases the lesion is more limited, and implies a very partial disorder of the nerves. It has been observed that atrophy, when caused by disease of the brain, occurs much more slowly than when it is occasioned by an affection of the nerves of the part. The reason of this difference is not very obvious.

This variety of atrophy is very common in young children during dentition, from the sudden and often total suspension of the nervous influence, constituting a species of local paralysis, which often terminates in complete wasting of the affected parts. It is most frequently observed in the lower extremi-

ties, sometimes in one, and at other times in both; but it also occurs, though much less frequently, in the upper extremities, particularly in the deltoid muscle, which is occasionally transformed into a pale, flabby, membranous layer, not more than a few lines in thickness.

Remarkable examples of atrophy of the upper extremities occasionally occur from pressure of the head of the humerus on the axillary plexus of nerves, thereby interrupting the nervous influx. When such an accident takes place in very young subjects, and is permitted to remain unrelieved, the growth of the limb, if not positively arrested, is imperfectly executed, and the consequence is that not only the muscles, but even the bones become singularly stunted in their development, their shafts being very thin, and their muscular prominences unnaturally small and indistinct.

It is probable that a mere perversion of the nervous function of an organ is capable of producing atrophy. In neuralgia of the testicle, that organ is sometimes remarkably diminished both in size and consistence, not so much, apparently, from an actual loss of nervous influx, as from a change in its character. What corroborates this view is the fact that the testicle, while the wasting process is in operation, is often so exquisitely sensitive as to be intolerant of the slightest manipulation.

The effects of a deficient supply of blood in producing atrophy are well known, inasmuch as cases of this description are sufficiently frequent in practice to make them an object of special interest. When any part is deprived of the usual quantity of this fluid, it very soon becomes enfeebled, its substance is rendered pale and flabby, and it at last loses the power of action, although every other condition for its performance may remain unimpaired. Thus, the testicle wastes after tying the spermatic artery; and, for the same reason, the muscles of the lower extremity occasionally shrink after securing the principal vascular trunk of the thigh. Atrophy of the heart is sometimes produced by ossification of the coronary vessels, and a case is recorded in which the spleen, from the obstructed condition of its artery, was not larger than a filbert. In old age, many of the capillaries are obliterated; and it is not improbable that to this circumstance is owing that diminution of the size of the organs which constitutes senile atrophy. To the same cause is to be attributed the wasting of the lung and heart, from the accumulation of fluids in the pleuritic and pericardiac cavities.

Atrophy attendant upon mere want of exercise is no doubt essentially due to deficient nervous and vascular supply; in conformity with the law, mentioned under the head of hypertrophy, that the development of an organ is usually in proportion to the amount of its use. The wasted and attenuated condition of the legs in club-foot and other affections depriving the muscles of their functions, or interfering with their proper exercise, is probably owing entirely to this cause, as is shown by the fact that, when the disability is removed, the individual gradually recovers the use of his limbs, the calves often becoming strong and plump, as if there never had been any arrest of growth. The only or chief, exception to this is where the muscles have undergone the fatty degeneration, in which case they never regain their original development, but always remain weak and puny.

Atrophy from inflammation is very common. A good example of this species of wasting is seen in what occurs in the gall-bladder from the presence of biliary concretions, and which is sometimes followed by complete wasting of this organ, its coats being converted into a thin fibrous mass, having hardly any trace of the original reservoir. Hepatitis often gives rise to atrophy of the parenchymatous structure of the liver, and orchitis, especially when supervening on mumps, is not unfrequently succeeded by impotence. How the lesion, in these and other cases, is produced, is not easily determined. It is probable that the inflammatory deposits may so choke up

the capillary vessels of the parts as to deprive them of their customary and necessary supply of nutritive material; or, if this conjecture be untenable, that the pressure exerted by these effusions causes the absorption of some of the anatomical elements of the affected structures, thus reducing them, as it were, to their primitive condition.

Atrophied structures are prone to undergo the fatty transformation, and it is not improbable that this transformation itself occasionally acts as an exciting cause of the wasting process. However this may be, it is certain that the two lesions are sometimes so intimately associated as to render it impossible to determine which preceded the other, or what part they played as cause and effect.

The change of color experienced by an atrophied organ is necessarily greatly influenced by the natural complexion of the part, but does not possess any special surgical interest. The weight of the affected structures is generally considerably diminished, but their bulk often remains unaltered, and it is not uncommon to meet with cases where it is even greater than natural.

The treatment of atrophy, occurring in an external or accessible part of the body, as a muscle, resolves itself into the use of the warm and cold douche, frictions, either dry or through the medium of stimulating embrocations, and the application of electricity, as described under the head of wasting palsy. The general health must be amended, strychnine and tonics being given when there is marked evidence of debility. The affected part must be gradually and steadily exercised, or, as it were, re-educated; the influence of a strong will frequently directed upon it being often of essential service in rousing its latent faculties.

SECT. VI.—CONTRACTION AND OBLITERATION.

By the term contraction is meant the diminution of a canal, tube, or passage to an extent incompatible with the due performance of its functions. It is strictly synonymous with the term stricture, the signification of which is so well understood by the surgeon. The lesion is liable to occur in various degrees, from the slightest possible change in the size of a canal to the complete obliteration of its caliber.

The chief interest of this subject, surgically considered, relates to the contractions that occur in the mucous canals, or excretory ducts, as they are called, and in the bloodvessels, in both of which the lesion is frequently productive of the most disastrous consequences; attended, in the former, by retention of the secretions of these tubes and of the contents of the reservoirs with which they communicate, and in the latter by an impediment to the circulation which, in one case, may lead to atrophy, and, in another, to softening, ulceration, or gangrene.

Contractions of the mucous passages, to which the ensuing remarks are more particularly designed to apply, are deserving of great attention, both from the frequency of their occurrence, and from the great suffering which they so often entail upon those who are the subjects of them. They are met with in nearly every mucous outlet of the body, but are more common in the male urethra and in the nasal canal than anywhere else. Doubtless stricture often exists in the smaller excretory ducts, as those of the prostate and salivary glands, without our knowledge, or without awakening any serious functional disturbance; but in the larger passages the slightest coarctation is generally a source of more or less annoyance, if not of great pain and inconvenience.

The causes under whose influence contraction takes place are mainly two;

first, inflammation with plastic deposit, and secondly, mechanical compression. Of these the first is by far the more common.

The inflammation giving rise to this lesion may be either acute or chronic; in the former case generally doing its work rapidly, with bold and well-marked symptoms; in the latter, on the contrary, the injury is often inflicted in a slow and stealthy manner, without perhaps exciting any suspicion on the part of the patient of what is impending. The plastic matter, the real cause of the contraction, is generally deposited into the submucous areolar tissue, either exclusively, or partly there and partly into the interstices of the mucous membrane itself. However this may be, it soon becomes organized, and is ultimately transformed into cellulo-fibrous or fibro-cartilaginous tissue, which, gradually contracting upon itself and upon the neighboring structures, thus diminishes, in a proportionate degree, the caliber of the tube in which it is situated. It is in this manner that all organic strictures, properly so termed, of the mucous outlets of the body are formed.

The second cause of contraction is of a purely mechanical character, although in most cases, if not in all, the lesion is attended with inflammation and plastic deposit, secondary, however, in their character. It is thus that stricture of the nasal canal may be produced by the pressure of a tumor in the sinus of the upper jaw; of the bronchia, by the pressure of an aortic aneurism; and of the Fallopian tubes, the biliary ducts, and ureters, by the pressure of an enlarged viscus or morbid growth in their immediate vicinity. The same cause often induces constriction and even complete obliteration of the bloodvessels. A tumor, compressing the aorta, has been known to give rise to permanent closure of that vessel as effectually as if it had been surrounded by a ligature.

The extent of the contraction varies, both in length and in diameter, in such a manner as to render it impossible to specify it in a general manner. In some cases, it may not exceed the fraction of a line, while in others it may involve the whole length of the affected tube.

The effects of such a lesion upon the parts concerned are often extremely distressing. Thus, in the urethra, the obstruction is attended with difficulty of micturition; in the nasal canal, with impediment to the passage of the tears into the nose; and in the œsophagus, with difficulty of deglutition.

The prognosis, in ordinary cases, is not at all serious, as the obstruction generally admits of relief, except when it has been induced by the compression of some internal tumor or an enlarged viscus, in which case it will almost necessarily be irremediable.

The treatment of the inflammatory form of contraction must be conducted according to the general principles laid down in the chapter on lymphization; by antiphlogistic remedies in the earlier stages of the disease, and afterwards by alterants, rest, light diet, purgatives, leeches, and a regular, systematic course of dilatation by means of bougies, either alone or aided by incision, scarification, or free division of the affected structures. Great care must be taken, in the employment of dilatation, to conduct it in the most gentle and cautious manner, the object being to excite the absorbent vessels, while the capillaries are, if possible, kept in a perfectly passive condition. In this way, we get rid, in time, of the effused matter, upon the presence of which the constriction essentially depends, without provoking any further deposition.

SECT. VII.—FISTULE.

A fistule is a narrow track, straight or tortuous, of variable depth, having generally two distinct orifices, lined by an adventitious membrane, and bathed with a thin, gleetty fluid, intermixed with the natural contents of the

part, organ, canal, or cavity affected. The disease, which is always of a consecutive nature, occurs in different regions of the body, and is developed under the influence of various causes.

Although the abnormal track has usually two openings, one of which is superficial and the other deep-seated, yet this is by no means constantly the case. Hence the distinction of fistules into complete and partial. The terms recent and old, often used by writers, refer merely to the duration of the disease.

The lesion may occur in almost any situation, but originates most frequently about the anus, perineum, face, groin, and mammary gland. Fistule of the neck, thoracic cavity, the biliary apparatus, the stomach, colon, and small bowel, kidney, pancreas, and urinary bladder, is comparatively rare. It takes place in both sexes and at every period of life; but children and young persons suffer much less frequently than the old and middle-aged.

The nomenclature of fistule is quite extensive. The names are derived either from the parts in which the abnormal passage is situated, as anal, perineal, broncho-pleural, and recto-vaginal, or from the nature of the discharge, as salivary, urinary, and stercoraceous.

Fistules vary much in their extent. The longest tracks occur along the spinal column in connection with psoas abscess. In this affection, the matter generally escapes in the groin, just above Poupart's ligament, in the upper part of the thigh, or, lastly, in the ileo-lumbar region, the channel which is thus established varying in length from six to twelve inches, and being always lined by a well-organized, adventitious membrane. Passages of considerable length are sometimes met with in the internal organs, as between the kidney and lung, between one coil of intestine and another, or between the urinary bladder and the cutaneous surface. In other situations, on the contrary, the track is remarkably short, being hardly two or three lines from the surface, or from the cavity with which it communicates.

The diameter of these abnormal tracks is also very variable. Sometimes they are so small as scarcely to admit the finest bristle; while at other times they are sufficiently capacious to receive a goose-quill or the end of the finger. The narrowest tracks usually occur in the lachrymal passages, salivary glands, anus, and perineum. It is not often that the fistule is of the same uniform diameter throughout; on the contrary, it is almost always larger at one point than at another.

The external orifice, generally of a rounded or oval shape, may be so narrow, on the one hand, as to be hardly perceptible, or, on the other, so large as to admit the end of a probe, a goose-quill, or a finger. It may have sharp and well-defined margins; be surrounded by a soft, spongy, florid rim; or, be depressed, inverted, or infundibuliform. The number of external orifices varies in different cases, from one to as many as six or a dozen; when it is very considerable, the affected surface commonly presents a cribriform appearance.

The internal orifice may be of the same size as the external, or it may be smaller or larger. In its shape it is usually irregularly rounded, and it is seldom that it is found multiple, even when the number of external openings is considerable.

Although the direction of the passage may be perfectly straight, yet, in general, it is more or less flexuous, serpentine, oblique, or winding. Occasionally it forms nearly a right angle with the surface on which it opens. When several tracks exist, they often run together, and open by one common orifice upon the reservoir with which they communicate.

A fistule, in its recent state, is simply a raw surface, secreting purulent matter. It is, in fact, an ulcer, an open sore, a solution of continuity, which must undergo a process of reparation before it can be justly entitled to its

distinctive appellation. The track, however, soon becomes smooth, and is speedily coated with an adventitious membrane, varying in thickness from a mere film to half a line, a line, or even the sixth of an inch. This new layer, at first soft and easily detached, gradually augments in density, and is at length inseparably united to the parts which it serves to line. Its color, like its consistence, is very much influenced by its age, and by the nature of the secretion or excretion which passes over it. At an early period it is red, pink, or rose; in cases of long standing, on the contrary, it is either white, gray, or slightly bluish. The free surface of the membrane is smooth and polished; or it is rough, mammillated, or studded with villi of various shapes and sizes. The other surface is attached by means of short cellular substance to the parts upon which it lies. Bands of lymph sometimes extend from one side of the abnormal channel to the other, very much as in the bridle stricture of the urethra; but this is rare.

The membrane here described is formed out of the plastic lymph of the blood, and is of the same nature as the pyogenic membrane of a chronic abscess. Around the anus, in the perineum, and in some other regions, it bears no little resemblance to the mucous tissue, but differs from it in having no follicles and no distinct epithelial layer. It is liberally supplied with vessels, nerves, and, probably, also with absorbents, is the seat of a constant secretion of gleet or other matter, and is liable, like all new textures, to inflammation and its consequences. In ancient cases it occasionally acquires a dense, fibrous, or fibro-cartilaginous consistence.

The nature of the discharge in this disease varies with the situation of the abnormal passage. In general, it is thin and gleet, as in chronic gonorrhœa, and mingled with the natural secretions, or excretions of the reservoir with which the fistule communicates. When, however, the lining membrane labors under inflammatory irritation, the discharge is either entirely suspended, or it is bloody, purulent, or muco-purulent.

The parts in which the abnormal track is situated are variously affected. In some cases they are nearly natural; but in general they are firm and callous, from the effusion and organization of plastic lymph, which, being often present in large quantity, completely obliterates the meshes of the connecting cellular tissue.

Finally, the causes which give rise to fistules are either mechanical or vital. To the first class belong wounds, contusions, and lacerations; to the second, ulceration, gangrene, and abscesses. There is a variety of fistule which may be regarded as a remnant of embryotic organization. Its most frequent situation is the antero-lateral part of the neck. Like the ordinary fistule, it may terminate in a cul-de-sac, or it may have two orifices, of which the external is sometimes scarcely visible. The abnormal passage itself is usually very narrow, and seldom extends beyond two or three lines in depth.

The *treatment* of fistule must be regulated by circumstances. In recent cases, before the passage has become lined by an adventitious membrane, a cure will sometimes follow the use of stimulating injections, as a weak solution of nitrate of silver, sulphate of copper, tincture of iodine, or acetate of lead, repeated twice in the twenty-four hours; or by touching the parts lightly once a day, or once every other day, with the solid lunar caustic, or with the end of a probe dipped in a solution of the acid nitrate of mercury. Strict attention should be paid to cleanliness, and the parts should be maintained in a state of absolute rest. It is seldom, however, that a permanent cure can be effected in this way, especially if the fistule be of any extent, or situated where it is influenced by the contraction of muscular fibres, as, for example, when it involves the anus. The best plan, in fact, nearly always, is not to lose any time in experimenting with these remedies, but at once to lay open the abnormal passage in its entire length, so as to afford the parts

an opportunity of healing from the bottom by the granulating process, a tent being interposed between the edges to prevent their readhesion. Occasionally a seton may be passed through the track, and be retained until it ulcerates out. In some forms of fistule, as in the vesico-vaginal and urethral, a very delicate operation is generally required in order to effect a cure, consisting in paring the margins of the opening and bringing them together by several points of suture.

The healing of a fistule is often materially retarded, if not effectually prevented, by the presence of a foreign body, as a mass of dead cellular tissue, a loose piece of bone, a bullet, or a portion of wadding, or, by the contact of some irritating fluid, as the urine, or of fecal matter. The indication, of course, is to remove the extraneous substance whatever it may be, and then to manage the case upon the principles just laid down.

Occasionally, again, the difficulty in respect to a cure may depend, at least in part, upon deficient tone of the system, or some disorder of the general health. The patient, for example, may be anemic from organic disease, intemperance, or want of wholesome air and food. Such cases are not uncommon in large cities and in the wards of crowded, ill-ventilated hospitals, and readily suggest their own treatment.

The prudent practitioner is sometimes sorely perplexed in this disease as to the propriety of attempting a radical cure, or whether he should interfere only so far as to palliate the patient's suffering. In general, it will be best to let each case be governed by its own rules. When the fistule has been of long standing, and has acted all along as a drain upon the system, serving perhaps to counteract some other affection, such as phthisis or a tendency to apoplexy, no operation should be practised, since it could hardly fail to provoke mischief. In fact, serious organic disease of any kind is a contra-indication to an operation. The only exception to this is where the fistule is a cause of excessive local distress, completely depriving the patient for days of sleep, appetite, and comfort. Under such circumstances the surgeon could hardly refuse his aid; but before doing this, he would be sure to open a new source of counter-irritation, in the form of an issue or seton, in some other and more eligible portion of the body, thus establishing a drain at least equal to that which he is about to suppress in order to afford temporary mitigation. In ordinary cases there is of course no reason for delay; the operation is promptly performed, and a rapid recovery is reasonably anticipated.

CHAPTER VI.

CONGENITAL MALFORMATIONS.

CONGENITAL malformations, surgically considered, constitute a subject of the deepest interest, both because they are of frequent occurrence, and because they generally require an extraordinary amount of knowledge and skill for their successful management. Presenting themselves under different forms, or characters, they exhibit every variety of grade, from the most simple departure from the normal standard to the most pitiable and disgusting deformity, well calculated to elicit the sympathy and aid of the considerate and humane surgeon. With a view to a more full appreciation of the nature of these malformations, they may conveniently be arranged under the following heads: 1st, deficiency of parts; 2dly, redundancy of parts; 3dly, displacements; 4thly, occlusions; 5thly, deviations of position; 6thly, adhesions of contiguous surfaces; 7thly, vascular tumors.

1st. The first class, consisting of a *deficiency* of parts, may be subdivided into two orders; the one comprehending fissures, or clefts, and the other an entire absence of certain structures, as a finger, hand, or ear.

The most common, and, in a surgical point of view, the most interesting, fissures are hare-lip, cleft palate, bifid uvulva, extrophy of the bladder, epispadias, hypospadias, and bifid spine, together with extraordinary patency of the fontanelles. Of these malformations some admit of relief by operation, whereas others are hopelessly irremediable; at all events, every attempt hitherto made to cure them has either signally failed, or sooner or later destroyed the patient. The operation for hare-lip is of daily occurrence, and, when properly executed, rarely disappoints expectation; besides, if it fail, it admits of repetition. Staphyloraphy has also become a common procedure, being frequently, if not generally, crowned with success. Extrophy of the bladder, consisting in a deficiency of the anterior wall of that viscus and of its protrusion at the linea alba, has hitherto resisted every means directed for its relief. Epispadias and hypospadias are difficult of cure; and cleft of the vertebra, with protrusion of the envelopes of the spinal cord and of the cephalo-spinal liquid, is nearly always a fatal affection. The closure of these fissures is effected by paring their edges, and afterwards approximating them by suture, ultimate union being accomplished through the intervention of plastic matter. The tumor in bifid spine is emptied with the trocar, and then injected with some slightly stimulating fluid, with the hope of exciting obliterative inflammation. In general, the operation, is speedily followed by convulsions, coma, and death.

In the second order of cases the deficiency consists in the absence of certain structures, as a finger, a hand, or even an entire arm. The genital organs suffer perhaps more frequently in this way than any other parts of the body. Thus it is by no means uncommon to find the vagina absent, or the vagina and uterus, or these organs along with the ovaries and Fallopian tubes. Sometimes the testes are wanting, or, if present, they exist only in a rudimentary form, perhaps hardly equalling the volume of an ordinary bean. The penis, too, may be absent; or, instead of being large and well grown, it

may, at the age of puberty, be less than that of a child at the eighth or tenth year.

2dly. A congenital *redundancy* of structures is sometimes met with, consisting, chiefly, in hypertrophy of the integuments of various regions of the body, or in the addition of a supernumerary finger, toe, tooth, or ear. To the same category belong the anomalous divisions of certain arteries, as the brachial and femoral, high up in their respective limbs. A redundancy of skin and cellular substance is most common about the neck, hands, feet, and genital organs, as the prepuce and vulva, where the superfluous structures sometimes occur in large, pendulous masses. A supernumerary toe, thumb, or finger is no unusual occurrence; occasionally each hand and each foot are provided with such an appendage. I have seen one well-marked case of four ears; an increase of the natural number of teeth is not uncommon. In some of these cases the supernumerary organ is buried in the alveolar process of the jaw, where I have known it to be productive of such an amount of disease as to require a serious operation for its removal. Most of these malformations admit of cure by retrenchment with the knife, and the operation may generally be safely executed at an early age.

3dly. Congenital *displacements* occur in various parts of the body, but principally in the articulations and in the abdominal viscera. The joints that are most liable to this form of dislocation are the hip, shoulder, and wrist; but it has also, although very seldom, been met with in those of the jaw, clavicle, elbow, and knee. The deformity thus produced is often very great, and what aggravates the case is the circumstance that it rarely admits of relief, however skilfully and perseveringly it may be treated. The malformation, as will be shown elsewhere, probably begins at an early period of foetal life, and goes on gradually increasing until it attains an irremediable stage.

The most common form of displacement of the abdominal viscera occurs in what is called congenital hernia, caused by a want of closure of the inguinal canal during the descent of the testis. The consequence is that, soon after the child has begun to breathe, the diaphragm, pressing the bowels against the walls of the abdomen, forces them down into the scrotum. The portion of tube thus displaced is generally a loop of small intestine, but now and then other organs are pushed down along with it. The most suitable remedy for such a defect is steady compression upon the neck of the hernia by means of a well-adjusted truss, which generally eventuates in an effusion of lymph, and the obliteration of the sac of the tumor.

4thly. Congenital *occlusion* may occur in any of the mucous outlets of the body, but is much more frequent at the anus and genital organs than anywhere else. Closure, properly so called, of the anus may be produced by a continuation of the integuments across from one buttock to the other; or it may depend upon the existence of a fold of mucous membrane situated just within the anus, an arrangement not unlike a hymen. In either case, relief may easily be effected by the knife, patency being afterwards maintained by the frequent insertion of the finger. The prepuce is sometimes completely impervious, or if an opening be present, it answers very imperfectly the purpose of an outlet for the urine. The vagina is occasionally imperforate, being closed by what is termed the hymen; and there is reason to believe that certain forms of sterility are due to occlusion of the uterus, or of the Fallopian tubes.

5thly. Congenital *deviations* of position are infrequent. The most interesting, in a surgical point of view, is the deformity of the nasal septum, which is sometimes so great as to interfere materially with the functions of the nose, one of the anterior nares being sometimes completely occluded by the projection of the partition towards the corresponding side. A simple operation,

consisting in the removal of the incurvated portion of the septum, generally effectually relieves the difficulty.

There is occasionally a remarkable congenital incurvation of the penis, disqualifying the organ for the easy and full discharge of its functions. The defect is always associated with hypospadias, and consequent shortening, or imperfect development of the spongy structure of the urethra. An admirable operation for the cure of this deformity, devised by my colleague, Professor Pancoast, will be described in the chapter on the genital organs.

Deviation of position is often associated with permanent contraction or shortening of the muscles and tendons, as is seen in club-foot, wry-neck, and other analogous distortions. This class of lesions is one of great practical interest, having opened to the modern practitioner a wide field for the exercise of his ingenuity and skill, as well as of his patience. Taken in hand soon after birth, they may frequently be promptly remedied by the use of the most simple appliances, whereas under opposite circumstances the treatment will generally be very tedious, even if aided by the free division of the affected structures. The rectification of these malformations forms one of the most interesting chapters in the history of subcutaneous surgery, one of the great discoveries of modern times.

6thly. Congenital *adhesions* are sometimes observed, chiefly between the fingers and toes; more rarely between other parts, as the eyelids and the ball of the eye, the ear and the scalp. The uniting medium is generally merely a fold of common integument, the severance of which often effectually releases the parts from their restraint, and restores them to usefulness.

7thly. I may mention, finally, as another class of congenital affections, those peculiar vascular tumors known as *nevi*, or *mother's marks*; they occur in different regions of the body, especially the head and face, and constitute an exceedingly interesting and important form of morbid growth. Their composition is variable; sometimes they are essentially composed of dilated and tortuous capillary veins, connected by areolar tissue; at other times they are made up mainly of enlarged and diseased capillary arteries; lastly, there is a third species which seems to partake of the character of both the others, the two sets of vessels being so intimately blended as to render it impossible to determine which predominates.

These vascular growths, however constituted, almost always begin in the substance of the skin, from which, as they augment in size, they gradually extend to the cellular tissue beneath; they are of a soft, spongy consistence, readily receding under pressure, and expanding under mental emotion. Their color is variable; the venous varieties being usually of a dark purple, and the arterial of a red scarlet hue. The latter are of a truly erectile character, and hence they commonly pulsate, heaving and throbbing synchronously with the contraction of the left ventricle of the heart. The growth of both varieties is generally steadily progressive, and the consequence is that they often acquire a considerable bulk.

Most of these morbid growths readily admit of cure, especially if timeously begun. This may be effected, 1st, by ligation; 2dly, by excision; and 3dly, by escharotics.

In regard to the causes of these various malformations, it would be entirely out of place to inquire into them here. My sole object has been to bring the subject briefly before the reader in its practical relations; any other information respecting it may readily be obtained by a reference to the many works specially devoted to such discussions. Some of these malformations are doubtless owing to an arrest of development, dependent upon a defective organization of the germ; others are probably caused by irritation of the nervous centres; while others, again, are perhaps due to faulty position of the fœtus in the uterus, or violence inflicted upon it during gestation.

CHAPTER VII.

TUMORS, OR MORBID GROWTHS.

SECT. I.—GENERAL OBSERVATIONS.

WHAT is a tumor? The best definition that, in my judgment, can be given of it is that it is an enlargement of a part, structure, or organ, produced by abnormal deposit. This abnormal deposit may be an entirely new formation, or it may be merely a superaddition to the original one. It may, moreover, be benign or malignant; that is, it may simply incommode by its situation, weight, and bulk, or it may, after a certain period, destroy not only the part in which it appears, but also the patient. It may be stated, as a general law, that most of the benign tumors, or innocuous growths, are the result merely of some alteration in the function of the primitive tissues; many, indeed, are nothing but local hypertrophies, or enlargements produced by inflammatory deposits, supernutrition, or the retention of some normal secretion. On the other hand, malignant tumors are always caused by the deposit of a new substance which is either entirely distinct from the natural structures, or which bears but a very faint resemblance to them, in its physical, chemical, and vital relations. The only exception, perhaps, to this law is the hydatid tumor, which, although it is altogether foreign to the natural organization, is of a non-malignant character.

The number of malignant formations, so far as is at present known, is comparatively small, while the number of benign is very considerable. Occurring at nearly all periods of life, and in nearly all the organs and tissues of the body, they possess certain features in common with each other, which renders it necessary to study them in a general point of view. Such a proceeding is indispensable to a correct appreciation of the structure, diagnosis, and treatment of these affections. The principal topics to be considered, in connection with these circumstances, are, first, the physical properties of the morbid growth; secondly, its relations to the surrounding structures; and thirdly, its history.

1st. It would be difficult to point out a *situation* where tumors may not occur. With the exception of the tendons, fibrous membranes, cartilages, and bloodvessels, they are found in all parts of the body, and it would hardly be proper to affirm that even these structures are altogether exempt from them. As a general rule, it may be stated that malignant growths are most common in glandular organs, as the mamma, liver, and mucous follicles; in the cellulo-adipose tissue, as in the case of melanosis; or in the peritoneum, stomach, bowel, and bones, as in that of colloid. Tubercular deposits occur almost everywhere; but, surgically considered, more frequently in the lymphatic glands than anywhere else. Epithelial cancer has a peculiar predilection for the cutaneous and mucous textures at the various outlets of the body. Benign tumors are most common in the skin, cellulo-adipose tissue, nose, uterus, and ovary. Hydatid formations are seen chiefly in the liver, breast, testicle, and bones.

Tumors affect various *forms*, depending not merely upon the nature and

amount of resistance offered to their development, but also, in some degree, upon the original shape of the part wherein they originate. A sebaceous tumor is generally globular; a fatty one either flat or pendulous; a polypoid one pyriform, conical, or pediculated. Malignant growths are commonly distinguished by the irregularity of their surface, which is often lobulated, or marked off into ridges and depressions.

In their *volume*, tumors range, in every possible gradation, from that of a millet-seed, as in the little granule on the eyelid, to that of the patient's body, as in ovarian cysts and elephantiasis of the scrotum, those enormous masses which are sometimes absolutely more bulky and heavy than the subject in whom they are developed. Fatty, fibrous, and osseous growths occasionally acquire a large size, but they are almost the only ones of their class that do. Among the heterologous tumors, those which attain the greatest magnitude are the encephaloid and colloid; scirrhus, melanotic, and other formations of this description, being usually comparatively small.

In respect to their *consistence*, some tumors are soft, some solid, some semi-solid. Tumors containing serous fluid, as hygromatous cysts of the neck and of the ovary, are always soft and fluctuating, unless they are overlaid by a large quantity of solid substance, when they may partake of the latter character even more than of the former. Fibrous and osseous tumors are known by their great hardness, which is equal to that of the natural structures. Scirrhus is the most firm of the heteroclite tumors, its name being derived from that circumstance. Occasionally one portion of a tumor is soft, another hard, and a third, perhaps, semi-liquid. Ovarian growths exhibit these varieties of consistence more frequently, and in a more perplexing degree, than any other, whether benign or malignant.

The *color* of a tumor is generally a matter of secondary consideration, as it is seldom that the morbid growth is sufficiently exposed to admit of direct inspection, except in some of the mucous outlets. In the early stage of all formations of this kind that take place beneath the external surface of the body, there is usually an absence of discoloration, and it is only when the growth bears too heavily upon the skin, pushing it out in every direction, or when it manifests a disposition to ulcerate and evacuate its contents, that it causes the skin to be red, livid, or purple. In tumors of the nose, uterus, and anus, color often affords us great assistance in our discrimination of the case. A gelatinoid polyp can never be mistaken for a fibrous one, its complexion being always a diagnostic of its character. It may be assumed, as a general rule, that the lighter a tumor is externally the greater is the probability of its being benign, and conversely.

Mobility is an important quality in a tumor, its amount varying according to the nature of the affected organ and the degree of resistance offered by the surrounding parts. Some morbid growths are never movable, others always are, whatever may be their age, volume, or situation. A sebaceous tumor never contracts such firm adhesions as not to be susceptible of being pushed about; while an exostosis is always immovable from its very commencement. Most of these formations, whatever may be their character, contract adhesions to the surrounding tissues as they augment in age and volume, their pressure exciting inflammation and plastic deposits, which thus become the bond of union between the normal and abnormal structures.

Tumors are endowed with various degrees of *sensibility*, depending upon the peculiarity of their structure and the amount of compression exerted upon them by the parts in which they are developed. Most tumors, whether innocuous or malignant, are free from pain during their earlier stages; but, as they increase in size, they encroach upon the neighboring tissues in such a manner as to interfere with their movements, and thus seriously compress their nerves, whilst the latter, in their turn, more or less compress the nerves

of the advancing mass. Occasionally the pain is characteristic, as, for example, in scirrhus of the mammary gland. Encysted tumors of the skin are usually entirely free from pain, or, if there be any pain, it is the result of accidental circumstances.

2dly. In regard to the *relations* which tumors bear to the surrounding structures, several circumstances deserve to be noticed. The first is the manner in which they are bound down, or inclosed in their habitation. Every tumor must necessarily have an appropriate residence, but, like a settler in a new country, it is seldom content with the spot originally assigned to it. On the contrary, soon lacking room, it is sure to encroach upon, fret, and worry the parts around it, which, as already seen, are not slow to resent the invasion. Mutual oppression and mutual discomfort are the result. The healthy structures successfully resist for a while the intrusion, but gradually they yield before the enlarging mass, which thus often converts the muscles into mere ribbons and the bones into mere shells. Function, too, may be seriously interfered with; the ranula filling the mouth, the goitre compressing the neck, and the polyp closing the womb.

In the second place, as the tumor progresses, it is apt, either by the continued pressure which it exerts upon the superimposed parts, or in consequence of the gradual decay of its own structure, to produce ulceration, followed by more or less discharge. This tendency, although most conspicuous in the heteroclite formations, is not peculiar to them, but is also witnessed in some of the benign growths, as the encysted and adipose. Large vessels are sometimes laid open during the progress of the disease, thereby inducing copious hemorrhage.

Tumors often occasion serious disease in the surrounding lymphatic ganglions. This is particularly true of malignant tumors, in some of which it forms a very conspicuous and almost unmistakable feature. In cancer of the jaw the ganglions of the neck enlarge; of the breast, the ganglions of the axilla; and of the testicle, the ganglions of the groin; either by actual extension of the morbid action, or from sympathetic irritation.

Finally, an intimate *sympathy* exists between tumors and the constitution, operating at one time beneficially, at another, prejudicially. The progress of malignant growths is often stayed for months and years, simply by attention to the general health; on the other hand, it is frequently astonishingly hastened by disorder of the system, and, in fact, by whatever has a tendency to produce derangement of the secretions, especially those of the liver, uterus, and kidneys.

3dly. The *history* of the case often furnishes important points of comparison. Tumors occur at all periods of life, in both sexes, in all classes of society, and in all varieties of temperament. Certain forms of malignant disease, however, are most common at one period, and others at another. Thus, scirrhus is almost peculiar to elderly subjects, while encephaloid is most frequent between the ages of twenty and fifty. The scrofulous tumor is most common in childhood and adolescence. Benign growths of every description are often observed in early life, but the greatest number of cases occur in young adults.

Rapidity of growth and great bulk imply inordinate vascular activity, and lead to a suspicion of malignancy. There is no tumor that attains so great a bulk in so short a time as the encephaloid, and certainly none that is more surely fatal. Ovarian cysts of the non-malignant type, often acquire an astonishing development in a comparatively brief space. Sebaceous, polypous, osseous, and fatty tumors, on the contrary, usually grow slowly, and occasionally even enjoy a period of repose.

Constitutional involvement may be occasioned by sheer malignancy, or by the injurious effects exerted by the morbid growth upon important structures

in its neighborhood. In general, rapidity of development, large size, and early formation of adhesions, along with enlargement of the lymphatic ganglions, and constitutional disorder, may be regarded as evidences of a malignant tendency.

Certain tumors have a disposition to return after extirpation; others, on the contrary, never relapse. All malignant growths, without exception, possess this repullulating tendency, and hence their removal is rarely followed by a permanent cure. Relapse, however, may also occur when the tumor is perfectly benign, but then it is generally dependent upon imperfect extirpation. Thus, an encysted tumor will almost be certain to recur if a portion of its sac be left behind.

It is seldom that a tumor disappears spontaneously; nevertheless, such an occurrence is possible, and there are several ways in which it may be effected, as by absorption, enucleation, ulceration, and gangrene. The former of these modes of cure is the most common; one of the best examples of it occurs in the scrofulous tumor, so frequently met with in the neck and about the angle of the jaw in strumous children, from exposure to cold and derangement of the digestive organs. The disease essentially consists in an inflammatory enlargement of one or more lymphatic ganglions, which after having existed perhaps for years, finally goes away without any assignable cause, merely, to all appearance, in consequence of an improved state of the general health, and of a change in the nutrition of the part.

Sometimes a tumor becomes enucleated, and drops off, leaving perhaps merely its inclosing cyst. It is thus that the fibrous tumor of the uterus is occasionally detached; and the same thing may happen to an exostosis, particularly if it be large and situated upon the skull. In such cases the vascular connection between the morbid growth and the circumjacent structures is probably, as a preliminary step, in a great degree destroyed, so that the tumor, gradually dying and acting as a foreign body, is at length cast off by the living tissues.

A cure is occasionally effected by profuse suppuration, or, more correctly speaking, by suppuration and ulceration. The kind of tumor most easily influenced in this way is the scrofulous, which is either completely disintegrated and broken down, or it is dissected off by ulcerative action, and is finally detached as an effete substance.

Lastly, gangrene seizing upon a tumor may so interfere with its circulation as effectually to destroy its vitality. Such an occurrence, although very rare, may take place in a malignant as well as in a benign growth. Some years ago, I attended an elderly lady on account of scirrhus of the mammary gland; after the disease had been going on for upwards of a year, the carcinomatous structures were suddenly attacked by gangrene, and in less than a week they dropped off in the form of a black slough, leaving in their stead a large excavated cavity.

SECT. II.—BENIGN TUMORS.

The benign or non-malignant tumors may be arranged under the following heads: 1. Hypertrophic; 2, vascular; 3, adipose; 4, horny; 5, fibrous; 6, cartilaginous; 7, osseous; 8, calcareous; 9, neuromatous; 10, cystic; 11, hydatid; 12, polypoid; and 13, myeloid. The latter, however, must, for the present, occupy an equivocal position in this arrangement. As for myself, I have very little doubt but that it will ultimately be found to be merely a variety of encephaloid.

1. HYPERTROPHIC TUMORS.

I employ the term "hypertrophic" to designate a class of tumors which are produced by the gradual enlargement of an organ, in consequence of an increase of its nutrition. A good type of this form of tumor occurs in the thyroid body, in what is generally known as goitre. This affection, which commonly begins very early in life, consists essentially in an abnormal development of the component elements of the gland, simply as the result of a preternatural supply of blood. What the immediate cause of this increased supply is does not admit of easy explanation. It is possible, although problematical, that it may originally depend upon inflammatory irritation; but, even if this be true, it can hardly be supposed that this action would continue through a series of twenty, thirty, and even fifty years, as we know it often does, from the steady and persistent increase of the morbid mass. Whatever, therefore, may set the process in motion must, after a time, cease to exert its influence, while the perverted movement, once begun, daily progresses, until the structures affected by it are incapable of further change. This idea derives additional support from the fact that goitre, after having attained a certain degree of development, often remains stationary for a long period, when, perhaps suddenly and without any obvious cause, it again commences to grow. If such a tumor be examined in its earlier stages, it will be found that, while the tissues are unnaturally red, firm, and distinct, and that, while the thyroid arteries which supply them with blood are unnaturally voluminous, there is no evidence whatever of plastic deposits justifying the belief that inflammation had any agency in the production of these changes. If, at a later period in the disease, we find various morbid products, such as the pathologist is accustomed to regard as the consequence of inflammation, it only shows that they are the result of secondary causes, developed during the progress of the hypertrophy, which is itself, no doubt, often a source of inflammation to the affected tissues.

Hypertrophy of the prostate gland, generally described as senile enlargement, is often produced in a similar way. The same cause usually presides over the development of those enormous growths of the mamma which are occasionally observed in young females, in which that organ has been known to acquire a bulk many times exceeding the natural one. Congenital enlargement of the tongue affords another well-marked example of the same mode of formation.

A chronically enlarged tonsil is another specimen of this form of tumor, only that the hypertrophy is usually attended with an inordinate amount of plastic deposit. The inflammation, however, after a time, frequently disappears; but not so the enlargement. On the contrary, when it has once been fairly established, it often steadily progresses until the gland has attained an enormous bulk, simply in consequence of the increased nutrition of its proper tissues, aided by occasional subsequent attacks of inflammation, to which the parts are always remarkably prone after having once been assailed by this disease.

The encysted tumor of the skin, the common sebaceous tumor of authors, is essentially a hypertrophic formation, awakened by obstruction of the outlet of a skin follicle, caused either by inflammation or by the impaction of sebaceous matter. The natural secretion being thus retained, presses upon the walls of the follicle in every direction, thus inviting a preternatural afflux of blood, probably attended, in the first instance, by interstitial deposits, but gradually subsiding as the cyst becomes tolerant of the presence of the altered and now foreign substance. That this is true does not admit of doubt, espe-

cially if we reflect upon the fact that this form of tumor often steadily increases for many years without any demonstrable evidence of inflammatory irritation.

To the same category as the above affections belong those chronic lesions of the lymphatic ganglions in which there is not only more or less augmentation of their volume, but marked induration and alteration of their proper tissue. Sometimes a large tumor is formed in this way by a single gland, but, in general, such growths consist of an agglomeration of several bodies of this kind, united so as to form a bulky mass, of a nodulated character, and of extraordinary firmness.

If we adopt the term which I have here employed to designate these changes, we shall be able to dispense altogether with the word "sarcoma," introduced by Mr. Abernethy, and so constantly used since his time, in reference to certain alterations produced in our organs as a consequence either of simple supernutrition or inflammatory deposits, or both conjoined. Sarcoma literally signifies flesh, and is therefore wholly inapplicable, not only to this but also to every other form of morbid growth, which never has any resemblance, not even the faintest, to flesh. The sarcomatous testicle, for example, as it was formerly called, in conformity with the nomenclature of the English surgeon, is merely a chronic enlargement of that organ, the result of inflammatory deposits and supernutrition of its proper structures.

The mammary gland not unfrequently enlarges in a similar manner, its substance being indurated and distinctly defined, but not so completely masked as to lose all trace of its primitive character. The organ is simply hypertrophied, and is therefore capable, under judicious management, of regaining its natural properties.

Much is to be expected from medical treatment in this class of tumors. The remedies upon which our chief reliance is to be placed are purgatives and sorbefacients, with strict attention to the diet. Occasionally, valuable aid is derived from topical bleeding, especially when there is decided evidence of overaction with tendency to plastic effusion from inflammatory accession. The bowels having been duly attended to, the best internal remedies are, in the more recent cases, the milder forms of mercury, and, in the more chronic, the different preparations of iodine, of which Lugol's solution and the iodide of potassium are entitled to preference. The object is to change capillary action and to promote absorption of redundant material, whether the product merely of simple or of perverted nutrition. The action of internal remedies is generally very much increased, under such circumstances, by local applications, employed so as to excite the secretions without irritating the skin. They may consist of unguents, embrocations, or liniments, used several times in the twenty-four hours, their beneficial effects being aided by rest and other means calculated to favor restoration of structure and function. Blistering occasionally exerts a most powerful influence in affording relief. Cutting off the supply of blood to the part by tying the main artery leading to it has sometimes been successfully practised. Excision is performed only as a dernier resort; partial, as in the case of an enlarged tonsil, complete, as when the mammary gland or a lymphatic ganglion is involved.

2. VASCULAR TUMORS.

The vascular tumor, of which a good idea may be formed by reference to fig. 25, essentially consists, as the name implies, of a network of small blood-vessels, connected together by areolar substance. It is generally met with as a congenital affection, its foundation being laid during foetal life, and it is not uncommon for it to acquire a considerable bulk before birth. Most gene-

rally, however, it is quite diminutive when the child is born, and it often

Fig. 25.

Vascular tumor of the scalp.

continues so until some time after, when, perhaps, all of a sudden, and without any assignable cause, it takes a new start, growing with remarkable rapidity. The ordinary sites of the vascular tumor are the head, face, and mucous membranes, especially that of the rectum, where it often presents itself in the form of what is called an internal pile. Their color ranges from a deep rose to scarlet or purple. They are of a soft, spongy consistence, and vary in size from that of a mustard seed to that of a foetal head.

The vascular tumor exhibits considerable variety of structure; being sometimes essentially composed of veins, sometimes of arteries, and sometimes, again, of both arteries and veins together, so equally balanced, in number and caliber, as to render it difficult to determine which predominate. When the tumor is of an arterial character it generally pulsates syn-

chronously with the left ventricle of the heart, and constitutes a real erectile growth, similar to that of the cavernous body of the penis. As these formations will claim special attention in the chapter on the diseases of the vascular system, no further notice of them will here be necessary.

3. FATTY TUMORS.

The fatty tumor is quite common. It may occur in any part of the body, with the exception, perhaps, of the palm of the hand, the sole of the foot, fingers, and toes. It is seen, however, more frequently about the back, shoulder, and neck, than in any other regions. The upper eyelid is also a common seat of it. Sometimes, but more rarely, it occurs in the orbit of the eye, in the walls of the abdomen, in the perineum, the labium, and underneath the tongue, and even in the substance of this organ. Large masses of this kind occasionally form in the internal cavities of the body, as in the omentum and mesentery, and around the kidneys.

The number of fatty tumors varies, in different cases, from one to several hundred. In general, they are solitary, or, at most, there are only two or three, occupying different regions of the body, or grouped more or less closely together. In a medical gentleman, aged thirty-eight, who attended my lectures some years ago, I counted upwards of two hundred, from the volume of a small pea up to that of a large marble. They all had a doughy, inelastic feel, and most of them were of a globular shape; a few were slightly flattened, or compressed. They were situated principally on the forearms, the inside of the thighs, the loins, abdomen, and pectoral muscles, the latter of which were literally covered with them. None existed on the head, neck, and upper part of the back. The general health was good, and the tumors had been first observed about sixteen years previously. During two severe attacks of acute disease, accompanied with great emaciation, many

of them entirely disappeared. To satisfy myself of the true nature of these tumors, I was permitted to remove one, about the size of a filbert, which proved to be composed entirely of fatty matter.

In their volume, these tumors vary from that of a small pea to that of an adult head. Sometimes, indeed, they are much larger, measuring many inches in diameter, and projecting a great distance beyond the surface. Professor Leidy presented to me, a short time since, a section of a fatty tumor which weighed upwards of seventy pounds; it had been developed in the abdomen of an elderly person, and contained large masses of bony matter. Dr. Bray, of Evansville, Indiana, some years ago, extirpated a fatty tumor which weighed nearly forty pounds. The patient made a good recovery.

In their shape, fatty tumors are generally somewhat globular, with a lobulated surface; but as they augment in volume they are liable to become elongated, and to assume a pyriform, gourd-like, or pediculated configuration. These changes, which are well represented in fig. 26, no doubt depend upon their weight, by which they are gradually dragged out of their original shape, as well as position. For the same reason they sometimes shift their seat, descending from the point where they originally appeared to one below it, perhaps several inches distant. Thus, a fatty tumor developed in the groin, has been known, in time, to pass down between the scrotum and the thigh. This migratory tendency, which is interesting as a matter of diagnosis, is most common in those parts of the body which are abundantly supplied with loose cellular substance, and in those cases in which the tumor has a large bulk and a pediculated attachment.

Fatty tumors are always invested with a capsule, by which they are connected with the surrounding structures, and through which they obtain their vessels, nerves, and absorbents. This covering is not a new formation, produced by inflammatory action, but is the result simply of a condensation of the circumjacent cellular substance; hence it varies very much in its appearance in different cases and in different circumstances. In the early stage of the affection, and especially when the tumor is diminutive, it is, in general, very thin, soft, elastic, and transparent; but in cases of long standing and large size, it is always more or less dense, firm, resisting, and of a fibro-cellular, or distinctly fibrous texture. Its thickness ranges between a mere film and a layer of a line or more in depth. External pressure, especially if long continued, and the pressure also of one part of the tumor upon another part, no doubt exert an important influence upon the anatomical character of this investiture, serving to adapt it to the varying circumstances of the shape and bulk of the morbid growth. The adhesion of the capsule to the skin is sometimes remarkably close, requiring great care in separating it.

Attached to the inner surface of this covering are numerous processes,

Fig. 26.

Fatty tumor.

which dip into the interior of the morbid growth, separating it into lobes, lobules, and granules, until the component tissues are resolved into their ultimate elements. These processes are usually very delicate; but occasionally, as when there is a hypertrophous condition of the fibro-cellular substance, they are quite dense and tough, forming distinct bands, of a whitish or grayish color, between the different structures.

Fatty tumors do not receive much blood, at least not as a general rule; hence they seldom bleed much when they are extirpated. It is only when they are of large size, or when they grow very rapidly, that they are likely to be very vascular. The capsule and its processes serve to conduct the vessels into the interior of the tumor, and to direct, as it were, the distribution of their branches and ramifications. As the morbid mass is always free from pain, and is tolerant of the rudest manipulation, it may be concluded that it receives very few nerves. Its absorbent vessels are also few in number. It may, furthermore, be inferred that, inasmuch as the general health is usually unimpaired throughout the whole progress of the affection, however long it may continue, it does not possess any important sympathetic relations with the general economy.

The minute structure of this form of tumor is well displayed in fig. 27.

Fig. 27.

Minute structure of a fatty tumor.

It is made up of cells, exactly similar to those of natural fat, interspersed through areolar tissue, as seen in the larger drawing; the small figure *a* represents isolated cells, showing the crystalline nucleus of margaric acid. Various other substances, of an adventitious character, generally present themselves upon the field of the microscope, in the form of molecules, granules, and globules, especially in old fatty growths. It is upon these accidental occurrences that some pathologists have attempted to found certain subdivisions of the fatty tumor, which, while they are of doubtful histological propriety, are altogether destitute of practical value.

Fatty growths are most common in the subcutaneous cellular tissue, but they are not confined to this substance; for in many cases they send prolongations around the muscles, tendons, fasciæ, vessels, and other structures. Thus a fatty tumor of the neck has been known to extend deeply between the trachea and œsophagus, or to dip in between the carotid artery and jugular vein, or to pass down behind the sternum and clavicle into the chest. A fatty growth of the wall of the abdomen sometimes extends into the cavity of that name; and, on the other hand, such a tumor occasionally begins in the subperitoneal cellular tissue, and ultimately descends through the inguinal canal, or some abnormal outlet, down into the scrotum, thus simulating hernia of the groin. It must be obvious that all such arrangements, which, however, are fortunately rare, must greatly embarrass both our diagnosis and our attempts to remove the morbid mass.

Fatty tumors are soft, doughy, and semi-elastic; properties which, in general, enable the surgeon readily to distinguish them from other morbid growths. Their boundaries are usually well defined, especially when they are superficial or pediculated. Sometimes, however, they are insensibly lost in the surrounding parts, being spread out beneath the skin, and sending processes among the muscles, or their fasciculi. In many cases they have an irregular, lobulated surface; while in other cases, and perhaps in the majority, they are perfectly smooth and uniform. There is no enlargement of the subcutaneous veins, no disease of the skin, no pain, and no tenderness

on pressure. The progress of the tumor is, in fact, quite indolent; the only inconvenience which the patient experiences being caused by its weight and bulk. The general health is usually perfect. These circumstances, with a careful consideration of the history of each case, will commonly serve to distinguish fatty tumors from other morbid growths, whether benign or malignant in their character.

Fatty tumors are liable to inflammation, suppuration, ulceration, and gangrene. These events, however, are very infrequent, and are usually induced by mechanical pressure, by caustic applications, and by inefficient nourishment, in consequence of a loss of their vascular and nervous supply from the pendulous or overgrown character of the morbid mass. In a tumor of this kind, about the volume of an orange, which I removed many years ago from the top of the left shoulder of a girl of eighteen, the ulcer had a remarkably foul, unhealthy aspect, with thin, everted edges; the pain was at times quite severe, and the discharge was of a sanious nature, intermixed with globules of fat. Various attempts had been made, but without success, to heal it up, and no cause could be assigned for its formation. The general health had been a good deal impaired, and for some time past there had been irregularity of the menstrual function. The ulcer was included in the incisions, and a speedy recovery was the result.

When the fatty tumor becomes inflamed, it may suppurate, the pus occurring either as an infiltration or as a distinct abscess. Occasionally it serves as a nidus for the deposit of osseous matter, as in the case already referred to.

Again, such tumors now and then undergo a sort of fibrous or cartilaginous degeneration, not uniformly, but at certain points of their extent. Nodules, varying in size from a hazel-nut to a pullet's egg, may thus be formed, having a firm, characteristic consistence, more or less movable, and contrasting singularly with the other structures. Finally, they occasionally contain cysts filled with various kinds of substances, as oily, serous, or gelatinous. The walls of the cysts may be very thin and transparent, or thick, opaque, and perhaps even partially calcified.

It is not easy to determine how fatty tumors are developed. The difficulty which surrounds the subject is not cleared up by assuming that they are merely hypertrophies of the natural adipose tissue. This is doubtless the fact; but we cannot explain why such an occurrence should take place at one point rather than at another, or why, indeed, it should happen at all. The exciting cause of the morbid growth has sometimes been traced to external injury, as a blow, contusion, or steady mechanical compression; but in the generality of cases no reason whatever can be assigned for its production.

Both sexes are liable to this formation, but whether in an equal degree or not, is not ascertained. It is most common in young adults and middle-aged persons.

The medical treatment of this class of morbid growths is most unsatisfactory; for there is no remedy of which we have any knowledge that is capable of arresting its progress, or causing its removal. If the reverse is occasionally the case, it serves only as an exception to the rule, and nothing else. The instance of Mr. Brodie, in which he succeeded in removing a large mass of fat from a man's chin and neck, by the free and persistent use of the solution of potassa, may be regarded as a remarkable example of unexpected success. He commenced with half a drachm of the fluid three times a day, and gradually increased the dose to a drachm. At the end of a month there was a sensible diminution in the volume of the tumor, which steadily continued as long as the medicine was persevered in. Some time afterwards Mr. Brodie substituted the tincture of iodine, which had just then come into use, but the tumor again increased. Finding this to be the case, the alkali was resumed and continued, off and on, until the tumor was almost entirely

dispersed. Altogether, the man took an enormous quantity of the medicine. I am not aware that the same happy effects have been realized from this remedy by other practitioners.

All local applications are equally unavailing. This is true alike of steady and systematic compression, of mercurial and other inunctions, and of frictions with stimulating liniments and embrocations. The absorbent vessels in these tumors are few and feeble, and this is probably the reason why all remedies of this description are so utterly valueless as curative agents.

The manner of excising such tumors is generally sufficiently simple. Any diseased skin that may exist should be removed along with the morbid mass, which should be enucleated by a rapid dissection, care being taken that not a particle of the deposit is left behind; otherwise reproduction may take place. When the tumor is superficial the operation is easily performed and soon over; but when it is deep-seated, or when it sends processes among the

surrounding structures, it may be one of great difficulty and perplexity, requiring the most consummate skill for its successful execution, and the most thorough knowledge of the anatomy of the parts. For the reasons already mentioned, the operation is sometimes nearly bloodless. I have, indeed, seldom found it necessary to apply more than two or three ligatures, whatever may have been the volume of the tumor.

Fig. 28.

Horny excrescence growing from the scalp.

4. HORNY TUMORS.

The skin is occasionally the seat of a very curious growth, known as the horn-like excrescence, from its resemblance to the horn of the sheep and goat. A more appropriate name would be the horny tumor. It is met with principally in those parts of the body which abound in sebaceous follicles, as the face and forehead. In seventy-one cases collected by Ville-neuve, the tumor in twenty-six was seated on the scalp, in five on the nose, in two on the cheek, in one on the lower jaw, in four on the chest, in four on the back, in three on the anus and penis, in four on the buttocks, in twelve on the thigh,

in two on the knee, in two on the ham, in one on the leg, and in three on the foot. In the cases that have come under my own observation, it was seated on the lower lip, the ear, and the chin; others have met with it on the scrotum and hand. It appears to occur with nearly equal frequency in both sexes, and it occasionally begins at a very early period of life, although

in the great majority of instances it does not come on until after the age of forty. In two cases I have seen small but well-marked growths of this kind in children under ten years of age. Several such excrescences are sometimes observed in the same person.

The size, shape, color, and consistence of the horny tumor are subject to much diversity, depending upon its age, and other circumstances. A length of from three to six inches by half an inch to an inch in diameter, as in fig. 28, is by no means uncommon. In the British Museum there is said to be a growth of this description, eleven inches in length by two and a half in circumference; and examples of a still more remarkable nature have been reported by authors. In that curious book, *An Essay for the Recording of Illustrious Providences*, by Increase Mather, are briefly mentioned the particulars of the case of a "man that has an horn growing out of one corner of his mouth, just like that of a sheep; from which he has cut seventeen inches, and is forced to keep it tied by a string to his ear, to prevent its growing up to his eye."

The shape of these excrescences is usually conical, being larger at their adherent than at their free extremity, which is always somewhat tapering, and their direction is either spiral, twisted, or bent, so as, in the main, to bear a striking resemblance to that of the horn of a sheep. In a case recorded in the *New York Medical Repository* for 1820, an enormous growth of this kind, measuring fourteen inches in circumference at its shaft, is stated to have consisted of three branches. The surface is generally marked by rough circular rings, indicative of the successive steps of their development. Now and then it is imbricated, knobbed, or covered with small pearl-colored scales. In color they vary from a dingy yellow to a dark grayish, brown, or black, according to their age, and the amount of their exposure. They are more or less flexible, and of a firm, fibro-cartilaginous consistence. Their internal arrangement, as seen on a section, is longitudinally lamellated, as in fig. 29.

When burned, these excrescences exhale a characteristic animal odor. They are chiefly composed of albumen, in union with a small quantity of mucus, phosphate of lime, and choride of sodium, with a trace of lactate of soda. On the addition of acetic acid, numerous epidermic scales become apparent, possessing all the characteristic properties of such structures. Under the microscope, the minute texture of these growths exhibits epithelial cells, which, according to Erasmus Wilson, are of a flattened shape, closely condensed, and, here and there, fibrous in their arrangement. They are somewhat larger than those of the epidermis, and possess nuclei, for the most part of an oval shape, their long diameter measuring $\frac{1}{2600}$, the short $\frac{1}{3300}$ of an inch. The average size of the flattened cells is about five times greater than that of the nuclei.

Human horns are generally, if not invariably, connected with the sebaceous follicles, in which they probably take their rise. Their development is frequently directly traceable to the effects of chronic inflammation, or external injury, as a burn, wound, or contusion. When first observed, they are quite soft, semi-transparent, and invested by a distinct cyst, which, extending over their base, is gradually and insensibly lost upon their trunk. Very soon, however, they become hard, and, assuming a darker hue, thus acquire the real properties of the horny tissue as it exists in the inferior animals. Their growth is always very slow, from three to five years elapsing before they attain any considerable bulk.

Fig. 29.

A section of a horn showing its lamellated structure.

Although these excrescences sometimes drop off spontaneously, a cure rarely, if ever, follows such an event; for, as the matrix remains, it soon becomes the starting-point of a new growth, which, pursuing the same course as its predecessor, may, in time, acquire a similar, or even a greater, bulk. The proper remedy is extirpation, performed in such a manner as to include the whole of the epigenic cyst in two elliptical incisions, the edges of which are afterwards carefully approximated by suture and adhesive strips. It has been suggested that we might get rid of these bodies by softening and dissolving them with alkalies and water-dressings; and then, after they have dropped off, to prevent their reproduction by touching the matral cyst freely and repeatedly with nitrate of silver, with a view of preventing the tendency to abnormal cell-formation. Such a procedure, however, besides being tedious, must be very uncertain, and is, I imagine, altogether more disfiguring in the end than excision.

5. FIBROUS TUMORS.

The fibrous tumor owes its name to the peculiarity of its structure, which strongly resembles the fibrous tissue in the normal state. One of the best specimens of this variety of morbid growth is to be found in the uterus of elderly females, where it sometimes attains a weight and magnitude equal to those of the body of the patient. It also occurs in the cellular tissue, both subcutaneous and intermuscular, in the testicle, the ovary, and other parts of the body. My cabinet contains a large fibrous tumor, weighing nearly five pounds, which I removed from the interior of the scrotum of a young man of twenty-five, but which had no connection whatever with the testicle. A remarkable fibrous tumor is sometimes seen growing pendulously from the lobe of the ear. Keloid formations of the skin obviously belong to the present class of morbid products, although they usually contain an inordinate quantity of plastic material. Fibrous growths occasionally occur in the interior of the joints, especially the elbow and knee, in the latter of which they sometimes attain the volume of a pullet's egg. The dura mater, periosteum, and fibrous envelopes of the muscles are all liable to their formation, although the occurrence is unusual. Finally, fibrous tumors are often met with in the neck, either just beneath the skin or deep among the muscles and lymphatic ganglions.

The fibrous tumor, although of slow growth, may, in time, acquire an enormous bulk, as is exemplified in the immense masses which we occasionally find in the neck, the uterus, and some other parts of the body. It feels heavy and incompressible, is globular, ovoidal, or pyriform in shape, and has generally a smooth, even surface, although cases not unfrequently occur where it is remarkably lobulated, or marked by numerous elevations and depressions. In the uterus and the joints it is often attached by a narrow neck, but almost everywhere else it is in immediate contact, on all sides, with the structures in which it is developed, its adhesions being effected solely by cellular tissue. Generally solitary, it occasionally occurs in considerable numbers, more particularly in the uterus, where there are sometimes from six to a dozen in the same specimen.

The structure of the fibrous tumor is characteristic. As its name indicates, it is composed of fibrous matter, the filaments of which cross each other in every conceivable manner, forming thus an intricate network, which the most careful dissection fails to unravel. These filaments are of variable size and shape, and are so intimately compacted together as to constitute a dense, firm, inelastic substance, so characteristic of this kind of product. It is only in rare cases that their passage across each other leaves any interspaces for the lodgment of fluid or solid matter. They are of a grayish or pale drab

color after maceration, but in their natural state they are rosaceous, reddish, or even purple, their complexion depending upon the amount of blood they contain. Occasionally they have a silvery, glistening appearance.

The fibrous tumor has seldom any distinct capsule; the tissues around it are, it is true, usually a good deal condensed and thickened, but the covering thus derived is altogether adventitious and secondary, forming none of the essential elements of its growth. Few vessels can be traced into its substance, and these are rarely of any considerable size; a circumstance the more surprising when it is recollected what immense bulk it sometimes acquires. No reliable chemical examination has yet been made of this variety of tumor, but it is probable that it consists essentially of gelatine, as this substance is largely furnished by protracted boiling. Under the microscope it exhibits nucleated cells, sometimes in great numbers, of an oval, rounded, or elongated form, which are always rendered very conspicuous if the part be previously treated with acetic acid, as in fig. 30.

Growths of this kind sometimes contain colloid matter, lodged in distinct cells in their interior; it possesses the ordinary physical and microscopical characters, and probably serves

to give additional impulse to the development of the tumor, which often increases with great rapidity, and thus soon acquires a large bulk.

The fibrous tumor seldom takes on malignant action, although it is not incapable of it. Its general tendency is gradually to increase, to impair function, and ultimately to wear out life by its secondary effects. The older formations of this kind nearly always contain adventitious deposits, especially the calcareous, which often exists in considerable quantity. The cartilaginous is also not uncommon. Sometimes large cavities, containing serosity, pus, and other substances, are found in them. Their progress is usually painless, except when they compress important parts, the inconvenience which they occasion being dependent mainly upon their weight and bulk.

There is a form of fibrous tumor to which the term *fibro-plastic* has recently been applied, as denotive of its peculiar composition. It is, in fact, merely a modification of the one just described, with a predominance of the plastic element, or, at all events, a very conspicuous exhibition of it. It is met with chiefly in certain pendulous growths of the ear, in elephantiasis, and in certain formations of the skin, especially in keloid. It is also found in the subcutaneous and intermuscular cellular tissue of the neck, trunk, and extremities. When cut, it grates under the knife, the surface exhibiting a pale yellowish, greenish, or bluish glistening basis-substance, intersected by whitish, opaque filaments. These filaments, which, by their interlacements, form the stroma of this variety of tumor, are generally disposed in wave-like lines, but in many specimens they are very irregular, and seem to observe no definite arrangement. The matter which occupies the cells of the stroma is

Fig. 30.

Microscopical characters of a fibrous tumor from the submaxillary region, from a drawing by Dr. Packard.—472 diameters.

very succulent, being pervaded by a peculiar fluid, of a yellowish, oily appearance, which gives the mass an infiltrated, anasarcaous condition.

The fibro-plastic tumor essentially consists of plastic matter, its development being effected from nucleated blastema, in the same manner as in ordinary lymph-growth. It occurs principally in young and middle aged subjects, and is usually more rapid in its march than the purely fibrous formation, into which it sometimes partially degenerates, its plastic material being supplanted by the fibrous.

The fibrous tumor, as already stated, sometimes takes on malignant action, its tissues serving as a nidus for the deposition of carcinomatous matter. It is impossible to determine what are the circumstances which predispose to, or influence, such an occurrence; but there can be no doubt that it is governed by the same laws as those which preside over the development of cancer in the primitive structures generally, and that the change does not consist merely in a degeneration, properly so termed, of the fibrous substance, but of an entirely new formation. What has recently been described as the *recurring fibroid tumor* is probably originally of a malignant nature, but does not show its real character until it is called into play by some disturbing agency, either local or constitutional, or, perhaps, both. At all events, this morbid growth often remains for a long time in a state of latency, when, it may be all of a sudden, it assumes an extraordinary degree of activity, and soon exhibits the worst malignant tendencies. Casual inspection of the fibroid tumor might lead to the supposition that it was of a fatty substance, so closely do its external properties resemble those of the adipose tissue; but a careful examination with the microscope soon dispels this illusion, and clearly proves that it is essentially composed of the fibrous element, with, now and then, a small quantity of oily or fatty ingredients. Its texture is sometimes remarkably lobulated, soft, and even brittle, the slightest traction separating it into numerous fragments; it often sends out small processes, which, extending far among the surrounding structures, are apt to be left behind during extirpation, unless great care is used in tracing them out. In its color it varies from drab or grayish to white or pale yellowish. A very common site of this tumor is the superior maxillary sinus; it is also not unfrequently seen upon the face, especially at the side of the nose, taking its rise, apparently, in the periosteum of the upper jaw.

The diagnosis of the fibrous tumor must mainly be deduced from its history, and its consistence. Its development, as a general rule, is tardy, there being a marked difference, in this respect, between it and the carcinomatous formations, even between it and scirrhus. Usually beginning in a little hard nodule, or lump, several years commonly elapse before it attains any considerable bulk, especially when it is developed among the external tissues; its progress is comparatively painless, the chief inconvenience occasioned by it being of a mechanical nature. The tumor feels hard, firm, and inelastic; it is more dense than encephaloid, but not as solid and dense as scirrhus. Its consistence is usually uniform; not hard at one point, and soft at another, but of the same character throughout. Its surface, too, is commonly smooth; and there is nearly always, unless the growth is very large, an absence of enlargement of the subcutaneous veins. In its earlier stages it is somewhat movable, except when it springs from the periosteum; but by degrees it contracts adhesions, and becomes firmly fixed in its position.

The fibrous tumor is rarely, in any of its forms, amenable to local or constitutional means. When it is favorably situated, pressure, steadily and systematically pursued, may sometimes be serviceable; but it is so seldom that this is the case that hardly any calculations of a curative character are to be based upon it. In the early stage of the development, before any great firmness and density of structure have been attained, a mild course of mercury

may be tried, its constitutional impression being persistently yet most gently maintained for several successive months, or alternated with that of iodide of potassium, also an agent of some consequence in the softer forms of fibrous growths, although rarely of any benefit in those of maturer development. But the surest remedy, when the tumor is accessible, is excision, performed early and efficiently, by dissection and enucleation. Hemorrhage is usually slight, and recurrence impossible, unless, as sometimes happens, the morbid mass has become the nidus of carcinomatous deposit. As this cannot always be certainly predicted beforehand, the prognosis should not be too sanguine.

6. CARTILAGINOUS TUMORS.

The cartilaginous tumor, to which Müller has applied the term *enchondroma*, holds, histologically speaking, a position intermediate between the fibrous and osseous, being harder than the former and softer than the latter. Occurring in various parts of the body, as the ovary, testicle, mamma, and parotid gland, as well as in the inter-muscular cellular substance, it is most frequently found in connection with the skeleton, its most common sites being the metacarpal bones and the phalanges of the fingers. I have seen large and numerous growths of this kind form simultaneously upon both hands and both feet, causing hideous deformity and almost complete loss of function of the affected parts. Although it occasionally takes place in elderly subjects, yet it is by far most frequent in young persons, especially such as are of a weak, rickety constitution; and is often associated with a remarkably stunted state of the body. The annexed sketch, fig. 31, from a specimen in my possession, conveys a good idea of the external characters of a cartilaginous tumor as it occurred upon one of the fingers.

The structure of this variety of tumor is subject to great diversity; hence it is rarely found to be of a uniformly cartilaginous character, but, in most cases, its substance is intermixed with fibrous and fibro-plastic matter, if not also with more or less of osseous, or calcareous, especially when the growth is of long standing; not unfrequently it contains large cysts filled with various kinds of substances, either solid or fluid. To the hand it generally imparts the sensation of unusual firmness and solidity; it is destitute of elasticity, is generally distinctly circumscribed, and is nearly always strongly adherent to the structures from which it springs. Its surface is sometimes smooth, but more commonly it is lobulated, or marked by irregular prominences and depressions. No pain usually exists, or, if suffering is present, it is owing rather to the pressure which the tumor exerts upon the neighboring parts than to any disorder of its own sensibility.

Ordinarily the consistence of this tumor ranges from that of the vitreous humor, or solid albumen, to that of cartilage, different sections of it often exhibiting, as just stated, different degrees of firmness. In general, the mass is easily cut with the knife, the instrument

Fig. 31.

Enchondromatous tumor: external view.

Fig. 32.

Minute structure of enchondroma.

sometimes causing a creaking noise. It is of a whitish, grayish, or bluish aspect, and is characterized by a peculiar linear arrangement. Under the microscope it presents numerous cells, as in fig. 32, of an oval or rounded shape, from the $\frac{1}{700}$ to $\frac{1}{1500}$ of an inch in diameter, loosely imbedded in an intercellular hyaline substance, and containing each one or more nuclei and nucleoli. In the older growths, some of the nuclei and nucleoli are shrivelled, others are filled with oil granules, while others, again, are marked by projections similar to those of cartilage in process of ossification.

Chemistry has shown that this tumor is mainly composed of chondrine, a peculiar form of gelatine, in union with phosphate of lime. The animal matter is readily extracted by boiling, and differs from ordinary gelatine chiefly in being precipitated by some of the salts of lead, alum, and iron.

The cartilaginous tumor is sometimes enveloped by a distinct cyst, composed of condensed cellular substance; at other times, it is entirely destitute of such a covering, especially when it originates in the interior of the organs. Its vascularity is often very great, a circumstance which readily explains the astonishing rapidity which occasionally marks its growth, cases having been observed in which, in the course of a few months, it attained the bulk of an adult's head, or even of the chest of the patient. Such an occurrence, however, is extremely uncommon; for, in general, the progress of the cartilaginous tumor is singularly tardy, although it may, in time, acquire an extraordinary volume.

The progress of the cartilaginous growth is variable; in general, it is painless and indolent, causing little or no inconvenience, save what results from its weight and pressure; sometimes, however, it inflames and ulcerates, and in this way a large cavity is occasionally formed, attended with copious discharge and excessive constitutional disturbance, rapidly followed by hectic fever. Portions of such tumors sometimes, as already stated, undergo various transformations, as the cystic, fatty, and calcareous. It is also probable that it may occasionally become the seat of carcinoma, resembling, in this respect, some of the other benign formations. The only remedy for this tumor is early and efficient extirpation. When it is closely connected with bone, amputation will generally be required.

7. OSSEOUS TUMORS.

Osseous tumors, usually known by the name of exostoses, are mostly found in connection with the skeleton, especially the skull and thigh-bone, presenting themselves in various forms and sizes, from that of a pea up to that of a foetal head; hard and compact, like the normal bone, which they closely resemble in structure and composition; slow and painless in their progress; never degenerating into malignant disease; unamenable to ordinary medication; and requiring removal only when they seriously interfere with the exercise of important functions. The exciting cause of this class of tumors is not well understood; occasionally their development may be traced directly to external injury, but in general no reason whatever can be assigned for it. Commencing usually upon the outer surface of the bone, beneath the periosteum, their foundation is sometimes laid in the periosteum itself, the connection with the primitive bone being, perhaps, originally of a cartilaginous character. The osseous tumor is most common in persons after the meridian of life, and occasionally occurs in large numbers, depending apparently upon the existence of a real exostotic diathesis.

8. CALCAREOUS TUMORS.

The calcareous tumor is very uncommon, and is generally the result of a degeneration of a lymphatic ganglion, nearly always one of the neck, in the vicinity of the lower jaw. The gland having perhaps been for a long time enlarged and indurated, usually from a deposit of tubercular matter, gradually diminishes in size, and is finally transformed into a hard, firm substance, resembling baked earth. It has none of the properties of genuine bone, and consists almost entirely of carbonate and phosphate of lime, cemented together by a minute quantity of animal matter. It is usually of small size, of a spherical form, and surrounded by an imperfectly constructed capsule. As it is not amenable to absorption, the proper remedy is excision, performed whenever it is found that the little tumor is in the way of comfort, or good looks.

Calcareous deposits are sometimes found in other structures, as fibrous tumors of the uterus, the vaginal tunic of the testicle, the bronchial lymphatic glands, and the pulmonary tissues; but as they do not interest the surgeon they may well be passed over here.

9. NEUROMATOUS TUMORS.

The nerves of animal life, especially the radial, ulnar, median, tibial, and peroneal, are subject to two forms of tumors, or morbid developments, known, respectively, as the neuromatous growth and the painful tubercle, although their structural differences are not always very well defined. The latter of these affections, incidentally noticed by Petit, Cheselden, and other observers, was first accurately described by Mr. William Wood, of England, in 1812. The neuromatous tumor, properly so denominated, has been particularly studied and delineated by Mr. Robert W. Smith, of Dublin, who published a splendid monograph on the subject in 1849.

The neuromatous tumor may be solitary, or there may be a considerable number, varying in size from that of a pea to that of an almond, an egg, or even an adult head. It is solid to the touch, firm, inelastic, and of an oblong, ovoidal, or irregularly compressed form. When small, it has generally a distinct cyst, of a cellulo-fibrous structure, filled with a transparent jelly-like substance, and developed within the neurilemma of the affected nerve, the filaments of which are separated from each other, and spread out over the surface of the tumor. In cases of long standing, or when the tumor has acquired an unusual bulk, the morbid mass is remarkably dense, white, or nearly so, homogeneous, and destitute of a cyst, properly so called.

The neuromatous tumor occurs in both sexes, and at various periods of life, though it is most common in males and in middle age. Its progress is usually slow, and it seldom attains any great volume. The exciting causes are generally very obscure, but in some cases it is plainly traceable to the effects of external injury, as a wound, blow, or bruise. Occasionally it follows upon amputation, the nerves of the stump becoming enlarged and bulbous. The pain which attends this disease is very variable, both in degree and character. In most cases it is of a neuralgic nature, exceedingly severe, sharp, darting, pungent, or stinging, and liable to periodical exacerbations, dependent apparently upon atmospheric vicissitudes, and disorder of the digestive functions. The slightest pressure, friction, or manipulation causes an increase of suffering, which, under such circumstances, not unfrequently amounts to great agony. The parts beyond the tumor, especially those supplied by the affected nerve, are cold, numb, and almost powerless. The pain is sometimes seated in the neighborhood of the tumor rather than in the tumor itself; and occasionally,

again, though this is rare, there is an entire absence of local distress. The general health may remain good, but in the great majority of instances it is

more or less impaired; and the system, constantly tortured by the excessive suffering, is gradually reduced to the utmost prostration.

The accompanying sketch, fig. 33, affords an excellent illustration of the anatomical characters of a neuromatous tumor of the leg, situated along the course of the peroneal nerve. It had existed for nearly twenty years, during the last three of which it had been exquisitely tender and painful. The extirpation was effected by Dr. Dalton and Dr. Hoffman, of Ohio, who were kind enough to send me the specimen. The operation was followed

Section of a neuromatous tumor, with the nerve passing to and from it.

Microscopic structure of a neuromatous tumor.

by sloughing of the fourth and fifth toes.

A large quantity of fibrous matter enters into the composition of the neuromatous tumor, forming a stroma interspersed with granules and corpuscles, as seen in fig. 34.

The only effectual *treatment* is excision. As long, however, as the tumor is painless, or causes no inconvenience by its size or situation, the best plan is to let it alone. When the reverse is the case it is our duty to extirpate it. The operation is usually quite simple, and devoid of danger. In general, an attempt should be made to enucleate the tumor, by pushing aside the nervous filaments

which are spread out over its surface, and which may thus occasionally be preserved from harm. When this is impracticable, from the manner in which the parts are fused together, the morbid mass should be exposed by a free incision, and lifted out of its bed by dividing the affected nerve immediately above and below, over a grooved director. The loss of motion, occasioned by this proceeding, even when it involves a comparatively large nerve, is usually restored in a very short time. Indeed, the chief inconvenience to which it gives rise is a sensation of coldness in the distal part of the limb, which may, however, remain for years. Amputation has been resorted to for the cure of this complaint; but it is difficult to conceive of a case where it would really be necessary.

The painful subcutaneous *tubercle*, seen in fig. 35, is generally situated, as

the name implies, just beneath the skin, in the areolar tissue, where it is usually connected with one or more very delicate nervous filaments, slightly enlarged, and surrounded by cellulo-fibrous, fibrous, or fibro-cartilaginous

Fig. 35.

Painful subcutaneous tubercle.

matter, freely interspersed with corpuscles, as seen in fig. 36. On being cut out, it looks very much like a small mass of adipose substance. Few vessels can be discerned in it. It is always remarkably small, seldom exceeding the volume of a pea; very movable; exquisitely tender to the touch; and the seat of frequent pain, often of a neuralgic character, and subject to constant exacerbations from the most trifling causes. It is said to be most common in the lower extremities, but this does not accord with my experience, most of the cases that have come under my observation having occurred in the arm, forearm, and shoulder.

The painful tubercle is generally single, or, if multiple, it is seldom that we see more than two or three in the same person. It occurs in both sexes, but much more frequently in women than in men, the reverse being the case in regard to the neuromatous tumor. Its development is usually tardy, and several years often elapse before it becomes very tender and painful. Women of a nervous, hysterical temperament appear to be most prone to its occurrence. During its development it always involves the skin.

The situation of this tumor just beneath the skin, or in the skin and areolar tissue, the absence of discoloration of the surface, the peculiar character of the pain, the intolerance of manipulation, and the history of the case, will generally suffice to determine the diagnosis.

The only remedy for this affection is free excision, including a small portion of the surrounding healthy integument. The disease never returns at the cicatrice, although it may occur afterwards in other parts of the body.

Fig. 36.

Microscopic structure of the subcutaneous tubercle.

10. ENCYSTED TUMORS.

The class of encysted tumors is a large and important one; for it comprises quite a number of morbid products, which, whether they be viewed with

reference to the frequency of their occurrence, or the extraordinary bulk they are capable of attaining, deserve more than ordinary attention. Their contents, which are of a singularly diversified character, may be either solid, semi-solid, or liquid. Their structure is sometimes very simple; at other times extremely complex. Hence the division of encysted tumors into simple and compound. In regard to their origin, some are of new formation, but many, if not most, are merely so many alterations effected in the primitive structures; in fact, merely so many hypertrophies. Occurring in nearly every organ and tissue of the body, they are particularly liable to show themselves in the skin and mucous membranes, the glandular organs, as the breast, testicle, liver, and thyroid body, in the ovaries, and in the subcutaneous cellular substance. While no period of life is exempt from them, they are most common between the ages of twenty and forty-five, especially in females, who are also more subject to them than males, and in whom they occasionally attain an enormous volume.

In respect to their structure, some of these tumors are of the most simple character possible, consisting merely of a thin cyst, sac, or capsule, occupied by the natural secretion of the part, more or less altered by its protracted retention. An excellent type of this variety of morbid product is afforded by the sebaceous tumor, which is, in reality, nothing more than a sebaceous follicle of the skin, in a state of hypertrophy from the occlusion of its orifice, and the consequent retention of the sebaceous matter. The immediate cause of the obstruction is inflammation, producing adhesion of the opposite edges of the outlet of the follicle, and thus constituting the first link in the chain of morbid action. The second is the retention of the normal secretion of the follicle, which, being tightly pent up, undergoes important changes, both in its physical and chemical properties, leading to irritation, and sometimes even to inflammation of the sac, which, gradually enlarging before the accumulating and burdensome mass, at length forms a tumor perhaps as large as a medium-sized orange. The little encysted tumor which we sometimes find upon the lower lip and upon the vulva arises in a similar manner. The probability is that ranula owes its origin to a similar circumstance. Certain encysted tumors beneath the skin, containing serum, blood, or solid matter, are produced by the occlusion of one of the cells of the cellular tissue, the walls of the affected cavity forming a characteristic cyst. Obstruction of a lactiferous duct has been known to produce the encysted milk tumor of the breast. In all these instances, as well as in many others that might be adduced, we perceive that the mode of formation is extremely simple, obstruction of the natural outlet of the part, and the retention of its proper secretion being the exciting cause of the disease.

Sometimes the cysts which form the distinguishing feature of this variety of morbid product are an entirely new growth, and then it is not always easy to explain their origin. The cysts which are found in cystic sarcoma of the testicle have been supposed to owe their development to obstruction of the seminiferous tubes, but I question whether such a mode of explanation is at all tenable. In the few cases in which I have had an opportunity of examining these tumors, I have been led to conclude that their origin was altogether foreign to the canalicular structure of the organ. It is certain that hundreds, and sometimes thousands, of cysts are formed in the testicle long after its seminal tubes are apparently completely annihilated, as is proved by the large size which such tumors often attain, and by the total absence of the primitive structures. The more plausible conjecture is that the development is effected in the plastic matter which accompanies the morbid action, in the same manner that cells are formed in the original tissues. The cysts found in osteo-sarcomatous formations of the lower jaw have probably a similar origin.

The contents of this form of encysted tumor must necessarily vary, as may be gathered from what precedes, according to the structure and functions of the affected part. Thus, in the mamma the tumor contains milk, in ranula saliva, and in a sebaceous formation sebaceous matter; altered, in every instance, in its physical and chemical properties, by the action of the inclosing cyst. The cyst itself is always solitary, and generally composed of a single layer, its external surface, which is rough and flocculent, being adherent more or less firmly to the surrounding tissues, while the internal one is usually smooth, shining, or glossy, without septa, and in immediate but loose contact with the proper contents of the tumor. It is usually of a cellulo-fibrous structure, and varies in thickness from the merest film up to that of a stratum several lines in depth. In cases of long standing we find it occasionally partially converted into a substance resembling fibro-cartilage, cartilage, bone, or earthy matter.

A cyst is said to be *multilocular*, or compound, when it consists of a number of compartments, cells, or cavities, or, to use a familiar expression, rooms, or chambers. This arrangement is brought about by the existence of membranous processes, which are attached to the inner surface of the parent cyst, from which they branch out so as to intersect each other in different directions. It might be very easily imitated by sewing pieces of linen across a common bag, separating the main cavity into a number of small ones. The chambers sometimes communicate with each other; at other times they are perfectly closed at every point. What is very remarkable, is that they frequently contain different kinds of products; one, perhaps, a serous fluid, another a jelly-like substance, another blood, and, finally, a fourth, perhaps, a solid material. In general, the older the cyst is the more likely will it be to contain some *outré* substance. The walls of these sacs are generally very thick, and of a dense fibrous structure, with a tendency to the fibro-cartilaginous degeneration. The septa, or internal partitions, are of a similar character. Numerous vessels occur in them, thus enabling us to explain the rapid growth and large bulk which these tumors occasionally attain.

The most common situation of this tumor is the ovary; it is also found in the mammary gland, the thyroid body, the testicle, and the cellular tissue. It is of irregular shape, and often grows with great rapidity.

Encysted tumors are seldom benefited by constitutional medication; indeed, apparently never, except in so far as it may have a tendency to improve the general health, and thus retard their development. Their contents do not seem to be amenable to the action of the absorbents. When situated superficially and of small size, they are sometimes benefited, though seldom cured, by compression, aided by sorbefacient applications, particularly the dilute tincture of iodine. A more certain plan is to break the cysts or incise them subcutaneously, so that, their contents having escaped into the surrounding cellular substance, their walls may collapse, and ultimately unite by adhesive inflammation. When the tumor, however, is deep-seated, sometimes iodine injections may be advantageously employed, the operation being performed in the same manner as in hydrocele of the vaginal tunic of the testicle. A seton, too, is an eligible procedure. When the cysts are large or numerous, and, above all, when the primitive textures are, in great measure, if not entirely, annihilated, the only course likely to succeed is excision of the entire mass, care being taken not to leave the slightest remnant, otherwise reproduction will be certain to occur. Too much stress cannot be laid upon this injunction. For want of this precaution, I have known a patient obliged to submit to not less than three distinct operations for the cure of a tumor originally not larger than a pigeon's egg, and which ought to have been effectually removed at one sitting. A secreting surface, hardly the size of a pin's head, is large enough to reawaken disease. The removal may some-

times be effected by enucleation; at other times, and more generally, a minute dissection is necessary. The proceeding need not be at all bloody, unless the tumor is seated among very vascular parts, or the knife is carried too far away from the encysted mass.

11. HYDATIC TUMORS.

Under this head I propose to describe a form of morbid growth, essentially dependent upon the development of a cyst, inclosing an entozoon, vesicular worm, or parasite, denominated a hydatid. It is, as will be perceived, altogether different from the other varieties of cystic tumors, and therefore requires separate consideration. The term hydatid is a generic one, including several species of vesicular worms, of which the most important, surgically considered, is the *acephalocyst*.

This hydatid most commonly infests the liver, ovary, and uterus, but is also met with, although very rarely, in the mamma, testicle, bones, and serous cavities. I have a beautiful specimen which I removed from the deltoid muscle. Varying in volume between a mustard seed and a small orange, it is of a globular figure, of a whitish, semi-opaque appearance, and composed of a vesicle, or bladder, filled with serous fluid, and surrounded by a cellulo-

Fig. 37.

Hydatids inclosed in a common cyst.

fibrous capsule, which thus isolates, and protects it from the circumjacent structures. It is usually gregarious, numbers of them inhabiting a common cyst, as seen in fig. 37; sometimes, however, there is only a solitary one, which is then commonly proportionably large. The contents of the animal are of a clear liquid character, remarkably saline to the taste, but destitute of odor and coagulability. The inclosing cyst is of a fibrous, or cellulo-fibrous structure, more or less vascular, and possessed of considerable strength.

It is evidently a kind of adventitious membrane formed from plastic matter. Between this cyst and the parasite is commonly interposed a soft, pulpy, dirty-looking substance, the precise nature and object of which are not known. In consequence of their peculiar mode of generation, a large hydatid is sometimes found to contain several smaller, one within the other, like so many pill-boxes.

Although the hydatid itself consists of two distinct layers, it is generally so weak and delicate as to break under its own weight when removed from its inclosing cyst, shrinking into a soft, pulpy mass, not unlike the white of a hard-boiled egg, both in appearance and chemical composition. To the inner surface of the parasite are attached numerous little bodies, as in fig. 38, hardly as large as a grain of sand, of a spherical shape, and of a grayish color, each consisting of a delicate cyst, filled with echinococci. These animals, which derive their origin and support from the hydatid, soon separate themselves, acquiring thus a sort of independent existence, great num-

bers being often seen floating about in the parent liquor when they are yet hardly the two-hundredth part of an inch in diameter.

Fig. 38.

Cysts of echinococci.

Fig. 39.

Echinococci.

Each echinococcus consists of a body and a head, the latter being encircled by a row of teeth. The body, which is composed of solid, granular matter, has a curiously speckled appearance, owing to the presence of numerous ovoid bodies immediately beneath its outer coat. The teeth are spinous, sharp, hook-like, and perfectly characteristic. They are not easily decomposed, and are therefore capable of affording important diagnostic information. The various appearances here described are well illustrated in fig. 39.

Hydatids are usually short-lived, rarely lasting beyond a few years. Various causes may destroy them. Thus, some perish from suppuration, some from gangrene, some from the gradual drying up of their contents, and not a few from the pressure of their young. Under such circumstances, the inclosing cyst is often remarkably thickened, and even partially transformed into fibrous matter. I have seen cases where it had put on the appearance of the interior of an aneurismal sac. Great mischief, sooner or later, results from their presence, especially during the progress of their decay, nature often failing to eliminate them, and thus permitting them to excite violent irritation. A hydatid of the liver will occasionally induce fatal peritonitis, and the hardest structures, the osseous not excepted, are not always capable of withstanding its progress. A case has been reported of a parasite of this kind having perforated the scapula. In the lungs acephalocysts sometimes find their way into the bronchial tubes, from which they are afterwards ejected by expectoration.

There are no signs by which the existence of this parasite can be diagnosed. Its presence in the discharges is the only reliable evidence of the kind. Some years ago I removed a small tumor from the arm, which had the character of an ordinary encysted formation, but which was unexpectedly found to contain an acephalocyst, the animal rolling out upon the floor before I had extirpated the inclosing capsule. No treatment, except excision, is of any avail in this affection, and that, of course, is only admissible when the tumor is situated in an external and accessible part of the body.

12. POLYPOID TUMORS.

These are certain growths, long known to pathologists and practitioners, to which the term polyp, polypus, or polypoid has been applied, apparently from some fancied resemblance they bear to the form of the animal described under that name by naturalists. They are found exclusively in the mucous cavities of the body, where they often attain a large bulk, and become a source of serious mischief. Occurring at all periods of life, they are particularly common in middle-aged and elderly subjects, and present themselves

in several varieties of form, differing essentially from each other in their structure and habits, if not also in their mode of origin.

The situations in which these growths are most commonly met with are the nose and uterus; they are also sufficiently frequent in the ear, the maxillary sinus, the vagina, and the rectum. In the larynx and throat they are rare, but not, perhaps, as much so as is commonly supposed. They are generally solitary, but occasionally considerable numbers occur in the same subject and even in the same cavity. Their volume varies from that of a small pea up to that of an adult's head, depending upon the nature of the tumor, the locality which it occupies, and the amount of resistance offered to its extension. Their shape, which is usually materially influenced by that of the cavity in which they are developed, is conical, pyriform, or globular, their attachment being generally effected by a narrow footstalk, root, or pedicle. Most of these growths belong to the class of benign structures, and hence the inconvenience which they occasion is chiefly of a functional character.

Polypoid tumors may conveniently be arranged under four heads, which, judging from personal observation, comprise all the known and generally recognized varieties, without including any of the subordinate divisions made by certain authors, and which are altogether dependent upon accidental circumstances. These are the *gelatinoid*, *fibrous*, *granular*, and *vascular*, which possess features sufficiently distinctive to entitle them to separate notice.

The *gelatinoid* polyp, the most common of all this class of morbid growths, rarely occurs in any other situation than the nose; it is, however, occasionally observed in the ear, larynx, vagina, and certain portions of the alimentary tube. As its name implies, it is of jelly-like appearance, looking, indeed, very much like an oyster, being of a soft, spongy consistence, and generally of an irregularly pyriform shape, with a narrow pedicle, sometimes nearly an inch in length. Occurring either singly or in clusters, it often completely closes the cavity in which it grows, although it rarely acquires much bulk; is destitute of sensibility; readily breaks under pressure; and is remarkably hygrometric, expanding in wet weather, and shrinking in dry. When pricked, a thin yellowish and slightly coagulable fluid exudes, which under the microscope shows nucleated cells lying in a transparent blastema. The growth consists essentially of cellular substance supported by mucous membrane—a reflection from that of the part to which it is attached—and is nourished by a few straggling vessels, which are often of considerable length and thickness. When extirpated it is remarkably apt to be reproduced.

The *fibrous* polyp owes its name to the peculiarity of its structure, which is of a dense firm character, the fibres interlacing with each other in every possible manner. In the recent state it is of a reddish, purple, or livid hue, but after maceration for a short time it exhibits a pale grayish aspect, and then displays its characteristic fibrous arrangement to great advantage. It is usually exceedingly tough, hard, and incompressible, offering great resistance to the knife, which emits a creaking noise as it is drawn through its substance. Although it has seemingly very few vessels, its removal is frequently attended with copious hemorrhage, both arterial and venous. Being nearly always solitary, it generally grows quite rapidly, often attaining a large bulk in a short time, and is usually attached by a broad base, not by a narrow pedicle, as is the case with the *gelatinoid* polyp. The most common habitations of this growth are the uterus, nose, and maxillary sinus. When extirpated, it has a tendency to recur; and cases are not wanting where it manifests a malignant disposition.

The *granular* polyp, found chiefly in the uterus and nasal fossa, is, on the whole, very uncommon, and seldom attains any great bulk. It is of a pale rose-color, grayish, or whitish; of a soft, fragile consistence; globular, ovoi-

dal, or conical in shape: and from the size of a currant to that of a grape, its connection being usually effected by a long slender pedicle. Its structure is granular, homogeneous, and inelastic looking, when cut, somewhat like a macerated salivary gland, and containing a small quantity of serous fluid. It has few vessels, grows slowly, and is easily detached, sometimes reappearing after extirpation.

The *vascular* polyp, occurring mostly in the ear, nose, uterus and rectum, is of a florid color, soft and spongy in its consistence, and usually attached by a narrow base. A section of it displays a cellular structure pervaded by numerous vessels, none of which, however, are of much volume, but still sufficiently large to produce copious hemorrhage when accidentally opened. The tumor, in fact, possesses many of the properties of the erectile tissue. Notwithstanding this, it seldom attains much bulk, and is generally slow in its progress, with little disposition to recurrence after removal.

We are hardly sufficiently familiar with the structure and functions of polypoid tumors to enable us to explain their origin. The probability is that most, if not all, take their rise in a species of hypertrophy of the tissues with which they are connected and from which they grow. Thus, the granular polyp apparently always begins in the mucous follicles of the part, which, as it expands, inveigles other structures, which thus serve to impart to it its distinctive features. In the vascular variety, the vascular element predominates, in the gelatinoid, the cellular, and in the hard, the fibrous. Whoever has examined a fibrous polyp of the uterus must have been struck with its firm adhesions to that organ, and the perfect identification of its substance with that of the parenchymatous structure. Dr. Da Costa informs me that he has often found, in addition to fibrous tissue, muscular fibres and fibre-cells in this species of womb growth, rendering it thus highly probable that the fibrous polyp of this viscus is merely a species of hypertrophy of its proper substance. In the nasal fossa it is probable that this form of tumor always originates in the periosteum; at any rate, such a conclusion is plausible when we recollect that it is usually attached by a very broad base to the floor or septum of the nose.

These morbid growths are liable to various transformations, especially the fibrous, fibro-cartilaginous, cartilaginous and osseous; a circumstance which has induced some writers to make these changes the bases of so many additional divisions of these morbid products. They are, however, altogether accidental, and are seldom found except in cases of long standing. A more serious occurrence is the supervention of carcinomatous disease, if we concede the possibility that a structure, originally benign, may, during its march, take on malignant action. Without altogether denying such an occurrence, it must, to say the least, be extremely rare, and it would perhaps be more rational to conclude, in the absence of positive facts, that the tumor in most cases was primitively of a cancerous character, than that it became so during its progress. The fibrous polyp is more liable to this kind of degeneration or assumption than any other.

All polypoid tumors act obstructingly, closing the cavities in which they are developed, and thus interfering with the exercise of their functions. As they augment in size, they encroach upon the surrounding structures, pressing them out of shape, and causing more or less serious deformity. In this way, moreover, they may be productive of severe pain and great increase of the natural discharge of the part. In the nose and uterus they often give rise to serious hemorrhage.

The period of life at which these bodies appear varies according to circumstances. In the uterus they are most common in elderly females; in the nose, in young adults; in the rectum, in children; in the larynx, in advanced life.

No medical treatment of which we have any knowledge is of any avail in

getting rid of these tumors. Sorbefacients, whether employed externally or internally, or both, are utterly useless. The only reliable remedy is extirpation, a proceeding which, if properly executed, rarely fails to afford at least temporary, if not permanent relief. In performing the operation it is important to effect complete clearance, since, if the least germ of the morbid product be left behind, repullulation will almost be inevitable. As it is, even with the best possible care, it is very difficult, especially in the gelatinoid variety of the affection, to prevent this occurrence. The methods of operation are torsion, ligation, and excision, of which the first should generally be preferred, as the least likely to cause suffering and hemorrhage. These procedures will be described in connection with polypoid tumors of different parts of the body.

13. MYELOID TUMORS.

The name of this tumor, which literally signifies marrow-like, was given to it by Mr. Paget, although its structure had been previously described by Lebert. It has been noticed in different parts of the body, but in particular in or upon bone, the mammary gland, uterus, cerebral membranes, the subcutaneous cellular tissue, and in the eyelids and conjunctiva, occurring in various sized masses, generally of a rounded, or ovoidal shape, and of a consistence varying from that of tallow or suet to that of fibro-plastic tissue. The cut surface has a smooth, compact, shining appearance, with blotches of a dark crimson, brownish, pink, or modena hue, either uniformly, or in various degrees of combination, all these tints being sometimes commingled. Much stress is laid upon these colors by pathologists as diagnostic characters of myeloid tumors, affording, as they do, the most ready external means of discrimination between them and other analogous formations.

A considerable quantity of fibrous, cellulo-fibrous, or fibro-plastic matter, generally enters into the morbid growth, presenting itself in the form of whitish, grayish, or yellowish filaments, scattered about irregularly, and frequently so arranged as to intercept small cells, filled with serum, sanguinolent fluid, or pure blood. Sometimes large cysts occur, similar to those which we find in tumors of the thyroid gland, and occupied by similar liquids. In the more recent specimens a section of the mass generally furnishes, on pressure, a small quantity of a thin yellowish fluid, altogether different from cancer-juice. When the disease is developed in the cancellous tissue of the bones, where its occurrence is more frequent than elsewhere, the tumor disparts the compact layers, forming a kind of cyst-like expansion, in which the new matter is lodged, and which, under such circumstances, often contains a large amount of osseous substance, soft, cellulated, of a reddish or pale yellowish tint, and easily recognized by sight and touch.

The minute structure of the myeloid tumor essentially consists of cells, nuclei, and nucleoli, imbedded in a finely granular matrix, and interspersed with filaments of fibro-cellular tissue. More or less fatty substance is frequently present, and the stroma is usually very vascular; a circumstance which readily explains the rapid development of this variety of morbid growth. Of the cells, as described by Paget, some are small, and of an oval, lanceolate, angular, or elongated figure, their contents being dimly dotted with single nuclei and nucleoli; others are round, oval, or flask-shaped, measuring from $\frac{1}{300}$ to $\frac{1}{100}$ of an inch in diameter, and occupied each by nearly a dozen nucleolated nuclei. Intermingled with these corpuscles are free nuclei, of various forms and sizes, giving evidence of having escaped from the older cells.

The myeloid tumor is generally rather rapid in its growth, occurs in both sexes and at different periods of life, but more commonly in the young and

middle aged than in the old, and is capable of attaining a considerable bulk. From its tendency to destroy effectually the structures in which it is developed, and from the fact that it occasionally displays a malignant tendency, recurring after extirpation, and ultimately causing death, there is strong reason to conclude that it is generally merely a modified form of encephaloid or fibroplastic growth. Nevertheless, we are not warranted, in the existing state of the science, in expressing a very positive opinion regarding the true nature of the disease. Further observation alone can afford any valuable clue to this.

Myeloid tumors furnish no diagnostic signs. They generally grow more rapidly than any other class of tumors, except the encephaloid, but their real nature can never be positively determined until after their removal. Of their treatment, or the influence of remedies in checking or arresting their progress, we are equally ignorant. When connected with the bones of the extremities, nothing short of amputation will of course hold out any prospect of relief, and even this is commonly very remote and uncertain. If excision be determined upon, the knife should be freely carried through the sound tissues, so as to guard as much as possible against relapse.

EXCISION OF BENIGN TUMORS.

To the above account of benign tumors may be appended, by way of practical precept, a few remarks respecting the proper method of removing these morbid growths with the knife.

1st. Interference should, as a general rule, be avoided when the tumor is stationary, or nearly so, painless, and not inconvenient by its size or situation.

2dly. If an operation be determined upon, the system should always be subjected to a certain degree of preliminary treatment, even when the tumor is comparatively small, experience having shown that extirpation is often followed by erysipelas.

3dly. While the object should be to effect the most thorough removal, care should be taken not to interfere unnecessarily with the surrounding tissues, but to respect them as much as possible by keeping the knife in close contact with the morbid growth.

4thly. If the tumor be of unusual bulk, it will generally be necessary to remove a portion of its tegumental covering, making, for this purpose, an elliptical incision; otherwise all the skin should be retained, due allowance being always made for its astonishing contractile powers. If this precaution be neglected, there may be a deficiency of flap when the surgeon comes to approximate the edges of the wound.

5thly. Diseased integument should always be removed along with the morbid growth.

6thly. In general, extirpation may be effected by a single incision carried across the centre of the tumor, either vertically, or in a curvilinear direction. It is only when, as already stated, the morbid growth is very large, that an elliptical incision will be required.

7thly. Care should be taken, in making the incisions, to give them such a direction as shall favor drainage, or prevent bagging. Hence, one of the extremities should always correspond with the most dependent portion of the tumor.

8thly. By keeping the knife in close contact with the tumor, it may sometimes be promptly and effectually enucleated with the hand, finger, or scalpel. Another advantage resulting from the observance of this precaution will be the avoidance of hemorrhage.

9thly. Any large arteries that may be divided should either be compressed by an assistant until the extirpation is completed, or they should immediately be tied, loss of blood being carefully guarded against in all proceedings of this kind. When the surgeon is operating alone, or when he has no good assistants, the bleeding may be temporarily checked with the serrefine, fig. 40, a kind of wire forceps, or the contrivance depicted in fig. 41. These instruments hold on by their own elasticity, and will be found of great service in extensive and tedious dissections, especially when it is necessary to cut the same artery several times.

Fig. 40.

Serrefine.

Fig. 41.

Small forceps for temporarily checking hemorrhage.

10thly. When all oozing of blood has ceased, the edges of the wound are accurately approximated by suture and adhesive strips, aided, if necessary, by a light compress and bandage, to keep the flaps in close contact with the raw surface beneath; the object being to secure union by the first intention.

11thly. The part is always to be kept perfectly at rest until the wound is healed; the case being treated in every respect upon ordinary antiphlogistic principles. In general, the dressings should not be disturbed before the end of the third day, especially if the absence of fetor and discharge indicates that everything is progressing favorably.

SECT. III.—MALIGNANT TUMORS.

Under the term malignant are comprised certain morbid products which have the effect, within a variable period after their formation, of destroying not only the tissues in which they are deposited, but also the life of the patient. The pathological anatomist usually describes them under the name of the heterologous, heteroclite, or heteromorphous products, in reference to their want of similarity to the natural structures, but the prefix malignant is justly applicable to them, on account of their destructive disposition. The formations which are usually embraced under the present head are scirrhus, encephaloid, colloid, melanosis, and canceroid, the latter having been only lately added to the list as a distinct affection. From this catalogue tubercle is usually excluded, although it is by far the most common as well as the most destructive of all the heteromorphous developments, especially when it occurs in the lungs and serous membranes. In the external parts of the body, however, it is less so, and hence, perhaps, the reason why surgical writers generally exclude it from this position. It would greatly simplify the study of these affections if the term "cancer," by which some of them continue to be designated, were altogether discarded from surgical nomenclature. This expression, introduced in the infancy of the science, is entirely figurative, and therefore calculated to mislead the mind of the inquirer.

Of the extensive prevalence of cancerous disease some idea may be formed when it is stated that, in five years, namely, from 1838 to 1842, inclusive, 11,662 persons died of it in England alone, independently of the cases which occurred in London. Of these cases, 8,746 occurred among women, and 2,916 among men, or in the ratio almost of three to one. This difference is due to the extraordinary frequency of carcinoma of the uterus and mammæ, particularly the former, which suffers nearly as often as all the other organs together.

These various morbid formations, although they differ widely in many of their characters, yet possess certain features in common with each other, which may be briefly enumerated before we proceed to speak of them individually.

1st. They are all deficient in plastic material, while they contain an unusual amount of albuminous substance, or the protein principles of the blood. The consequence is that they are less organizable than the ordinary lymph-products, and also less capable of maintaining a long existence in the parts among which they are deposited.

2dly. Under the microscope they are found to consist of two parts, a fibrous stroma, and granules or cells, which bear to each other the relation of containing and contained parts. The former is either of new formation, or it is composed of pre-existing tissue, in an altered state. The cells often contain nuclei and nucleoli, and possess, in many cases, an astonishing multiplying faculty; a circumstance which adds greatly to the rapidity and malignancy of the morbid growth.

3dly. They occur in nearly all the organs and tissues of the body, in both sexes, at all periods of life, in all temperaments, and in persons of all occupations, often existing simultaneously in a number of localities. They frequently display a marked hereditary tendency, forming at or soon after birth, and also a disposition to appear in several members of the same family.

4thly. They present themselves under different varieties of form; generally as a distinct, circumscribed tumor, but very frequently also as a stratum, or infiltration.

5thly. They are all deposited, as a secretion, in a fluid form, but soon assume a concrete character, which, after a time, they again, in part, lose, their tendency being to become disintegrated, and to work their way to the surface, by exciting ulcerative action in the surrounding tissues. The resulting sore is incapable of forming healthy matter and healthy granulations; or, in other words, it remains open and intractable, either for an indefinite period, or until the patient perishes from the effects of the local and constitutional irritation.

6thly. They are all of constitutional origin, or connected with a contaminated state of the blood and solids, a perfectly healthy individual being incapable of their attack, which generally takes place without any assignable cause. Owing to this circumstance, they always manifest a tendency to reappear after extirpation, either at the original site, or at some other point.

7thly. Their progress is generally rapid, most of them causing death in from nine to eighteen months from the time of their first appearance. As they advance, especially when ulceration is about to begin, they involve the neighboring lymphatic ganglions, transmitting to them, through the agency of the absorbents, some of their own material, or exciting similar disease by sympathetic irritation.

The so-called cancer-cells have been, and still are, a prolific source of dispute. While there are some who altogether deny their existence, as a distinct and specific entity, the great majority of pathologists agree in the opinion that they are peculiar to this class of morbid growths, and they do not hesitate therefore to assign to them an important histological and diagnostic rank. Without attempting to decide a question of such grave importance, for which our knowledge is perhaps still too imperfect, it may confidently be assumed that all carcinomatous formations are intimately connected with, if not directly dependent upon, the presence of cells, of a more or less complex structure, which thus influence their development, and serve to impart to them their distinctive features. Time will probably show whether these cells are new cells, or merely cells which naturally exist in all organs and tissues, in a state of disease, alteration, or degeneration.

The accompanying sketches, from Beal and Druitt, will serve to convey a good idea, in a general point of view, of the nature of these cells, and of their disposition in the fibrous stroma, or basement-structure, above alluded to.

Fig. 42.

Fig. 43.

Fig. 42 represents cells in the earlier stages of carcinoma, with nuclei at *a*; magnified 200 diameters. In fig. 43, the cells, termed mother-cells, are older and larger, or, in other words, further advanced in their development.

Fig. 44.

Fig. 44 exhibits the cells as they lie in their fibrous stroma; at *a*, some of the cells are loaded with fat, and others with melanotic pigment, unmistakable evidences of increasing age and gradual decay.

In its shape the cancer-cell is pretty regularly spherical, and about the $\frac{1}{1000}$ of an inch in diameter, with an oval, eccentric nucleus, situated in its interior, and generally occupied by one

or more nucleoli. These arrangements may be rendered particularly distinct if the matter under examination be treated with acetic acid, which makes the cell pale and transparent, and brings out the nucleus in bold relief. In some varieties of carcinoma, the cell frequently exhibits a caudate configuration.

The occurrence of ulceration in cancer is a direct consequence of the changes wrought by age and disease in the cancer-cells. As the morbid growth progresses, the cells become opaque, irregular, flattened or compressed, and infiltrated with oil and different kinds of pigmentary substances. They undergo, in fact, changes very similar to those which are witnessed in lymph or plasma. As a general rule, it may be stated that the largest and most perfect cells are found in scirrhus or hard cancer, especially in those of slow growth. The more imperfect cells are seen in encephaloid and other rapidly developing forms of the disease.

1. SCIRRHUS.

The term scirrhus is employed to designate a morbid product which is more dense and firm than any of the natural tissues, excepting tendon, cartilage, and bone. Hence it is often called hard cancer, an expression which was applied to this substance in the infancy of the science, from some fancied resemblance which it was supposed to bear to the claws of that animal. It is to be regretted, as already stated, that it is not altogether abolished from surgical nomenclature, as its retention is only calculated to add confusion to a subject unfortunately sufficiently obscure.

The occurrence of scirrhus is as frequent as its character is malignant and

unforgiving. It is observed at various periods of life, but rarely until after middle age. The youngest subject in which I have ever seen the disease was a mulatto child three months old, whose case has been reported by Dr. S. W. Gross, in the North American Medico-Chirurgical Review for May, 1857. It presented itself in the liver, which was otherwise perfectly healthy, in the form of white tubercles, which were of a firm, almost fibro-cartilaginous consistence, and exhibited under the microscope all the characteristics of genuine scirrhus. Scirrhus of the skin is also occasionally observed at a comparatively early period; but everywhere else it is rare until after the age of forty, when it becomes sufficiently common. The period of its greatest frequency is from the forty-fifth to the fifty-fifth year.

Females are more liable to scirrhus than males, but in what precise proportion has not been ascertained. The influence of temperament, habit, and occupation upon the production of the disease also remains undetermined. It is generally supposed that persons of a dark bilious temperament are particularly subject to it, but for such an opinion there is no valid reason.

Certain organs and tissues are more prone to scirrhus than others. Thus, what are called the glandular viscera, as the liver, mamma, and uterus, are particularly liable to suffer, though the testicle, which belongs to the same class, is singularly exempt from the disease, so much so, indeed, that we may well question whether it is ever attacked by it. The stomach, anus, rectum, and colon are often invaded in both sexes. Scirrhus was supposed at one time to be very common in the lip and penis, but recent researches tend to show that this is not the fact, but that the affection, formerly so regarded, is nothing but epithelial cancer, a milder form of malignant structure. Whether this, however, is really so, future observation must decide. Meanwhile, it is positively certain that canceroid disease is often much more rapidly fatal than scirrhus. The bones, muscles, tendons, ligaments, aponeuroses, vessels, nerves, salivary glands, brain, lungs, spleen, and urinary organs are nearly entirely exempt from this heterologous formation.

Like the other heteromorphous products, the scirrhus may appear under several *varieties* of form, as the tuberoid, stratiform, and infiltrated, of which the first is the one, surgically speaking, of the greatest interest. The other two occur chiefly in the internal organs, particularly the œsophagus, stomach, colon, and rectum, the submucous cellular tissue of which they often so completely transform as not to leave a vestige of the original structure; at the same time that they encroach very seriously, if not fatally, upon the caliber of the tube. The affected part is dense and crisp, cutting almost like fibro-cartilage, and has a pale yellowish or grayish appearance, with white fibrinous intersections. The stratiform variety is occasionally met with in the skin and subserous cellular tissue, but the occurrence is uncommon. Scirrhus of the uterus generally presents itself as an infiltration.

The best example of the tuberoid variety occurs in the mamma and liver; it is also sometimes seen upon the serous membranes and in the skin, or in the skin and subcutaneous cellular tissue, in the form of little nodules, often not larger than a current, a pea, or a filbert. Sometimes the tumor consists of one single mass, as in the liver, but more generally it is made up of several, which together may form a growth as large as an orange, or even a fist, hard, dense, inelastic, and almost incompressible, grating under the knife, of variable shape, but generally globular or ovoidal, movable, and deeply inlaid in the tissues among which it is situated. These tissues occasionally afford the tumor an imperfect capsule, but in general there is no such investment, the heteroclitic matter being often spread out in the most irregular and grotesque manner, like the claws of the animal from which the disease has derived its generic name. The fibrous intersections which pervade the interior of

the morbid mass are the remains of the normal tissues, variously changed by the disease. They are generally of a dense, firm consistence, and of a grayish, bluish, or rosaceous color, thus strikingly contrasting with the abnormal deposit. It is questionable whether the fibrous bands, as they are commonly called, are ever entirely of new formation. In the mammary gland they generally consist of imprisoned lactiferous tubes.

Structure.—A section of a scirrhus tumor, especially in its more matured stages, exhibits a whitish, homogeneous aspect, and affords, upon being scraped, a peculiar lactescent fluid, somewhat unctuous to the touch, which has received the name of *cancer-juice*, and upon which much stress has been laid by modern pathologists as denotive of malignancy. It is seldom present in very recent specimens, and my researches have led me to believe that it is a result of partial softening of the heteromorphous mass, preparatory to ulceration. We sometimes find it united with a considerable quantity of free oil.

Scirrhus has a very feeble circulation, its vessels being remarkably small, and probably wholly derived from the surrounding parts. Of their precise arrangement, however, we have no definite idea. The paucity of vessels affords a satisfactory clue to the slow growth and comparatively small size of the morbid product, and a reason, also, why there is so seldom any considerable hemorrhage after ulceration has set in. No nerves have been demonstrated in its substance, but their free distribution is inferred from the sharp, lancinating pain which forms so characteristic a symptom of the disease. Lymphatics also exist; as is proved by the fact that if arsenic be applied to an open scirrhus ulcer, it is often absorbed into the system, producing similar effects as when taken directly into the stomach.

Pathologists have laid much stress upon the existence of certain subdivisions of scirrhus tumors, as the mammary, pancreatic, lardaceous, and reticular, as if the appearances which these expressions are intended to designate were not purely accidental, depending upon the character and amount of pre-existing tissue, the age and mode of aggregation of the heteroclitic matter, and above all, the state of the patient's general health. I must object the more strenuously against the use of these terms, because they have only a tendency to complicate the subject and create confusion. I am sure that, with all my opportunities for observation, I have never seen a scirrhus tumor to which the word mammary or pancreatic could be applied with any degree of propriety; and it is equally certain that the lardaceous and reticular varieties, as they have been termed, although they may sometimes present a faint resemblance to the objects after which they have been named, must be exceedingly rare.

Chemically examined, scirrhus is found to consist largely of albumen and fatty matter, the two together forming more than one-half of the entire mass. In a specimen of scirrhus of the uterus, analyzed by Hecht, the fatty substance amounted to fifty per cent. Fibrin exists sparingly in all cases. Gelatine is said to be occasionally present, but this is questionable. In an examination by Foy, upwards of thirty per cent. of earthy salts existed, fully one-half of this quantity being in the form of subphosphate of lime.

The facts which chemistry has revealed in regard to the composition of scirrhus are valuable, as showing that this substance is formed of materials very much of a non-plastic character, and consequently incapable of resisting, for any length of time, the influence of surrounding agents. It is reasonable to suppose that its composition is not alike in all cases, but that it is greatly influenced by the site and age of the morbid product, and, therefore, that it varies not only in different stages of the malady, but also in different portions of the same specimen.

The *minute structure* of scirrhus consists of two parts, a fibrous network, and a soft granular matter. The former is made up of filaments, of a whitish or grayish color, which, intersecting each other in every conceivable direction, form meshes, of variable shape and size, for the lodgment of the granular element. These filaments, which are well shown in fig. 45, are of a fibrous structure and generally consist, not of new matter, but merely of pre-existing tissue, condensed and altered by the heteroclite deposit. Their appearance is occasionally very distinct in recent specimens of scirrhus, especially of the liver and mamma, but ordinarily it is necessary to scrape away the granular matter before they can be brought into full relief.

Fig. 45.

Stroma of scirrhus.

The essential element of scirrhus, contained in the meshes of the fibrous structure, consists mainly of cells and free nuclei, lying in a transparent and slightly granular matrix. The cells vary much in shape; some being round, some oval, and others, again, caudate, or furnished with tail-like prolongations. In size they range from the $\frac{1}{800}$ to the $\frac{1}{1700}$ of an inch in diameter, most of them being large and well defined, especially in the more matured specimens of the disease. They have each a delicate, but distinct wall, and generally inclose one or more nuclei. The nuclei are, for the most part, of an oval shape, and often, in turn, inclose well-marked nucleoli. Sometimes the nuclei escape from their cells, and scatter themselves through the uniting substance as if in search of new homes. Finally, crystals, granules, oil-drops, and old, degenerated cells are often found in the same specimen under the field of the microscope. The various forms of cell-formation are well shown in fig. 46, from a drawing by Dr. Da Costa.

Fig. 46.

Cells of scirrhus.

Progress.—The progress of scirrhus is generally more slow than that of the other heteromorphous deposits, both as it respects its tendency to ulceration and the destruction of life. It is seldom that a scirrhus tumor of the breast becomes an open sore under twelve, fifteen, or eighteen months; not unfrequently, indeed, several years elapse before it takes on this kind of action. I had at my Clinic, two winters ago, an elderly lady, formerly a patient of Sir Astley Cooper, in whom the disease had been regularly progressing for more than twenty years before any disposition to ulceration became apparent. Several other cases, somewhat less in their duration, have been under my observation. In general, however, the tendency to ulceration shows itself within the second year, commencing usually in a superficial portion of the tumor, sometimes at one, and at other times at several points, the process being preceded and accompanied by more or less discoloration of the surface, and by the adhesion of the skin to the subjacent parts. The color is always dark, purple, or livid, the vessels immediately concerned in its production being enlarged and deeply congested, frequently presenting an appearance as if they were inlaid in the cutaneous tissues. The part at length giving way, an unsightly ulcer is exposed, having hard,

steep, and rounded edges, and a foul-looking bottom, generally incrustated with spoiled lymph. The discharge is always of a sanious, ichorous, or sanguinolent nature, more or less fetid, irritating, and often remarkably profuse. It tarnishes silver, imparts a green color to syrup of violets, and, on admixture with sulphuric acid, evolves a peculiar gas, having many of the properties of sulphuretted hydrogen. No granulations ever form upon such an ulcer; hence it never heals, the plastic matter which it secretes losing its vitality as soon as it is deposited. There are, of course, exceptions to this rule; but they are very uncommon, and I have never met with any. Sometimes the scirrhus ulcer has a remarkably excavated appearance, as if it had been dug out with a punch. The parts immediately around the ulcer are always very tender, discolored, and œdematous.

Another tendency of the scirrhus tumor is to contract adhesions to the structures among which it is situated. This disposition, which often manifests itself at a comparatively early period, is always very conspicuous in the latter stages of the malady. The immediate cause of the adhesions is an effusion of ordinary plastic matter; but in some cases, especially in such as are of long standing and of unusual size, they are owing, at least in part, to the heteromorphous deposit itself, which, under such circumstances, often breaks through its original boundaries into the skin, cellulo-adipose tissue, muscles, glands, and even bones, involving them all in one common mass.

But a tumor of this kind not only involves the parts with which it lies in immediate contact, but it often extends its influence to others further off. The structures which are most liable to suffer in this way are the lymphatic ganglions, which often take on the same kind of action, becoming enlarged and indurated, and exhibiting, on division, precisely the same appearances as the original tumor. Sometimes, again, parts still more remote become involved in the morbid action. Thus, in scirrhus of the mamma we often see not only great contamination of the axillary lymphatic ganglions, but serious swelling of the corresponding arm, evidently from an extension of the primitive affection.

Thus the tendency of this disease is to spread and to contaminate the surrounding structures, making itself deeply felt not only at home but abroad; not merely locally but constitutionally. In exceptional cases, the morbid influence is closely circumscribed, limiting itself, perhaps, for years, to the spot in which it originally appeared; but even then it eventually breaks through its barriers, and spreads among the surrounding parts. Finally, after having inhabited the part for a time, nature occasionally makes an effort at extrusion, the tumor being invaded by gangrene, and at length detached as a slough. Such an occurrence, however, is extremely rare. I have seen but one instance of it. The patient was an elderly lady, fat, and otherwise healthy, who had a medium-sized scirrhus tumor in one of the mammary glands which had troubled her for several years. All of a sudden, without any assignable cause, inflammation set in, and in a few weeks the whole mass was lifted from its bed as neatly as if the operation had been performed with the knife. Some time afterwards the disease broke out in the axillary lymphatic ganglions, and made rapid strides towards a fatal termination.

Symptoms.—The symptoms of scirrhus necessarily resolve themselves into local and constitutional. The former can only be satisfactorily studied as they appear in an external tumor, such, for example, as that which involves the mamma. In taking hold of such a tumor we are struck with its extraordinary hardness and density; it feels firm, incompressible, and inelastic. If it be of recent origin, it will be found to be perfectly circumscribed and movable, the examiner being able to grasp it with the fingers, and to push it about beneath the skin; at a later period, however, it contracts adhesions to the surrounding parts, and thus becomes firmly fixed in its situation. The

morbid product may appear as a solitary tumor, or several little lumps may appear simultaneously or successively, and, gradually coalescing, a considerable sized mass may thus be formed.

The pain of scirrhus is peculiar. It is sharp and lancinating, darting through the parts like an electric spark, or causing a sensation as if needles were thrust into them. It makes its appearance at an early date, gradually increasing in severity, and becoming at length a source of intense suffering. It may be steady and persistent, but more generally it is intermittent, coming and going apparently as whim or caprice may dictate. It is always aggravated by damp states of the atmosphere, and by whatever has a tendency to impair the general health. In some cases we find it to be of a neuralgic character; and under such circumstances, instead of being limited to the morbid mass, it often shoots about in different directions among the neighboring structures. During the latter stages of the disease it is generally so constant and violent as to deprive the patient of sleep and appetite, thus rapidly urging on the fatal issue.

During the progress of the disease the skin is tied down to the morbid mass, and soon becomes hard and livid, its vessels being at the same time very much enlarged and deeply congested. Presently ulceration sets in, the resulting sore having a steep excavated appearance and a foul discharge, without the ability to form granulations, to produce healthy pus, or to undergo reparation. The tumor is now firmly adherent to the surrounding structures, and there is generally, though not invariably, lymphatic involvement. A discharge of blood sometimes attends the ulcerative stage, but it seldom exceeds a few drachms, or, at most, a few ounces. The bleeding may be purely capillary, or it may proceed from a tolerably large vessel, arterial or venous, laid open by the morbid action, and unable to retract in consequence of the condensation of the circumjacent tissues.

Scirrhus in its earlier stages, produces little or no constitutional disturbance. The affection is strictly local, annoying and fretting the parts directly involved in it, but not awakening any general sympathies. A little mental disquietude, the result of the consciousness that there is a suspicious tumor or lump, is the only thing that excites attention. By and by, however, the health begins to fail; the appetite is impaired; the sleep is interrupted by the severity and frequency of the pain; the secretions are disordered, and some of them are, perhaps, entirely suppressed; the bowels are irregular; the assimilative functions suffer; occasional attacks of fever take place; the flesh and strength gradually decline; the spirits are depressed; and life is beset on every side by the treacherous and unrelenting enemy. During the latter stages of the malady, sometimes even before there is any serious lymphatic involvement, the countenance assumes a peculiar sallow, cadaverous expression, so denotive of the cancerous cachexy; diarrhœa and sweats set in; the limbs become anasarctous; and at length the patient dies utterly exhausted, being literally pricked, fretted, and stung to death by the disease.

During the progress of this disease scirrhus deposits often appear in other parts of the body; the blood becomes thin and colorless; and the solids are emaciated, pale, and flabby. Even the bones often experience important changes, especially those of the thigh, which are sometimes rendered so fragile as to give way from the slightest cause. Many years ago I had under my charge, on account of scirrhus of the mamma, an old lady of seventy-three, who broke her right femur a few days before she died, simply by turning round in bed.

2. ENCEPHALOID.

Although encephaloid and scirrhus closely resemble each other in their structure and composition, yet they exhibit sufficiently distinctive features to justify us in considering them as different diseases. As the progress of morbid anatomy advances, we shall doubtless become more enlightened in regard to their intimate relations, and also in regard to the relations which they sustain towards the tissues in which they occur, as well as to the system at large.

Encephaloid has various synonymes, of which the most common are, soft cancer, medullary sarcoma, cerebriform cancer, and fungus hematodes. Mr. John Burns, of Glasgow, who was the first to describe it, gave it the name of spongoid inflammation. All these various appellations have reference either to the appearance, consistence, or structure of the morbid product, and are, therefore, more or less appropriate. That of encephaloid, however, is, on the whole, the least objectionable, and is the only one that ought to be retained. There is a form of the disease, to which attention was first called by Mr. Hey, of Leeds, under the name of fungus hematodes, which I shall designate as the hematoid variety, and which, in my judgment, is the only one that deserves separate consideration. The terms solanoid, napiform, and reticulated, devised by some of the French and German pathologists, to specify particular states of encephaloid, ought to be discarded from the nomenclature of the disease, as they are only calculated to lead to confusion by keeping up a refinement which does not exist in nature.

The disease is more common in the mamma, eye, testicle, uterus, liver, lymphatic ganglions, periosteum and bones, than anywhere else. With the exception, however, of the muscles, tendons, nerves, cartilages, ligaments, and aponeuroses, there is no part of the body in which it has not been observed. Occasionally it takes place, either simultaneously or successively, in a considerable number of structures, resembling, in this respect, the other heteromorphous products, and constituting a genuine encephaloid diathesis. It appears in both sexes, and at all periods of life, from early infancy to old age, but the greatest number of cases occur between the twentieth and fiftieth year. The subjoined table, constructed for me by Dr. Cassot, shows the age in ninety-one cases.

Years.	No. of cases.	Years.	No. of cases.
1 to 3	8	30 to 40	14
3 " 7	4	40 " 50	18
7 " 14	5	50 " 60	7
14 " 21	9	60 " 70	4
21 " 30	20	70 " 75	2

The *localization* of encephaloid is materially influenced by the age of the patient. Thus, in the mamma the disease is almost peculiar to middle age; in the testicle, to young adults; in the eye, to childhood. Of the relative frequency of the disease in the two sexes, we have no reliable data. In the cases analyzed by Dr. Cassot, there was a predominance of males, and in my own practice I have certainly seen it oftener in men than in women; but this may have been a mere coincidence.

The *chemical* composition of encephaloid, as determined by the analysis of Foy, probably the most accurate that has yet been made, shows the greatest possible resemblance to that of scirrhus by the same chemist. To enable the reader to compare the results of his examinations I shall subjoin his two tables in parallel columns:—

ENCEPHALOID.		SCIRRHUS.	
Albumen	47.00	Albumen	42.00
White fatty matter	7.50	White fatty matter	5.00
Red fatty matter	5.35	Red fatty matter	3.25
Osmazome	4.00	Fibrin	5.85
Fibrin	6.50	Water	5.00
Water	8.00	Oxide of iron	1.65
Oxide of iron	1.35	Sub-phosphate of lime	16.60
Sub-phosphate of lime	6.30	Carbonates of { Soda	5.00
Carbonates of { Soda	2.75	Carbonates of { Lime	6.60
Carbonates of { Lime	4.00	Carbonates of { Magnesia	0.85
Carbonates of { Magnesia	1.00	Hydrochlorates of { Potassa	4.10
Hydrochlorates of { Potassa	2.70	Hydrochlorates of { Soda	3.25
Hydrochlorates of { Soda	2.00	Tartrate of soda	0.85
Tartrate of soda	0.35		
	100.00		100.00

It will thus be perceived that the chief differences in the composition of the two substances consist in the presence of osmazome in encephaloid, in the lesser quantity of earthy salts, and the greater quantity of albumen. The fibrin exists in nearly equal proportions. The analyses make no mention of gelatine, which has been asserted by certain chemists to exist in both substances, especially in the more recent specimens. Doubtless the composition of encephaloid is greatly influenced by the age and site of the deposit, the general health of the patient, the condition of the blood, and even by different portions of the same tumor.

The similarity of the minute *structure* of the two products is hardly less remarkable than that of their chemical constitution. Most specimens exhibit, under the microscope, a stroma and corpuscles, closely resembling those of scirrhus. The stroma, or basis-structure, exhibited in fig. 47, is made up of a fibrous substance, not equally well developed in every specimen, but in general sufficiently distinct to admit of easy recognition. The firmer varieties usually contain two kinds of fibres, both hollow, but one is opaque and granular, the other hyaline and studded with cells and nuclei. The other element, the essentially cancerous substance, consists of corpuscles, of a rounded, ovoidal, or caudate shape, exactly similar to those of scirrhus, only that the latter arrangement is commonly more distinctly marked. Nearly all include large, oval nuclei, and not a few also nucleoli. Besides these two substances, most specimens contain pigment matter, granules, and oil globules. The various forms of cancer corpuscles are well displayed in fig. 48. The caudate bodies are particularly distinct.

In regard to its arrangement, the encephaloid matter presents itself under three *varieties* of form, as a tumor, a stratum, and an infiltration, the first being the most common, and, surgically considered, the only one of any particular interest. It varies in volume from that of a pea to that of an adult's head, its shape being generally somewhat ovoidal, and its surface more or

Fig. 47.

Stroma of encephaloid.

less lobulated as in fig. 48, from a specimen in my cabinet. Its configuration, however, is always greatly influenced by the amount of pressure exerted upon

Fig. 48.

Elongated and caudate cells of encephaloid.

it by the parts in which it is situated, and hence it is occasionally very much flattened, or irregularly compressed. When seated in the external structures,

Fig. 49.

Tubercoid form of encephaloid.

as in the subcutaneous and intermuscular cellular tissue, over the bones, in the mammary gland, and in the lymphatic ganglions, it has generally a well-marked cyst, of a grayish, whitish, or rosaceous appearance, and of considerable firmness and thickness, which thus serves to define its limits and to isolate it from the original textures. Extending from the inner surface of this envelope are numerous processes, which, passing through the interior of the diseased mass, intersect each other in various directions, and thus form cells, cavities, or lodges, for the accommodation of the new matter, just as in scirrhus, only that they are generally larger and more fully developed. The encephaloid matter, freed from its stroma, or fibrous element, is of a soft, jelly-like consistence, very much like that of the foetal brain, viscid to the touch, of a whitish or slightly reddish tint, miscible with water, of a peculiar sperm-like odor, and readily coagulable by heat, alcohol, and acids, thus showing its protein character.

If a section be made of an encephaloid tumor, it will be found to present, in most cases, not a little variety of form, or diversity of appearance and consistence. Thus, one part may be soft and white, like brain, another perhaps feel, look, and cut like fibro-cartilage, while a third may be composed essentially of a reddish semi-concrete substance, bearing a striking resemblance to the contents of an old aneurism. Most of these differences are due to the age of the tumor, and the changes experienced by the included primitive tissues; but the latter are so distinct and peculiar as to entitle them

to be considered almost as a separate formation. It is to this morbid product that, as was before stated, the term *hematoid* ought to be applied, as expressive of its blood-like structure. It looks, in fact, more like a mass of firmly coagulated and semi-organized blood than any other substance to which it can be compared. Occasionally a more solid substance is mixed up with the hematoid, as the fibrous, or fibro-cartilaginous, and when this is the case it generally creaks under the knife, cutting a good deal like a raw turnip, or the rind of bacon. I have found this form of tumor most commonly in the mamma, liver, testicle, and lymphatic ganglions, the latter of which, when thus affected, occasionally exhibit a singularly areolar structure, a section bearing a close resemblance to the surface of a sponge, the cells being occupied by the hematoid matter.

Encephaloid sometimes, although rarely, occurs as an infiltration chiefly in the lungs, liver, uterus, and lymphatic ganglions, the proper structure of which it subverts and ultimately completely effaces, forming a dense, solid mass, of a pink, grayish, or ash color, grating under the knife, inelastic, and almost incompressible. The stratiform variety is also uncommon. It is seen chiefly in the submucous cellular tissue of the stomach and rectum, and beneath the pleura and peritoneum, in small, thin, whitish patches, from the diameter of a dime to that of a dollar.

Encephaloid, being an extremely vascular structure, is endowed with a high degree of vitality, growing generally with great rapidity, and often attaining an uncommon bulk in a few months from its first appearance. Its vessels are unusually large, and are probably derived from the pre-existing tissues, although cases occur where the circumstances are such as to lead to the belief that they are now and then created, at least in part, by the heteroclitic matter itself. If such a conclusion be admissible, as I think it is, it follows that encephaloid has occasionally, like plastic lymph, a double circulation, one peculiar to itself, and the other common to it and the tissues with which it lies in contact. Be this as it may, the vessels are generally remarkably voluminous, thus strikingly contrasting with those of scirrhus, at the same time that they afford a ready explanation of the differences in the rapidity and size of the two formations. Their walls also are unusually brittle, and hence they are liable to give way under the most trifling causes, producing those apoplectic depôts which we so often see in their interior, and those frightful hemorrhages which occasionally attend their open condition.

Of the absorbent vessels of encephaloid nothing special is known. Doubtless, however, they exist in large numbers, otherwise it would be difficult to account for the facility with which morphine and other articles, applied to encephaloid ulcers, find their way into the general system. Nerves are also probably freely distributed through the morbid mass, although it is a singular fact that this disease is generally much less painful than scirrhus. The reason, however, is not the paucity of nerves in the one, but the manner in which they are compressed in the other, the structure of encephaloid being so much softer than that of scirrhus, and therefore admitting of greater comfort to its nerves.

It is not unusual for encephaloid tumors to contain serous cysts, as well as other adventitious products, thus complicating their structure, and occasionally throwing a doubt over their diagnosis. In general, the cysts are small; but I recollect an instance where a cavity of this kind contained fully a pint of serum, its walls having a peculiar honey-combed appearance. Apoplectic depôts, as already stated, are most common in the hematoid variety of encephaloid tumors.

It is seldom that an encephaloid tumor, after having once taken a fair start, remains even temporarily stationary; on the contrary, its tendency is to pro-

ceed, steadily and regularly, in its work of disorganization, until it destroys life either by hemorrhage or by irritation, the period at which this takes place varying, on an average, from nine to twelve months. Death sometimes occurs in an almost incredibly short period. I remember the case of a youth of eighteen, a patient of Professor Post, in the New York Hospital, who had a large encephaloid tumor upon the scapula, measuring a foot in its greatest diameter, from which he died in less than eight weeks from its first appearance. On the other hand, a patient occasionally lives a long time. I am now attending a gentleman, aged forty-two, who has been laboring under encephaloid of the antrum for more than four years. Great softness of texture, bulk, and rapidity of growth are the circumstances which particularly predispose to an early unfavorable issue.

The period at which the encephaloid tumor becomes an open ulcer is indefinite; sometimes it takes place within a few months, at other times not under a year, or a year and a half, although this is uncommon. The immediate cause of the ulceration may be the pressure of the morbid mass upon the skin, the formation of an abscess, or the occurrence of a slough. However this may be, the sore is always characteristic. Its edges are thin, undermined, jagged, or irregular, and its bottom, which is sometimes of considerable depth, has a foul, bloody, fungous appearance. In some instances it is covered with numerous excrescences, or large fungous granulations, giving it a peculiar cauliflower-like aspect. The parts immediately around are of a deep red, livid, or purple color. The discharge is usually profuse, and of a sanious, bloody, or sanguinolent character, a development of pure laudable pus never being seen. Copious hemorrhage occasionally takes place, especially in the hematoid variety of the disease, and by its frequent repetition often rapidly undermines the general health, urging on the fatal crisis. The occurrence is particularly common in encephaloid of the eye, uterus, and mamma. Of the many cases that I have seen of the encephaloid ulcer, I have never known one to heal even temporarily. Intractability is one of its distinguishing features.

Lymphatic involvement often occurs at an early stage of the disease, sometimes long before ulceration sets in; at other times, however, it does not take place until the tumor has opened. As a general rule, it may be stated that the more rapid the growth is the earlier will there be disease in the neighboring ganglions, and conversely. The constitutional cachexy is always well marked in the more advanced stages of the affection, and the patient's doom is often depicted in legible characters upon his countenance several months before it is finally sealed in death.

An encephaloid tumor is distinguished by its comparative softness, by the rapidity of its growth, by its great bulk, and by its lobulated surface. The pain is generally slight, at least until ulceration takes place; and there is nearly always considerable, sometimes enormous, enlargement of the subcutaneous veins. In its earlier stages, the tumor is movable, as in scirrhus, but as it advances it contracts adhesions, and at length becomes permanently fixed.

3. EPITHELIOMA.

There is a class of affections which were formerly known under the name of scirrhus, from their supposed identity with that disease, but which modern research has shown to be so different from it as to entitle them to be regarded as separate formations. They comprise the various forms of malignant disease of the cutaneous and mucous tissues, more particularly carcinoma of the lip, gums, tongue, face, anus, and penis. They are not, however, limited to these parts; for they sometimes invade the deeper structures, as the bones, muscles, lymphatic ganglions, liver and lungs, although their occurrence here

is very infrequent. The names by which these formations are now generally designated are epithelioma, canceroid, and epithelial cancer, which, as they are sufficiently expressive of their true character, may all be appropriately used as fancy may dictate.

Epithelioma is more common in men than in women, the latter being more liable to scirrhus. In the male the lip and penis are most frequently attacked. What is called chimney sweeper's cancer is merely a form of epithelial disease of the scrotum. Lupus, the *noli me tangere* of the older writers, is nothing but canceroid of the skin of the face, an affection sufficiently common in both sexes, and often committing the most frightful ravages. In whatever form it may appear, it seldom shows itself before the age of thirty-five or forty. Another circumstance worthy of note is that the disease usually occurs only in one part of the body, its origin being apparently much less connected with the constitution than that of the other varieties of carcinoma.

The causes of this disease are not well understood. Sometimes it is directly traceable to external injury, as long-continued pressure. Thus, Dr. Da Costa has mentioned to me the case of a shoemaker, where it was clearly attributable to the effects of a small board worn habitually upon the abdomen while the man was working at his trade. Epithelioma of the lip is often charged, whether correctly or not I will not pretend to determine, to the irritation produced by the pipe in smoking. Chimney sweeper's cancer is generally ascribed to the irritation occasioned by the lodgment of soot in the folds of the scrotum. Sometimes the disease originates in a wart or cicatrice. Epithelioma of the penis, until lately regarded as true cancer, has been very commonly referred to the irritation arising from a want of cleanliness due to the existence of a long and tight prepuce. A sharp tooth, brought constantly in contact with the tongue, is, as is supposed, an exciting cause of epithelioma of that organ. Cases have been collected which tend to prove that the disease occasionally manifests a hereditary predisposition. Dr. Foster, of Terre Coupee, Indiana, has communicated to me the particulars of three cases which occurred in three members of the same family, two having died from epithelioma of the face, and one from epithelioma of the foot.

Canceroid generally begins in the form of a tubercle, crack, or wart-like excrescence, hard to the touch, movable, and somewhat tender on pressure. As the disease advances the part extends in different directions, and becomes more defined in its character. By and by ulceration sets in, sometimes almost simultaneously at several points, the exposed surface having a foul, unhealthy, fungating appearance, with irregular granulated edges, and a hard, rough base. The discharge is generally abundant, and of a thin, sanious, acrid description, often eroding the skin in the neighborhood. The ulcer is intractable, manifesting no disposition to heal, or, if granulations should form, they speedily degenerate and lose their vitality, the recuperative powers being too feeble to carry on the work of repair. Once begun, the disintegrating action never stops, and hence its ravages are often most frightful, as, for example, in the case from which the adjoining cut, fig. 50, was copied, where the disease successively involved skin, muscle, bone, cartilage, and fibrous membrane, sparing nothing that fell in its way. The pain attend-

Fig. 50.

Epithelial cancer in a state of ulceration.

ing the disease is of a sharp, darting, or pricking nature, and often extends through the surrounding parts. Hemorrhage occasionally occurs, chiefly in the fungating form of epithelial ulcer, and may be sufficiently copious to cause serious debility. Cases have been observed where the disease laid open large-sized arteries and veins.

During the progress of the disease, lymphatic involvement occurs; sometimes early, but generally not until after the lapse of eight, twelve, or fifteen months. Thus, in epithelioma of the lip the ganglions of the jaw become enlarged, and in that of the penis the ganglions of the groin. The constitution also suffers severely, but usually not so early as in ordinary carcinoma, though ultimately not less fatally.

If a section be made of an epithelial cancer it will be found to grate under the knife, and to exhibit a firm whitish or grayish mass, more or less vascular, and of a radiating structure. In the lip and penis, it generally also contains well-marked papillæ, of varying size and shape, some being single, others united, which, however, are altogether adventitious, or they occur only in epithelioma of the mucous or muco-cutaneous surfaces. Minutely examined, the morbid growth is observed to consist mainly of cells not unlike those of pavement epithelium, only that they are larger. The cells vary considerably in their shape, some being rounded, some oval, and some fusiform, angular, or elongated. The older ones are sometimes flattened, shrivelled, or curled up, as if, partially deprived of vitality, they were about to become effete. They usually contain one or two small nuclei, and either lie in superimposed layers, united by fibrous matter, or they are inclosed in peculiar cysts, which are almost characteristic of this class of morbid products. These appearances are well seen in fig. 51, from a drawing by Dr. Da Costa. Sometimes these cells and nuclei are unusually large and distinct, strongly resembling such as occur in true carcinoma. Mixed up with the cells of epithelioma, especially if the disease has made some progress, are great numbers

Fig. 51.

a. Cyst inclosing small cells; b. Large, rather round cells; c. Empty cyst.

Fig. 52.

a. Papilla taken from an epithelial cancer, magnified 250 diameters; b. Separate epithelial cells

of free nuclei, and granules, and sometimes, also, of crystals of cholesterine, pigment cells, and blood corpuscles. The papillæ, previously alluded to, consist of loose fibrous tissue and bloodvessels very densely coated with layers of epithelial cells and free nuclei. Fig. 52 represents one taken from a cancroïd affection of the lip. It will thus be perceived that the disease is deficient in some of the elements of ordinary cancer; a circumstance which accounts for its more manageable character.

Epithelial cancer is generally comparatively tardy in its growth. In a case of cancer of the tongue, reported by Dr. Da Costa, in the Philadelphia Medical Examiner for April, 1852, twenty-two years elapsed from the ap-

pearance of the disease to the time of the operation for its removal. Cancer of the lip often lasts a number of years before it terminates fatally, though this is not its ordinary tendency, most persons dying in from eighteen months to two years. I have seen cases of lupus of the face continue their ravages for nine, fifteen, and twenty years before the disease finally caused death. Under such circumstances, the ulceration occasionally for a time suspends its action, and then resumes it, perhaps now with increased vigor.

4. COLLOID.

Since the attention of pathologists has been more closely directed to this affection, it has been found to be a good deal more frequent than was formerly imagined; nevertheless, compared with some of the other heterologous formations, it is sufficiently rare. The name by which it is usually known has reference to the peculiar jelly-like appearance of one of its principal constituents, and is therefore quite appropriate. It has also been described under the terms gelatiniform, alveolar, and gum cancer.

The favorite seats of this morbid product are the omentum, stomach, rectum, ovary, lower jaw, subcutaneous cellular tissue, and the bones of the extremities. The testicle, mamma, uterus, and lymphatic ganglions are also occasionally attacked by it. It has never been seen in the eye and its appendages.

It may occur simultaneously in a considerable number of organs, but manifests less tendency to general diffusion than any of the other heterologous formations, except the epithelial. It takes place in both sexes, and at all periods of life after puberty, but is most common between thirty-five and fifty. In two instances of enormous colloid tumors of the omentum, observed by myself, the patients were, respectively, forty and forty-nine. In a case which I noticed in the body of the sphenoid bone, beneath the dura mater, the age was thirty-nine.

Colloid occurs under two *varieties* of form, as a tumor, and as an infiltration. The latter is most common in the alimentary canal, particularly the stomach and rectum; the former, in the glandular organs, the peritoneum and omentum, ovary, cellular tissue, and the bones. In the bones it is most frequent in those affections known under the vague names of osteo-sarcoma and spina ventosa, which are sometimes almost exclusively composed of this substance. In the infiltrated variety of colloid, the new matter occupies the meshes of the cellular substance, forming cysts, from the size of a mustard-seed to that of a hazel-nut, which are filled with the characteristic jelly-like matter, and which, as they increase in volume and number, so completely subvert the primitive structures as ultimately to leave no trace of them.

In the other variety of colloid, the heteroclitic matter occurs in the form of a distinct tumor, from the volume of a marble to that of an adult head, of a globular, rounded, or irregular shape, and of a firm, dense consistence. In the peritoneal cavity, I have seen, on two occasions, enormous tumors of this kind, one of which was supposed, by estimate, to weigh not less than twenty-five pounds. It extended from the pelvis to the diaphragm, surrounded the colon and part of the stomach, and almost completely concealed the abdominal viscera; its length being nearly one foot, its breadth upwards of eight inches, and its thickness from two and a half to three inches. The patient, aged forty-nine, had been laboring under the disease for four years. In the other case, that of a gentleman of forty, the tumor occupied the same situation, and was also of extraordinary extent. When the disease was first noticed, eight months before he died, the morbid mass was already of large size, forming an immense protuberance, which bore upon the walls of the abdomen

in every direction, without causing the slightest inconvenience, save what resulted from its bulk.

The surface of the colloid tumor is generally rough, knobby, or distinctly lobulated, according to the volume and arrangement of the component cysts. Occasionally it bears a strong resemblance to the exterior of a pudding stone. The knife, as it passes through it, makes a creaking noise; it contains very little cellular substance, and the investing cyst is usually very thin. In the larger masses, considerable sized vessels may be seen running over the surface, and penetrating the walls of the principal cysts, without, however, passing through their contents.

Colloid consists of two component elements, a stroma, and the peculiar jelly-like matter from which the deposit derives its distinctive features. The former is of a fibrous character, and is arranged in such a manner as to form cells, loculi, or cavities, from the size of a pin head up to that of a small marble, rounded, ovoidal, or angular; communicating with each other, and lined by a thin, delicate, transparent membrane, which, excepting that it is not a shut sac, closely resembles the serous tissue. The stroma is of new formation, and generally possesses great firmness and density; it creaks under the knife, and is of a dull, whitish, grayish, or pale yellowish color. The cystiform structure of colloid is easily recognized in all specimens of the disease, and is so remarkable that, once seen, it can never be forgotten. It is well illustrated in the annexed cuts; fig. 53 showing the external arrangement, and fig. 54 the internal.

The fibrous matter of colloid is almost destitute of free cellular substance.

It receives, however, an abundant supply of vessels, as I have satisfied myself by dissection, and as is evinced also by the rapid development of the morbid growth, and the great bulk which it occasionally attains. In one case in particular I had no difficulty in tracing several large, straggling arteries into a tumor of this kind, showing that it had a very active circulation. The manner, however, in which the vascular system of the morbid product is arranged is not determined; nor is it ascertained

Fig. 53.

Fig. 54.

Colloid tumor. Fig. 53, external appearance. Fig. 54, internal structure. From a preparation in the author's collection.

whether it is of new formation, or derived solely from the surrounding and included healthy structures. Of the character of its nerves and absorbents, we are equally uninformed.

The other element of colloid is an unorganizable product, of a whitish, greenish, or yellowish color, and of the consistence of ordinary jelly, whence the name by which the disease is usually known. In the older cells the matter is sometimes as firm as moist cheese, or the white of a hard-boiled egg, opaque, and of a white pearly or yellowish hue, interspersed with minute dark points. Sometimes, again, it resembles currant jelly, half dissolved glue, or a solution of gum shellac. However this may be, it never adheres to the walls of the cells, and is, therefore, easily enucleated, or pressed out. When perfect clearance has been effected of the cells of a mass of colloid, the fibrous structure exhibits very much the appearance of a piece of sponge, the alveolar arrangement being then particularly conspicuous, hundreds of cells being often visible upon a surface less than an inch in diameter.

Although the soft matter of colloid looks so much like jelly, chemical analysis has shown that it is entirely destitute of this substance, its principal

constituents being albumen, casein, and osmazome, in varying proportions. Destructive analysis has yielded, in the 100 parts, 48.09 of carbon, 7.47 of hydrogen, 37.44 of oxygen, and 7.00 of nitrogen.

Under the microscope colloid appears as a homogeneous substance, with now and then a slightly granular arrangement, or large irregular plates. In this basis-structure are seen nucleated corpuscles, and large parent cells, enclosing several smaller ones. Cancer cells, such as occur in scirrhus and encephaloid, are occasionally found in it, but not as a necessary constituent, since in some specimens they are entirely absent. Moreover, it is worthy of notice that corpuscles, very similar to those of colloid, sometimes occur in gelatinoid infiltrations of the spleen, heart, and thymus. The stroma of colloid is essentially composed of fibrin.

It is impossible, in the existing state of our knowledge, to determine the precise nature of colloid, or to assign to it its proper position in the scale of the heterologous formations. It is certainly destitute of many of the properties of carcinomatous disease, and yet its career, so far as I have had occasion to watch it in my own practice, is not the less positively fatal especially when it occurs in the internal organs. In the osseous structures, it may occasionally be removed without relapse, and the same thing may probably be true in regard to colloid in some other situations; but upon this subject we are in need of further light. It has less disposition to ulcerate, and to contaminate the surrounding lymphatic ganglions, than the other heterologous formations.

5. MELANOSIS.

Melanosis, sometimes called black cancer, occurs most commonly in the cellulo-adipose tissue beneath the skin, in the folds of the mesentery and omentum, around the kidneys, in the mediastinal cavities, the lymphatic ganglions, the eye, liver, lungs, and parotid glands. It is also met with, though more rarely, in the serous and fibrous membranes, the bones, ovaries, heart, pancreas, and spleen. Occurring usually alone, it occasionally coexists with some of the other heterologous deposits, especially the scirrhus and encephaloid, and may attack quite a considerable number of organs either simultaneously or successively. It takes place in both sexes, and at all periods of life, but is most frequent in adults and middle-aged subjects.

An instance in which the melanotic diathesis prevailed to a remarkable extent came under my observation in 1855, in a man, aged fifty-eight years, who, after a confinement of nearly twelve months, finally died in a state of extreme exhaustion, the prominent symptoms having been harassing cough, occasional discharges of blood from the bowels, irritability of the bladder, frequency of the pulse, and copious night-sweats. Melanotic tubercles existed in the subcutaneous cellular tissue in various regions, the lymphatic ganglions of the groin, axilla, and bronchia, the omentum and peritoneum, stomach, large and small bowels, pancreas, liver and gall-bladder, kidneys and supra-renal capsules, urinary bladder, prostate gland, seminal vesicles, lungs and pleura, heart, and thyroid body. The spleen and large vessels were sound. The brain, bones, and muscles were not examined. A remarkable feature in the case was the existence of numerous white and grayish tubercles in the midst of the black, showing that the former were in a nascent condition, having not yet undergone the melanotic transformation.

The melanotic matter is deposited in several *varieties* of form, of which the tuberoid is the most common. It occurs in small masses, of a rounded, ovoidal, or irregular shape, with or without a cyst, and from the size of a pin-head to that of a walnut. Of a dull sooty, brownish, or black color, they are generally invested by a distinct capsule, formed out of the cellular tissue

in their immediate vicinity, which thus serves to separate and protect them. Fibrous bands generally intersect their interior, and vessels are often seen ramifying over their surface, none of them, however, dipping into the proper melanotic matter. It is by the union of several of these smaller masses that large tumors are sometimes formed, reaching, now and then, the volume of a fist or even of a foetal head. Cases occur in which this matter presents itself in small points, or in irregular patches, generally beneath some serous membrane. Finally, it is sometimes found in a liquid form.

Melanotic matter, in a pure state, is of a sooty black, dark brown, or dull bistre color, its consistence varying from the fluidity of ink to that of fibro-cartilage. Its chemical constituents are albumen, fibrin, and a dark, highly carbonized substance, not unlike the cruor of the blood, with a minute quantity of iron, soda, magnesia, lime, and potassa. It is opaque, without odor or taste, and miscible with water and alcohol; it imparts a characteristic stain to linen, resists decomposition, and emits an empyreumatic smell when burned.

Examined microscopically, melanotic matter is found to consist of a fibrous network, inclosing numerous meshes, which are filled with free, unadherent pigment cells, of a pale yellowish, dark, or dark brown hue, and of a rounded,

Fig. 55.

Microscopic structure of melanosis.

oval, or irregular figure; they are of great delicacy, and are occupied by colored granules, a few of the larger or older ones sometimes containing a nucleus with its nucleolus. These appearances are well represented in fig. 55. Pigment cells are not present in all cases, and their granules are occasionally seen in other structures, both healthy and morbid, as in the lung pigment and in the elements of carcinomatous growths.

The precise nature of melanosis is undetermined. I am, however, inclined to believe that it is merely a modification of encephaloid, the chief difference consisting in the superaddition of black pigment.

What corroborates this view is that tumors partaking of the character of both these formations, occasionally co-exist, either in the same, or in different parts of the body; and also, that they exhibit similar histological elements.

Of the causes of this deposit nothing is known. It is always effused in a liquid form, and is wholly unorganizable, receiving neither vessels nor nerves; though these are freely distributed through its fibrous stroma. It has been supposed that black cancer might be communicated by inoculation, or immediate contact, but experiments upon the inferior animals have refuted this conjecture.

After having remained stationary for an indefinite period, this matter manifests a disposition to disintegration, the softening process generally beginning at some superficial point, and thence gradually extending to the skin, which, giving way, leads to the establishment of a foul, non-granulating, unhealthy ulcer, which no skill can cure. The discharge is generally of a sanious character, mixed with and discolored by the heteroclitic secretion. Its progress is usually more tardy than that of scirrhus and encephaloid, except when it exists simultaneously in a great number of organs, as in the case above described, where it terminated fatally in a little over a year. The general health often suffers long before ulcerative action sets in, the patient becoming thin, haggard, and sallow.

Having thus described each malignant tumor separately, I shall, in the next place, offer some remarks on the origin of this class of affections, their diagnosis, and treatment.

Local Origin.—It has been supposed that all malignant diseases are occasionally of a purely local character, having their origin in causes entirely independent of the general system; or, what amounts to the same thing, that they may be developed under the influence of local injury. But such an opinion, it seems to me, is hardly tenable; at all events, it admits of great doubt whether such a result really ever follows such a cause; it certainly could not, one would suppose, unless there is a predisposition, a readiness, as it were, on the part of the system, to generate cancer cells, or to take on malignant action; else why is it that external violence, as a blow or bruise, so seldom gives rise to this horrible and unmanageable complaint? Why, in other words, is it that a blow will produce cancer in one person and not in another; or, still farther, why will one individual suffer and a thousand escape?

Cancer of the lip has often been attributed to the irritation produced by the hot and filthy stem of the earthen pipe in smoking. But it may well be asked whether the use of the pipe and the occurrence of this frightful disease should not be viewed rather in the light of a coincidence than in that of cause and effect? Be this as it may, it is unquestionable that thousands of persons smoke and yet never suffer from cancer of the lip. So in regard to many of the other circumstances alleged to be capable of inducing malignant disease, as grief, mental anxiety, loss of rest, unwholesome food, and disorder of the menstrual function, which are so often accused of provoking carcinoma in the mamma and uterus. Unless, therefore, a predisposition exists in the system to the development of these affections, it admits of great doubt whether it is possible for any local irritation to originate them. It is far more probable that they take their rise in the blood, but how, or in what particular element of this fluid, we are of course totally ignorant. It has been asserted that cancer cells have been detected in the blood, but if this has been the fact it is certain that they were not formed there, but that they were simply introduced through the agency of the vessels during the progress of carcinomatous disease. To arrive at any other conclusion would be absurd.

Can a tumor of an innocent, benign, or non-cancerous character, in its progress, become malignant? in other words, is such a growth capable of what has been termed the carcinomatous degeneration? It seems to me that it is not difficult to give a correct answer to this question. If the term "degeneration" is restricted to its true and legitimate signification we must reply in the negative, for no tumor, whatever be its structure, can, by a mere conversion or transformation, pass into a malignant condition. Such a change can be effected only under the influence of a vital process, involving the development and actual existence of the cancer cell; and I cannot, for my own part, see any good reason why a new growth, tumor, or deposit should be more exempt from such a disease than a primitive, original, or pre-existing tissue, whatever be its structure. Nay, indeed, may it not be supposed that the more feebly a part is organized, the more prone will it be to take on such a process? That this change does sometimes occur, may be inferred from the circumstance that tumors, believed to be cancerous, but which cannot be positively proved to be so, remain, occasionally, in a state of latency for ten, fifteen, twenty, and even thirty years, and then, all of a sudden, manifest a malignant and destructive action, generally followed by the worst consequences.

It would be of great practical utility if we knew the origin of cancer, or if we were acquainted with the causes, local and constitutional, under the influence of which malignant diseases, properly so called, are developed. But

upon this subject, unfortunately, we are entirely ignorant, nor is it likely that our inquiries concerning it will lead to a satisfactory solution of a question which has occupied so much attention.

Carcinoma is sometimes *hereditary*; not, however, so frequently as is generally supposed. Besides, it should be remembered that there is a difference, and that a very wide one, between the transmissibility of this disease from the parent to the offspring, and its coexistence, or successive development, in different members of the same family. The latter occurrence, although also very infrequent, is much more common than the former, of which my own experience has supplied me with only a few examples. Lately, I saw a lady with a well-marked cancer of the mammary gland, whose mother and maternal aunt had died of the same disease. In the summer of 1850, I prescribed for an aged female with a cancer of the lip, whose mother had perished from cancer of the breast, and the father from cancer of the tongue. But the most remarkable and instructive instance of this kind, probably, upon record, is that related by Dr. Warren, in his work on Tumors. A man died of cancer of the lip; his son had a similar disease in the breast, from which, after having undergone an operation at the age of sixty, he finally lost his life. Two of his sisters had cancer of the mammary gland; they were operated upon, but ultimately died from a relapse of the malady. A daughter of one of the ladies had a cancer of the breast, which was removed at an early period; she recovered, but perished some years after from disease of the uterus. A daughter of the gentleman had a cancer of the breast, and there was reason to believe that other members of the family were affected by the same malady.

A case, almost equally remarkable, of this hereditary tendency to cancer, has been communicated to me by Dr. J. M. Warren. In this instance, a man who died of cancer of the penis, lost his father, grandfather, and great-grandfather from the same disease.

More frequently, as has been already stated, the disease occurs, either simultaneously or successively, in several members of the same family. My own practice has afforded me a number of instances of this kind, and there is not a writer on carcinoma that does not narrate examples of it. In one remarkable case, four out of six members of one family have died of the disease; one from cancer of the uterus; another from cancer of the mammary gland; a third from a malignant polyp of the nose; and the fourth from carcinoma of the thoracic viscera. Professor Gibson gives an instance of cancer of the breast in four sisters.

Diagnosis.—Epithelial cancer is usually sufficiently easy of recognition. Its situation at the junction of the skin and mucous membranes, or upon either of these structures; its origin in a crack, fissure, or wart-like excrescence; its extraordinary firmness, the part feeling like a mass of fibro-cartilage; its slow growth; its small size; and the absence, for a long time, of severe pain and constitutional taint; are features that cannot be mistaken.

The only characteristic sign of melanosis is the peculiarity of the color of the tumor; hence, when it is situated superficially, as when it occupies the skin, eye, parotid gland, or lymphatic ganglions, it is quite impossible to mistake the nature of the disease.

Colloid tumors are liable to be confounded with fibrous and enchondromatous formations; but a careful consideration of the history of the case, and a thorough examination of the morbid mass will generally serve to clear up any doubt that may arise in regard to the diagnosis. Colloid growths are usually situated in the peritoneal cavity, in the ovary, or in the bones; they are slow in their progress, smooth or rough on the surface, of uniform consistence throughout, and free from pain, their bulk being usually enormous, and the general health greatly disordered. Fibrous tumors advance slowly,

seldom attain a great bulk, and do not usually seriously undermine the constitution. The enchondromatous growth is harder and less elastic than the colloid; its progress is rather rapid, and its outlines are always well defined, which is seldom the case with alveolar cancer.

Almost the only disease with which encephaloid is liable to be confounded is scirrhus, and it will therefore be necessary to point out their differential diagnosis. For this purpose I give the subjoined table of the characteristics of the two affections.

ENCEPHALOID.	SCIRRHUS.
<ol style="list-style-type: none"> 1. The tumor is soft and elastic, not uniformly, but more so at some points than at others. 2. It grows rapidly and soon acquires a large bulk, perhaps ultimately attaining the volume of an adult's head. 3. The pain is slight, and erratic, until ulceration begins, when it becomes more severe and fixed. 4. There is always marked enlargement of the subcutaneous veins. 5. The ulcer is foul and fungous, with thin, undermined, and livid edges, and is subject to frequent and copious hemorrhage. 6. There is generally early lymphatic involvement. 7. Occurs at all periods of life. 8. Is most frequent in the eye, testicle, mamma, lymphatic ganglions, bones, and cellular tissue. 9. The disease usually terminates fatally in from nine to twelve months. 	<ol style="list-style-type: none"> 1. Uniformly hard and inelastic, feeling like a marble beneath the skin. 2. Growth is slow, and bulk comparatively small; the tumor rarely, even in the worst cases, exceeding the volume of a double fist. 3. The pain begins early, is distinctly localized, and is of a sharp, darting, burning, or lancinating character. 4. In scirrhus these vessels retain their natural size, or are only slightly enlarged. 5. The ulcer is incrustated with spoiled lymph, and has steep, abrupt edges, looking as if it had been punched in the part; bleeding little, and seldom. 6. Usually not until late, or just before ulceration is about to occur. 7. Seldom before the age of forty-five. 8. Never occurs in the eye and testicle, and seldom in the bones and lymphatic ganglions. 9. Seldom sooner than eighteen months or two years.

It is not improbable that an encephaloid tumor might be confounded with a chronic abscess, or an aneurism, especially when it is so situated as to receive an impulse from a neighboring artery. The very mention of the possibility of such an occurrence will be sufficient to put the young and inexperienced practitioner upon his guard, and serve to point out to him the absolute necessity of the most profound caution in every case of a suspicious character.

It has been proposed, in cases of doubt, to solve the difficulty by means of the exploring needle, or, rather, of an instrument so constructed as to admit of the removal of a portion of the morbid growth just sufficient to answer the purposes of a microscopic examination. I must confess, however, that I have a great aversion to all such procedures, believing that they generally prove prejudicial to the part, by provoking an increase of the morbid deposit, the puncture, unless very small, serving as a new centre of action. I have witnessed in at least two instances great harm from the operation, and have therefore of late years uniformly discountenanced it, except when the tumor is seated in an extremity, so as to admit, if found to be cancerous, of prompt removal by amputation.

The microscope is certainly not infallible as a means of diagnosis. It is often a valuable auxiliary, but nothing more. The practical surgeon must indeed be dull who cannot, as a general rule, determine the character of a morbid growth before he attempts its removal. The merest tyro in the profession has no difficulty in discriminating between a gelatinoid and a fibrous polyp of the nose, a scirrhus and an encephaloid tumor of the breast, or a common hypertrophied ganglion of the neck and a malignant growth of the

same part. Every new growth, whether benign or malignant, has its peculiar features, not less than every pre-existing one. I believe that, with proper care, and a reasonable knowledge of morbid structure, such as every cultivated surgeon ought to possess, it is, in general, as easy to determine the difference between a malignant and a non-malignant tumor as it is to determine the difference between a muscle and a tendon. In making these remarks I have no desire to underrate microscopical researches; on the contrary, I only wish to state that they have not, in my judgment, effected all the good that has been claimed for them, especially in this particular department of pathology and practice, and that, therefore, their results should be received with some degree of allowance. In fact, the whole subject of morbid growths, benign and malignant, should be revised and re-examined. When there is so much dispute as there confessedly is at present respecting the real nature of the cancer-cell, or, whether indeed there is such a cell at all, it well becomes the practitioner to look with distrust upon many of the alleged discoveries of the microscope. Besides, he should not lose sight of the value of his unassisted senses, nor cease to cultivate them in the highest possible degree.

After a malignant disease, whatever may be its character, has made considerable progress, so as to impress itself upon the constitution, the diagnosis, however obscure it may have been in the early stages of the affection, is no longer doubtful. The worn and haggard features, the sallow complexion, and the emaciated and exsanguine condition of the system, are characters which it is impossible to mistake. The countenance bears the impress of the disease, looking as if it had been stamped with the seal of malignancy.

TREATMENT.

The treatment of the various forms of malignant growths may very properly be discussed under one general head, since they are evidently all governed by the same laws, both as it respects their origin, progress, tendency, and termination. All internal remedies, of whatever kind and character, have proved unavailing in arresting their march, or in modifying them in such a manner as to render the surrounding structures tolerant of their presence. The vaunted specific of the empiric, and the enchanted draught of the honest but misguided enthusiast, have alike failed in performing a solitary cure; and the science of the nineteenth century must confess, with shame and confusion, its utter inability to offer even any rational suggestions for the relief of this class of affections. But, although this is the case, yet it by no means follows that the subjects of these complaints may not be benefited by general and local treatment, if its application be directed by common sense and sound judgment. Every practitioner of experience knows how much ordinary local diseases are influenced by constitutional measures; and if this be true of these lesions, how much more must it be true of the malignant, in the production of which both the solids and fluids play such an important part. The attention of the surgeon should be particularly directed to the patient's diet, bowels, and secretions, and to the avoidance of all sources of local irritation, calculated to favor the morbid growth, and hasten the fatal issue.

The *diet* should, in general, be of a bland and unirritant character, but at the same time sufficiently nutritious to preserve a sound condition of the blood, and maintain the tone of the muscular system. All condiments, coffee, strong tea, pastry, hot bread, and the coarser kinds of vegetables and meats should be abstained from. Eggs, fish, oysters, and the white kinds of meat may be used once a day in moderate quantity, but oftener than this

they should not be indulged in, unless there is some special reason for it, founded upon the state of the general health. Frequently a purely farinaceous and milk diet is found to answer better than any other, the patient not only thriving under it, but the disease being apparently kept in check by it.

The *bowels* should be maintained in a soluble condition, but all active purgation must be carefully avoided. The most suitable aperient, when a tendency to constipation exists, is a blue pill, with one grain of ipecacuanha, or equal parts of blue mass and jalap, at bedtime, followed, if necessary, by a Seidlitz powder in the morning. If evidence of gastro-intestinal irritation arise, the blue mass may be advantageously replaced by a small portion of calomel. In this way, while the bowels are maintained in a tolerably free state, the secretions are also duly preserved; a matter of no little moment in the treatment of all malignant diseases without exception, especially when they are attended with marked constitutional disturbance.

Sleep is procured and pain allayed by anodynes, the constipating effects of which are counteracted by the conjoined use of ipecacuanha or tartar emetic, in suitable doses. When the suffering is of a neuralgic character, the anodynes may be combined with arsenic or arsenic and strychnine.

If marked *debility* exists, recourse must be had to tonics, as quinine and iron, aided by a nutritious diet and the use of brandy, wine, ale, or porter. Night-sweats are best controlled by aromatic sulphuric acid.

Great care should be taken to keep the affected part perfectly at *rest*, and free from pressure and excitement. If it be the breast or testicle that is diseased, the organ must be well suspended, the dress worn loose, and all manipulation studiously abstained from. If the surface is tender, hot, and swollen, or œdematous, some mildly astringent and anodyne lotion will be of service, or the part may be painted several times a day with a weak solution of iodine. When the local inflammation is unusually severe, as is evinced by the discoloration and pain, nothing, according to my observation, will afford such prompt and decided relief as the application of from four to six leeches, unless it be a small blister, kept on until there is pretty free vesication. Some cases are greatly benefited by the use of an opium, belladonna, or cicuta plaster, renewed every ten or twelve days. All caustic applications are to be carefully avoided, inasmuch as they can never do any good, but may do a great deal of harm by establishing sores which it will afterwards be impossible to heal.

When the parts take on *ulcerative* action, the resulting sore must be kept constantly clean by frequent ablutions; while the excessive fetor which so generally attends must be allayed by the free use of the chlorides. The best dressing will be an emollient poultice, particularly that made of powdered elm bark, sprinkled, if there be much pain, with a little morphia, pulverized opium, or laudanum. If the ulcer be very sensitive, it should occasionally be touched, very lightly, with the solid nitrate of silver, or it should be kept constantly covered with the dilute ointment of the nitrate of mercury. When the discharge is very profuse, sanious, and offensive, a lotion composed of from two to four drops of nitric acid to the ounce of mucilage of gum arabic will be found exceedingly beneficial in diminishing its quantity and changing its character.

The affected glands in the neighborhood of the diseased organ often require attention, especially when they are very painful and bulky. The remedies should be of an anodyne and antiphlogistic character, especially leeches, iodine, and saturnine lotions.

The treatment of carcinomatous diseases *by compression* was introduced to the notice of the profession early in the present century by Sir Charles Bell, and, after having been alternately eulogized and condemned, has at

length fallen into merited disrepute. Some years ago Mr. Arnott, of London, made an attempt to revive this mode of treatment, especially in cancer of the mammary gland, by the invention of a cup-shaped apparatus furnished with an elastic air-cushion, in order to apply the pressure in a more gentle and equable manner. The suggestion, emanating from so eminent an authority, attracted much attention at the time, and led to numerous trials, both in Europe and in this country, but with results so discouraging as to have caused its entire abandonment.

In regard to *extirpation*, all experience has proved that it cannot be relied upon as a means of permanent cure. The only benefit which it can confer is temporary relief for a few months, or, at most, for a year or two; and this is true no matter in how masterly and thorough a manner the operation may be executed. Hence not a few surgeons of the present day have expressed themselves as altogether averse to such a procedure, believing that it will only serve, in the great majority of instances, to hurry on the case to a fatal crisis. My own conviction is that interference with the knife is, as a general rule, only productive of harm, and that the patient will live quite as long without as with it, and, on the whole, in a state of greater comfort. Nevertheless, there are cases, although it is difficult to define their character, where we occasionally see an operation followed by highly beneficial results, not only ameliorating pain, but apparently preventing an extension of the disease, and relieving the mind of that terrible feeling of anxiety which is so sure to attend the more severe forms of carcinoma. The cases which have done best in my own hands, after operation, were females with scirrhus breasts, which, after having been long in a quiescent state, at length assumed a threatening ulcerative tendency, or which had actually, in a slight degree, yielded to this process.

Epithelial cancer is less liable to recur after extirpation than scirrhus, encephaloid, or melanosis. Removed in its earlier stages, there is occasionally a strong probability that there will be either no relapse at all, or only after a considerable period. One reason probably of this is the fact that the disease is more of a local character than the ordinary forms of carcinoma.

General Rules for conducting Excision of Malignant Diseases.—When excision is determined upon, it is a matter of paramount importance that it should be performed in the most thorough and complete manner, in order that the parts may be effectually guarded against relapse. The slightest atom of the new tissue, the most minute cancer cell, nay, possibly, the smallest particle of cancer juice, may, if left behind, endanger a reproduction of the malady.

1st. To accomplish this object, it is necessary that the incisions should be carried through the healthy tissues at some distance from the morbid deposit. Should any part have escaped the knife in the first instance, it should be traced out immediately after the extirpation of the main mass, and be excised with the most scrupulous exactness. Free use should be made, in this stage of the operation, of the sponge and finger; of the former, for clearing away the blood, and of the latter, for ascertaining the consistence of the surface of the wound. The sight alone should never be trusted in a case of this kind, inasmuch as it is a great deal more deceptive than the sense of touch. Not a particle of the least suspicious substance should be left behind. Skin, muscle, glands, vessels, nerves, and bone should all be sacrificed, if necessary to the success of the operation. Nay, the very atmosphere of the disease should be destroyed; and, with this view, the surgeon should always remove a considerable amount of healthy substance.

2dly. The operator should endeavor to preserve as much of the common integument as possible, in order to afford a complete covering to the surface of the wound. This rule is one of great importance, and should never be

departed from. Another precept, of nearly equal consequence, but one which is not generally sufficiently insisted upon, is to preserve as large a quantity as practicable of the subcutaneous cellulo-adipose tissue, with a view of maintaining, unimpaired, the circulation of the skin. Whenever this is much interrupted, as it necessarily must be by a very close dissection, there is additional danger of a speedy return of the abnormal action, and also greater risk of erysipelas immediately after the operation.

3dly. When only a portion of an organ is involved by the heteromorphous matter, the rule is to remove, not a part, but the whole of it. Thus, in cancer of the mammary gland, the practice invariably is to extirpate the entire organ, no matter how small a portion may be implicated in the disease. Upon this point, surgeons have long been agreed. When the disease is seated in an extremity, especially the distal portion, the proper operation is amputation, not excision.

4thly. In removing a malignant tumor we should always endeavor to avoid loss of blood. This is a good rule, even when the patient is tolerably plethoric; but its observance is especially important in lean and fat subjects, the latter of whom, in particular, generally bear the loss of this fluid very badly. I deem it a matter of great moment to guard against hemorrhage in every operation of this kind, not so much on account of the immediate recovery of the patient, as on account of the danger of relapse, which, I confidently believe, is frequently very much increased by this accident.

5thly. It is a matter of great consequence, in reference to the question of relapse, that the whole of the wound left by the operation should be healed by the first intention. For this purpose, the parts should always be approximated as nicely as possible, not only at their edges, but also over the surface of the wound, that there may be no cavities or pouches for the lodgment of matter, but that the restorative process may proceed in the best and most rapid manner at every point. The most suitable dressings are a light compress and bandage, aided by adhesive strips or collodion plaster. Sutures are objectionable, because the tract made by them occasionally serves as a point of departure for new deposits, thereby promoting relapse. They cannot, however, always be dispensed with, especially when there is a scarcity of integument.

6thly. When the integument is defective, it is sometimes practicable to borrow the requisite amount from the surrounding parts; an operation first suggested, I believe, by Martinet, who imagined that we could thereby generally, if not always, effectually prevent a return of the disease. He thought we might thus change the functions of the parts in such a manner as to restore their healthy nutrition, and so counteract the tendency to the production of cancer.

I have had recourse to this procedure in a number of instances, in different regions of the body, especially in epithelial cancer of the lips and eyelids; but in none with any permanent or even protracted benefit. For a time the transplanted parts retained their healthy character; but at the end of a few months they gradually became hard and rigid, and soon thereafter exhibited all the evidences of carcinomatous disease.

7thly. When a sufficiency of integument cannot be obtained, and the wound is obliged to heal by the granulating process, it is worthy of consideration whether the whole of the raw surface should not be effectually cauterized with the nitrate of silver, or the acid nitrate of mercury, so as to form a superficial eschar. The practice certainly derives support from the beneficial effects which are said to follow the treatment of cancer by cauterization in the hands of the empirics, as well as in the hands of some scientific practitioners.

Finally, considerable diversity of opinion has existed among surgeons as

to the time when the operation should be undertaken with the best prospect of ultimate success. The preponderance of professional sentiment, however, has always been in favor of early interference, on the ground that the longer the disease is permitted to remain, the greater, all other things being equal, will be the risk of contamination. The advocates of this measure, indeed, never countenance a resort to the knife when there is positive evidence that the disease has invaded the adjacent parts, or the system at large. Some, it is true, employ it with a view of prolonging life, or alleviating suffering, but never with the hope of effecting a radical cure.

Treatment after Operation.—The treatment after removal of the affected structures must be conducted upon general principles. Everything should be done calculated to insure union by the first intention. When the patient has recovered from the immediate effects of the operation, he should be put upon a general course of treatment intended to maintain his health as near as possible at the normal standard. Above all, strict and constant attention should be bestowed upon the diet.

Of the propriety and importance of attention to the patient's diet, after excision, no one can entertain any doubt. The force of this remark will appear the more evident when it is recollected that the progress of cancer has occasionally been stayed for months, and even years, by a regular and persistent system of starvation, barely allowing a sufficient quantity of food, and that of the most bland and unirritant character, to maintain the due play of the vital functions, without too great a reduction of the heart's action.

The kind of diet is, doubtless, a matter of no little moment. As a general rule, it may be stated that meats, soups, and the coarser varieties of vegetables should be proscribed, on account of their heating and indigestible character. For the same reason, condiments, wine, spirits, and fermented liquors are to be eschewed. Among the more suitable articles may be mentioned stale bread, toast, and soda biscuit, hominy, rice, sweet and Irish potatoes, mush, macaroni, baked apples, figs, and ripe fruits. Not only should the food be perfectly simple and easy of digestion, but great care should be taken that it is always thoroughly masticated, and that the quantity at each meal is never so great as to crowd and oppress the stomach. As drinks, the best articles are water, milk, and weak tea. Coffee is too stimulating, and must be avoided.

Of late years almost an exclusive milk diet has been used in several remarkable cases after this operation, and with effects so encouraging as to deserve farther trial. The facts published upon this subject by Dr. Pierce, Dr. Bowditch, and several others, are exceedingly interesting and instructive, and should receive attentive consideration.

As there are no remedies which will eradicate the cancerous poison from the system before operation, so are there none which will prevent its reproduction after. Of the numerous articles that have been employed for this purpose there is not one that can be viewed in the light of a specific, or as a counteragent to the morbid action.

Some of the older surgeons, and, indeed, quite a number also of the modern, strongly insist upon the establishment of a kind of perpetual drain in the neighborhood of the original disease, as a means of preventing relapse after extirpation. The principal measures that have been suggested for this purpose are the issue and seton; but with this mode of treatment I have no experience.

Should relapse ensue, and the patient become debilitated, recourse must be had to supporting measures, as quinine, iron, brandy, and nutritious food, aided by gentle exercise in the open air. Pain must be allayed by the free use of anodynes, and night-sweats by elixir of vitriol, or oxide of zinc, given in as large doses as the stomach will tolerate. Constant attention must be

paid to cleanliness; fœtor must be destroyed by the chlorides; and the utmost care must be taken to protect the parts from the pressure of the clothes and rude contact of every description. The most suitable local remedies are leeches, the dilute tincture of iodine, emollient cataplasms, medicated with anodynes, and opiate plasters.

Contra-indications to Surgical Interference.—The following circumstances may be enumerated as contra-indicating the removal of malignant tumors:—

1st. No operation should be performed when the disease is congenital, or when it manifests itself soon after birth. Under such circumstances, a resort to the knife is almost certain to be followed by relapse, and that, too, in a very short time, owing, probably, to the fact that the system is, as it were, saturated with the cancerous poison. Cases of this kind are peculiarly virulent and intractable, resisting all attempts at cure, frequently, indeed, even at palliation, and rapidly tending to a fatal termination. The occurrence of the disease in several members of the same family may also be regarded as contra-indicating ablation, inasmuch as it is denotive of a constitutional proclivity to malignant action.

2dly. Interference should be avoided when the disease exists in several parts of the body; as, for instance, when it affects the mamma and the uterus, or the testicle and the eye. Although all these organs are accessible to the knife, yet a resort to it under such circumstances would be highly injudicious, inasmuch as it could not possibly eventuate in any permanent good, but, on the contrary, be almost sure to hasten the patient's destruction. No surgeon, however reckless, would think of operating when the external disease is associated with carcinoma of an internal part.

3dly. Operation is never resorted to, at least not as a curative agent, when the morbid growth has attained unusual magnitude: when there is serious local involvement; or, lastly; when there is marked evidence of the carcinomatous cachexia. Thus, in cancer of the mamma, no surgeon who values his reputation, or who has any regard for the welfare of his patient, thinks of interfering when there is great bulk of the tumor, or firm adhesion of the organ to the surrounding parts; when the skin is changed in structure, ulcerated, indurated, or dimpled; when there is enlargement of the axillary, subclavicular, or sternal lymphatic ganglions; when there is œdema, with numbness and loss of function in the corresponding limb; and, finally, when, in addition to some of the symptoms just mentioned, the features exhibit all the evidences of the cancerous cachexy. The same circumstances guide the surgeon in carcinoma of the testicle, eye, lip, penis, and extremities. If the knife is ever employed when the malady has made such progress and such inroads, it is with a view solely to palliation, not to cure. Of the propriety of such a course, every surgeon must be his own judge.

4thly. When the disease advances very rapidly, as it not unfrequently does in encephaloid, breaking through its original boundaries, and leaping, as it were, suddenly into the surrounding tissues, it may be assumed, as a general rule, that ablation will be improper; or that, if had recourse to, speedy repullulation will be the consequence. Rapid growth, constituting what has sometimes been denominated the acute form of malignant action, always implies a bad state of the constitution, and imperatively forbids surgical interference. There is another symptom which is equally portentous, but which has not, I think, engaged sufficient attention. I allude to the œdematous appearance of the parts immediately around the morbid deposit, or at a distance more or less remote from it. This condition, which is seldom absent in external carcinoma in its latter stages, is not unfrequently present at an early period in encephaloid, especially the hematoid variety of this affection, and always denotes the very worst state of things, both local and constitutional. The immediate cause of this symptom is obstruction of the

lymphatic vessels and ganglions. Observation shows that nothing but mischief is to be expected from interference when the malady has attained this crisis.

5thly. A quickened state of the pulse, occasioned by the local irritation, augurs unfavorably. Excision, performed under such circumstances, is nearly always followed by speedy relapse; and it is, therefore, the duty of the surgeon to discountenance it.

6thly. Latent cancers should not be tampered with. Cases constantly occur in which, from neglect of this precaution, the patient loses his life, within a very short period after operation, from a return of the disease in its worst form. The reproductive powers of the part, if not of the system generally, usually manifest an astonishing activity under such circumstances, and the consequence is that the malady soon accomplishes its work of destruction.

7thly. It is not necessary here to insist upon the propriety of refraining from operation when there is serious disease of an important internal organ. Such a complication could hardly fail to predispose to relapse, if not to the speedy destruction of the patient.

Reproductive Tendency of Malignant Diseases after Operation.—Of the reproductive tendency of carcinomatous diseases, after extirpation, or destruction by the actual or potential cautery, writers have made mention from the earliest periods of medical science to the present time. Hippocrates was fully aware of the fact; and he entered his protest against all operative proceedings, under the conviction that, however early or well executed, they could not possibly afford any permanent relief, or guard the patient against a return of his malady. Similar views have been advanced by nearly all succeeding writers. If a different sentiment has occasionally been expressed, it has been by men who have had a very imperfect knowledge of the disease, who have been poor observers, or who have wilfully concealed the truth, from interested and dishonest motives.

The period at which relapse occurs varies from a few weeks to a number of years. On an average, it may be stated to be from four to six months. Occasionally it takes place within an almost incredibly short period. In one of my cases, the malady returned in less than three weeks. The original disease, which exhibited all the marks of genuine scirrhus, was of eight months' standing, and was seated in the left mammary gland, which it involved nearly in its whole extent; the nipple was somewhat retracted, and there was a slight enlargement of one of the lymphatic ganglions, which was removed in the operation. The dissection was performed with much care, and every particle of the morbid structure was apparently cut away; the greater portion of the wound united by the first intention, but a part of the centre remained open and became the starting-point of the new growth. The woman, who was forty-six years of age, died three months after the operation, having endured the most horrible torments.

Sometimes a relapse does not take place until the end of the first year; and in a few instances it is postponed to a later period, as the expiration of the second, third, and even fourth year.

But, although such cases are extremely interesting, yet they are altogether of an exceptional character; for, where one instance of this kind occurs, hundreds take place where the disease proves fatal within the first six months after the operation. In the exceptional cases, the affection is probably more localized than under ordinary circumstances; the malignant action, while it has a tendency to reappear at the cicatrice, or in the immediate vicinity of the original disease, having apparently no disposition to invade the general system.

All malignant diseases possess this tendency to relapse after ablation, but

not in an equal degree. Encephaloid undoubtedly enjoys it to a far greater extent than scirrhus, and scirrhus than colloid. Melanosis also relapses with great frequency and promptness, and may be placed next to encephaloid in this respect. Again, it must be borne in mind that a genuine cancer is more certain to return than a cancrroid affection, and, also, that it is more apt to prove rapidly fatal.

The reproductive tendency of malignant disease, after operation, is well illustrated by the following case:—A man, aged thirty-two, consulted me in April, 1851, on account of an epulis of the lower jaw, first noticed three months previously; it was firm, elastic, free from pain, of a pale-red color, and attached to the gum and jaw, extending from the ramus to the first bicuspid tooth. Two operations had already been performed upon it, each being followed by rapid relapse. On the 27th of April I removed the parts, along with the corresponding portion of the jaw. On the 24th of September I operated upon him a second time, removing the whole of the new growth, which was about the size of a pullet's egg, and about three-quarters of an inch of the anterior extremity of the ramus of the bone, from which the diseased structure seemed to spring. On the 31st of August, 1852, I excised the ramus at the articulation, the disease having attacked its inferior extremity. The man remained well until the winter of 1853, when the disease broke out in front of the ear, and soon formed a tumor of the size of a small fist, from the effects of which he rapidly sank. It is worthy of remark that the general health had been all along pretty good, and that the wound always healed well after each operation.

In a case of cancer of the lip, the particulars of which have been communicated to me by Dr. Barclay, of New York, also five operations were performed, the patient having survived the first excision a little more than seven years. In a case of encephaloid of the thigh, reported to me by Dr. C. S. Tripler, of the Army, the man did not die until five years after the first operation. I am acquainted with the history of a number of other examples nearly equally remarkable.

With the renovative tendency of melanosis every one is familiar. Hardly an example of permanent cure by operation is upon record. I recollect a remarkable instance of this recurring action which occurred, many years ago, in the practice of the late Professor McClellan, of this city. The disease seemed to have begun in several small subcutaneous tubercles of the abdomen, about the size and appearance of shot, which soon became exquisitely painful, and gradually bursting through the skin, were at length converted into foul, fungous sores, attended with a highly fetid, sanious discharge. Many of these tumors were extirpated, some in their crude, others in their open state; but, although the wound generally readily healed, they were always promptly succeeded by a new growth in the immediate vicinity of the original. The man became much emaciated, and finally died completely exhausted, with all the evidences of the melanotic diathesis.

The most interesting and extraordinary example of recurring encephaloid, of which I have any knowledge, is one which has been for nearly three years under my personal observation. The patient is an unmarried woman, aged forty-four, who in March, 1857, perceived in the left breast a small tumor, which was excised the following October. During the next sixteen months two more operations were performed, but as the mammary gland had been only partially removed, I extirpated the whole of it, along with a fourth tumor, in May, 1859, when the case was placed under my charge by Dr. Russell, of this city. The disease soon reappeared in the cicatrice, and in three months and a half again required the use of the knife. After four operations by myself the case fell into the hands of my former clinical assistant, Dr. Asch, who attended her until May, 1861, when I performed the twenty-

second operation, the number of tumors removed, from first to last, being fifty-one, varying in size from a small almond to a pullet's egg. The encephaloid character of all was unmistakable. They generally recur at or near the cicatrice within a few weeks after extirpation, and speedily assume a fungating appearance. They are of a soft, vascular, brain-like structure, inclosed in a distinct capsule, and the seat of a thin, fetid discharge with little or no disposition to bleed. Occasionally she complains of sharp, shooting pains in the tumors, extending to the shoulder.

Her general health has all along been excellent; there is no lymphatic involvement in the axilla or elsewhere; menstruation has been going on well; and she has always rapidly recovered from the effects of the operations. The records of surgery may be challenged for a parallel case of this disease.

When malignant disease returns after extirpation, its tendency, as a general rule, is to assume the encephaloid type. This is true of all the different forms of these affections, whether they reappear at the site of the original disease, in the neighboring lymphatic ganglions, or in the internal organs. Hence the reason why the secondary disease is usually so rapidly fatal.

CHAPTER VIII.

SCROFULA.

THE term scrofula had formerly a far more limited application than is accorded to it in modern times. It was originally employed to designate a glandular swelling of the neck, strikingly resembling the neck of the swine, whence its derivation. At present, however, it has a much wider signification, being made to include within its range quite a variety of diseases apparently of the most opposite character, yet in reality essentially alike in every particular. As meaning the same thing, the words struma and tubercular disease are frequently used.

The affections which may be comprised under this term are pulmonary phthisis, chronic enlargement of the ganglions of the neck and other parts of the body, hip-joint disease, psoas, lumbar, and chronic abscesses, Pott's disease of the spine, certain forms of follicular ulceration of the mucous membranes, arachnitis, otorrhœa, ozæna, ophthalmia, eczema, and ulceration of the bones. The fact is, the class of scrofulous maladies is almost endless, affecting as they do almost every part of the body, and assuming as they do almost every form of morbid action.

Scrofula consists essentially in the deposition of a peculiar morbid product long known by the name of tubercle. An attempt has lately been made to draw a distinction between the matter of tubercle and the state of the system which predisposes to its occurrence. It is difficult altogether to deny the propriety of this distinction; for there are unquestionably cases which we are in the habit of designating as strumous, where, nevertheless, there is not, so far as we are able to determine, the slightest strumous deposit. There would seem to be merely a strumous irritation in the part, without the part being in a condition to furnish any specific secretion, such as that to which we apply the term strumous, tubercular, or scrofulous.

There is another distinction, which, however, is fast losing ground, which it is more difficult to reconcile than that just mentioned. I allude to the alleged difference between phthisis and scrofula. It would be easy, if a work on surgery were the proper place to discuss the subject, to adduce argument upon argument to show the utter fallacy of this opinion. I have long taught the identity of these diseases, and endeavored to prove that the only real difference between them depends, not upon any difference in the morbid action, but solely upon the difference of structure, tubercular disease sharing the same fate, in this respect, as ordinary inflammation and as the other heterologous deposits. A tubercle in the lung is essentially the same disease as a tubercle in a bone or a lymphatic ganglion, having the same origin, running the same course, and producing the same results. Why then consider them as different?

Tubercular disease occurs at all periods of *life*. Sometimes, indeed, it exists as an intra-uterine affection, thus leading to the conviction that it is occasionally hereditary, or that it is transmitted in the very act of impregnation. When it occurs as phthisis, it is most common between the twentieth and fortieth year, and it is remarkable that after the age of puberty it exists rarely in any part of the body without involving the lungs. In children, the

disease, considered in a general point of view, is most liable to happen between the third and tenth year. A vast majority of the cases of scrofulous disease that are met with in practice, in the form of coxalgia, Pott's disease, caries of the short bones of the extremities, arachnitis, ophthalmia, otorrhœa, tonsillitis, and chronic enlargement of the lymphatic ganglions, occur at this period of life, and constitute an immense source of mortality. It is a remarkable fact that adults seldom suffer from external scrofula; and, on the other hand, it is equally remarkable that children suffer comparatively little from consumption, so common among persons after the age of twenty. In old age the disease rarely occurs in any form.

Struma is frequently *hereditary*. The children of consumptive parents are often cut off by the same disease, or they suffer in various parts of the body, as the bones and joints, the lymphatic ganglions, the eye, ear, and serous membranes. Whole families are sometimes destroyed by it. Occasionally the disease skips one generation, and reappears in another, owing, doubtless, to some temporary improvement in the intermediate offspring.

The tubercular deposit has been observed in nearly every *structure* of the body. The only parts, perhaps, in which it does not occur, are the skin, vessels, nerves, ligaments, aponeuroses, tendons, and voluntary muscles. Of the organs, properly so called, there is not one which is not, at times, its seat. Experience, however, has shown that it manifests a decided preference for certain organs and parts of organs. Thus, it occurs most frequently in the lungs, particularly their summits, then in the lymphatic ganglions, next in the spleen, serous membranes, and mucous follicles of the alimentary canal, then the bones and joints, and finally the liver, kidneys, testes, and false membranes of the serous cavities. Its coexistence in various parts of the body, or its almost universal diffusion, is sufficiently frequent, and constitutes the so-called strumous diathesis.

The deposit being a direct product of the blood, occurs both in the interstices and upon the free surfaces of the organs. Hence it exhibits itself in various *forms*, of which the tubercular is by far the most common, the stratiform and infiltrated being, indeed, exceedingly rare. The tubercular variety occurs in little masses, from the size of a millet-seed to that of a pea, of a pale yellowish or grayish color, and of a consistence ranging from that of curds or soft putty to fibro-cartilage, hundreds and even thousands often existing in a very small compass. When very numerous and closely grouped together, they sometimes coalesce, so as to form a considerable sized tumor. The stratiform variety of the deposit is most common upon mucous surfaces, while the infiltrated is met with chiefly in the lungs, around tubercular excavations, and in the lymphatic ganglions. Whatever shape it may assume, it is always deposited in a fluid state, from which, however, it passes speedily into the solid form, which it retains for a certain period—generally from six to twelve months—when, becoming softened and disintegrated, the part makes an effort to rid itself of it. These changes are followed by the formation of a cavity, named a strumous abscess, of which the best examples occur in the lungs, bones, and lymphatic ganglions. The matter is peculiar; being generally of a yellow-greenish color, of a cream-like consistence, and intermixed with small whitish flakes, very similar to broken-down grains of boiled rice.

Microscopically examined, it is observed to consist of a transparent matrix, inclosing granules, nuclei, cells, and oil-globules, the relative proportions of which vary in different specimens, and even in different portions of the same mass, the chief circumstances which influence its minute structure being the age of the deposit, the nature of the affected organ, and the general condition of the subject. Most of the granules are very minute, and afford an albuminous reaction; they exist in great numbers in yellow tubercle, and often contain so much fatty matter as to be completely dissolved by ether.

The free nuclei, or true tubercle corpuscles, are round, ovoidal, oblong, or almost shapeless, and vary in size from $\frac{1}{2500}$ to $\frac{1}{3500}$ of an inch in diameter. They constitute a large proportion of the morbid product, and are generally intermixed with epithelial cells, oil globules, and crystals of cholesterine. The adjoining cut, fig. 56, from a drawing by Dr. Da Costa, conveys a good

Fig. 56.

Tubercle corpuscles.

Fig. 57.

Tubercles in enlarged mesenteric glands from a scrofulous patient.

idea of the microscopical characters of tubercle as it occurs in different parts of the body. In fig. 57, it is seen as it is deposited in the lymphatic glands.

Tubercular matter, in its crude state, consists almost entirely of albumen, with a small quantity of earthy salts, particularly phosphate and carbonate of lime. Some specimens also contain a little fibrin, casein, extractive matter, and pyine; but the great and pervading substance is albumen, or protein matter.

The microscopical and chemical examinations of this matter are extremely valuable, inasmuch as they go to show the low grade of its vitality, and its consequent inability to maintain, for any length of time, its parasitic existence. Certain authors, founding their opinion upon these facts, look upon it as an unorganizable product, very much of the same nature as that of colloid and melanosis. In this view, however, I cannot concur; for I have investigated tubercular matter too often, and under too many varying circumstances, not to be convinced that it is susceptible of organization, although certainly in a less degree than scirrhus and encephaloid. It is, in point of vitality, a more humble substance than either of these; it occupies a lower grade in the scale of cell development; and has a greater quantity of protein matter. Nevertheless, we must concede to it a certain degree of life-power, a certain form of organization, otherwise it would be impossible to explain the various changes which it undergoes, and the fact that it occasionally contains distinct vessels, clearly traceable into its interior, and intended to minister to its nourishment and protection. The matter of colloid is very different from that of tubercle, in having no attachment to the cells in which it is contained, in being alike in all stages of its existence, and in never experiencing any transformations. The same is true of melanosis. If this substance is occasionally very hard, it is because of its involvement with its fibrous matrix, or the surrounding tissues. Tubercle, on the contrary, is always firmly adherent to the parts with which it is in contact, except when it is effused upon mucous surfaces, acquires a firm consistence during its development, and often undergoes absorption, or the earthy transformation. Besides, the softening process frequently begins in the very centre of the morbid product, which could

certainly not happen if it were an inorganic substance. Those who deny the vascularity of tubercle attempt to account for the occasional existence of vessels by supposing that they become imprisoned in its substance during the progress of its formation. That this view is sometimes true is highly probable, but it is applicable only to certain parts of the body, and then only under certain circumstances. The explanation is undoubtedly not admissible in those cases where the tubercular matter is deposited upon the free surface of the serous membranes or in the substance of the adventitious, where its vascularity is so often observable. This matter, however, is not always organizable. Like coagulating lymph, it is sometimes deprived of its vitality almost in the very act of its secretion. This is particularly the case when it is effused upon the free surfaces of the mucous membranes, especially those of the urinary passages, whose irritating contents speedily render it effete.

Of the exciting *causes* of tubercular disease our knowledge is rather conjectural than positive. It may be fairly inferred, however, from the numerous observations that have been made upon the subject, that, when the tendency to the disease exists, anything calculated to produce excessive debility, or an impoverished condition of the blood and solids, may provoke the morbid deposit. The causes which are most likely to bring about this effect may be thus stated: 1. Meagre and unwholesome diet, deficient in fibrinous, albuminous, gelatinous, and fatty qualities. 2. Protracted disorder of the digestive organs, particularly the various forms of dyspepsia. 3. Exposure to cold, and confinement in damp, ill-ventilated, ill-lighted apartments. 4. Exhausting fevers. 5. Excessive and long-continued evacuations of blood. 6. Severe courses of mercury. 7. Stoppage of habitual discharges, as the menstrual and hemorrhoidal. 8. Protracted mental depression. 9. Tertiary syphilis. All these causes act by lowering the vital principle, and diminishing the plastic properties of the blood.

The immediate cause of the disease is inflammation, which regulates, not only the quantity, but also the quality of the deposit. The inflammation is generally of a low grade, and is therefore not characterized by the ordinary phenomena, although it is not the less effective on that account. The reasons which may be adduced in support of this view are the following:—

1. Irritation of the lung, mechanically excited, will frequently give rise to tubercle in that organ, as is occasionally seen in cases of foreign bodies, accidentally introduced through the larynx. In the inferior animals, as the dog and rabbit, mercury dropped into the trachea will often induce the disease in a short time. Miners, needle-grinders, and weavers, who are habitually exposed to the inhalation of gritty and irritating matter, are particularly prone to phthisis.

2. This view of the origin of the disease is countenanced by the composition of the deposit; for we know of no substance which contains so much albumen, or albumen and fibrin, that is not the product of inflammation.

3. Tubercle bears a great resemblance to coagulating lymph, especially the more degraded forms of that substance, and this, as every pathologist is aware, is always the result of inflammatory action.

4. The disease is often developed under the immediate effects of cold, and various other causes which have a tendency to produce congestion of the internal viscera. Indeed, it is well known that dyspeptics and persons who live upon unwholesome food, or in damp and ill-ventilated apartments, are peculiarly liable to suffer from this disease.

The *duration* of strumous disease is too variable to admit of any accurate general statement. Phthisis usually destroys life in from nine to eighteen months; tubercular arachnitis often terminates fatally in a few days; while external scrofula may last for years, and finally eventuate in recovery.

The *symptoms* vary, of course, according to the nature of the affected structure, but, whatever this may be, there are certain appearances which are hardly ever absent in any case. Thus, whether the disease be seated in the lungs, in a bone, a joint, or simply in the cellular tissue, in the form of a cold abscess, there is always, during the progress of the malady, excessive emaciation; for, with the exception of the glandular viscera, the brain, nerves, and a few other structures, there is hardly an organ in the body that does not, in some degree, participate in the general atrophy. The fat gradually but surely disappears; the muscles are pale, flabby, and attenuated; the cellular tissue is deprived of its moisture; the skin is soft and blanched; the hairs grow slowly, and many drop out; the nails are thin, and frequently incurvated; and the bones, although they retain their size, are unusually light, and saturated with sero-oleaginous fluid. The blood also is altered. It is impoverished, thin, pale, and deficient in globules. The clot is unnaturally small and dense, and, when the disease is fully established, with a tendency to suppuration, is almost always covered with a buffy coat. The fibrin is not materially changed until softening sets in, when it increases disproportionately in quantity, and so continues until suppuration begins, when it attains its maximum. These changes are generally very conspicuous in phthisis, psoas abscess, and extensive disease of the lymphatic ganglions.

Scrofula has been supposed to be *contagious*, and many experiments have been performed, both upon man and the inferior animals, with a view of deciding the question. In no instance, however, has the operation succeeded. Kortum applied scrofulous pus to sores and wounds in the necks of children, but always failed to induce the disease. Hébreard and Lepéllitier performed similar experiments upon dogs and guinea-pigs with a like result. Finally, Goodlad and others attempted, with no better success, to create the disease in their own persons by inoculation. The idea of the contagious character of phthisis was formerly very prevalent, but is now obsolete.

Persons who are affected with scrofula, or who are laboring under what is termed the *strumous diathesis*, exhibit certain peculiarities which may be considered as almost characteristic. These refer mainly to the state of the complexion, the digestive apparatus, and of the circulation.

The complexion is generally brunette, and the hair, for the most part, dark, although in both these respects the greatest possible diversity exists. The eyelashes are drooping and of extraordinary length; the pupils are habitually dilated; the upper lip is tumid; the face is pale and puffy; the hands and feet are nearly always cold; the body is unusually impressible by atmospheric vicissitudes; the abdomen is hard and distended; there is a deficiency of muscular strength; and the intellect is dull and sluggish, instead of being sprightly and precocious, as is usually represented. The digestive organs are subject to frequent derangement; the appetite is irregular and capricious; the bowels are either constipated or relaxed, seldom entirely natural; digestion is feeble and imperfect; great annoyance is experienced from flatulence and acidity; and the individual is often a martyr to dyspepsia. Children predisposed to struma are particularly prone to cutaneous eruptions about the scalp, to purulent discharges from the ears, and to chronic enlargement of the tonsils.

There is another class of strumous subjects of a state of mind and body almost the opposite of that just described. The complexion is light and florid, the eye blue, the mind unusually active, and the cutaneous circulation quite vigorous. The parts of the body which are most liable to suffer, in this form of constitution, are the bones and joints, the eye, skin, and lymphatic ganglions, particularly those of the neck, consumption being much more rare than in the dark variety.

Scrofulous Ulcer.—Various scrofulous affections of the skin give rise to ulceration, but, perhaps, the most characteristic ulcer of this kind is that consequent upon suppuration of the lymphatic ganglions of the neck, groin, and axilla. Be this as it may, the features of the scrofulous ulcer are so peculiar as to require distinct notice.

The surface of the scrofulous ulcer is always unhealthy, being coated with rough, aplastic matter, of a pale yellowish or grayish color, hard, and firmly adherent to the subjacent structures. There is reason to believe that this matter, which possesses none of the characteristics of laudable pus, is often intermixed with disintegrated tubercular substance. In many cases the bottom of the ulcer is formed by altered lymphatic ganglions, of a reddish appearance, and so much softened as to break down under the slightest pressure; sometimes, however, they are hard, almost of a fibrous consistence, and as if they had been partially dissected from the surrounding parts. In some cases, in fact, they separate, or slough out, several perhaps coming away at the same time, or in more or less rapid succession. No healthy granulations exist upon such a sore, unless it is in a healing condition, and even then they form and maintain themselves with great difficulty.

The edges of the ulcer are characteristic. They are of a bluish, purplish, or reddish hue, undermined, hard, jagged, thin and sharp at some points, thick and obtuse at others. Occasionally they look as if they were bent in towards the bottom of the ulcer. They are generally remarkably insensible, incapable of forming granulations, and deeply congested, the blood passing through the vessels in a very languid and imperfect manner. In fact, the skin, having lost its support, is excessively impoverished, and has great difficulty in maintaining its vitality.

The parts around the scrofulous ulcer are generally hard, either from the presence of indurated and diseased ganglions, or from interstitial deposits; usually, in fact, from both. The skin is red and congested, and not unfrequently also somewhat œdematous, pitting on pressure. The swelling is often great and disfiguring; in short, characteristic of that peculiar appearance from which the disease originally derived its name, the neck, when that is the affected region, strikingly resembling that of the swine.

The scrofulous ulcer may be single, or there may be more than one; variable in shape and extent, and frequently communicating with considerable sinuses. The discharge is ichorous, or thin and whey-like; sometimes thick and yellowish; in either case, apt to be intermixed with the débris of disintegrated ganglions, flakes of lymph, and broken-down tubercular matter.

Treatment.—The treatment of scrofula, like that of cancer, has been exceedingly diversified and empirical, for there is hardly a solitary article of the materia medica that has not, at one time or another, been called into requisition. Even at the present day, when the pathology of the disease is so much better understood, the greatest uncertainty prevails in regard to our therapeutic measures, and the consequence is that few practitioners approach the disease without doubt and misgiving as to the benefit they may be able to confer by their treatment. Strumous affections have always afforded a vast field for the charlatan, and his pretensions have never been more impudently paraded before the public than in our own day. One, if not the chief, reason of this is that so few practitioners really understand the nature of this class of diseases; they seem to forget, or not to know, that they occur in every possible form and under every variety of circumstances, and that, in order to meet them successfully, it is necessary constantly to vary our remedies according to the exigencies of every particular case. I am certain, from no little experience upon the subject, that the results of our treatment hinge most materially upon a just discrimination of the different states of the system under which these affections occur. To treat every case of scrofula alike,

without regard to the state of the system which attends it, is the climax of absurdity. Let the practitioner remember that scrofula has no specifics, and he will soon cease to employ his remedies empirically. The indiscriminate use of iodine and cod-liver oil in this affection has done mankind and the profession an immense deal of harm.

It will be sufficient, for practical purposes, to consider scrofulous subjects as being divisible into two great classes, the enfeebled, and the vigorous; that is, those who have but little constitutional stamina, and those who, although affected with a strumous taint, are comparatively stout and robust, possessing a ruddy complexion, and an active cutaneous circulation. The latter, undoubtedly, constitute the minority of the cases that come under our observation, but they are, nevertheless, sufficiently common, and so well marked as to be easily recognized by the most superficial observer. Now, to treat these two classes of subjects on the same principle, as is so generally done, is contrary to the dictates both of sound sense and daily experience. While cod-liver oil, iodine, and tonics will perform wonders in the naturally weak, they will be of little avail in dislodging and curing the disease in the naturally robust; and, conversely, while the lancet and tartar emetic will be of immense service in the latter, their employment can scarcely fail to be eminently prejudicial in the former. Let it not be imagined, however, that one mode of treatment is applicable to all cases of this form or that form of the disease; on the contrary, circumstances constantly arise during the progress of each particular case which imperatively call for a change of remedies, and it is in the knowledge of this circumstance that the great art of curing the malady lies.

It is well, as a general rule, to begin the treatment with some mild but efficient aperient, to clear out the bowels, and improve the secretions. Our course must then be shaped by the peculiarities of the case. If the patient be naturally very feeble, or has become so in consequence of protracted suffering, an alterative and tonic course must at once be instituted, as the most likely to meet the indications; but if, on the other hand, he is strong and plethoric, as denoted by the state of his pulse and complexion, much time will be gained, and structure saved, by the use of antiphlogistics, especially tartar emetic and Epsom salts, in the form of the saline and antimonial mixture, properly guarded with tincture of opium. The lancet must be employed with the greatest care; but I am satisfied that it is often of immense benefit in arresting the morbid action, and that it has fallen into too much neglect in the treatment of scrofulous diseases. In scrofulous inflammation of the eye, throat, and lymphatic ganglions, its effects are often marked and permanent. But there is a time when the employment of antiphlogistics ceases to be proper, and when they may be superseded by other remedies, similar to those generally applicable in the more common form of the disease. If the depletory system of treatment is carried too far, it cannot fail to do harm by exhausting the vital powers, and thus creating a disposition, in different parts of the body, to the deposition of tubercular deposits.

Among the various remedies that have been employed from time to time for the cure of scrofula, *iodine* holds a prominent rank. This article was first introduced to the notice of the profession, as a therapeutic agent, in 1820, by Dr. Coindet, of Geneva, and since that time its efficacy in the treatment of this affection has received the most ample confirmation. Indeed, it may be regarded as the remedy *par excellence* in this disease. It may be employed alone, or in union with other substances, as potassa, iron, mercury, lead, quinine, barium, and ammonia, and hence much judgment is often required to determine what particular form of the remedy is best adapted to a particular case or form of the malady. As a general rule, it may be observed that, when a purely alterative effect is desired, it may be exhibited by itself, in substance,

in tincture, or in the form of Lugol's concentrated solution, consisting of one scruple of iodine and double that quantity of iodide of potassium, dissolved in seven drachms of water. Of this the patient may take from five to ten drops every eight hours, in a wineglassful of sweetened water, the dose being gradually increased to fifteen, twenty, twenty-five, and even thirty drops, according to the tolerance of the system.

With the same view the *iodide of potassium* is not unfrequently administered alone; and, when scrofula is associated with constitutional syphilis, rheumatism, or mercurial disease, it certainly constitutes one of the best forms in which iodine can be exhibited. With whatever view it may be employed, it is proper always to begin with small doses, as four or five grains, if the patient be an adult, and gradually to increase them to ten, twenty, and even thirty grains, three or four times a day. The most eligible way of giving it is in water, or in union with the fluid extract of sarsaparilla. Some patients take it very well in hop tea, and when there is much restlessness at night, or nervous irritation, this is perhaps the best form in which it can be exhibited.

When the liver is at fault, or when there is a syphilitic taint of the system, or much disorder of the secretions, the *protiodide of mercury* may be advantageously prescribed, in doses varying from the fourth of a grain to half a grain, three or four times a day. The *biniodide* may be employed with the same view, but it should be recollected that it is much more potent, and that, therefore, greater caution should be observed in its administration. The dose, which at first should never exceed the one-twelfth or one-sixteenth of a grain, may be gradually augmented to a fourth or even half a grain, given in the form of pill, or dissolved in alcohol.

When an alterant and tonic effect is indicated, nothing can be better than the *iodide of iron*, or the iodide of quinine. The former of these articles is one of the most valuable anti-scrofulous remedies that we possess, and one which rarely entirely disappoints expectation. In my own practice I have found it particularly beneficial in strumous disease of the cervical ganglions, of the upper lip, the eye, and joints. I often give it in solution, but more commonly in the form of pill, in combination with quinine and opium. If vascular action be present, a minute portion of tartrate of antimony and potassa may be added to each dose. In children, who cannot take pills well, the best mode of administering it is in combination with syrup of orange-peel, or syrup of sarsaparilla.

The *iodide of quinine* has been advantageously employed in the treatment of scrofulous tumors, in cases where iodine and tonics are indicated, in doses from one to two grains every six or eight hours.

In whatever form iodine be employed, whether as a simple or compound, it must be borne in mind that the system should be free from all vascular excitement, and that, after it has been exhibited for a fortnight, it should be pretermitted for several days, when it may be resumed, and given as before. Employed in this manner it exerts a much happier influence upon the progress of the complaint, and is much less likely to disagree with the stomach and bowels, than when given uninterruptedly. In case it acts as an irritant, it must be exhibited in smaller doses, or be combined with opium or hyoscyamus. Great mischief often results from neglect of this precaution.

Another remedy of great value in the treatment of scrofulous disease is *barium*. It has repeatedly succeeded in my hands when other means have proved inefficient or entirely unavailing; it is particularly valuable in chronic enlargement of the cervical ganglions, both before and after the establishment of suppuration. It is chiefly adapted to patients with a languid circulation, a pale tallow-like complexion, a flabby tongue, indigestion, and cold extremities. Its use is contra-indicated when there is inflammatory excitement, or congestion of any important organ. The best mode of administration is the

official solution of the United States Pharmacopœia, beginning with six or eight drops, and gradually but cautiously increasing the dose to ten, twelve, or fifteen drops, three times a day, in a wineglassful of hop tea, or half an ounce of the simple syrup of sarsaparilla. Exhibited in large quantities, it is liable to cause nausea, heartburn, diarrhœa, griping, headache, rigors, and profuse sweats; in a word, all the symptoms of mineral poisoning.

There is an *iodide of barium* which is worthy of trial in scrofulous affections. The dose is one-eighth of a grain three times a day, gradually increased to one, two, or even three grains.

In some cases of *scrofula bromine*, in the form of iodide, answers a good purpose, although, as a general rule, it is very decidedly inferior to iodine. The average dose, for an adult, is from five to ten grains thrice a day.

There is no medicine which has been more frequently or more extensively employed in the treatment of strumous diseases than *mercury*. The preparations most commonly used are calomel, blue mass, corrosive sublimate, and the black sulphuret, or Ethiop's mineral. Of these the bichloride is the best. It should be given in minute alterative doses, as the one-sixteenth or one-twentieth of a grain, three times a day, either in the form of a pill, or along with sarsaparilla. Thus administered, it yields hardly in efficacy to iodine, and is probably superior to barium. In employing mercury, in any form, care should be taken that the system be properly prepared for its reception, and that it be not carried so far as to induce salivation. If it be found to act as an irritant or excitant in any way, it must be at once discontinued, or exhibited in smaller quantity. Whether mercury produces its beneficial effects merely by correcting the secretions, and thereby improving the general health, or by suspending or modifying the tubercular action, we have no means of knowing.

When the disease has existed for a considerable length of time, and especially when there is a decided tendency to emaciation, great benefit may be expected from the use of *cod-liver oil*, given in half ounce doses thrice in the twenty-four hours, in good ale, or along with a little brandy. The value of this remedy is no longer a matter of doubt, but rests upon the general testimony of the profession. Although it contains a minute quantity of iodine and bromine, it is probable that its good effects depend chiefly upon its nutritive qualities. However this may be, it unquestionably improves the condition of the digestive organs, and acts slightly upon the urinary and cutaneous secretions. To derive much benefit from it, its use must be continued, steadily and persistently, for a long time.

Whatever remedies may be employed, the closest attention should be paid to the bowels, diet, exercise, and dress. Constipation should be counteracted by mild aperients, as blue mass and rhubarb, or, when there is much disorder of the secretions, by a few grains of calomel, followed by a little oil. Active *purgation*, however, must be studiously avoided, as it will inevitably do mischief by inducing debility. Torpor of the liver must be promptly met by mild mercurials, and acidity by alkalies, of which bicarbonate of soda, either alone, or in union with a little ginger, is the most valuable. The alkalies were at one time much in vogue in the treatment of scrofula, in the belief that they possessed a kind of specific power, but their influence was evidently much overrated. Emetics are occasionally of service, especially when there is much nausea, depraved appetite, and headache.

The *diet* of a scrofulous patient should be light, unirritant, and rather nutritious than otherwise. It should consist principally of the farinaceous articles, with milk or weak tea at breakfast and supper, the latter of which should always be very light, and taken at least three hours before retiring to bed. Coffee, fresh bread, pastry, and everything else of an indigestible nature must be proscribed. The food should be well masticated, and never used in

such quantity as to oppress the stomach. In the latter stages of the malady, or even earlier, if the strength seems to require it, some of the lighter meats, a little fresh fish, or a few oysters may be taken twice a day, along with a glass of porter, ale, sherry, port, or Madeira, or, what is better than all, of brandy and water. Sometimes an almost purely animal diet seems to agree best with the stomach. Many patients are greatly benefited by the free use of whiskey, rapidly becoming strong and fat under its influence. It should be taken repeatedly in the twenty-four hours, in quantities suited to the state of the stomach and system.

As an important auxiliary *exercise* claims particular attention. It may be taken on foot, in a carriage, or on horseback, as may be most convenient or agreeable to the sufferer, and should be indulged in whenever the weather admits of it. Care is taken that it is never carried to fatigue. In bad weather, the patient may use dumb-bells, or amuse himself in sawing wood, planing, or anything else to which he may have access. Children should be carried about in their nurses' arms, or in handcars.

Particular attention must be paid to the patient's *clothing*. He must be warmly clad. Flannel should be worn next the surface, both in summer and winter, the feet should be protected with thick shoes and stockings, and the skin should be maintained in a healthy, perspirable condition by frequent ablutions with tepid water, impregnated with common salt, ground mustard, strong soap, or any other exciting substance.

A change of *air* is sometimes of vast service, and has been known to be of itself almost sufficient to effect a cure in this disease. The locality selected should be as healthy as possible, and not liable to great or sudden variations of temperature. If the atmosphere be dry, it matters little whether it be cold or warm, provided it does not run into either extreme. A residence near the sea-shore is often of immense benefit.

In the latter stages of the disease, when the patient is harassed with hectic fever and diarrhœa, the treatment must be of a tonic and stimulant character. The diet must be highly nutritious; porter, ale, wine, and milk-punch must be freely used; the bowels must be restrained with astringents; the excessive sweats must be controlled with quinine and elixir of vitriol; and sleep must be procured and pain allayed with anodynes.

There is no doubt that the state of the *mind* is capable of exercising a powerful influence upon the cure of scrofula, especially when seated in the external parts of the body. We may assume this to be a fact from the astonishing benefit which so often followed the royal touch, a practice which is said to have originated in the time of Edward the Confessor, near the middle of the eleventh century, and which continued down to the reign of Queen Anne. The belief in the efficacy of the royal touch seems to have been a long time almost universal in Britain. It was particularly prevalent in the reign of Charles II., who, in one single year, touched nearly 100,000 persons, who flocked to him from all parts of England, Ireland, Scotland, Jersey, and Guernsey. The practice was generally accompanied by prayers and other religious ceremonies, and particular days and seasons were set apart for its observance. The effect of this singular remedy was variable; in some of the patients a cure followed almost immediately after they were touched; in others, the relief was more tardy, but in the end not the less effectual; occasionally the process was obliged to be repeated; and in some cases the treatment was entirely useless. Richard Wiseman, who was surgeon to Charles II., and a most sagacious observer, must have had great confidence in the efficacy of the royal touch; for he expressly declares that "His Majesty cured more persons of scrofula in one year than all the surgeons of London in an age."

The *local treatment* of scrofula merits some attention, although it can be

alluded to here only in a very general manner, as each affection comprised under this denomination requires a mode of management in some respects peculiar to itself. The most important topical remedies are leeches, blisters, issues, pustulation with croton oil, tincture of iodine, embrocations, and sorbefacient unguents, especially such as have iodine for their bases, as the iodides of mercury, lead, potassium, iron, barium, and zinc. Leeches are often of immense service; and, as to counter-irritants, they can rarely be dispensed with in any case. Of the various sorbefacient applications none holds a higher rank, in my opinion, than the tincture of iodine, either pure, or, as I generally prefer, considerably diluted with alcohol. It is used as in ordinary inflammation, and often exerts a powerful influence upon the progress of external scrofula, especially of the joints and cervical ganglions. Blisters, too, are a valuable means of relieving local congestion, modifying capillary action, and removing morbid deposit. If the part affected be a joint, rest, long and faithfully continued, will be necessary, if, indeed, not indispensable. If abscesses form, they must be opened, with the precaution, if possible, of excluding the atmosphere, experience having shown that such ingress is highly prejudicial, not on account of anything noxious in itself, but because of its tendency to cause decomposition of the contents of the sac, and, consequently, violent reaction, or hectic irritation. The swelling is attacked in its most depending part, the knife being introduced in a valve-like manner, and the opening immediately closed with adhesive strips, supported by a compress and roller. The practice of permitting such accumulations to continue until they have seriously impaired structure, or caused intense suffering, cannot be too pointedly condemned.

When the enlarged glands obstinately resist treatment, they should be excised, provided that they are sufficiently accessible to the knife, and also that there is no serious internal disease forbidding interference. An operation is particularly indicated when the morbid growths press upon important neighboring structures, or when they are a source of deformity, as when they are situated in the neck or about the angle of the jaw. The dissection is often tedious and bloody, especially when a large chain of glands has to be removed, and is then very liable to be followed by erysipelas and other bad consequences.

The scrofulous *ulcer* must be treated rudely at first, and gently afterwards. The undermined edges are cut away with the knife or scissors, and the surface is thoroughly touched with dilute acid nitrate of mercury, the solid nitrate of silver, or sulphate of copper, the application being repeated every other day until there is an appearance of healthy granulations, when milder means, such as opiate cerate, or the dilute ointment of nitrate of mercury, take its place. If disintegrated ganglions are present they should be removed with the knife, or destroyed with the Vienna paste; for so long as they remain no substantial progress can be made towards a cure. Sinuses are traced out with the bistoury, unless they involve important structures, when stimulating injections, or the seton, must be used instead. Valuable aid will often accrue in these cases from the daily application of the dilute tincture of iodine to the surface immediately around the ulcer.

CHAPTER IX.

WOUNDS.

SECT. I.—GENERAL CONSIDERATIONS.

THE term wound is a generic one, being employed to designate all injuries attended with a division of tissue, inflicted by sharp, pointed, or blunt instruments and weapons of every description. The breach, or solution of continuity, may be apparent or concealed; that is, upon and in the skin, as well as in the more deep-seated structures, or the skin may retain its integrity, and the wound be strictly subcutaneous.

Wounds are constantly made by surgeons in the legitimate exercise of their professional duties, as in the removal of limbs, tumors, and urinary calculi, and in the restoration of lost or mutilated parts. In general, however, they are inflicted accidentally, and hence, as this may happen in a great variety of ways, they are very properly arranged under different heads, according to the manner in which they are produced. Thus, a wound is said to be incised when it is caused by a sharp instrument; lacerated or contused, when it is made by a blunt body; and punctured, when the weapon is narrow and somewhat pointed. A gunshot wound is a breach inflicted by a ball. In a poisoned wound the tissues are inoculated with some peculiar virus, either secreted by an appropriate apparatus in the bodies of certain animals, as the bee or snake; contained in the salivary fluid, as in the dog in hydrophobia; or developed after death, as in the human subject in the dead-house. The term penetrating is employed when the wound communicates with a cavity, as a joint, the chest, or the abdomen.

Wounds are also generally named according to the region of the body which they occupy, or the particular tissues, organ, or cavity which they affect and interest. Thus we are accustomed, in common parlance, to speak of wounds of the head, neck, chest, abdomen, and extremities; of wounds of the skin, muscles, tendons, vessels, and nerves; of wounds of the stomach, heart, lungs, liver, and brain; and of wounds of the joints, pleura, pericardium, and peritoneum.

Finally, wounds may be superficial or deep; recent or old; simple or complicated; oblique, transverse, or longitudinal. The meaning of these terms is too obvious to require any particular explanation. The most common complications which attend their occurrence, or which arise during their progress, are, hemorrhage, the presence of foreign matter, abscesses, mortification, erysipelas, pyemia, and tetanus. These accidents, whether in their individual or combined capacity, often completely change the character of a wound, rendering complex what was originally perhaps perfectly simple, and dangerous what was, in the first instance, perhaps so insignificant as hardly to attract serious attention.

The characteristic features of wounds will be pointed out in connection with the different classes of injuries to which they relate. The prognosis and treatment will also receive due attention. I shall therefore content myself here by stating, in general terms, that the great and leading indica-

tions, in every wound, whatever may be its nature, are, first, the stoppage of hemorrhage; secondly, the removal of extraneous matter; thirdly, accurate approximation and retention of the edges of the solution of continuity; and, lastly, the prevention of inflammation, tetanus, and other untoward occurrences. In every case, the most prompt attention should be given; the parts should be handled in the most cautious and gentle manner; and the dressings, which are never to be too officiously interfered with, should always be as light as possible. In short, whatever is done, should be done with a view to the most speedy and perfect restoration of the injured structures.

1. MODE OF DRESSING WOUNDS.

The most important retentive means are adhesive plaster and sutures, aided, if necessary, by the bandage and attention to the position of the wounded parts.

There are various substances which are endowed with adhesive properties, and which are therefore well adapted to retain the edges of a wound in contact with each other. Those, however, which are usually employed for this purpose are the common adhesive plaster, collodion, and isinglass plaster.

The old *adhesive plaster* is composed of resin and lead plaster, in the proportion of one part by weight of the former to six parts of the latter, melted together over a gentle fire, and spread smoothly by machinery upon muslin, which is rolled up, and kept in the shops ready for use, care being taken to protect it from the heat. The addition of a little soap renders it more pliable, and prevents it from cracking in cold weather, without impairing its adhesiveness. To attain the same end, some pharmacutists are in the habit of incorporating with it spirits of turpentine, but such an addition is highly objectionable, as the plaster, when thus prepared, is liable to irritate the skin, and thus induce a tendency to erysipelas and the development of small ulcers, to say nothing of the probability of its interfering with the adhesive action of the wound.

The plaster, when intended to be used, is cut into suitable strips with a pair of scissors, carried in the direction of the length of the cloth, not in that of its breadth, as it is much more yielding in the latter than in the former, and therefore liable, when it becomes heated on the skin, to let the edges of the wound gape more or less. Trifling as this precept may appear, I consider it to be of great practical importance, and am satisfied that it is much less insisted upon than it should be. When the wound occupies a limb, each strip should be long enough to extend about three-fourths round it; on no account should it completely encircle it, lest it obstruct the return of venous blood, and at the same time cause pain and tension. The width of each strip should be uniform, and should vary, on an average, from half an inch to an inch, according to the exigencies of each particular case.

Previously to applying the plaster, the surface of the skin should be divested of hair, and well wiped with a dry cloth, as the least moisture prevents it from adhering. The shaving of the parts is necessary to facilitate the removal of the plaster, which would otherwise be difficult and painful, and which might, by its traction, even seriously compromise the safety of the adhesive process. These important preliminaries being disposed of, bleeding having ceased, or nearly so, and the edges of the wound being carefully held together by an assistant, each strip is heated by holding its back against a pitcher or coffee-pot filled with boiling water, and then applied in such a manner as that its centre shall correspond with the wound, each extremity firmly grasping the opposite side. If the wound is very long and deep, the first strip should be stretched across its middle, which thus becomes the starting point of all the rest. The interval between each two strips should not, on an average,

exceed the eighth of an inch, as this will afford ample space for the drainage of blood, serum, and lymph, of which there will generally be more or less after every injury of this description, especially if it be of considerable extent. Care must be taken that the adhesive strips are laid down in as smooth and even a manner as possible; hence, the parts should always be put in the position in which it is intended to keep them during the treatment. If the strips turn up in folds, or are partially detached, they should be immediately replaced by others, more skilfully applied. Finally, care must be taken, on the one hand, not to invert the edges of the wound or to draw them together too firmly, and, on the other, not to approximate them so loosely as to endanger their partial separation. In short, everything must be done in a neat, accurate, workman-like manner.

Much has been said of late years respecting the value of *isinglass* plaster; it is alleged that it is more bland than the common plaster, that it is quite as adhesive, and that it possesses the additional advantage of not provoking irritation, which the other undoubtedly sometimes does, especially in persons of a delicate, sensitive skin. Moreover, it is claimed that isinglass, when spread on gauze, will, by its transparency, admit of complete surveillance of the wound, thus enabling the surgeon to witness the changes going on in and around it. Notwithstanding these supposed advantages over common adhesive plaster, my conviction is that the latter, as prepared by the modern pharmacist, is decidedly superior to it, in every particular. The idea that common adhesive plaster is apt to cause erysipelas and ulceration of the skin is in great measure, if not wholly, chimerical; at all events, it has seldom fallen to my lot to meet with such occurrences. In the next place, it is much stronger than isinglass plaster, and therefore it affords better support to the parts. Thirdly, it is less liable to become prematurely detached; and, lastly, although it is opaque, yet as there is always an interval left between each two strips for drainage, it is obvious that it cannot in the slightest degree interfere with the examination of the wound and its vicinity. I, therefore, as a general rule, limit the use of isinglass plaster to the dressing of small wounds or little cuts, and employ the common plaster for wounds of large size. The principles regulating its application do not differ from those already laid down. The strips should be of appropriate length and width, and moistened on the glazed surface with a sponge wet with hot water.

The credit of having introduced *collodion* for surgical purposes is due to Dr. J. P. Maynard, of Boston, by whom it was first used in 1847. It is a solution of gun cotton in ether, assisted by a little alcohol, and is a transparent, colorless fluid, of a syrupy consistence, which, when applied to a dry surface, allows of the rapid escape of the ether, leaving a thin, bluish film, possessed of remarkable adhesive and contractile properties. Being impervious to water, it is less liable to be prematurely detached than isinglass or common resin plaster. Put upon wounds or abraded surfaces, it produces sharp pain, which, however, speedily subsides, and does not afterwards return. It may be applied by means of a camel-hair pencil, or a small brush, directly to the affected parts, as in the case of small, superficial cuts; or upon strips of silk gauze, or patent lint, of suitable width and length, when the wound is so large and deep as to require firm support. As the ether evaporates very rapidly, the dressing should be applied with as much celerity as possible, everything being thoroughly arranged beforehand, and the edges of the wound well dried and supported by an assistant. Personal observation induces me to believe that collodion makes an excellent dressing in solutions of continuity about the neck and face, or in all the more movable regions of the body, and in those cases where it is particularly desirable to exclude the contact of the air.

Within the last few years *caoutchouc* has been pressed into the service of

the surgeon on account of its adhesive qualities; an excellent sticking plaster may be prepared from it by spreading a solution of it, with a stiff brush, upon gauze silk, or thin calico, after the fashion of collodion. One great advantage which it possesses over most other materials is that it is completely impermeable by water.

Whatever substance be employed, it should be allowed to remain on so long as it seems to answer the object for which it was applied. The moment, however, it becomes a source of irritation, loses its hold, or interferes with drainage, it should be removed; but before this is done the new substitute should always be in full readiness, so that the parts may not be unduly exposed to the air, before the dressing is renewed. Surgeons, I think, often err in being too anxious to meddle with the adhesive plaster; too early interference has a tendency to interrupt the adhesive process, and may, in persons of bad, irritable constitutions, give rise to erysipelas and other accidents. I have, more than once, after severe operations, retained all the adhesive strips for upwards of a fortnight; until, in fact, complete cicatrization had taken place. Such good luck, however, is rare; and it more generally happens that the dressings, plaster and all, have to be changed at the end of the second, or, at farthest, the third day. Much, of course, will depend, in every case, upon the state of the weather, the size and situation of the wound, and the amount and character of the discharges.

When the wound is extensive, only a few strips should be taken off at a time, otherwise we shall endanger the separation of its edges. Before the dressing is reapplied, the parts should be thoroughly cleansed with tepid water, pressed from a sponge held at some distance; no wiping must be done, nor must the wound be roughly squeezed. If there is matter at its bottom or between its edges, it should be pressed out in the most gentle and careful manner; all rough manipulation being not only painful but injurious to reparative action. Sometimes the necessary cleanliness may be readily effected with a moist sponge or soft cloth passed lightly over the surface. Great skill is required in removing the plaster to the best advantage of the parts. Each strip should be raised by taking hold of one extremity with the thumb and finger of one hand, while the other hand is engaged in supporting the wound; the other end being treated in a similar manner, the portion corresponding with the wound is lifted off last, and thus all danger of injury is effectually obviated.

The principal sutures employed in surgery are the interrupted, twisted, continued, and quilled. To these may be added the important modifications introduced by Professor Pancoast, namely, the plastic suture, as he terms it; the clamp suture of Dr. Sims; and the button suture of Dr. Bozeman; all of which will receive proper attention, in connection with plastic operations and the treatment of vesico-vaginal fistule.

The *interrupted suture*, which is more frequently employed than any other, is made with a needle, either straight, or slightly curved, and armed with a single, well-waxed ligature, either of silk or of linen, as may be found most convenient; for, in a practical point of view, it is really altogether immaterial which it is. The instrument, which should be very sharp, and spear-shaped, is introduced through the edge of the wound, from without inwards, at a suitable distance from its surface, and then pushed from within outwards at precisely the same point at the opposite side, leaving the thread in its track. A second stitch is then to be taken in a similar manner, and thus the operation is continued until a sufficient number has been introduced, when the ends of each ligature are to be tied with a reef-knot, and cut off close. The distance at which the needle should be inserted from the wound must of course vary in different cases and in different regions of the body; but, in general, it should not be less than half a line, nor more than a quarter of an inch.

The depth at which it is passed should be such as to admit of accurate approximation of the wound, about one-third of the thickness of the edge being behind and the rest in front of the needle. In

Fig. 58.

no case of superficial wound should the instrument embrace muscular or aponeurotic substance. The interval between each two stitches must also necessarily vary, according to circumstances, from a few lines to an inch or more, and should be supported, after the sutures have been tied, with adhesive plaster, as seen in fig. 58. When the wound is very small, it may be sewed up with a common cambric needle, and a proportionately delicate thread.

The *twisted suture* is made by introducing a needle through the edges of the wound, and passing a thread round it, so as to confine it in its place. It makes an admirable retentive ap-

paratus, but it is of more limited application than the interrupted suture. From the fact that it is generally employed in the treatment of hare-lip, it is often called by that name.

Various instruments are employed for making the twisted suture. The one to which I give the preference is what is called the lady's toilet pin, consisting of a round steel pin, very sharp-pointed, and furnished with a glass head; it readily penetrates the tissues, and creates less irritation than the common sewing needle, formerly so much employed for this purpose. Twenty-five years ago surgeons were in the habit of using a silver needle, with a movable steel point, as seen in fig. 59; a cumbersome, awkward in-

Fig. 59.

strument, now happily discarded. Dieffenbach recommended what is called the insect pin, which, however, has never come into general vogue, at least on this side of the Atlantic. In small wounds of the forehead, face, and neck, in which it is of so much importance to avoid a scar, I have been in the habit, ever since I entered the profession, of employing a very delicate gold pin, with a head of sealing-wax, and there is not, I am sure, any article better suited to fulfil such a purpose. Insusceptible of oxidation, it causes no irritation, and may therefore be retained an unusual length of time, without detriment to the parts.

Whatever instrument may be employed, transfixion is effected in the same manner as in the common interrupted suture. The wrapping material is

Fig. 60.

Fig. 61.

also similar, the thread varying in thickness according to the particular object to be attained. It is wound round the pin elliptically, as in fig. 60, as it arranges itself much more evenly and smoothly when thus applied than when applied in the form of an 8, as in fig. 61, and as recommended in the books. As many pins or needles having been inserted as may be deemed advisable, the threads are passed from one to the

other diagonally across the gap, so as to effect complete apposition there also, and so obviate the necessity for using adhesive plaster. Finally, the

ligatures being tied, the operation is completed by cutting off the points of the pins with a pair of forceps, delineated in the adjoining sketch, fig. 62, the object being to prevent them from hurting the patient, or being caught in his clothes.

Fig. 62.

Pin pliers.

Instead of confining the pin with a thread, Mons. Rigal uses a thin narrow ring of gum-elastic, which answers the purpose most admirably, drawing the parts firmly and evenly together. The only objection to it is that it may cause too much pressure in the event of there being unusual swelling in the lips of the wound. Dr. Washington L. Atlee, of this city, has employed this form of suture in quite a number of his ovariectomy cases, and thinks it possesses decided advantages over the ordinary contrivance in that operation. The annexed cut, fig. 63, exhibits the shape and mode of application of the ring.

The time during which the pins are retained varies from thirty-six hours to three or four days, according to the circumstances of the case. Their removal should be effected with great care, in a direction contrary to that of their introduction, the parts being well supported at the time. The threads being generally firmly glued to the surface and edges of the wound, are allowed to remain until they drop off of their own accord, which usually happens in a day or two after. The support thus afforded is often of great service to the imperfectly organized bond of union, and its premature removal sometimes necessitates the employment of adhesive plaster, or the insertion of a new pin.

The *continued suture*, fig. 64, is similar to that used by the glover, on which account it is generally known as the glover's suture. It is made with a needle armed with a suitable thread, which is passed diagonally from one side of the wound to the other, on the same principle as in the interrupted suture. Its use is almost exclusively restricted to the treatment of wounds of the intestines, where it will again be noticed.

The *quilled suture*, fig. 65, so called from the fact that it was originally made with the assistance of two quills, is employed chiefly in the treatment of lacerations of the perineum, with a view of effecting more even and accurate contact of the opposed surfaces. The older surgeons were in the habit of using it in sewing up deep muscular wounds, as those of the thigh and abdomen. No one, however, thinks of resorting to it for such a purpose at the present day; for in the latter case, the object can be attained much more easily by the ordinary interrupted suture, extending down nearly to the peritoneum; and in the former by methodical support with the compress and bandage.

The quilled suture is made by passing a stout double thread through the sides of the wound, at intervals of an inch or an inch and a half, and tying

Fig. 63.

India-rubber suture.

its ends over a piece of bougie, quill, or wood, lying parallel with the cut, but about half an inch from it.

Fig. 64.

The Glover's, or continued suture.

Fig. 65.

Quilled suture.

Although sutures undoubtedly act as foreign bodies, necessarily exciting a certain degree of irritation in the tissues into which they are inserted, yet I have by no means that dread of them which they seem to have inspired in the minds of many practitioners. It has rarely happened to me to witness any ill effects from their employment, and in those cases in which this event did happen the fault, I am inclined to believe, was due more to the indiscretion of the surgeon, or the want of stamina on the part of the patient, than to any untoward operation of the sutures themselves. Provided the threads, or needles and threads, are clean, of suitable size, and properly inserted; the constitution of the patient in good condition; and the wounded structures in a tolerably sound state; it is difficult to understand how they could become a source of serious irritation, much less of erysipelas or severe ulceration, effects which have all been charged to their action. My rule has therefore always been to use them freely, and to allow them to remain as long as they seem to answer the purpose for which they were introduced. The moment this object is attained, or they are found to be productive of injury, they should be withdrawn.

The best material for sutures is unquestionably metal, and it matters not, according to my experience, whether this is silver or iron, provided it is properly tempered, perfectly smooth, and sufficiently pliant and thin. This substance, although noticed in connection with this subject by different writers, was first introduced into regular practice by Dr. Sims, of New York, to whom too much credit cannot be awarded for what must be regarded by every surgeon as one of the greatest additions to our armamentarium of the present day.

The advantages of the metallic suture over every other are now so well established, as to render it unnecessary to offer any comments in its favor. It is sufficient to say that it is entirely free from all irritating properties, and that it may be retained for weeks and even months without provoking suppurative action, so common when silk or thread is employed.

The wire is introduced in the same manner as the thread, the short end being firmly twisted round the long one, in order to prevent it from slipping out of the eye of the instrument. Quite a number of needles have been devised for facilitating the insertion of the wire, but it is questionable whether they possess any particular advantage over the one in common use. Perhaps the most unexceptionable is one with two holes, with a vertical groove between them on each side. It is hardly necessary to add that the ends of the suture instead of being tied should be simply twisted together.

The annexed engravings will serve to convey an idea of some of the best forms of this kind of needles. Fig. 66 represents Mr. Price's instrument;

Fig. 66.

Price's needle for wire suture.

it is grooved on both surfaces, and is pierced with two holes, nearly half an inch apart, the wire being passed from the lower to the upper, and then doubled and twisted at the end to hold it. Mr. Murray's needle, fig. 67, has a groove and open box end, while Mr. Lister's, fig. 68, has a single eye and

Fig. 67.

Murray's needle.

Fig. 68.

Lister's needle.

a groove at the side. Ingenious contrivances of a similar kind have been constructed by Dr. Levis and Dr. Goddard, of this city.

Some care must be taken in removing the wire suture, lest the edges of the wound should be forcibly separated. To prevent this the loop should be cut on one side very close to the edge of the wound, when the twist may be seized with the forceps, and the wire gently drawn out. The length of time during which the suture is retained must depend upon circumstances. From three to five days is a good average period.

Rest and easy *position* are essential elements in the treatment of wounds. If the part be exercised, or subjected to motion, it will be difficult, if not impossible, to preserve apposition, and to limit inflammatory action. If the wound be transverse, and seated in an extremity, it will be impossible to prevent it from being torn open, unless the muscles which pass along it are maintained in a relaxed condition. Thus, if the wound involve the front of the thigh, the limb is extended, and flexed if it affect the posterior aspect. In each case, the muscles immediately concerned in the lesion are put in a state of perfect repose.

In very large and deep wounds, it is hardly possible to keep the edges in contact, in their entire extent, without the aid of compresses and *bandages*. Let us suppose that the injury is seated in the thigh, and that it is accompanied by extensive division of the muscles. In such a case, adhesive plasters and sutures, however skilfully applied, would scarcely be sufficient to give the wound the support which is necessary to keep the deep portion of

the edges in apposition with each other. More or less separation would almost be inevitable. To fulfil this indication, so important to the adhesive process, it is indispensable to lay a stout compress along each side of the limb, opposite the deep part of the wound, and to confine it with a roller, extending from the toes upwards as far nearly as the groin. In all wounds of this description, whether the result of accident or of operations, great care must be taken to prevent the retention of fluids, otherwise suppuration will take place instead of union by the first intention. Large intervals should be left between the adhesive strips, and holes should be cut in the bandage where it lies over the affected part; in some cases it will even be proper to leave a small tent at the bottom of the wound, bringing it out at the most dependent point, to drain off the discharges.

The most suitable bandage for supporting the wounded parts is the common roller, carried upwards from the distal portion of the limb to a short

Fig. 69.

Fig. 70.

Invaginated bandage for longitudinal wounds.

distance above the seat of the injury. The invaginated bandage, represented in figs. 69, 70, and formerly so much in vogue, is a dangerous contrivance, unworthy of scientific surgery.

2. MODE OF HEALING OF WOUNDS.

The parts having been properly adjusted, the duty of the surgeon, as far as manipulation is concerned, is temporarily at an end. Nature, the physician of wounds, as she was called by Paracelsus, must do the rest. "Warily," says this eccentric man, in his "Great Surgery," published in 1536, "warily must the surgeon take heed not to remove or interfere with Nature's balsam, but protect and defend it in its working and virtue. It is the nature of flesh to possess in itself an innate balsam which healeth wounds. Every limb has its own healing in itself; Nature has her own doctor in every limb; wherefore every chirurgeon should know that it is not he, but Nature, who heals. What do wounds need? Nothing. Inasmuch as the flesh grows from within outwards, and not from without inwards; so the surgery of wounds is a mere defensive, to prevent Nature from suffering any accident from without, in order that she may proceed unchecked in her operations." If these sentiments, uttered more than three centuries ago, could only be firmly impressed upon the mind of the modern surgeon, there would be much less meddlesome practice of every kind than there is now, notwithstanding our boasted knowledge, and our contempt for the fathers of the profession.

Modern surgeons have described five distinct modes according to which wounds are supposed to heal. The first is by immediate union, or the direct growing together of the raw surfaces; the second, by scabbing, or the formation of a crust of blood covering over the wound; the third, by the effusion

of lymph, and the conversion of this into fibro-cellular tissue; the fourth, by granulation, and the development of epithelial matter; and the last, by the junction or inosculation of the granulations with each other. The old doctrine, so ably advocated by Hunter, and so long entertained by practitioners generally, assumes that there are but two modes of cure; the one consisting in union by the first intention, or primary adhesion, and the second in the formation of granulations, filling up the gap, and thus repairing the injury, the last stage of the process being the development of new skin. This latter mode of repair constituted what was so long known in the schools as union by the second intention, or union by granulation.

The idea that *immediate union* of a wound may take place was first advanced by Dr. Macartney, of Dublin, and is now prominently taught in all the British schools of surgery, if not also in those of this country. It assumes that two raw surfaces, laid closely and evenly together, will promptly coalesce with each other, independently of inflammation and effusion of lymph or blood, vessel inosculating, as it were, with vessel, muscular fibre uniting with muscular fibre, skin adhering to skin, and nerve becoming again continuous with nerve. It is alleged, it is true, that this occurrence is uncommon, and that it requires for its production a good constitution, an entire absence of local inflammation, and the greatest possible caution in respect to the management of the parts. When these conditions are present, it is asserted that even large wounds are capable of this kind of union; and a case, observed by Mr. Paget, is usually referred to as an illustration and proof of the possibility of such an occurrence. This case is briefly as follows: A female, aged thirty-three, had had her breast and several axillary glands removed on account of cancer. The flaps, which were very large, were carefully approximated, and kept in place with isinglass plaster; the general health seemed to be excellent, and union took place in the ordinary way, the whole line of incision having firmly closed by the end of the third week, except at one narrow spot, at which granulations arose from the pectoral muscle. Erysipelas and phlebitis now set in, and carried off the patient in four or five days.

"I cut off," says Mr. Paget, "the edges of the wound with the subjacent parts, expecting to find evidence of union by organized lymph, or, possibly, blood. But neither existed; and the state of the parts cannot be better described than by saying that scarcely the least indication remained of either the place where the flap of skin was laid on the fascia, or the means by which they were united. It was not possible to distinguish the relation which these parts held to each other from that which naturally exists between the subcutaneous fat and the fascia beneath it. There was no unnatural adhesion; but as the specimen, which is in the Museum of St. Bartholomew's, will still show, the subcutaneous fat which did lie over the mammary gland was now connected with the fascia over the pectoral muscle, just as, for example, the corresponding fat below the clavicle is naturally connected to the portion of the same fascia that lies there. The parts were altered in their relations, but not in their structure. I could find small points of induration where, I suspect, ligatures had been tied, or where, possibly, some slight inflammation had been otherwise excited; and one small abscess existed under the lower flap. But with the most careful microscopic examination, I could discover no lymph, or exudation corpuscles, and only small quantities of what looked like the debris of such oil particles or corpuscles of blood as might have been between the cut surfaces when the flaps were laid down. In short, we cannot otherwise or more minutely describe this healing than by the term "*immediate union*;" it is immediate, at once in respect of the absence of any intermediate substance placed between the wounded surfaces, and in respect of the speed with which it is accomplished."

No one, it seems to me, can examine the history of this case without being struck with the fact that it was just such an one as must, of necessity, have been followed by inflammation and a deposit of fibrin; the operation was evidently a severe one, the dissection was extensive, the relations of the parts were completely changed, and it is impossible to conceive that the flaps, although carefully laid down and confined by isinglass plaster, could have united without the intervention of plastic matter. If the use of the knife is ever productive of inflammation, it surely ought to be under such circumstances. That inflammation was present, is proved by the circumstances, referred to by the reporter, that there were several little points of induration apparently corresponding with the site where ligatures had been applied, and mention is also made of the existence of a small abscess, clearly denotive of the same fact. Thus, then, it is perfectly certain that both inflammation and deposit of lymph had occurred at several places, and it may be imagined, without any stretch of the imagination, that nature had treated the rest of the wound in a similar manner, with this difference only that less lymph was effused there than elsewhere. The union, too, was more prompt and effectual. Hence, long before the woman expired, the plastic matter, poured out as a consequence of the amputation of the breast, was completely absorbed, having fulfilled its purpose as a bond of connection between the opposed surfaces; so that, when the parts were examined with the microscope, not the slightest trace of it could anywhere be discovered. Different textures, it is well known, possess different faculties of furnishing plastic matter, as well as of removing it after it has been deposited. Thus, in amputation of the leg, when the flap is exposed to the air, we observe that muscles, fibrous membrane, skin, and cellular tissue are much more rapidly glazed with lymph than adipose substance, vessels, or bone, the latter of which, in fact, rarely exhibits any evidence of its presence until the end of the first week, and then it always shows itself first on the medullary membrane, then on the cancellated structure, and lastly on the outer compact substance.

Now, if we take into consideration all the circumstances that can be brought to bear upon this question; the fact that all injuries whatever are followed by inflammation, if the patient survives their effects long enough, as well as by more or less effusion of lymph; that some structures take on this action more readily than others; that inflammation is often slight in one part and severe in another; and that lymph, when no longer of any use, is invariably absorbed, nature abhorring a substance which she does not need, as in the case of a wound after the completion of the solidifying process; taking, I say, all these circumstances into account, I am satisfied that it is impossible for any wound, however induced, situated, or treated, to heal by immediate union, or without the intervention of inflammation and effusion of lymph.

The only case, it seems to me, in which such a mode of union would be at all possible, is where the edges of a wound, as, for instance, one of the hand, are carefully approximated immediately after the receipt of the injury, thus affording the vessels and other structures an opportunity of promptly regaining their natural relations. But even here it is more rational to conclude that the vessels, irritated and fretted by the injury which they have sustained, would pour out a thin film of lymph, serving as a bond of reunion between the divided parts.

The second mode in which a wound is said to be capable of healing is by the process of *scabbing*, and here also, it is alleged, the cure is effected without the intervention of inflammation, or the deposition of plastic matter. An injury of this kind being inflicted, the blood coagulates upon its surface, where it soon forms a hard, solid crust, which thus protects it from the contact of the air and other injurious influences until it is covered over with new skin,

when nature's shield, now no longer required, is cast off as an effete substance. This mode of healing is rare in man, but sufficiently common in the inferior animals, as the horse and cow, owing to their being so much less liable to active inflammation and its consequences. It is occasionally imitated by the surgeon's dressing, consisting of lint dipped in blood, or smeared over with collodion, so as to protect the raw surface from the contact of air and dirt. The principal proof deduced by the advocates of this mode of cure rests upon the supposed fact that inflammatory deposits occurring in a case of this kind would effectually destroy the process by prematurely detaching the scab, and so leading to the development of granulations, or union by the second intention. No one, however, has ever demonstrated that there is no inflammation when a wound is incrustated in this way; on the contrary, the whole theory is a mere speculation, unsupported by a single proof. The difference between such a wound and an ordinary open one, is simply this, that, in the former, there is very little inflammation, whereas in the latter, there is a good deal, but in neither is it wholly absent.

With regard to the third mode of cure, or union by *adhesive inflammation*, all pathologists stand upon the same ground, none disputing the possibility of its occurrence. The only conditions which it demands for its speedy and successful accomplishment are, first, that no coagulated blood shall intervene between the contiguous surfaces, and, secondly, that the part and system shall be maintained in such a state as not to permit the inflammation to transcend the limits of lymphization. According to this doctrine, union cannot take place without more or less inflammation and the effusion of a certain amount of plastic matter, serving as a bond of connection between the opposed surfaces, glazing and gluing them together, and ultimately, after having enjoyed the properties of nucleated blastema, assuming the character of cellulo-fibrous tissue. Now, if the views which it has been my object all along here to inculcate be correct, it follows that all union is the result of adhesive action; that is, of a certain degree of inflammation just sufficient, and no more, to pour out the requisite amount of coagulating lymph for effecting the cohesion of the raw surfaces. If the quantity of this substance is very small, or its vitality greatly impaired, no union will occur; nor will such an event take place if the effusion be attended with high excitement; for under such circumstances the lymph that is poured out will be aplastic and associated with suppuration, causing the parts to gap and compelling them to heal by granulation or union by the second intention. In the more favorable cases of adhesive inflammation, the intervening substance is soon removed by absorption, without being transformed into cellulo-fibrous tissue, which can only be needed when the union is tardy, or when it is effected through the medium of an inordinate quantity of plastic material; when, in short, the apposition has been somewhat imperfect, and yet not sufficiently so as to offer any serious obstacle to cohesion, or to cause suppuration. In general, when the process of reunion goes on kindly, the merest conceivable film of lymph is sufficient for the purpose; the vessels, nerves and absorbents soon extend from one side to the other across the intervening substance, and as soon as coalescence has occurred, and complete interchange has been established, the new matter, now no longer needed, is speedily removed, precisely in the same manner and for the same reason that the callus is removed after the union of a broken bone; nature, as already stated, being averse to letting anything remain that is not needed if she can get rid of it.

The fourth mode according to which wounds may heal is by the *granulating process*, or union by the *second intention*. This occurs in all cases where the adhesive inflammation is thwarted, whether in consequence of defective action, mismanagement, or any other cause whatsoever. The surface of the wound gaping, it gradually becomes covered with granulations, by which the cavity

is ultimately filled up, cicatrization constituting the last act of the process. The manner in which these bodies are formed, as well as their structure and functions, having already been considered under another head, nothing further need here be said respecting them.

Finally, the new doctrine teaches that a wound may heal by the direct conjunction of granulations, or by a kind of *secondary adhesion*. This mode of cure, it is alleged, may occur whenever we place in contact the edges of an open wound, thereby bringing the granulations more closely in apposition, and so favoring their coalescence, coherence, or direct growing together. To my mind this mode of union does not differ from the ordinary process which we notice during the development, aggregation, and adhesion of granulations upon the surface of wounds and ulcers; hence, if this opinion be correct, such a distinction is as unnecessary as it is unscientific. I question, however, whether there is, in either case, anything like a direct adhesion; on the contrary, it seems more probable that whenever granulations unite they cohere through the medium of a thin film of plastic matter, as is the case with the raw surfaces of a recent wound, as previously described, and which is rapidly transformed into nucleated blastema, or germ cells, which thus form the basis of new tissue.

If what has now been said be correct, it follows, as a necessary corollary, that there are only two modes in which wounds unite, long recognized by surgeons, easily comprehended, and in perfect harmony with the results of observation and experience. These two modes are, as was previously stated, adhesive inflammation, or union by the first intention, and repair by granulations, or union by the second intention; in other words, there is no form of union without inflammation and lymph; and the only difference in the two processes here mentioned is that in the one the plastic matter serves as a direct bond of connection between the opposed surfaces, while in the other it is converted into a series of elaborately organized bodies which, by their coalescence, ultimately fill up the gap left by the retracted edges of the wound.

A subcutaneous wound heals on the same principle as an open one, only that, the contact of the atmosphere being prevented, there is less inflammation. Inflammation, however, is never, as some have asserted, entirely absent; for we always find after the operation of tenotomy, an operation which supplies us with one of the best examples of this class of lesions, that the parts continue to be sore and tender for some time afterwards, and that, as when the tendo-achillis has been divided, the person walks with great difficulty, or, as more generally happens, is altogether disinclined, if not actually unable, to move about. The lymph that is poured out here is highly organizable, and is therefore readily transformed, at first, into nucleated blastema, then into cellulo-fibrous matter, and ultimately into tendinous tissue, closely resembling that which it serves to unite.

SECT. II.—INCISED WOUNDS.

An incised wound is one inflicted with any sharp cutting instrument, as a knife, a sword, or an axe. It may vary in extent from the slightest possible incision to a gap of frightful length and depth. The largest lesions of this description are generally made designedly by the surgeon in the extirpation of tumors, in the amputation of the limbs, and in the resection of joints. In general, they are open, and therefore in contact with the air; but in some instances they are subcutaneous, and therefore exempt from such exposure. Every incised wound, however simple, is characterized by three phenomena, deserving of special consideration; 1st, by an effusion of blood; 2dly, by

more or less pain; and 3dly, by a retraction of the edges of the divided structures.

1st. The *hemorrhage* varies in quantity, from a few drops to several ounces, or even quarts, according to the extent of the injury, and, above all, the vascularity of the affected tissues. When the capillaries alone are involved, the blood oozes rather than flows away, whereas the reverse is the case when a tolerably large vessel is divided. The hemorrhage may be strictly arterial, but in general it is both arterial and venous. In the former case the fluid is of a scarlet color, and spirts out in jets, synchronously with the contraction of the heart; in the latter, on the contrary, it is of a dark modena, or purple complexion, and issues in a continuous stream, as in bleeding at the arm. Some parts of the body being more vascular than others, are naturally inclined to bleed more when divided. Thus, a wound of the cheek bleeds more freely than one of the leg, and both less than one of the lip. Again, a part that has been habitually irritated for a long time will, when divided, emit a much greater amount of blood than it will if it be in a healthy state. A familiar example of this occurs in excision of the tonsils, an operation which is sometimes attended with profuse hemorrhage, in consequence of the enlargement of the vessels, and their inability to retract on account of inflammatory effusions.

2dly. The *pain*, like the hemorrhage, attendant on an incised wound, is influenced in its extent, by the size of the lesion, the nature of the affected textures, and the temperament of the individual. In general, it very soon subsides, and does not afterwards return, unless there is an undue amount of inflammatory action. When a large nerve has been implicated in the injury, there is usually, in addition, some degree of numbness in the surrounding tissues, and occasionally, also, partial paralysis in the distal parts.

3dly. The *retraction* of the edges of the wound is dependent upon the natural resiliency of the cutaneous and muscular tissues. It is very materially influenced, however, in its degree, by the depth of the wound, by its situation, and also by the amount of motion to which it may be subjected immediately after the receipt of the injury. Thus, a wound of the hairy scalp, extending down to the bone, will scarcely gape any, while one on the forehead, arm, or leg will exhibit a frightful cavity, in consequence simply of the muscular contraction of the part, or, in the case of the two latter, on account of the change of posture.

The *treatment* of such an injury is perfectly simple. The first object is to arrest the hemorrhage, provided this has not been already done by the natural efforts. In all cases where it is of a capillary character it soon ceases spontaneously; or, when this does not happen, it may be promptly stopped by exposing the surface of the wound to the cold air, or by pressing upon it a sponge wet with cold water. When, on the other hand, it proceeds from a vessel of considerable size, the more prudent course will be to apply the ligature; for, although it may be temporarily suppressed, yet it will be very liable to break out again upon the slightest exertion; or, at all events, as soon as reaction takes place. The manner of performing this operation will be pointed out under its appropriate head.

The hemorrhage having been arrested, the next thing to be attended to is the cleansing of the wound. Every foreign substance, no matter how delicate or minute, must be carefully picked away with the forceps, removed with the fingers, or dislodged with a stream of water, squeezed from a sponge. The finest hair, if allowed to remain, would act as an irritant, and impede the adhesive process. The same remark is applicable to the blood that may cover the wound, or incrust its edges. It is just as necessary to remove this as it is to remove dirt or any extraneous substance whatever. Even the slightest possible layer of blood is likely to prove a barrier to immediate re-

union; for although it is unquestionable that this fluid may occasionally become organized, yet such an event is never expected or wished for under such circumstances. Hence the whole surface of the wound should be thoroughly freed of blood, not roughly, of course, but as gently as possible, before we attempt the approximation of its edges. If the blood has coagulated and become adherent to the wound, it may readily be detached with the fingers, forceps, or handle of the scalpel. Finally, the circumjacent parts, if covered with hair, are carefully shaved and washed.

The object of these preliminaries is to place the wound in the best possible condition for union by the first intention, or the establishment of the adhesive process. To insure this, the edges must be carefully approximated in their entire extent, and retained in contact for a certain period, by appropriate means, aided by rest and proper position of the part. If the wound be of small extent, nothing will be required beyond a strip or two of adhesive plaster. If, on the other hand, it is long and deep, it will probably be necessary to use, in addition, a few sutures, if not, also, a compress and bandage.

The wound being dressed, and the parts concerned placed at rest in a relaxed, and, if possible, also in an elevated position, little remains to be done by the surgeon, except to watch and assist nature in her reparative efforts. Within a short time after the edges of the wound have been approximated, inflammation is set up, and this is speedily followed by an effusion of plastic lymph, not only upon their surface, but also into the surrounding tissues. The interposed layer, hardly as thick as the most delicate spider's web, soon becomes organized, by an interchange of vessels and nerves between the opposite sides, and thus forms the bond of union between the divided structures. In the meantime the inflammation gradually subsides, the surrounding tissues regain their accustomed functions, and the consolidation is completely established. The resulting cicatrice remains rough for some time, but by degrees it becomes polished, and finally assimilates itself to the natural skin, except that it is whiter, free from hair and sebaceous follicles, and less capable of resisting the effects of disease.

But it is not always that the healing process advances so favorably as it has just been described. In many cases, indeed, it is materially retarded, interrupted, or even entirely prevented. Various causes may contribute to bring about this untoward result; of which the most common are the presence of some foreign body in the wound, or the want of accurate apposition of its edges, too much motion in the part, improper applications, or an undue amount of morbid action. It is the duty, therefore, of the practitioner not only to attend well to every case of the kind in the first instance, but to watch it most sedulously throughout its entire progress, inciting action when it is deficient, and repressing it when it is too high.

If the symptoms assume an untoward tendency, the adhesive action threatening to pass into the suppurative, the sutures and plasters should immediately be slackened, and recourse be had to the water-dressing, either warm or cold, simple or medicated, according to the tolerance of the part and system. In general, simple water will be found to answer better than anything else, and may often be advantageously employed from the very commencement, especially if the wound be very large, in anticipation of inordinate action. The diet, bowels, and secretions must be properly regulated; and if suppuration be inevitable, the most agreeable and soothing application will generally be a light emollient cataplasm. Gaping of the wound should be counteracted by the use of adhesive strips, aided by position, and, if necessary, by a few loose stitches and the bandage.

SECT. III.—LACERATED WOUNDS.

A lacerated wound is a lesion in which the tissues, instead of being smoothly divided by a sharp cutting instrument, are torn rudely and forcibly asunder. The edges are ragged and irregular, there is little pain or hemorrhage, and the surrounding parts, frequently bruised and discolored, are cold and benumbed. The injury most commonly occurs in factories, grist-mills, and steamboats, from the clothes and limbs being accidentally caught in the machinery. Extensive lacerations are often caused by weapons of war; by the teeth of the inferior animals, as the shark, dog, and bear; by the passage of the wheel of a cart or carriage; and by falls from a considerable height, in which the body strikes against a hard and projecting object, as a stone, a post, or an iron-railing.

A lacerated wound differs from an incised one, 1st, in the slightness of the attendant pain; 2dly, in its indisposition to bleed; 3dly, in its tendency to suppurate and slough; and, 4thly, in its liability to be followed by tetanus and other nervous symptoms.

The *pain* in lacerated wounds is generally very trifling; indeed, instances are frequently met with in which it is entirely absent, the patient being unconscious at the moment and for some time afterwards of having received any serious injury. Thus in the case of Wood, the miller, as detailed by Cheselden, the arm was torn off at the shoulder, and yet so slight was the pain that the man was not aware of what had occurred until he observed the limb moving round on the wheel. I have seen several instances in which the tendons of the fingers, along with a portion of their muscular bellies, were pulled out with such velocity as not to be productive of the least local distress, the patient not being conscious of having been injured until a short time after the accident. When the lesion is very grave and extensive, as when a limb is suddenly severed from the trunk, the attendant shock must necessarily be so severe as to obliterate, in great measure, all local sensation. Upon the occurrence, however, of reaction, the pain becomes frequently very violent, requiring large doses of anodynes for its suppression.

The absence of *hemorrhage* in a lacerated wound forms a very striking feature, and is the direct consequence of injury done to the vessels. In an incised wound there is no impediment to the flow of blood, because the vessels are divided evenly; in a lacerated one, on the contrary, they are torn into shreds and fragments, which readily intercept the fluid as it sweeps over them, and thus promote the formation of a coagulum, often extending high up into the tube. The vessels, moreover, are partially paralyzed, from the injury sustained by the nervous filaments of the affected parts; hence they are incapable of contracting upon their contents and of propelling them onwards. In addition to these circumstances, there is frequently, especially in severe lacerations, excessive prostration of the system, which powerfully contributes to the coagulation of the blood, and the formation of an internal clot. This indisposition to hemorrhage is present even when very large vessels are wounded. In the celebrated case of Wood, above alluded to, the arm was torn off along with the scapula, and yet there was no hemorrhage. Many instances of a similar kind have been published, among the more remarkable of which are those related by La Motte, Morand, Carmichael, Mussey, Gibson, and Allan.

Lacerated wounds are frequently deceptive in their appearance, the amount of injury being much greater than the surgeon is at first led to suppose. The skin, for example, may be affected very slightly, perhaps, indeed, hardly at all, while the muscles, aponeuroses, vessels, and even the nerves may be exten-

sively severed, or torn up. In many cases the bones are crushed, large joints laid open, and the soft structures completely pulpified. Hence too much caution cannot be observed in our examinations, as well as in our prognosis.

The *treatment* of a lacerated wound is to be conducted upon the same general principles as that of an incised one. All extraneous matter is removed, the vessels, if necessary, are tied, the parts are neatly approximated, and every precaution is used to moderate the resulting inflammation. In applying the ligature, care is taken to select a sound portion of the artery, otherwise secondary hemorrhage will almost be certain to follow the sloughing process. When the hemorrhage is venous, it may, in general, be promptly and effectually arrested by the compress and roller, which should be so arranged as not to impede the return of the blood to the heart. All undue constriction must be avoided. Ligation is rarely called for, even when the largest veins are torn across. Although it is not probable, from the ragged character of the wound, that much of it will heal by the adhesive process, yet it is always best to treat the case with reference to this object. For this purpose the edges, after having been neatly trimmed, are lightly approximated, and maintained by adhesive strips, supported by a bandage; all tension is carefully avoided; and large interspaces are left between the plasters for the purpose of drainage. Sutures may usually be dispensed with, although I have not the same dread of them that some surgeons have; for I have, in many cases, derived the greatest benefit from their employment, while I have rarely seen them do any harm. They should never be retained longer than forty-eight hours, and they may be removed even earlier, if they appear to act injuriously. If any parts are entirely deprived of vitality, they may at once be cut away, but as there must generally be some uncertainty on the subject, it is a good rule to let them alone, and intrust their separation to the efforts of nature; or, at any rate, to wait until it is perfectly certain that they have perished.

To moderate the inflammation, the water-dressing is used, either warm or cold, as may best comport with the comfort of the patient. On the appearance of suppuration it may, unless acting very kindly, give way to the linseed cataplasm, which, in its turn, is superseded as soon as the granulating process is fairly established, by the opiate cerate. If the inflammation run very high, threatening to terminate in gangrene, purgatives and nauseants are freely used, and leeches applied to the parts immediately around the wound. The lancet is rarely required, except in very robust and plethoric subjects, in whom, under such circumstances, it cannot be resorted to too early or hardly too vigorously. Mercury is frequently indicated at the very commencement of the treatment, on account of the concomitant derangement of the biliary and digestive apparatus, produced by the shock of the injury. It should be administered in moderate doses, either alone or in combination with opium, Dover's powder, or morphia and antimony. Anodynes must be freely given to allay pain and insure sleep. Much judgment is required not to carry the depletion too far. In all cases due allowance must be made for the waste which must necessarily attend a wound of this description, as well as for the depression which the system experiences in the first instance, and which often continues to exert its baneful influence for days and weeks together.

Secondary hemorrhage may arise as soon as reaction takes place, or it may be postponed until the sloughs begin to separate. In the latter case, it will not be likely to occur before the fifth or sixth day. When there is reason to expect such an event, as there will be when a considerable sized artery is implicated, the patient should be most sedulously watched until the crisis is past, a tourniquet being placed loosely around the limb, and the nurse instructed in its use, so as to be fully prepared to meet the emergency the moment it arises. For the want of such precaution life might be destroyed in a few minutes, before it is possible for the attendant to reach the bedside.

Tetanus is most frequently met with in nervous, irritable subjects during the prevalence of hot, or damp, chilly weather, and often arises without any obvious cause, either as it respects the wounded part or the system. Large doses of anodynes, especially of opium and assafœtida, will usually promptly arrest it in its earlier stages, but when fully developed it almost always proves fatal, no matter what treatment may be employed.

When the laceration is seated in an extremity and involves important vessels and nerves, or when it is accompanied by a comminuted fracture, a compound dislocation, or a disorganized state of the soft parts, the probability is that amputation will be required. Should this be decided upon, the proper period for performing the operation is as soon as reaction is fully established. If it be undertaken while the patient is pale, faint, and nearly pulseless, he will be almost certain to die from the immediate shock of the operation, or, at all events, within a few hours after, from an inability to recover from the effects of it. On the other hand, the amputation should never be postponed until the system has been assailed by inflammation, since this would equally compromise the result. The time for interfering, then, is when the heart has resumed its wonted action, the pulse reappeared at the wrist, the color returned to the face, and the warmth been re-established in the extremities; then, but not until then, do we operate.

SECT. IV.—CONTUSED WOUNDS.

A wound is said to be contused when the parts, instead of being neatly divided by a sharp instrument, are bruised and severed by an obtuse body, its edges being ragged and shreddy. The injury may happen in a great variety of ways, as from a blow with a heavy bludgeon, the kick of a horse, the passage of the wheel of a carriage, the contact of a partially spent ball, or the explosion of a gun, shell, or rocket. An ugly contused wound is occasionally received by a fall from a considerable height, in which the person alights among sharp and disjointed stone, upon a pile of timber, or upon a mass of rubbish. The most severe accident, however, of this kind is that which follows the passage of the wheel of a railroad car, in which the body is often mangled in the most frightful manner, the soft parts being literally pulpified and the bones ground to pieces.

The effects of a contused wound are various. When the injury is very severe life may be destroyed on the spot, just as in a gunshot wound, from shock or loss of blood, and without any attempt whatever at reaction. In the milder forms, however, the consequences may be very trifling. From the manner in which the structures are bruised there is generally but little pain in the first instance and for some time afterwards; the part feels merely stiff and benumbed, perhaps somewhat sore and tender; by and by, however, when inflammation arises, the pain is often considerable, while in some instances it is extremely severe. When the injury is extensive, there is always great shock to the whole system; the patient is deadly pale, and almost bereft of consciousness, with hardly any pulse at the wrist, and great coldness of the extremities. When he recovers from this state he is apt to suffer from vomiting and various nervous disorders. If the weather be hot, or the constitution unusually irritable, he may be seized with locked jaw. Neuralgia is also liable to occur as a sequel of such accidents.

Another peculiarity of the contused wound is the trifling *hemorrhage* which usually attends it; resembling, in this particular, the lacerated and punctured wound. The vessels being bruised and paralyzed, are unable to propel their contents, which, in consequence, almost instantly coagulate, thus opposing an effectual barrier to the effusion of blood, which is also, at the same time, in

many cases, if not generally, deprived of its vitality in the midst of the injured and perhaps pulpified tissues. When, however, the lesion is very slight, the vessels are sure to throw out more or less blood, although the flow is never copious, except when a considerable sized artery has been laid open, when it may be so great as to prove fatal in a few minutes. Much, then, will depend, in every case, as far as bleeding is concerned, upon the extent and particular character of the lesion sustained by the coats of the vessels, and also, but in a minor degree, upon the injury inflicted upon the blood itself.

Although there is frequently little or no bleeding in a wound of this kind immediately after its occurrence, yet there is generally, if the injury be at all extensive, great danger of secondary hemorrhage. The period at which this will be likely to happen is when the sloughs begin to separate, which, on an average, will be from the fifth to the tenth day, according to the size of the breach and the amount of the concomitant contusion. Hence, as in lacerated and gunshot wounds, the patient should always be diligently watched during this period, lest, hemorrhage coming on unexpectedly, he should perish before he can obtain assistance.

Contused wounds rarely heal by the first intention; the parts are too much bruised to enable their vessels to pour out plastic matter; the inflammation is often extremely severe, and the surgeon is fortunate if he can restrain it within the limits of suppuration, and prevent the occurrence of gangrene. The latter event is by no means uncommon when the lesion is at all severe, and there are few cases of the kind in which more or less tissue is not deprived of vitality during the infliction of the injury. Under such circumstances sloughing will of course be inevitable.

Lesions of this kind are often followed by large abscesses, particularly when they occur upon the scalp, on the hands and feet, and deep among the muscles of the thigh, abdomen, back, and shoulders. The pus is sometimes extensively diffused beneath the muscles, and is frequently preceded by erysipelatous inflammation, especially in nervous, irritable, and intemperate individuals.

Serious injury is occasionally inflicted upon the trunk or upon a limb, without any outward evidence whatever of the fact, perhaps not even the slightest bruise, scratch, or discoloration of the surface. Such accidents are most frequently caused by the passage of the wheel of a carriage, the kick of a horse, machinery in rapid motion, or the blow of a cannon ball, and are easily accounted for by the elasticity of the common integuments, which enables them to glide out of the way of the vulnerating body, while the other and deeper-seated structures, which are destitute of this property, are sometimes completely destroyed by its contact, the vessels and nerves being cut to pieces, the muscles torn into shreds, the bones mashed, and the largest joints laid open. The scalp is sometimes extensively detached from the cranium by a fall upon the head without any external wound, and a partially spent cannon ball, striking the belly obliquely, has been known to tear open the bowels, spleen, and liver, without leaving any mark or trace whatever upon the skin. Such injuries, which are, to all intents and purposes, subcutaneous wounds, are peculiarly severe, and are liable to be followed by the worst consequences; often proving fatal on the instant, or, subsequently, from the effects of inflammation.

Differing from the lesions now described are what may be called, in the strict sense of the term, *contusions*, that is, injuries of the organs and textures without any actual division of substance, except upon a small scale, implicating chiefly the more minute vessels and nerves, along with the connective tissues. Of this form of accident the "black eye," the result of pugilistic rencontre, affords an excellent illustration; as does also the bruise upon the scalp from a blow with a stick. The immediate effect of such an injury is an

extravasation of blood from the rupture of the smaller vessels of the part, and more or less discoloration of the surface, usually of a reddish, bluish, or purplish tint, with a sense of numbness and a dull, heavy pain. The quantity of blood poured out varies from a few drops to many ounces, according to the extent of the lesion, the size of the vessels, and the nature of the affected structures; it is seldom considerable, unless there is an abundance of cellular substance, when it may be very great, as well as widely diffused. When the fluid presents itself as an infiltration, it constitutes what is technically called an *ecchymosis*, of which a good example is afforded in the extravasation which occurs in the submucous cellular tissue of the conjunctiva after a blow upon the eye in an ordinary fight. If, on the other hand, the blood is collected in a small circumscribed spot, the affection takes the name of "thrombus," while the term "depot" is employed to designate it when it is large and concentrated. This distinction is not without its practical value, and therefore deserves to be borne in mind. The accumulations of blood which occur on the child's head, and in the labium of the mother, during severe and protracted labor, are good illustrations of a sanguineous depot, which is often met with upon a large scale in severe contusions, both with and without wound. When the extravasation is copious, it is to be assumed, whatever may be its form, that it has been caused by the rupture of some of the larger vessels, and hence such an occurrence should always be regarded as one of a serious character, often placing limb and life in jeopardy.

In the *treatment* of contused wounds three leading objects are to be kept in view; the first is to arrest hemorrhage, the second to limit inflammation, and the last to promote the absorption of effused blood.

The hemorrhage is to be controlled in the usual manner; by compression and cold applications, if it be slight, or venous, and by ligature, if it be copious and arterial. When the bleeding vessel is concealed, as when the wound is subcutaneous, it may be extremely difficult to find it, owing to the bruised and injected state of the parts, which often renders the search one of great labor and annoyance; still, it is our only resource, and the sooner, therefore, the operation is performed the better, for it will certainly not at all facilitate the undertaking, if we wait until the supervention of inflammation. If the obstacles be unusually great, or if, in our attempt to tie the artery at the seat of injury, we should be compelled to interfere with important structures, it will be well to secure the vessel at some distance above the wound; trusting that the recurrent bleeding will cease spontaneously, or under the influence of systematic and persistent compression.

Although we can hardly expect to obtain much, if any, union by the first intention in a contused wound, still it will do no harm to try; for such an attempt will certainly not make matters any worse. We should, therefore, always proceed as if such an occurrence were not only practicable but probable; with this view the edges of the wound should be as nicely approximated as possible, care being taken of course not to draw them together at all tightly; for due allowance must be made for swelling and drainage, which will always be more or less considerable in this class of lesions. No fear need be entertained respecting the use of sutures, provided they be introduced loosely, and not too numerously. I never hesitate to employ them in such cases, with the restrictions here specified, and am not aware that I have ever seen any ill effects from them. It is only when they produce tension, or when they are made to embrace improper tissues, that they are likely to prove prejudicial. The same remarks are applicable to adhesive strips; they cannot be dispensed with, but it is plainly our duty to apply them with great care, and in such a manner as to leave free room for the escape of fluids. Some authors advise that the edges of the wound should be neatly trimmed prior to their approximation, but such a procedure is never justifiable, un-

less it is perfectly clear that the tissues are dead, or unless they are so ragged and irregular as to render it impossible to effect accurate apposition. It will generally be well to intrust this matter to nature, permitting her to do as she may consider best.

A few sutures and adhesive strips are usually the only dressings that will be required. The parts, having been properly arranged, should be kept constantly wet with evaporating lotions, of which alcohol and water, in the proportion of one part of the former to five of the latter, will generally be the best. Weak solutions of acetate of lead or Goulard's extract will also be serviceable. Such cases are generally benefited by slightly stimulating applications, which seem to have the power of giving tone to the weakened vessels, and thus warding off erysipelas, which is so frequent a result of this lesion when treated in the ordinary manner. Leeches and iodine may become necessary when the inflammation is very active, and in this case too a poultice will generally be found to be more grateful than cold water or astringent lotions. The bowels must be maintained in a soluble state; but the greatest care must be taken to guard against severe purgation, and, in fact, against all active depletion. Due allowance must be made, in every case, for the profuse discharges which are so liable to follow contused wounds. If mortification should occur, the treatment will not differ from that consequent upon ordinary inflammation. Pain and nervous symptoms are controlled by anodynes and antispasmodics. When granulations begin to spring up, the milder ointments will come in play, and will advantageously supersede the warm and cold applications; the former proving now too relaxing, and the latter too repressing.

The removal of extravasated blood is best promoted by the tincture of arnica, in the proportion of three ounces to the pint of water, diligently applied with patent lint; and by cold astringent lotions, such as acetate of lead, Goulard's extract, alum, and hydrochlorate of ammonia. After the lapse of a few days, the part may be frequently bathed with spirits of camphor, or soap liniment; painted with the dilute tincture of iodine; or covered with a poultice made of crumbs of bread and common salt, or of the bruised roots of briony. Under this treatment an ordinary ecchymosis will often vanish in a few days; in the more severe cases a much longer time may be required.

When the extravasated blood appears in the form of a depôt, or as a concentrated collection, attended with marked tension of the integuments, the speediest way of getting rid of it is to make a small opening, just sufficient to permit the blood to drain off, if it be fluid, or to be squeezed out, if it be coagulated. The walls of the sac are then approximated by a compress and bandage, and irritation is kept down by the ordinary antiphlogistic means.

Cavalry-men and grooms are exposed to a severe form of contusion of the tibia, from the kick of the horse. The accident is liable to be followed by violent inflammation, with a tendency to erysipelas and diffused abscess. Recovery is often slow, and suffering great, especially if there has been much concussion of the bone, or extensive injury of the periosteum. The treatment is conducted upon general principles, with the addition of free incisions to liberate the soft parts, the knife grating against the surface of the bone, as in the operation for whitlow.

SECT. V.—PUNCTURED WOUNDS.

A punctured wound is a peculiar injury, deriving its name from the nature of the instrument with which it is inflicted, and the manner in which the tissues are divided. It comprehends all those lesions which are produced

by nails, splinters of wood, thorns, pins, needles, pieces of bone, or fragments of glass: or by the thrust of a dirk, bayonet, lance, sword, or any other sharp-pointed weapon. The operation of tapping affords a familiar instance of such a wound. The sting of the bee, wasp, and other insects, and the bite of the snake, dog, rat, and other animals are all examples of this class of injuries, with this difference, however, that most of them are inoculated with the peculiar poison secreted by these creatures, and hence they naturally come to be considered separately. In common, every-day life, punctured wounds are most frequently met with in the hands and feet of the working classes. In dissecting and sewing up dead bodies the physician often punctures his fingers, and sometimes suffers severely in consequence, apparently, from the introduction of a peculiar septic virus, generated either during the act of dying or shortly after death.

Punctured wounds vary much in their extent, direction, and character; thus, they may be superficial or deep, narrow or wide, straight or crooked, simple or complicated; circumstances which will necessarily exert more or less influence upon their prognosis, treatment, and termination. Their depth is usually much greater than their width; hence it is often extremely difficult to determine the amount of injury done to the parts in which they are situated.

A punctured wound is peculiar, not only as it respects the mode of its production, but also in regard to its effects. The tissues are forcibly pressed asunder, and, consequently, more or less contused, if not also a good deal lacerated. The wound made by the bite of man and the inferior animals is usually both a punctured and a lacerated wound; so also when a splinter of wood, or a similar body, is violently driven into the flesh during an engagement on shipboard, or when a person is suspended by a hook or impaled upon a railing. A needle, nail, or bone, on the contrary, usually makes a purely punctured wound.

The *pain* attendant upon such an injury is frequently most excruciating, depending evidently, not so much upon the extent of the lesion, as upon the injury sustained by the nerves of the part, and the bruised and condensed state of the tissues. Hence the suffering, which is often immediate, is sure to be immensely increased if the resulting inflammation is at all severe. It is always greatest, other things being equal, in persons of a nervous, irritable temperament. Much also will depend, in this respect, upon the nature of the vulnerating body. The puncture, for example, made in the operation of tapping the abdomen with a trocar generally causes but little uneasiness, while that of a nail, penetrating the sole of the foot, deep down among the muscles, usually produces the most intense agony. Violent nervous symptoms often supervene upon such accidents, and in hot climates, as well as in the hot seasons in the colder latitudes, they are liable to be followed by tetanus, especially among negroes and the more intemperate classes of whites.

Punctured wounds are rarely attended with much hemorrhage, indeed frequently hardly any at all; if a large artery, however, has been penetrated, then the bleeding may not only be copious, but fatal, and that perhaps on the instant. The thrust of a sword, lance, dirk, or bayonet into the chest, abdomen, neck, or thigh, often literally taps the vessels, destroying the patient in a few minutes. The shock of such a lesion, too, may prove to be of consequence; even a slight puncture is sometimes followed by excessive prostration, and it has been found that soldiers, during engagements, are seldom able to continue the fight beyond a few minutes after they have been deeply pricked by the point of any of these weapons. The shock of the system is excessive, and the patient soon falls into a fatal syncope.

Another peculiarity of punctured wounds is their liability to be followed

by *erysipelas*, *angioleucitis*, abscess, contraction of the limbs, and wasting of the muscles. Mortification will not be likely to ensue unless the main artery or nerve of an extremity has been severed, or the system at the time of the injury is in a bad condition. Punctured wounds of the scalp, hands, and feet are particularly prone to be followed by severe nervous and inflammatory symptoms, and also by *erysipelas*, the latter generally coming on within less than thirty hours after the infliction of the injury. When the lymphatic vessels become involved, as they often do, the disease is indicated by a red line extending from the seat of the injury towards the nearest lymphatic ganglions. A similar phenomenon, along with more or less induration, is witnessed when the veins participate in the mischief; an occurrence by no means uncommon.

The secondary effects of punctured wounds are often very serious, entailing much suffering, with occasional deformity and loss of limb, and demanding much care on the part of the practitioner. Needles, pins, fragments of glass, and pieces of bone sometimes enter the tendons, ligaments, and aponeuroses, and causing severe and protracted irritation, ultimately lead to irremediable contraction.

The *treatment* of punctured wounds consists, first, in the extraction of the foreign body, in case it has not been already dislodged; secondly, in checking hemorrhage; and thirdly, in moderating inflammation and preventing the development of nervous symptoms.

To determine whether any extraneous matter remains in the wound, all that is necessary, in most cases, is simply to inspect the vulnerating body. If this exhibit marks of fracture, the probability is that a part of it has been left behind, if so, the probe and finger will assist in detecting it. Should the wound, however, be very deep and narrow, it may be necessary, before this can be done, to make an incision, the extent of which must depend upon the circumstances of each particular case, the only care to be observed being the avoidance of important structures, especially vessels, nerves, and tendons.

When a needle or other slender substance is imbedded in the flesh, or buried in the cellular tissue, we may often succeed in detecting it by folding up the skin over it, or making gentle and systematic pressure with the ends of the forefingers at its supposed site, which is generally indicated, at least in recent cases, by a little puncture, perhaps not as large as a flea-bite, upon the surface. Sometimes the local pain or tenderness affords valuable information as to the precise spot where the needle is lodged. I never hesitate, when there is reason to believe that the foreign body has been retained, to make, if necessary, a free incision for the purpose of extracting it; it is much better to do this at once than to temporize with the case, and to wait until bad symptoms arise, when such a procedure becomes inevitable, although it may now be too late to prevent altogether its bad effects.

In the sole of the foot pieces of bone, glass, and other small bodies are sometimes buried deeply beneath the plantar aponeurosis, where it is often quite impossible to detect their presence, however carefully searched for. I well remember a case of this kind which fell under my observation many years ago, in a most interesting boy, nine years old, who lost his life from this cause. As he was running about barefoot one morning, he trod upon a chicken bone, a fragment of which, nearly an inch long, entered the sole of the foot, lodging deeply in the substance of the flexor muscles, in contact with the metatarsal bones. Pain and swelling followed, but still the boy walked about for upwards of a fortnight, limping of course; the weather, in the meantime, being excessively hot. Suddenly symptoms of tetanus came on; Professor Willard Parker, then my colleague, and I now saw the case, and, although we made every effort to discover the foreign body, yet such was the swelling of the part and the depth at which it was situated that we

could not detect it. Death followed in a few days, when we found it so completely buried that it required a very elaborate dissection to remove it.

The bleeding in punctured wounds generally ceases spontaneously; if a large artery has been laid open, or divided, it must be exposed, and tied at each extremity, in the usual manner. If this cannot be done, compression may be tried, as in the treatment of aneurism; or, this failing, or not being deemed admissible, the main trunk of the vessel is tied at some distance from the injury.

To prevent the occurrence of severe pain and nervous distress a full anodyne should always be given, if the case be at all severe, immediately after the accident, and the part wrapped up in flannels, wrung out of warm water and laudanum and frequently renewed. If the general health suffer, a dose of calomel should be administered, followed by oil or senna. If fever arise, the antimonial and saline mixture with morphia may be required, to act on the skin and bowels, and to allay pain and induce sleep. If matter threaten to form, as indicated by the tension and throbbing of the part, free incisions must be made; erysipelas, angeioleucitis, and phlebitis must be treated in the usual manner. Nervous symptoms must be met with the liberal use of morphia and tartar emetic.

Along our Indian borders very severe wounds, of a punctured character, or partly of a punctured, and partly of an incised nature, are often inflicted with the *arrow*, which, as is well known, is capable of being projected, with extraordinary precision, to a great distance. Being usually made of the young willow, or other suitable wood, it varies in length from two feet to two feet and a half, and is feathered in the greater part of its extent, in order to facilitate its movements and increase its speed through the air. The head is generally furnished with a spear-shaped piece of flint, obsidian, or iron. This, which is technically termed the point of the weapon, is of a flattened conical figure, its length from base to apex ranging from three-quarters of an inch to an inch and a half; the corners, or angles, project in a line with the side of the free extremity, and are usually upwards of an inch in width, the whole arrangement being such as to enable the instrument to operate on the principle of the barb of a fish-hook. Thus constructed, the point is securely fixed in a notch on the head of the arrow by means of the tendinous shreds of the deer, coated over with the resin of the fir-tree.

It is supposed that many of our Indian tribes poison their arrows, so as to inflict a more deadly wound; but I am informed by an old pupil, Dr. William F. Edgar, of the army, that this practice is peculiar to the savages inhabiting the mountainous regions watered by Pitt River, one of the northern branches of the Sacramento. These people, it is said, use the poison of the rattlesnake, by grinding the dried head of that reptile into an impalpable powder, which is then applied by means of the putrid blood and flesh of the dog to the point of the weapon, the wound of which proves speedily mortal.

Dr. T. C. Henry, an army surgeon, writes me that wounds made by arrows often partake of the nature of incised wounds, or of those caused by the thrust of the small sword. The iron heads of these weapons are exceedingly thin, and being propelled with great force, make a clean cut, a portion of which not unfrequently unites by the first intention. Unless an important vessel is laid open, such wounds seldom bleed much. Sometimes the head of the arrow is broken off deep in the flesh, thus requiring a tedious dissection for its removal.

SECT. VI.—TOOTH WOUNDS.

Wounds inflicted by the bite of the human subject and of the inferior animals, as the dog, cat, or rat, partake of the nature of contused, lacerated, and punctured wounds. Such lesions are by no means uncommon, and, from the danger which so often attends them, are worthy of more attention than they have hitherto received. I have seen quite a number of cases of severe suffering occasioned by wounds received upon the fingers in the act of striking persons upon the mouth. The inflammation consequent upon such injuries is prone to assume an erysipelatous character, especially if, at the time of the accident, the constitution happened to be in a deranged state, and it is sometimes so violent as to be followed by mortification. In 1851, a distinguished jurist struck a man upon the mouth, wounding his finger slightly against his teeth. Erysipelas promptly supervened, and the hand had to be amputated; subsequently the disease reappeared in the stump, and necessitated the removal of the arm.

The following cases will serve as illustrations of this class of injuries, of which I believe no account has yet appeared in any of our systematic treatises on surgery.

Mary Jackson, aged 47, always in good health, struck the back of her hand against the tooth of a servant girl, producing the merest scratch of the skin over the knuckle of the right index-finger; the part bled only a few drops, and caused hardly any pain at the time. Within two hours afterwards, however, it began to throb and ache, the pain extending up the hand, and thence gradually up the limb as far as the axilla, where considerable enlargement of the lymphatic ganglions soon took place. The forefinger swelled rapidly, and to an enormous degree; the hand and arm were also much tumefied, and a deep red line was seen passing along the limb. Great constitutional disturbance came on, attended with loss of sleep and appetite; and a large abscess formed in the theca of the finger, followed by necrosis of the last phalanx and ankylosis of the other joints. The whole limb remained for a long time sore, tender, and swollen, and upwards of a year elapsed before the re-establishment of the general health.

James Black, aged 36, farmer, eight weeks ago struck a man upon the mouth, receiving a superficial abrasion over the knuckle of the little finger of the right hand. Violent erysipelas of the whole limb followed; the finger became enormously swollen, and a large abscess formed in it, eventuating in the death of its phalanges. The general health suffered greatly, and a fresh attack of erysipelas broke out after the amputation of the finger. Many months elapsed before final recovery occurred.

A medical gentleman, upwards of seventy years of age, received a small wound upon the left index-finger by striking a negro lad upon the front teeth. Erysipelas soon showed itself, attended with exquisite pain, and extending up the limb beyond the elbow. After much suffering, in which the constitution seriously participated, the inflammation at length disappeared, leaving the finger stiff, crooked, withered, cold, and benumbed.

Thomas Clark, aged 47, farmer, in good health, struck a man on his mouth, on the 24th of December, 1851, the knuckle of the metacarpal bone of the right ring finger coming in contact with the incisor teeth; the skin was slightly broken, but he experienced no pain at the time. The same evening, however, the hand and finger became painful and stiff, and the next day they began to swell and to present an erysipelatous appearance. Excessive suffering ensued, producing profound constitutional disturbance; and finally, in about three weeks, a large abscess formed in the hand, requiring the lancet.

When I first saw the case, at the end of this time, the thumb and all the fingers were stiff and immovable; the wrist-joint was also much affected, and, in fact, the whole limb was sore and painful. In August, 1852, the thumb and fingers were still rigid and useless; much colder than natural, benumbed, and considerably attenuated. Every attempt to bend the fingers was attended with severe suffering. The right ring-finger was ankylosed at the metacarpophalangeal joint. There was still much uneasiness in the palm of the hand. The whole limb had an atrophied appearance.

The bite of the human subject is often followed by violent symptoms, coming on soon after the infliction of the injury. I have witnessed quite a number of such cases, and in several have experienced much trouble in saving limb and life. I do not presume that the saliva has anything to do, in this class of wounds, with the production of the bad effects by which they are so liable to be succeeded; the parts are badly bruised, or bruised, lacerated, and punctured, and we well know how prone such injuries, however induced, always are to be followed by erysipelas and other serious consequences, especially when they occur in persons of intemperate habits, or disordered health.

The bite of the inferior animals, particularly when they are much enraged, is often succeeded by a very bad form of erysipelas. Many years ago I attended, along with Dr. Trimble, of Ohio, a child, about three years of age, who had been bitten in one of his fingers a short time previously by a rat. A severe attack of erysipelas soon came on, involving the whole hand and forearm, and causing the most violent local and constitutional suffering. The bitten part was converted into a large unhealthy ulcer, discharging a thin, sanious fluid, and was a long time in healing. Recovery finally took place, but not without permanent ankylosis of the finger, and partial atrophy of the hand and forearm. The bite of the dog, cat, and horse is liable to be followed by similar results. In India the slightest bite of the camel is said frequently to occasion severe inflammation and great general disturbance.

The treatment of tooth wounds and abrasions must be conducted upon the same general principles as ordinary contused and punctured wounds. I would strongly advise, however, that the part should always be well cleansed and bathed with warm salt water, to get rid of any saliva and other matter that may have been deposited by the teeth; after this the best application will be a lead and laudanum poultice, followed, if necessary, by leeches, and, if matter form, by early and free incisions. The dilute tincture of iodine, pencilled over the inflamed surface around the wound, will also be useful. The best internal remedies will be calomel and opium, with an active purge at the commencement of the treatment. When the case is obstinate, alteratives and tonics with change of air may be required.

SECT. VII.—GUNSHOT WOUNDS.

Gunshot wounds are injuries inflicted by fire-arms, as pistols, muskets, rifles, carbines, cannons, shells, and rockets; and are dangerous or otherwise according to their extent, the nature of the affected structures, and the state of the system at the time of their receipt. Occurring in all parts of the body, they may, in one case, be so slight as hardly to attract serious attention, while in another they may be so severe as to cause death upon the spot, either in consequence of shock or loss of blood, or, secondarily, from the violence of the resulting inflammation. Even when the person is so fortunate as to escape with his life, he often remains miserable ever afterwards on account of his mutilated condition, the repeated formation of abscesses, or the occurrence of neuralgic pains, which, hardly leaving him any respite from

suffering, keep his mind and body in a state of constant irritation, and utterly incapacitate him for enjoyment and useful exertion.

The wounding missiles which are generally employed in civil life, in this country, are pistol, rifle, and musket balls, varying in their volume from that of a body but little larger than a swanshot to that of a small marble. Until recently the ball in use in the American army was the round musket ball, which, with a view to greater efficiency, has been superseded by what is called the new rifle-musket ball, the weight of which is 500 grains. It is of a conical shape with a square hollow base and three grooves; and when fired with a charge of sixty grains of powder, at a distance of 200 yards, penetrates eleven one inch pine planks, placed one inch and a half apart. At the distance of 1000 yards it penetrates three and one-fourth of such planks.

The British, French, and Russians employ a considerable variety of balls adapted to the peculiarities of their respective services. The Enfield ball, used by the English since 1853, is rapidly superseding all other missiles of that description. It is a long conical ball, hollow in the base, weighing 3j and 3ij. The French Minié ball weighs 3j, 3ij and 3ij. The Russian ball, also conical, weighs 3j and 3vj.

It has been found in military operations that the conical ball, while it meets with much less resistance from the atmosphere than the round ball, passes to a much greater distance, and does more terrific execution upon entering the body, generally passing in a straight line, and fracturing and comminuting the bones in a most fearful manner; thus causing a much greater mortality, as well as a more frequent necessity for amputation.

The conical ball, moreover, is less liable to become flattened and divided than the round ball, and the aperture of exit is nearly always opposite to that of entrance, which was not so often the case formerly. It is alleged that much of the gravity of gunshot wounds in the Crimean war arose from the substitution of the conical bullet. To show with what power the Minié ball occasionally does its work, it may be stated that it has been known to pass through the bodies of two men and to lodge in that of a third standing some distance behind.

Sometimes two balls are united by a piece of lead, and put in a cartridge, thus producing, when fired, a terrible wound, as often happened in the Schleswig-Holstein war. The Russians in the Crimea also caused great mischief by this expedient. In the naval action off Camperdown, in 1797, great destruction was wrought by the Dutch, by firing bags of nails and pieces of old iron.

Cannon balls are made of cast iron, and range in weight, on an average, from one to sixty-four pounds, the larger being chiefly used at sea and in beating down batteries, and the smaller in field-service. Grape-shot are small balls, confined in a canvas bag, arranged round a wooden spindle by means of a cord, the whole bearing a faint resemblance to a bunch of grapes, whence the name. From this the canister-shot differs principally in being contained in a cylindrical tin-case, closed at each extremity with a piece of wood. Both these classes of missiles are accurately fitted to the caliber of the guns from which they are intended to be discharged. "Shells are large hollow spheres of iron loaded with gunpowder, which may act either in their entire form as solid balls, or subsequently by the explosion of their contents, and their subdivision into numerous splinters, by which their ravages are greatly extended. Shrapnell shells, so named from their inventor, are hollow spheres, loaded partly with gunpowder, partly with balls."

A pistol ball, if fired near, inflicts quite as deadly a wound as a musket or rifle ball. This missile is now generally of a conical shape, and operates with great effect, both upon the soft and hard structures.

A buck-shot wound is at present of rare occurrence. During the late war with Great Britain it was sufficiently common. Buck-shot are sometimes inclosed in wire cartridges, and are then very effective, carrying close for twenty yards, diverging somewhat at fifty, and entering separately at one hundred and fifty, readily penetrating a yellow pine board an inch thick.

Small *shot*, striking the body in a concentrated form, are capable of producing the same effect as a large bullet; if they are scattered, the injury will be less grave, unless they happen to hit an important organ, as the heart, brain, or spinal cord, when death may ensue in a few minutes, or, more remotely, from the resulting inflammation, as in several instances which have fallen under my own observation. Lachèse has ascertained by numerous experiments that a load of small shot discharged at a dead body, at a distance of ten inches, will make a clean round opening; at from twelve to eighteen inches the opening will be very irregular and ragged; whereas, at thirty-six inches, the shot will be scattered in such a manner as to enter separately, not making a common opening at all.

Grave injury is sometimes inflicted by the explosion of *percussion-caps*. Such accidents are sufficiently common among sportsmen, whose pleasures of the chase are often requited by the loss of an eye, and by the most excruciating suffering, from the lodgment of a piece of the foreign body in one of the chambers of that organ, or in the substance of the iris.

Persons are occasionally killed with *wadding* discharged from an ordinary fowling-piece. An instance occurred, some years ago, in one of our theatres where a man lost his life from this cause in a sham-fight upon the stage. The wadding, which was a common cartridge, struck the side of the head, fracturing the temporal bone, and passing across the brain, lodged against the falx of the dura mater, from which it was extracted by Dr. John Rhea Barton after death, which happened in an hour after the accident. In 1838, a girl was killed in England by the discharge of a gun loaded with paper pellets, some of which penetrated the body and lodged in the lungs and liver. In two other cases life was destroyed by a single pellet; in one, by laying open the fifth intercostal artery, and in the other by breaking the orbital plate of the frontal bone, and injuring the brain. A case is recorded of a man being fatally wounded by a kid-glove with a button attached to it; it was discharged from a blunderbuss, loaded with powder, and struck the person, who was standing ten feet off, upon his abdomen, in the cavity of which it was found on dissection.

It is well known that *gunpowder* alone, without any wadding, may, when discharged near the body from a gun, pistol, or fowling-piece, cause fatal injury. From the experiments of Lachèse it appears that, when the distance does not exceed six inches, and the weapon is large and strongly charged, the wound thus made will bear some resemblance to that produced by small shot, each particle which escapes combustion acting like a pellet. The fact that the mere explosion of powder near the body is capable of causing severe bruises, contusions, lacerations, and even death, has long been familiar to observers. The instances are quite numerous of great suffering, mutilation, and disfigurement having been produced by the lodgment of grains of powder in the eyes, face, neck, and other parts of the body. Stone quarriers are particularly liable to such accidents.

In its character, a gunshot wound partakes of the nature of a contused and lacerated wound; at the opening of entrance and for some distance around, the tissues are bruised, but as the ball passes onward it tears the parts, and at the opening of exit they often look as if they had been cut with a sharp knife. The effects of the transit of the missile upon the soft textures may be explained, as was first suggested by Sir Charles Bell, by a re-

ference to a diagram consisting of three concentric rings, as in fig. 71. The first, including the tubular wound, is bounded by tissues which are so compacted, condensed, or contused as to deprive them, to some extent, of their vitality, or, at any rate, to place them in such a condition as inevitably to lead to suppuration; consequently this portion of the wound seldom unites by the first intention. The structures between the first and second rings, having sustained less injury, will also inflame, but only, as a general rule, in such a manner as to give rise to a deposit of lymph, or lymph and pus; while those beyond the last circle will either retain their natural properties, or, becoming excited, will merely experience some slight serous infiltration.

Fig. 71.

The above phenomena may generally be studied to the greatest advantage in deep flesh wounds, as those of the thigh. In such cases there is often a considerable slough of the bruised tissues, upon the separation of which the parts are seen to suppurate and to form granulations, while farther on they are hard, next œdematous, and beyond this natural. These phenomena, however, do not generally pervade the entire length of the wound; for it frequently happens that a considerable portion of the track unites by adhesive action, the tissues being lacerated instead of contused, as they are in the early stage of the passage, and consequently favorable to restoration. The precise point where the tubular wound loses the character of a contusion and assumes that of a laceration cannot generally be ascertained; it will of course vary very much in different cases, and under different circumstances.

The preceding remarks in regard to the injury inflicted by the projectile are chiefly applicable to the smaller kinds of balls, such as the pistol and rifle; the larger ones are generally productive of more serious mischief, and hence it often happens that the wound sloughs in its entire length, from the opening of entrance to that of exit; there being afterwards, when the dead parts have separated, extensive and tedious suppuration, the matter, perhaps, burrowing deeply among the soft structures, and thus greatly retarding the process of repair.

Disposition of the Projectile.—The manner in which the projectile is disposed of varies; sometimes it lodges, and then, of course, it makes but one opening; at other times it passes completely through the part, and so leaves two apertures, one of entrance, and the other of exit. Cases occur where one ball may make three, four, or even more holes. Thus, if it should happen to encounter a sharp edge of bone, as the crest of the tibia, it may be cut into two or more pieces, each of which may afterwards issue at a separate point. Dupuytren met with a case in which a ball, cut into fragments, made five orifices; and at Antwerp the younger Larrey saw six holes made in a similar manner. Again, a ball piercing the surface, just above the wrist, may be unable to penetrate the aponeurosis of the forearm, but, travelling along for some distance under the integument, may emerge below the elbow; then, the limb being considerably flexed at the moment, it may re-enter the skin a second time at the lower part of the arm, and finally escape near the shoulder-joint; thus leaving four apertures, two of entrance, and two of exit. Such an occurrence is, of course, quite rare; but its possibility should not be forgotten, as it is of great interest in a medico-legal point of view. A man, for example, might be shot in a duel, and his friends seeing the number of openings in the limb, might accuse his adversary of foul play, on the ground that he had used more than one ball.

A ball striking an extremity may pass not only completely through it, but also through its fellow, thus making four openings; or it may perforate the upper part of the thigh, and then pass through the head of the penis, leaving

two orifices in the former and two in the latter, as in a case which I saw in the Hospital at Alexandria, under the care of Dr. Sheldon, after the engagement near Centreville, Virginia, on the 18th of July; or, finally, it may traverse both buttocks, or it may perforate one and lodge under the integuments on the outer side of the other, as in a man who was wounded in the battle at Bull Run.

When there is but one opening, it is natural to conclude that the ball has lodged, and this, as already stated, is usually the fact. Instances, however, occur, although they are very rare, where the reverse is the case. Thus, a ball has been known to pass for some distance into the pectoral muscle, and to be immediately ejected by the recoil of a rib. The knee-joint has occasionally been opened, the ball being supposed to have lodged in the head of the tibia, but upon amputating the limb no ball was found, although there was but one opening. Lastly, a ball may enter the body, perhaps rather deeply along with a piece of cloth, upon extracting which the missile may drop out. Instances, illustrative of the possibility of all these occurrences are circumstantially narrated in the admirable and instructive works of Percy, Guthrie, Hennen, Baudens, Macleod, and other military surgeons, and deserve an attentive perusal.

Large balls, fragments of shell, pieces of iron, and other substances, occasionally bury themselves deeply among the muscles, where, owing to the small size of the opening made on entering, they have been known to remain for a long time without exciting any suspicion of their presence. Larrey narrates a case in which he extracted a ball, weighing five pounds, from the thigh of a soldier, who had suffered so little inconvenience from it that it had been entirely overlooked by the surgical attendant; and Hennen refers to a similar instance as having occurred at Seringapatam. Here, however, the ball weighed twelve pounds.

Considerable difference generally exists between the *openings* of entrance and exit. The former is usually rounded with even or slightly inverted edges, as if the skin had been tucked in a little, and there is frequently more or less bluish or blackish discoloration of the adjacent surface, from the contact of burnt powder, deposited upon the ball at the moment of the explosion, and rubbed off as the ball strikes the body. When the discharge takes place within a few feet of the surface, scorched grains of powder often adhere to the skin, or are even imbedded in its substance. The opening of exit, on the contrary, has generally a slit-like appearance, looking rather as if it had been made with a sharp knife than an obtuse body; it is free from discoloration, and its edges, instead of being inverted, are turned out. I have met with cases where both openings had an incised appearance, but such a condition is rare.

The size of the two openings is variable. In general, the round ball will make a larger orifice of entrance than of exit, the reverse happening when the injury is inflicted with the conical ball. These peculiarities were remarkably apparent in the wounds of the Federal troops after the battle at Bull Run, on the 21st of July last. I had occasion also to notice the immense size of the openings in gunshot wounds of the integuments, made by the conical ball, especially when the two apertures were close together. In nearly all the cases of this class of lesions that I saw in the hospitals at Alexandria, Washington, and Georgetown, the holes, especially that of exit, were disproportionately large, as well as remarkably irregular and ragged.

Shell wounds, and wounds inflicted with stone, nails, splinters, and similar missiles, always exhibit a lacerated appearance, owing to the irregular shape of the vulnerating body. A similar character is often imparted by flattened bullets.

A ball, flying in a straight line, under a strong impetus, will, on reaching

the surface of the body, penetrate it in the same direction, dividing all before it in the cleanest and neatest manner, even to the bones, and probably issuing at a point directly opposite. If, on the other hand, its force is partially spent, then it will either not enter at all, or, if it do, it will be turned out of its course, the slightest resistance, as that offered by a tendon, ligament, or aponeurosis, serving to change its direction. The circumstances which tend to weaken the force of a ball are two, the attraction of the earth and the resistance of the atmosphere. It has been ascertained that a strong wind blowing perpendicularly to the direction of the American rifle-musket ball, will deflect it from its course 12 feet in 1000 yards, about one-fourth that distance in 500 yards, and about six inches in 200 yards. Besides, its impulse may receive a serious check by coming in contact with the person's accoutrement, or some article of dress, as a button, or breast-plate, or some substance that may happen at the time to be in his pocket, as a key, pencil, knife, watch, or piece of coin. If, from these, or any other cause, the force of the projectile is partially spent, it may, on reaching the surface, either glance off; or, if it enter, it will be likely to be deflected; and the course which it sometimes pursues under such circumstances is very remarkable. Thus a ball has been known to pierce the forehead, but instead of penetrating the frontal bone, it has passed round the skull, underneath the scalp, and lodged upon the occiput, at a point nearly opposite to that of entrance; or, what is still more extraordinary, it has travelled nearly completely round the head, issuing only a short distance from the place where it struck. In the same manner a ball has been found to describe the circumference of the chest, its course being marked by a reddish weal or line. Several well authenticated cases are mentioned by writers on military surgery where the missile, piercing the wall of the chest by the side of the sternum, made the circuit of the thoracic cavity by passing between the costal and pulmonary pleuræ, and either falling down upon the diaphragm, or lodging in the wall of the chest behind, without inflicting the slightest injury upon the lung. Examples of a similar kind occasionally occur in the abdomen, the ball, after entering the skin, being turned out of its direction by the tendon of the external oblique muscle, so as to pass round the belly beneath the integuments, and effect a lodgment near the spine, or, perhaps, escape somewhere upon the back. Finally, cases are not wanting, although they are certainly rare, where a ball has entered the abdomen in front, and issued behind, in a straight line, without wounding any of its contents. Such occurrences might challenge credibility, if the authors who have related them were not, from their high position and character for veracity, entitled to implicit confidence in their statements. They find their counterpart in sword, bayonet, and dagger wounds of the abdomen, in which the walls of that cavity are sometimes completely transfixed, and yet its contents escape unharmed.

A case is related by Dr. William H. Herring, of the army, where a musket ball, entering the superior and posterior part of the neck, was discharged at the end of five months by the anus, having, as was supposed, passed by ulceration into the pharynx and thence into the stomach.

Different tissues possess the faculty of deflecting balls in different degrees. Thus bone offers a greater amount of resistance than cartilage, cartilage than tendon, tendon than aponeurosis, and aponeurosis than muscle. Arteries, as already seen, often escape in a remarkable manner, their astonishing elasticity enabling them to glide away from the flying projectile. Common integument, too, readily throws a partially spent ball out of the straight line. Deflection of every description, however, is much less frequent now than formerly, owing to the substitution of the conical for the round ball, the former readily penetrating everything, even when fired at a great distance, whereas the latter is easily spent, and arrested on coming in contact with the more resisting tissues.

A ball, upon meeting a sharp bone, as the crest of the tibia, is sometimes cut in two as smoothly and evenly as if it had been divided with a knife. Some years ago I attended a gentleman, who, in a street rencontre, was wounded with a pistol, the ball striking the clavicle, which cut it into two nearly equal portions, one bounding off, and escaping, the other lodging in the lower part of the neck, from which I removed it several months afterwards. Cases have occurred in which, as before stated, bullets have been split into a number of pieces, each perhaps making a separate orifice in the skin.

The old round ball, in passing through the bones, often made a hole much larger than itself, especially when its force happened to be partially spent. Indeed, cases were occasionally observed in which the opening was so capacious as to admit, not only the ball, but also the barrel of the weapon from which it was discharged. The opening made by the conical ball is, on the contrary, comparatively much smaller; but, although this is the fact, the mischief which it inflicts is proportionably much greater, owing to the manner in which it breaks and comminutes the osseous tissue, the loose splinters themselves thus often becoming a source of severe injury to the soft parts.

Grave injury is sometimes inflicted upon a bone, even without the occurrence of fracture, simply from the violence of the shock which it experiences. The bullet strikes its surface with great force, bruising the periosteum, and causing dreadful concussion of the osseous tissue, but the force with which it is impelled is not sufficient to enable it to effect penetration. Erysipelatous inflammation is set up, followed by exhausting suppuration, and, perhaps, sloughing and death.

Windage of Balls.—The older writers on military surgery had much to say respecting the windage of balls. It is well known that the most horrible injuries may be inflicted upon the body by cannon shot, completely pulpifying the muscles, lacerating the vessels and nerves, laying open large joints, and literally mashing the bones, and yet, perhaps, hardly bruise the skin, much less produce any serious wound. To account for these phenomena, various theories were invented, and it is not a little strange that the correct explanation of them should have been reserved for comparatively modern times. Even as late as the early part of the present century, several writers puzzled their minds to solve the much vexed question by a series of ingenious reasoning and argumentation worthy of a better cause. Thus we find that one gentleman has endeavored to account for the accident by supposing that the ball, as it passes by the body, powerfully condenses the atmosphere, thereby creating a vacuum, which is instantly succeeded by the forcible expansion of the part and its consequent laceration. The explanation was intended to apply more particularly to injuries of this kind as they occur in the hollow viscera, as the stomach and bowels. Another ingenious speculator has imagined that the effect is due to the action of the electric current generated by the rapid movement of the missile through the air. Finally, Mr. Spence, an English naval surgeon, informs us that the cause, at least on ship-board, where such accidents are not infrequent, is the violent contact of the wadding and other substances, as pieces of canvas and rope-yarn, which are so liable to be carried along with the ball. We may admire the ingenuity which prompted these views, but their fallacy is too apparent to admit of deception. The true cause of these injuries is the manner in which the projectile strikes the surface. It has already been seen that a ball in rapid motion will, on reaching the body, pass through it in a straight line; or that, instead of this, it will, if it be large, as in the case of a cannon ball, carry away the part completely. But it is very different when the missile is projected lazily, or when, in consequence of the great distance over which it has travelled, its force is measurably exhausted. Then the slightest resistance

will tend to deflect it, or change its course; it no longer passes in a straight line, but rolls or turns upon its axis after the manner of a billiard ball, and hence if, while in this condition, it strikes the body, it may inflict the most frightful injury both upon the muscles and bones, and yet not perhaps leave a trace of its effects upon the skin, the elasticity of which enables it to slide out of harm's way, while the other and deeper structures, which possess this property in a less degree or not at all, readily yield to its influence, and are severely injured in consequence.

That the older notions upon this subject are of a purely hypothetical character is shown by the fact that, during naval and military engagements, soldiers often have pieces of their dress, accoutrements, and even of their persons carried away by balls in rapid motion, without sustaining any serious injury in their bones and muscles. The faculty possessed by the integuments of gliding out of the way of mischief is admirably exemplified in railroad accidents, which strongly resemble those inflicted by partially spent cannon balls, and in which they frequently escape in the most astonishing manner, while the deeper parts, soft as well as hard, are frightfully torn and pulped. These gunshot lesions are much less frequent now than formerly, in consequence of the general introduction of the conical ball, which does its work more neatly and effectually, as well as at a much greater distance, than the old round ball, which, however, is still occasionally used.

The distribution of wounds during a battle will necessarily vary with circumstances. In an engagement on the open field, the chances are that nearly all parts will suffer alike. In nearly four hundred cases of gunshot injury which I saw after the battle at Bull Run on the 21st of July, almost all the wounds were situated in the extremities, and in nearly equal proportion in the upper and lower. A few only had been struck on the head, chest, back, and abdomen. This cannot, however, be taken as a fair criterion of the result of the engagement, since those that were most severely wounded fell into the hands of the enemy. According to Hennen, of the wounds received in battle, ten will be in the upper extremity, seven in the lower extremity, seven in the head, four in the neck and chest, and two in the abdomen. Scriver, from his observations in the Crimean war, estimates that, in the open field, one-tenth of the wounds will be in the head, one-twentieth in the chest, and one-fortieth in the abdomen. Men, fired at behind breastworks, are most liable to suffer in the head, neck, chest, shoulders, and arms, the lower parts being protected by the defences.

Symptoms.—The symptoms of gunshot wounds necessarily resolve themselves into local and general, or into such as are peculiar to the part and system; and, it need hardly be added, vary greatly in their character, according to the extent of the lesion, the importance of the tissues involved, and the idiosyncrasy and other circumstances of the individual.

The *pain* consequent upon a wound of this kind is often quite insignificant, the person, although perhaps severely hurt, not being conscious of having received any injury until some minutes after it has been inflicted. In general, it is of a dead, heavy character, altogether different from that which attends an incised or punctured wound; it is only when a large nerve has been partially cut across that it is apt to be at all severe, and then it is usually very sharp, pricking, or burning. In this case, too, there will also be more or less numbness in the part below the wound, and sometimes, as when the principal nerve has been entirely severed, complete paralysis. Thus in gunshot wounds of the thigh, involving the division of the sciatic nerve, there is always loss of motion, and often, also, of sensation of the knee, leg, and foot, which feel as if they were cold and dead. The suffering is generally great when a bone is broken, a large joint penetrated, or a visceral cavity laid open, and the shock is then also much more severe and protracted. The pain,

however slight at the moment of the injury, is sure to be greatly aggravated upon the supervention of inflammation, so that the patient frequently requires large doses of anodynes for its suppression.

The *hemorrhage* in gunshot wounds is generally not at all in proportion to the severity of the injury, owing, as is commonly supposed, to the contused nature of the lesion. The structures immediately around the track of the ball are usually so much condensed that, unless the divided vessels are large, or numerous, the bleeding will, in the majority of instances, be so slight as to excite little, if any, alarm for the patient's safety. Very frequently, indeed, it amounts to the merest oozing, which soon ceases spontaneously, or under the application of cold water. If a large artery, however, happens to be laid open, the hemorrhage will not only be copious, but may be so great as to prove speedily fatal, perhaps in a few minutes at farthest, and, consequently, long before the surgeon will be able to interpose his skill for the preservation of life. Such an event will be more likely to occur if, as often happens in this class of injuries, the vessel is only partially divided, so as to prevent its retraction; here the blood will flow most freely, and, although it may be temporarily arrested by syncope, the clot will be washed away the moment reaction takes place, and thus the case will go on, the fainting recurring until the patient has bled to death. If, on the other hand, the artery is completely divided, there may hardly be any hemorrhage whatever until the occurrence of reaction, or, perhaps, not even until the separation of the sloughs.

The ball often passes directly in the course of a large artery, perhaps the principal artery of a limb, and yet the vessel may completely escape injury, or, at most, be merely grazed by the missile. The reason of this is the resilient power of the vessel, which enables it to jump, as it were, out of the way of the projectile. Such an artery, however, will be particularly obnoxious to gangrene, and therefore to secondary hemorrhage during the separation of the sloughs.

The hemorrhage is generally external, the blood issuing at both orifices of the wound. The reverse, however, may be the case, especially if the injured parts have been thrown out of their relative position, or if, as sometimes happens, there has been extensive separation of the muscles; in such an event a large quantity of blood may be effused among the deep-seated structures, with hardly any outward bleeding. In wounds of the chest, abdomen, and pelvis, the hemorrhage is usually internal, and therefore the more dangerous, because concealed.

Gunshot wounds are, for the reasons already mentioned, extremely prone to *secondary hemorrhage*. A large artery may have been merely grazed, and, inflaming, a slough may form, which, separating, may give rise to severe, if not fatal bleeding in the space of a few minutes. Or an artery, of considerable size, may have been completely severed, but its ends, as well as the surrounding parts, having been violently contused, a clot is instantly formed, which thus affords a temporary barrier to the escape of blood; by and by, however, reaction takes place, and then perhaps the artery is reopened, its contents now gushing out in a full stream; or the event may not take place for some days, perhaps not until after the establishment of suppuration or the occurrence of gangrene and sloughing. Sometimes the injured vessel is completely blocked up by the ball or other foreign substance, upon the removal of which copious hemorrhage ensues.

Secondary hemorrhage, the result of sloughing, usually occurs from the tenth to the fifteenth day; much, however, will depend, in this respect, upon the size of the ball and the amount of injury sustained by the soft parts around the wound, as well as by the vessel itself. In some instances it does not appear before the twentieth, twenty-fifth, or thirtieth day; and, on the

other hand, it occasionally occurs as early as the fifth, sixth, or seventh day. However this may be, the patient should be most sedulously watched until he has safely passed the critical period.

The *constitutional symptoms* of the lesion are subject to much diversity. The shock is sometimes severe in a degree altogether disproportionate to the violence of the injury; the stoutest and most courageous individual will often swoon away from the most insignificant wound, and, on the other hand, a man may have his limb completely shattered, and yet not evince any serious alarm; his mind is perfectly calm and collected, and he is perhaps able to give the word of command or cheer on his comrades up to the very moment of his dissolution. Temperament and idiosyncrasy have much to do in the production of these phenomena, and should have due weight in regard to our prognosis. It is said that veterans upon the field of battle generally, other things being equal, suffer much less apprehension and alarm from their injuries than new and inexperienced troops.

The subjoined case affords a good example of the manner in which shock occasionally causes death in gunshot wounds in civil life:—An army officer in 1851 fell in a duel near Louisville, the ball, which was very large, round, and fired from a rifle at a distance of forty yards, entering the left thigh a little above its upper third, lacerating the soft parts in the most horrible manner, laying open the femoral vein, and crushing the bone into numberless fragments. The missile then passed into the right thigh, where it lodged, producing, however, but little mischief. Although hardly a pint of blood was lost, yet the system never rallied; the face continued deadly pale, the extremities cold, and the pulse small and feeble, notwithstanding the free use of brandy, up to the moment of the patient's death, which happened in two hours after the rencontre.

Prognosis.—The prognosis of gunshot wounds varies with so many circumstances as to admit of being pointed out only in a very general manner. Some of the milder cases of this class of injuries often recover promptly, without a solitary untoward symptom, the parts occasionally uniting, as I have myself seen in several instances, by the first intention. In other cases, on the contrary, apparently of a mild character, severe nervous symptoms may arise, or the wound may take on erysipelas, or a bad form of inflammation, and the patient lose his life. Two years ago I attended, in this city, a young man who had been shot with a pistol, the ball, which was small, having entered the outer and back part of the arm, just above its middle, grazing the humerus, and lodging immediately under the integuments, from which I removed it an hour afterwards. The ordinary treatment was employed; but in thirty-six hours violent erysipelas set in, and death occurred in less than eight days from the time of the injury. On the other hand, seemingly the most desperate cases will sometimes recover. Much will of course depend, in every instance, upon the size and situation of the wound, the presence or absence of complications, the state of the patient's constitution, the condition of the atmosphere, and the nature of the treatment.

Some gunshot wounds must necessarily be fatal, either instantaneously, as when they involve one of the more important organs, or a large vessel, or, more or less remotely, as a consequence of the resulting inflammation, gangrene, or profuse and exhausting discharge. The danger to limb, if not to life, will be great when a large joint has been laid open, the main artery, vein, or nerve severed, the bone crushed, or the integument extensively stripped off; or when all, or nearly all, of these parts suffer together. Gunshot wounds of the lower extremity are, other things being equal, more dangerous than those of the upper, sharing, in this respect, the same fate as ordinary lacerated and contused wounds.

The presence or absence of complications will necessarily exert no little

influence upon the issue of the case. Thus, a person, even if but slightly wounded, will often suffer most severely, and perhaps even die of the effects of his injury, if he was laboring at the time he was hurt under any serious disease of some internal organ, as the liver, lung, or bowel. The habits of the patient must also be taken into the account; if he is intemperate, his chances of recovery will be diminished, and so also if his constitution has been enervated by long residence in a warm, unhealthy climate. Wounds inflicted in battle are generally more fatal than those received in civil life, especially if they are treated in crowded, ill-ventilated hospitals. Death then often occurs from sheer neglect, or the want of good nursing and suitable surgical treatment.

The causes of death in gunshot wounds are, first, shock and hemorrhage; secondly, tetanus; thirdly, pyemia and erysipelas; fourthly, gangrene; and fifthly, profuse suppuration and hectic irritation.

Remote Effects.—The remote effects of gunshot wounds are often very troublesome, entailing much suffering, and being occasionally followed by loss of life at the distance of many years. In a case of gunshot wound of the chest, related by Dr. M. H. Houston, of Wheeling, Virginia, a thick linen patch, with which the ball had been enveloped, remained in the left lung for twenty years, when the patient died in a state of extreme marasmus, his general health never having been good since the occurrence of the accident. Sometimes a bullet lodges in the head of a bone, where, although it may for a while be comparatively harmless, it ultimately causes necrosis, with inflammation and discharge in the soft parts, thus necessitating the removal of both substances, if not of the limb itself. It is related of Marshal Moncey that he died from the effects of a gunshot wound forty years after its receipt.

On the other hand, however, a ball may occasionally remain in the body for a long time—perhaps in an organ even of vital importance—without inducing any particular mischief. Thus, in a case recently reported by Dr. Henry Wurtz, of New York, an ounce bullet was found, on dissection, in the middle lobe of the right lung of an old soldier, forty-five years after its introduction at the siege of Badajoz. It was inclosed in a distinct cyst, an inch below the surface of the organ, having entered between the fourth and fifth ribs, as was proved by the existence there of an old cicatrice.

Treatment.—In the treatment of gunshot wounds five distinct indications are presented: 1st. To revive the patient, or promote reaction; 2dly. To arrest hemorrhage; 3dly. To extract the ball and any other foreign matter that may have entered along with it; 4thly. To remove any detached or loose pieces of bone; and 5thly. To circumscribe the resulting inflammation.

1st. The first indication is to relieve *shock*, and this is to be fulfilled by the employment of the ordinary restoratives. If the patient be faint, he must be placed at once in the recumbent posture, with his head as low as the rest of the body; cold water must be dashed upon the face, the fan be freely used, and smelling bottles held near the nose. If the symptoms are urgent, sinapisms are applied to the chest, spine, and extremities, a stimulating injection is thrown into the bowel, and, if the power of deglutition is not gone, brandy or wine and ammonia are given by the mouth. If there be internal hemorrhage, however, care is taken to bring up the pulse slowly and gently, allowing time for the formation of coagula, and guarding against the occurrence of violent inflammation. A kind look, or a soothing expression will often do more to revive the patient and encourage recovery than anything else.

2dly. If the *hemorrhage* be capillary, or caused by the division of very small vessels, it will probably cease of its own accord, or simply by exposure of the part to the cold air, or under the application of cold water, pounded

ice, or some astringent lotion. If it be venous, compression will probably suffice; but if it proceed from a large artery, such as the radial or tibial, nothing short of the ligature will do, and no time should be lost in its application. The case is very simple when the vessel is superficial, and the wound capacious; but under opposite circumstances the duty of the surgeon is often exceedingly embarrassing. Here it becomes necessary either to dilate the wound, so as to expose the artery and tie it at both ends, which is by far the best plan; or, where this is impracticable on account of the depth of the vessel, its proximity to important structures, or the great swelling and infiltration of the parts, as may happen when some time has elapsed since the receipt of the injury, to cut down upon the main trunk of the vessel, and to secure it as in the Hunterian operation for aneurism. The latter procedure, however, will rarely succeed, inasmuch as the bleeding is extremely liable to be kept up by the recurrent circulation; hence it is always best, if practicable, to cut

Fig. 72.

down at once upon the injured artery, and to apply a ligature to each extremity, which cannot fail to put an effectual stop to the flow of blood. The more promptly the operation is performed the better; if the surgeon wait till inflammation has supervened he will experience great difficulty, not only in exposing the artery, but also in inducing the ligature to maintain its hold upon its softened and partially disorganized tissues. When the hemorrhage has been very profuse, but has gradually or suddenly stopped, it will hardly be safe to intrust the case to the efforts of nature, because, when reaction occurs, the vessel will almost be sure to be reopened, and thus the bleeding may progress until the system is completely exhausted; but if the surgeon has done his duty, the parts will be placed in the best possible condition for speedy recovery. It is a good rule, in such cases, to do whatever may be necessary without the slightest temporizing.

3dly. The third indication is the *extraction* of the ball; but to do this it is necessary, in the first place, to ascertain where it is; to grope about in the wound without any definite ideas as to its precise location, would only be to inflict additional pain and injury. In order to conduct the examination with the greatest advantage, the part should be put as nearly as possible in the position in which it was at the time of the accident. This is the more necessary, because, as was before stated, the missile often pursues a very different route from what might be supposed from merely looking at the orifice of entrance or exit; the slightest resistance may change its direction, and compel it to lodge at a situation far beyond what it would have sought had it been permitted to pass in a straight line. Hence attention to the position of the part becomes, in all cases, a matter of paramount importance.

Care must be taken in searching for a ball not to mistake for it an osseous prominence. Stromeyer refers to two cases in which he saw this blunder committed; in one the surgeon cut down upon the head of the fibula, and in the other upon a metatarsal bone. The assertion of a patient that the ball has dropped out is seldom reliable, unless the missile is found in his pocket.

The best *probe* for conducting the examination is the finger, provided it is sufficiently long and slender; it possesses the same value, in such cases, as direct auscultation possesses in the exploration of the chest, or the finger in the examination of the uterus and rectum, and should therefore always be used when practicable. If the digit be inadequate, recourse is had to a stout probe, fig. 72 or fig. 73, at least from ten to twelve inches in length, as thick as a medium-

sized bougie, slightly flexible, and blunt-pointed, being composed either of silver or brass. The ordinary pocket probe is much too small. When such

Fig. 73.

an instrument as that just described is not at hand, the necessary exploration may be performed with a female sound or catheter, or even with a long, slender pair of bullet-forceps. Whatever instrument is employed, it should be passed along the track of the wound with all possible care and gentleness, and in such a manner as not to insinuate its point into the surrounding cellular tissue, or among the muscles, tendons, nerves, and vessels; a circumstance which may very easily happen if the surgeon do not observe the utmost caution in performing the operation. The contact of the probe with the ball usually produces a sensation of roughness and resistance, together with a dull noise if the instrument be struck against the foreign body by short jerks. The parts being now accurately maintained in the position in which the ball was found, the forceps take the place of the probe, the blades being firmly closed as they pass along the track until the point comes in contact with the extraneous substance, which is then seized and extracted, care being taken to include none of the surrounding tissues. Occasionally the operator will derive important aid in his manipulations from counter-pressure, the hand or the thumb and a few fingers being applied to the opposite side of the wounded parts.

Bullet-forceps and extractors, of various forms and sizes, are in use. The most important qualities of such an instrument are lightness, strength, and slenderness, with length of blade, which should not be less than four inches. The extremity should be well rounded off, and fashioned in such a manner that it shall adapt itself readily to the shape of the foreign body, and at the same time grasp it with great firmness, without the risk of including any of the adjacent structures. The old forceps, fig. 74, did good service during the reign of the round ball, but will hardly answer for the extraction of the conical. For the latter purpose Mr. Tiemann, of New York, devised, not long ago, the ingenious instrument depicted in fig. 75. It is quite slender in the blade, and is provided with short, stout teeth, projecting somewhat like the incisors of a mouse, their object being to take a firm hold upon any part of the bullet by partially burying themselves in its substance.

The instrument of Mr. Tiemann has been greatly improved by Mr. Gemrig, by making the end of one blade cup-

Tiemann's forceps.

shaped, with two curved prongs, separated in front by a narrow interval, and terminating each in a point. The other blade has only one prong, also curved, but central, and terminating in a point, which, when the forceps are shut, is received in the interval here alluded to, thus rendering its extremity perfectly blunt. The instrument, represented in fig. 76, answers for the round as well as the conical ball, and possesses the great advantage of facility of application with firmness of grasp.

The forceps delineated in fig. 77 were made last summer, at my suggestion, by Mr. Gemrig. They are about nine inches and a half in length, light, slender, and fenestrated at the extremity, which is scooped out in such a manner as to embrace the ball with great facility, while its inner surface, roughened like that of a stirrup, maintains its hold with extraordinary firmness.

European extractor.

When the wound is unusually large, and the ball not deeply seated, the extraction may sometimes be effected with a small lithotomy scoop, the common dressing or polypous forceps, or an instrument like that sketched in fig. 78, made for me by Mr. Kolbé, of this city. It consists of a silver tube, inclosing a steel stylet, terminating in two blades, cup-shaped on the inside, and movable by a hinge. The extremity of the instrument is seen grasping the ball. Fig. 79 represents a similar instrument used by the British and French surgeons.

The gimlet-like instrument, so much extolled by the older surgeons, is now rarely used, although it might still occasionally be employed with advantage when the extraneous substance is lodged in a bone thickly covered by muscles. The trephine, however, is generally preferred under this and other similar circumstances.

A ball, after having traversed the thickness of a limb, or of the body, occasionally lodges immediately beneath, or among the superficial muscles, where its presence is readily detected by the probe or finger. In such a case the best plan is to remove it by a *counter-opening*, that is, by cutting down upon it at the nearest point; a procedure which often saves an immense amount of pain and trouble.

When the ball cannot be found without much probing and the risk of inflicting serious additional mischief, reason and experience alike suggest the propriety of letting it remain, in the hope that it may either become encysted, or that it will be detached and washed away by the discharges. In general, however, every justifiable effort should be made to remove it, on the ground that, if left behind, it will be almost sure to excite violent inflammation, followed by profuse suppuration and extensive separation of the tissues. Such an event will be the more likely to happen if the ball has become rough, jagged, or flattened by contact with a bone; for then it never can be encysted, but must necessarily keep up irritation as long as it remains.

The great importance of not permitting balls to remain unextracted has been placed in a forcible light by the observations of Mons. Hutin, chief surgeon of the Hôtel des Invalides of Paris. Of 4,000 soldiers examined by this distinguished practitioner, within a space of five years, only 12 presented themselves who had experienced no inconvenience from the retention of foreign bodies, while the remainder, 200 in number, had all suffered more or less severely until they had been relieved by operation.

Another reason for the early extraction of these missiles is that persons soon after the receipt of their injuries will, in general, submit much more readily to the necessary operation than they will after they have partially recovered from their effects; their dread usually increasing in proportion as they get well, and beyond the reach of immediate danger.

When a ball has entered a movable joint, it should always be promptly extracted if it lie loose within its cavity; if, on the other hand, it has lodged in the adjoining bone, it should be allowed to remain, in the hope that it may soon be covered over with plastic matter, and thus become comparatively harmless. The only exception to this rule is where the ball projects into the cavity of the articulation, in which case it should be removed at all hazard, since its retention would inevitably lead to violent, if not fatal, inflammation, and utter uselessness of the part.

No sensible surgeon ever thinks of searching for a ball in any of the great cavities of the body; such a procedure would be sure to increase the dangers of the accident, and cannot, therefore, be too pointedly condemned.

If it be necessary to the welfare of the part and system to remove a ball, which is a comparatively innocuous substance, how much more important is it to extract the various *foreign bodies* which so often enter along with it, and the presence of which is an incessant source of irritation and annoyance, however protracted it may be. The rule here is imperative, and applies to the smallest, as well as to the largest substance; to the little piece of wadding and the stoutest splinter, the linen shred and the brass button; in short, to all extraneous matter whatever. Wherever it may be, it must be sought for, and, if possible, extracted without delay. There is no chance here of the formation of a cyst, as sometimes happens with a ball; nature admits of no such liberty. In naval and military engagements large pieces of wood, metal, and other substances are liable to be impelled into the body, in which

they are often buried at a great depth, or lodged among the muscles, which sometimes close over them in a sort of valve-like manner, rendering it extremely difficult not merely to extract but even to find them. Much may be done in such cases by the gentle use of the finger and probe, aided by counter-pressure.

4thly. Any detached *splinters* of bone, or pieces of bone so much loosened as to render it improbable that, if left behind, they will become reunited, should be removed as early as possible after the occurrence of the accident, experience having shown that their retention is always productive of extensive and protracted suppuration, if not of worse results. By the timely extraction of such bodies immense suffering may be prevented, and ultimate recovery vastly expedited. It is surprising that surgeons should ever hesitate in such a case; and yet the instances are not uncommon where the most culpable neglect is observed. A remarkable example of the kind fell under my notice in 1847, in the person of Lieut. George Adams, of the United States Marine Corps, who was desperately wounded in the right thigh by a large musket ball during our war with Mexico, at the battle of the National Bridge, between Vera Cruz and Jalapa. The soft parts were extensively injured and the bone was shattered into numerous fragments, not less than twenty-four of which, some of them upwards of an inch and a half in length, I removed nine months afterwards, from the enormous callus that had formed around the seat of the fracture; most of them were completely imprisoned in the osseous matter, and it was therefore found quite difficult to extract them. The incisions healed kindly, except at one point, which refused to close, and from which a small fragment of bone was subsequently removed by the late Professor Warren, of Boston.

When *powder* is imbedded in the skin, the first thing to be done is to pick out, with a cataract needle, or delicate bistoury, every particle of it, regardless of pain. If this be neglected the powder will speedily excite inflammation, besides causing disagreeable and permanent disfigurement by the bluish spots which it leaves. The operation is tedious, and is always attended with severe suffering. The resulting inflammation is to be combated in the usual manner; cold water, or cold saturnine lotions, being generally the best local remedies.

5thly. The fifth and last indication is to circumscribe and moderate the resulting *inflammation*. To accomplish this, attention to various points is necessary. In the first place, the parts must be properly dressed. Works on surgery generally direct that the orifices of the wound shall be lightly covered with lint and adhesive plaster. Is such a procedure rational? It certainly is not, for its direct effect must inevitably be to prevent discharge, of which there must always be more or less in every such case, and consequently to aggravate the local mischief. A much better plan is to allow the orifices to remain open, while we attempt, by means of a light compress and bandage, to close the sides, with a view of facilitating their union by adhesive action. The roller should be carried up from the distal part of the limb to some distance beyond the wound, care being taken to perforate it opposite its orifices, in order to admit of free drainage. In this manner nature may often be immensely assisted in the cure; the inflammation will generally be moderate, infiltration of fluids will be obviated, and the patient will frequently recover in a surprisingly short period, and with but little suffering. The bandage, however, must be used with great caution, for there is danger, especially if there be much swelling, of its producing injurious compression, and thus becoming a source of gangrene. My experience in the treatment of gunshot wounds is necessarily limited, but it is sufficient to justify me in asserting that adhesive plaster should, as a general rule, be dispensed with; it is certainly not easy to perceive how it is possible for it to do any good.

In gunshot wounds of the extremities, involving the deep muscles and aponeuroses, great advantage will accrue, during the progress of the treatment, from the use of the bandage, applied in such a manner as to prevent the formation of sinuses and favor the escape of pus. When considerable inflammation is present, the dressings may be kept wet with a spirituous lotion composed of two parts of alcohol to eight of water.

The part having been dressed, and placed at rest in an easy and elevated position, cold water is applied, provided there is no contra-indication to its use, on account of the state of the weather or the intolerance of the part and system. If the weather be mild, and the patient young and robust, cold will usually be borne better than warmth, and the most eligible form is that of water, either simple, or medicated with opium and acetate of lead. The use of cold water in the treatment of this class of lesions dates as far back as the time of Biondo, towards the middle of the sixteenth century, and its beneficial effects, although lost sight of for a long time, were again brought prominently before the notice of the profession by Kern, Larrey, Guthrie, and other army surgeons, during the continental wars which deluged Europe early in the present century. Cold water, however, is not tolerated equally well by all patients, and hence the rule is, where it disagrees, to substitute warm applications, either in the form simply of tepid water, or in that of a light emollient cataplasm, which, after all, makes, in many cases, an admirable dressing, soothing pain, and promoting discharge.

When much contusion exists, as is so often the case in shell and cannon wounds, I am satisfied that the best local remedy is some spirituous lotion, as, for example, two parts of alcohol to ten of water, with the addition, if there be offensive discharge, of a small quantity of chlorinate of soda, or Labarraque's solution. The tissues, deprived of nervous power, must be slightly stimulated, otherwise they will be in danger of running into profuse suppuration, if not gangrene.

If the inflammation assumes a threatening aspect, especially if it becomes erysipelatous, and is attended with great pain, tension, and swelling, free incisions, and sometimes counter-openings, must be made, otherwise extensive mischief will result from the burrowing of fluids, and the consequent destruction of the connective tissues. Besides, the parts, if not timeously relieved, might mortify. The older surgeons made it a rule of practice to dilate all wounds of this kind as soon as possible after their infliction, with a view of preventing these and other untoward results, but this procedure has become obsolete, the modern practitioner resorting to it only when the necessity arises in consequence of the severity of the inflammation; assuming that a man ought not to be cut merely because he has been shot.

The orifices of the wound will usually begin to granulate in from four to six days, even when there is slight gangrene of their edges, and the whole track will often close in an almost incredibly short time. Much of it, especially if it be long, will be in the condition of a subcutaneous wound, and therefore highly favorable to reparation. When the passage is slow in filling up, the healing process may be expedited by the use of slightly stimulating injections, thrown in twice in the twenty-four hours; few cases, however, will demand such interference. The wound at the point of exit generally heals first.

Conjoined with these local measures must be perfect rest of mind and body, along with good diet, gentle purgatives, and anodynes, for the double purpose of allaying pain and spasm, and inducing sleep. Opiates will generally be borne in large doses, and can rarely be dispensed with in any case, however mild. If the wound is severe, and especially if it be attended with serious hemorrhage, active purgation must be scrupulously abstained from, and also antimonials, on account of their depressing effects, and their tendency

to provoke tetanus. In all cases due allowance must be made, in our treatment, for the drainage which is likely to attend such injuries. Hence much judgment is often required to steer clear of difficulty and danger. Bleeding by the lancet is hardly to be thought of under any circumstances; in young and plethoric subjects, however, blood may occasionally be taken advantageously by leeches. In ordinary cases, the diet should be plain and simple, rigid abstinence not being required, excepting when there is unusual fulness of habit. If decided exhaustion be present, whether from shock, loss of blood, or inflammatory disturbance, prompt recourse must be had to milk punch, quinine, and nutritious food.

When a tendency to erysipelas or pyemia arises, the patient, in addition to the means already indicated, should be promptly put under the influence of iron and strychnia, or of these two articles with quinine and brandy; and, if large numbers of wounded are crowded together, no time should be lost in effecting their sequestration.

QUESTION OF AMPUTATION IN WOUNDS.

The most horrible wounds are generally those which are inflicted by machinery in rapid motion, the passage of a railway car or the wheel of a heavy wagon, and the explosion of fire-arms, violently lacerating and contusing the soft parts, extensively crushing the bones, and perhaps opening one or more of the larger joints. In many cases, the character and extent of the mischief are apparent at first sight; in others, as when it is principally subcutaneous, it becomes so only after a most patient and thorough examination. The latter class of injuries is particularly to be dreaded, as it is often impossible, even with the greatest care, to determine the extent of the lesion. When the examination necessary to ascertain the condition of the parts is likely to be painful or protracted, commiseration for the sufferer always dictates the propriety of administering chloroform, although the effect of the anæsthesia will rarely be required to be carried to the extent of complete unconsciousness, a few full and prolonged whiffs being generally sufficient to effect the desired tolerance.

In attempting to determine the question as to whether an attempt should be made to cut off or save a limb, not a little stress should be laid upon the age, habits, and previous health of the patient, the manner in which the injury was inflicted, and the number, variety, and importance of the structures involved.

Young adults bear severe accidents much better, other things being equal, than the two extremes of life, childhood and decrepitude, in both of which, but especially the latter, the power of reaction is generally very feeble, and the effect of shock and hemorrhage felt for a long time. Nevertheless, there is not a practitioner of any experience that has not occasionally witnessed striking exceptions even under these circumstances. A temperate man usually bears up under a severe wound much better than a dissipated one, and the resident of the country than the inhabitant of the crowded city; a person in ill health at the time of the accident will be likely to suffer more than one in an opposite condition. The worst class of accidents in civil practice are those inflicted by railway cars, steamboats, and steam factories, and these are often of such a nature as to require the prompt removal of the mangled and mutilated parts.

But of all the circumstances influencing the recovery of the patient, and the ability of the surgeon to save the mutilated parts, the most important, by far, is the extent of the injury, or the number and nature of the tissues involved.

To place this subject in a clear and tangible light, it is requisite to consider it somewhat in detail. Before doing this, however, it is proper to premise that amputation should never be performed in wounds of any kind until after reaction has taken place; as, if this precaution be neglected, the additional shock which the operation would necessarily impart to the system might prove fatal, either before the patient is removed from the table, or soon after. As long as he is deadly pale, the pulse small and thready, the surface cold, and the thirst, restlessness, and jactitation excessive, it is obvious that recourse to the knife must be wholly out of the question. The proper treatment is recumbency, with mild stimulants, sinapisms to the extremities, and other means calculated to re-excite the action of the heart and brain. Power being restored, the operation, if deemed necessary, is proceeded with, due regard being had to the prevention of shock and hemorrhage, the two things now mainly to be dreaded.

The advantage of primary over secondary amputation, in all severe wounds, is too obvious to require comment. Mr. Guthrie long ago ascertained that the loss after secondary operations, in gunshot injuries, was at least three times as great as after primary, and the results of his observations have been amply confirmed by the more recent experience of military surgeons. In the Crimean war, where the wounds were, for the most part, inflicted with the conical ball instead of with the round, as in the cases seen by Mr. Guthrie, the difference was less marked, but still strikingly in favor of primary interference. Thus, the mortality in 690 primary amputations was 175, or in the ratio of 25.3 per cent., and 38 in 89 secondary, or in the ratio of 42.7.

The following circumstances may be enumerated as justifying, if not imperatively demanding, amputation in cases of wounds, whatever may be their nature:—

1st. When a limb has been run over by a railroad car, fracturing the bones, and tearing open the soft parts, amputation should, as a general rule, be performed, even when the injury done to the skin and vessels is apparently very slight, experience having shown that such accidents seldom do well, if an attempt is made to save the limb, the patient soon dying of gangrene, pyemia, or typhoid irritation. The danger of an unfavorable termination in such a case is always greater when the lesion affects the lower extremity than when it involves the superior.

2d. No attempt should be made to save a limb when, in addition to serious injury done to the integuments, muscles, or bones, its principal artery, vein, or nerve has been extensively lacerated, or violently contused, as the result will be likely to be gangrene, followed by death.

3d. A lacerated or gunshot wound penetrating a large joint, as that of the knee or ankle, and accompanied by comminuted fracture, or extensive laceration of the ligaments of the articulation, will, if left to itself, be very prone to terminate in tetanus, mortification, or pyemia, and is therefore a proper case for early amputation.

4th. Gunshot wounds attended with severe comminution of the bones, the fragments being sent widely around among the soft parts, lacerating and bruising them severely, generally require amputation, especially in naval and military practice. Gunshot fracture of the thigh-bone is generally considered by military surgeons as a sufficient cause for primary amputation. The rule, however, admits of exceptions.

5th. Extensive laceration, contusion, and stripping off of the integuments, conjoined with fracture, dislocation, or compression and pulpification of the muscles, will, in general, be a proper cause for the removal of a limb.

In all severe lacerated and contused wounds, whether induced by cannon shot, falls, blows, machinery in rapid motion, or the passage of the wheel of a railroad car, the limb should be amputated, as a general rule, at a considerable dis-

tance above the apparent seat of the injury. If this precaution be neglected, mortification will be liable to seize upon the stump, owing to the fact that, in such cases, the injury, both of the soft and hard parts, usually extends much further than the naked eye can discover.

Should amputation be performed when a limb, the subject of a severe wound, laceration, or contusion, has been suddenly seized with mortification, manifesting a rapidly spreading tendency, extending, perhaps in a few hours, up as far as the middle of the leg, or even as high as the knee? In general, such cases are desperate; no local or internal remedies can arrest the morbid action; the system has sustained a profound shock, and the affected parts perish, not by inches, but literally by feet. I have repeatedly seen this variety of gangrene extend from the toes, instep, or ankle as far as the hip-joint in less than thirty-six hours, and that, too, in cases where there was but little visible injury, the mischief being evidently deep-seated, involving muscle, nerve, vessel, and bone. If amputation be not performed, the disease, whose march is indicated by a bluish or livid, crepitating, and tender streak along the limb, will be sure to terminate fatally in a few days, and the operation should therefore, in my judgment, be resorted to at the earliest possible moment, the surgeon not foolishly waiting for a line of demarcation, which cannot take place, since neither part nor system has the power of arresting the morbid action. The event, it is true, will generally be unfavorable, but as it is the only chance the patient has, he should, slender though it be, certainly have the benefit of it. In the few cases in which I have amputated under these unpropitious circumstances, the result in all has been fatal.

Lacerated, contused, and gunshot wounds are often of so frightful a nature as to render it perfectly certain, even at a glance, that the limb will be obliged to be sacrificed in order that a better chance may be afforded for preserving the patient's life. At other times, the injury, although severe, may yet, apparently, not be so desperate as to preclude, in the opinion of the practitioner, the possibility of saving the parts, or, at all events, the propriety of making an attempt to that effect. The cases which may reasonably require and those which may not require interference with the knife are not always so clearly and distinctly defined as not to give rise, in very many instances, to the most serious and unpleasant apprehension, lest we should be guilty, on the one hand, of the sin of commission, and, on the other, of that of omission; or, in other, and more comprehensive terms, that, while the surgeon endeavors to avoid Scylla, he may not unwittingly run into Charybdis, mutilating a limb that might have been saved, and endangering life by the retention of one that should have been promptly amputated. It is not every man, however large his skill and experience, that is always able to satisfy himself, even after the most profound deliberation, what line of conduct should be pursued in these trying circumstances; hence the safest plan for him generally is to procure the best counsel that the emergencies of the case may admit of. But in doing this, he must be careful to guard against procrastination; the case must be met promptly and courageously; delay even of a few hours may be fatal, or, at all events, place limb and life in imminent jeopardy. Above all, let proper caution be used if the patient is obliged to be transported to some hospital, or to a distant home, that he may not be subjected to unnecessary pain, exposed to loss of blood, or carried in a position incompatible with his exhausted condition. Vast injury is often done in this way, by ignorant persons having charge of the case, and occasionally even by practitioners whose education and common sense should be a sufficient guarantee against such conduct. The transportation of a patient to a distance of perhaps a hundred or a hundred and fifty miles upon a railway car, after he has been desperately wounded, in the hope, it may be, of obtain-

ing better aid, cannot be too severely reprehended, as involving not only the loss of precious time, but often also the infliction of additional injury upon a part and system already overwhelmed by shock and hemorrhage.

Resection in gunshot and other injuries involving the articulations is, as will be more fully explained elsewhere, applicable chiefly to the shoulder and elbow-joints, in cases unattended with serious lesion of the soft parts. In the former, a portion of the humerus, embracing, if necessary, from three to five inches in length, together with a part or even the whole of the glenoid cavity of the scapula, may be safely and expeditiously removed under such circumstances, and yet the patient have an excellent use of his arm. Experience shows that primary excision of the other joints, excepting, of course, the smaller ones, as those of the hand and foot, is generally very unfavorable.

Further observations upon this subject will appear in the chapter on amputation, and in those on fractures, dislocations, and resections.

SECONDARY EFFECTS OF WOUNDS AND CONTUSIONS.

Every practitioner occasionally meets with cases of wounds and bruises in which the patient, happily escaping from the primary effects of the injury, suffers severely from what may be termed the secondary effects, coming on several weeks or months afterwards. These lesions have not received sufficient attention from systematic writers. It has fallen to my lot to see quite a number of such cases, and I select the following from my note-book in illustration of the subject:—

A farmer, aged thirty, in August, 1851, got his left foot twisted and bruised by a fall from his horse. The accident was instantly followed by severe pain, and next day by excessive swelling, which, however, gradually subsided under the usual antiphlogistic remedies. In the course of a few weeks the man was able to exercise on crutches, but the foot was now observed to be very sore and tender, cold, clammy, withered and benumbed, and to be completely destitute of power. There was also frequent twitching of the three small toes, particularly at night, so as to interfere with sleep. These symptoms were aggravated in damp, cold states of the atmosphere, when there were also occasionally neuralgic pains in the part. The general health likewise materially suffered, the appetite being bad, the bowels irregular, and the mind much dejected. When I saw the patient, nearly a year after the accident, he had been subjected to various plans of treatment, with hardly even any temporary relief. I placed him upon tonics and alterants, and ordered the hot and cold douche, with frictions with veratria liniment and the use of the bandage; but many months elapsed before he experienced much benefit from the treatment, and I believe he has never entirely recovered the use of his foot and ankle.

A man, aged 25, cut himself, in October, 1852, with an axe on the instep of the left foot, directly over the internal cuneiform bone. The weapon penetrated the bone, and evidently severed the extensor tendon of the great toe, as the toe could no longer be moved by the effort of the will. The wound healed completely in a few days, but in a short time afterwards the parts became tender and remained so for several months. Meanwhile, the foot and leg grew sensibly thinner, and were habitually cold and clammy; a state of things which has now continued for several years. Whenever exercise is taken, the parts swell, and become tender. The muscles of the whole limb are flabby and wasted. The general health is much disordered; the man has lost thirty pounds of flesh, and has been unable to attend to any business

since the accident. His tongue is habitually coated, he sleeps badly at night, and he is subject to frequent fits of despondency.

A man, aged 35, consulted me in March, 1854, on account of an accident similar to the above. He was a bricklayer by occupation, and previously was always in good health up to October, when he cut himself with a hatchet in the left instep, immediately over the internal cuneiform bone, as nearly as possible in the same situation as in the preceding case. The wound healed rapidly, but the man soon began to suffer with exquisite pain and tenderness in the parts, extending up the leg, and subject to severe exacerbation from damp states of the atmosphere, exposure to cold, and derangement of the digestive organs. The suffering was not regular in its recurrence, but it was generally worse at night, and often sadly interrupted his sleep. The limb was cold and clammy, as well as much emaciated, and the parts immediately around the scar were hard, as if from the presence of organized lymph. The general health was much impaired, the tongue was coated, and the sleep was usually much interrupted by spasm of the limb. A prominent symptom in the case was great soreness in the hollow of the foot, in front of the heel. When the man attempted to walk, the foot became very tender, and began immediately to swell. Both in this and in the preceding case the patient was obliged to use crutches.

A lady, aged 27, the wife of a medical gentleman, in February, 1852, punctured the forepart of her right wrist, towards the ulnar margin of the forearm, with a small slender sewing needle, which entered the skin directly over the ulnar artery, and passed, apparently, obliquely inwards and outwards towards the centre of the joint, without, however, penetrating it. The needle was immediately withdrawn, but not examined, and the patient, consequently, was uncertain whether a portion had broken off and remained behind. The accident was followed by the most excruciating pain, pervading the entire extremity from one end to the other, but being particularly severe at the seat of the injury and in the thumb and first two fingers. A violent rigor soon succeeded, and for ten days the patient suffered the most horrible tortures, being frequently threatened with tetanus, and constantly annoyed with spasmodic twitches of the muscles of the hand and arm. Considerable swelling arose soon after the receipt of the injury in the forearm, wrist, hand, thumb, and the fingers above named. About the end of the tenth day a small circumscribed abscess formed at the site of the puncture, which, upon being lanced, discharged about a drachm and a half of thick pus, much to the relief of the patient. In a week the matter had reaccumulated, and the part was again lanced, followed by the same relief as before. Subsequently the skin was scarified several times, the cuts bleeding profusely at each operation, but not yielding any pus.

During the following summer the patient experienced severe and constant pain, especially in the anterior part of the arm, between the elbow and the insertion of the deltoid muscle; it was always more violent in the evening, and was of a dead, heavy aching character; the limb was stiff and numb.

When I first saw the patient, in November, 1852, she informed me that her general health had been very bad for the last six years, that she was subject to dyspepsia, and that she was naturally of a nervous, excitable temperament. She had formerly suffered, at intervals, from rheumatism. For the last four months she had had a seton in the upper and fore part of the arm, on account of the severity of her pain, which, however, at this time, was much less than formerly. She thought she had derived much benefit from the seton. Her hand and thumb, together with the fore and middle fingers, swelled every evening, becoming stiff and sore, so that she could with difficulty flex or extend them. In the day the parts felt much more comfortable. The pain and soreness were always greatest at night. Pressure at the seat

of the puncture gave rise to uneasiness rather than to pain, but was always followed soon after by so much distress as to prevent sleep during the succeeding night. The ring and little fingers were natural, free from swelling, and easily moved. The whole limb was cold and considerably wasted.

The probability is that, in this case, the needle pricked the ulnar nerve at the wrist, producing a condition of things, in her bad state of health, similar to that which occasionally results from the puncture of a nerve in bleeding at the arm.

Under the use of an alterative and tonic course of treatment, with strychnine and arsenious acid; the hot and cold douche, followed by friction with veratria ointment; a nutritious diet and exercise in the open air; the general health rapidly improved, and the local suffering finally disappeared, though the limb has never recovered its original powers.

Bad effects not unfrequently follow upon gunshot wounds; they present themselves in different forms and degrees, and often entail great suffering along with partial loss of function. Among the more common and annoying of these secondary effects are neuralgic pains and a sense of numbness in the parts, progressive atrophy of the muscles, contraction of the aponeuroses and tendons, and ankylosis of the joints.

In regard to the treatment of these secondary lesions, it is impossible to lay down any definite plan of action; every case must be managed according to the peculiarities of its symptoms. Much benefit may generally be expected from attention to the state of the general health, which is nearly always more or less seriously disordered. Neuralgic pains, altered sensibility, and atrophy usually require a course of tonics and arsenic, purgatives, the hot and cold douche, and dry frictions. Rigidity of the joints must be counteracted by passive motion and sorbefacients; contraction of the tendons and aponeuroses by the use of splints and the bandage.

MAGGOTS IN WOUNDS.

The development of maggots in wounds and compound fractures is a circumstance worthy of notice in a practical point of view. Such an occurrence is met with chiefly in hot weather, but I have also seen it in the autumn and early part of winter, in consequence of the artificial heat of the patient's apartment. In tropical climates the formation of maggots in wounds and ulcers is almost unavoidable, despite the best directed efforts to prevent it. The soldiers in Syria, under Larrey, and our troops during the war with Mexico, suffered greatly from this cause. Dr. Proctor informed me that wounds, however carefully cleansed one morning, were found, on the succeeding evening, to contain large numbers of these animals, and if the slightest neglect took place, they speedily collected in incredible quantities, and of prodigious size, their diameter equalling that of a small-goose quill, while their length ranged from three to nine lines. The soldiers had a great horror of them, and from the disposition which they evinced to burrow deep among the muscles, they were productive of no little pain and distress.

Fortunately the formation of maggots is not often seen in civil practice, where patients can enjoy all the conveniences and comforts of home; nor is it usual to meet with them in public institutions; still, the fact that such an occurrence is possible cannot be too firmly impressed upon the mind of the young and inexperienced practitioner.

The best preventive of this occurrence is cleanliness, with a frequent change of dressing, and burying the affected parts in light bran, so as to place them beyond the reach of flies, which, under almost any other mode of manage-

ment, are sure to find their way to the wounded surface, the slightest crevice affording them access to the much coveted spot. Moisture and a high temperature are the causes which most rapidly conduce to the formation of maggots. The means that prove most destructive to them are spirits of turpentine, creasote, and alkaline solutions, particularly chlorinated soda. Dr. Atkinson, of the British army, has found no remedy so efficacious as calomel, sprinkled upon the wound, or blown into it from a quill.

Horrible suffering has been known to result from the development of maggots in the nose, from the accidental deposition of larvæ during a fit of intoxication. Dr. Bamford, who formerly practised in Texas, has communicated to me the particulars of the case of a man who perished from the effects of maggots formed in the nasal cavities and frontal sinuses, from which it was found impossible to dislodge them by any means that could be devised for the purpose. The patient suffered great agony, and died in raving delirium. It is easy to conceive how, in a hot climate, in consequence of the want of cleanliness, the larvæ of the fly might be deposited in an ear affected with profuse suppuration, or, from a similar cause, even in the vagina. Disgusting as such an occurrence is, it is by no means a matter of improbability.

SECT. VIII.—POISONED WOUNDS.

Under this head are included four distinct classes of wounds: first, those inflicted by venomous insects and snakes; secondly, those caused by the bite of rabid animals; thirdly, those produced by inoculation with the poison of glanders; and lastly, wounds received in the examination of dead bodies, constituting what are called dissection wounds.

I. WOUNDS INFLICTED BY POISONOUS INSECTS.

There are various genera of insects which naturally secrete a poison, which, when instilled into the living tissues, is capable of producing serious and even fatal consequences. Of these the most common, at least in this country, are the humble-bee, the honey-bee, the wasp, hornet, and yellow-jacket. The poison of these insects is contained in a small vesicle in the abdomen, and is under the control of a peculiar muscular apparatus by which it is injected into the puncture made by the barbed sting of these little creatures. It is highly acrid in its qualities, especially in the honey-bee, hornet, and yellow-jacket, transparent, and of a sweetish taste at first, but afterwards hot and disagreeable, being particularly active during the heat of summer. When roused to anger, these insects sting with great fury, producing a wound which is instantly followed by a sharp, pungent, itching pain, and in a few moments after by a circumscribed inflammatory swelling, pale, and elevated at the site of injury. In some persons, owing to idiosyncrasy and other causes, the symptoms are exceedingly severe and even alarming, the patient having dimness of sight, vertigo, nausea, palpitation, and a feeling of indescribable oppression, with a disposition to swoon. Instances have occurred in various parts of the country of persons having been stung to death by a single honey-bee; one such case, of which I have the particulars, occurred, many years ago, in Kentucky, in a man upwards of thirty years old. He was wounded on the face, and died in a few hours. I know a young man who always suffers from severe sickness of the stomach and great nervous depression when he is stung by a bee. Violent effects sometimes proceed from the sting of a bee, wasp, or yellow-jacket in the fauces, œsophagus, or stomach, when these insects are accidentally swallowed in cider and other drinks.

As the sting is often left in the skin, in the infliction of this class of wounds, the part should be carefully examined, in order that, if present, it may at once be extracted. The most promptly efficacious remedies are, in general, salt water, alcohol, laudanum, vinegar, hartshorn, spirits of camphor, Cologne water, soap liniment, solutions of the acetate of lead, and dilute tincture of iodine. Turpentine is also a highly valuable article. Whether these and other similar remedies act by neutralizing the poison, or merely by relieving the resulting inflammation, we are unable to say. In those cases in which the system becomes affected, immediate recourse should be had to internal stimulants, of which the best are brandy and ammonia. If the insect has passed into the throat, a mustard and salt emetic will be the proper remedy, followed, if urgent swelling and impending suffocation ensue, by leeches to the neck, and, perhaps, by laryngotomy.

Various species of the *mosquito* tribes are poisonous, and therefore capable of inoculating the wounds which they make by their bite. In the Southern States, as well, indeed, as in some of the western, and along many parts of the Atlantic coast, the mosquito abounds in vast numbers, and often inflicts serious injury both upon man and animals. I have met with a number of instances in which the bite of this insect was productive of severe inflammation, and several in which it was followed by considerable ulceration. The late Professor Dorsey, of this city, observed a case of gangrene and death from a wound of this kind in a lady, previously in good health. So serious an effect as this is probably always dependent upon some idiosyncrasy, or upon the occurrence of erysipelas, consequent upon the bite. The stinging sensation and swelling which attend the application of the poison of the mosquito usually soon subside of their own accord, or under the use of some mild stimulant, as Cologne water, alcohol, vinegar, or laudanum. When the effect is more serious, the tincture of iodine and warm water-dressing may be necessary.

The poison of the *scorpion* has many of the properties of that of the bee and wasp, although it is much more active. It is of a whitish color and oleaginous consistence, and is contained in a small reservoir near the end of the tail, whence it is ejected through two little pores on each side of the sting. In North America and Europe the wound inflicted by the animal is comparatively harmless, the only effect generally being a tolerably smart but transient inflammation; but in Africa and Asia it is often followed by great suffering and even loss of life, death sometimes occurring in a few hours. In these countries the scorpion frequently attains an enormous size, having a huge body, and a length of from six to ten inches. Several species of this insect, of large size, are found in Texas and Mexico, but I am not aware that their sting is particularly venomous. The great Eastern remedy in this variety of wound is olive oil, and an idea prevails that its virtues are greatly increased by infusing in it the bodies of some of these animals previously to its application. Spirits of hartshorn would doubtless be a more valuable addition. Such a wound should always be immediately well washed with salt water, then scarified, next thoroughly rubbed with volatile liniment, and then covered with an emollient poultice. If constitutional symptoms arise, they must be met with anodynes, brandy, and ammonia, the treatment being very similar to that adopted for the sting of the bee and wasp.

Bad effects have occasionally followed the bite of the *spider*; and the fabulous stories about the poisonous qualities of the tarantula are known to every reader of history. As yet, we know too little of the character and habits of these insects to speak with any certainty of the effects of their bite; but judging from what has been published upon the subject by reliable authorities, it is fair to conclude that, while there has been much exaggeration and actual misrepresentation, there is also much that is true. The symptoms

of the bite of the tarantula, so far as they have been studied, would seem to be very similar to those produced by the sting of the common scorpion. Hence similar treatment would probably suffice.

2. WOUNDS INFLICTED BY VENOMOUS SERPENTS.

The number of poisonous serpents in different parts of the world is very considerable; but in this country there are, so far as is at present known, only three genera that are at all dangerous on account of their bite. These are the *crotalus*, *trigonocephalus*, and *elaps*. Of the *crotalus*, or rattlesnake, so called from the peculiar appendage to its tail, Professor Holbrook, in his *Herpetology of North America*, has described not less than six species, of which the banded, striped, and miliary are the most common; all are venomous, and consequently capable of inflicting deadly wounds. These reptiles formerly abounded in almost every section of the United States, especially in the swampy and mountainous regions, but are now hardly ever met with in our denser settlements.

All the different species of rattlesnakes are provided with two small sacs, each of which contains a minute quantity of poison, and communicates, by means of a short excretory duct, with the canal in the fang on each side of the upper jaw. It is inclosed by a bony framework, situated external to the proper jaw, and is under the control of appropriate muscles, the action of which aids materially in expelling its contents. The fangs, situated just at the verge of the mouth, are very long, sharp, and crooked, like the claws of a cat, and are naturally retracted and concealed in a fold of integument; but, when the animal is irritated, are capable of being instantly raised, and darted forwards with great force into the skin, followed by an emission of poison. The snake, then, does not bite, but strikes, making a punctured wound.

The annexed illustration represents the head of the rattlesnake, and one

Fig. 80.

Fig. 81.

of the poison fangs, with the canal along which the venom flows when the animal is in the act of inflicting its wound.

The poison of the rattlesnake is a thin, semi-transparent, albuminous fluid, of a yellowish color, with, occasionally, a tinge of green. According to Dr. S. Weir Mitchell, of this city, who has carefully studied its qualities, it is of a glutinous consistence, devoid of smell and taste, distinctly acid, of the specific gravity of 1044, and coagulable at a temperature of 140° to 160° . Its toxic activity is not materially, if at all, impaired by boiling and freezing, and alcohol, acids, alkalies, iodine, and chlorides, do not destroy its virulence. When dried, it retains its dreaded power for an indefinite period. Chemically examined, it is found to contain, besides coloring matter, and an undetermined substance, both soluble in alcohol, a trace of fatty matter, chlorides and phosphates, and two albuminoid principles, one coagulable at 212° F., the other, termed crotonine, not coagulable at this temperature, neutral in its action, freely soluble in water, and of a nitrogenous nature.

The quantity of venom contained in the poison-bag does not generally exceed a few drops; but it accumulates when the animal is inactive, and Dr. Mitchell had a snake which, on one occasion, ejected fifteen drops, its fang not having been used for several weeks. It is peculiarly acrid and deadly in hot weather and during the procreating season. In winter and early spring the reptile is in a torpid condition, and the poison is then diminished in quantity, and unusually thick, though not less virulent.

The effect of the wound of the rattlesnake varies with many circumstances, as the situation of the part, the acrid character of the poison, and the age of the patient. Experience has shown, as in the case of the bite of rabid animals, that most of those hurt in this way escape either entirely or suffer only in a very slight degree; the poison either failing to reach the tissues, or being too inert to make any decided impression upon the system. It is also known that adults are less liable to suffer than children, simply because they possess, as may be supposed, greater vigor of constitution, and consequently greater power of withstanding the influence of the venom. The deleterious effects of the poison seem to be much weakened, if not actually exhausted, by a rapid succession of bites. The experiments of Captain Hall, of Carolina, and of the late Professor Barton, of this city, place this subject in a very clear light. Of three dogs bitten in succession by a rattlesnake four feet long, the former gentleman found that the first died in less than fifteen seconds, the second in two hours, and the third in three hours. The subjects of Barton's experiments were chickens, and the results were almost identical with those of Hall. Of three fowls, bitten on three consecutive days, the first perished in a few hours, the second lived for some time, and the third finally recovered, although not without considerable suffering. Instances occasionally occur in the human subject of almost instant destruction from the bite of the rattlesnake; at other times the case proceeds more slowly, the patient not dying under several hours, or, perhaps, several weeks. Dr. Wainwright, of New York, lost his life in less than six hours from the time he was wounded. The animal, an uncommonly large one, had lain in a torpid state for some time, when, unexpectedly becoming warmed, he reared himself and struck his victim furiously on the last phalanx of the middle finger of the left hand. Although the wound was immediately sucked, and soon afterwards excised and cauterized, a ligature being also tied firmly round the wrist, the hand soon became enormously swollen, the tumefaction rapidly extending up the limb nearly as far as the axilla, and the surface, in the greater part of its extent, exhibiting a mottled bluish and greenish yellow hue. The pulse soon became very feeble, and beat one hundred and twenty in the minute; in four hours the patient was in a state of stupor, and died soon after in a completely comatose condition. Finally, in another series of cases, the patient, after having been near death's door for several weeks, eventually perishes, or recovers. When death occurs almost instantaneously, the probability is that

the poison is injected directly into the blood, the fang having penetrated some tolerably large vessel. Under such circumstances, the fluid is found to be thin and black, and refuses to coagulate when exposed to the atmosphere.

When this poison has been freely instilled into a wound, the *symptoms* will always be proportionably severe. The moment the inoculation has taken place, excessive pain is experienced in the part, rapidly followed by swelling, which soon diffuses itself extensively over the surrounding surface, and is attended with a livid mottled appearance, dependent upon extravasation of blood in the subcutaneous cellular tissue. If the wound, for instance, occupies a finger, the tumefaction speedily extends up the limb, as far as the shoulder, and, perhaps, over a large portion of the corresponding side of the trunk, a feeling of numbness, weight, and coldness attending the other symptoms.

Within a few minutes after the first manifestation of the local affection, marked evidence appears of the absorption of the poison into the system. The patient looks excessively pale, sees objects indistinctly, is sick at the stomach, perhaps ejecting its contents, and has frequent swooning fits, with clammy sweats, and coldness of the body. By and by, as the system becomes more fully impressed with the deleterious effects, insatiable thirst arises; a sense of constriction is experienced in the chest; the breathing is oppressed; the pulse is feeble and vacillating; great anxiety and restlessness exist; the tendons twitch; the mind wanders, or is furiously delirious; and death soon closes the scene. In the worst cases of the affection, a universal yellowness of the skin is observed, and the parts are not only frightfully swollen, but, if the patient survive some hours, large vesicles appear upon the surface, containing bloody serum, and indicating the approach of mortification. When death does not take place for a considerable number of days, large abscesses form in the cellular substance and among the muscles, and the system gradually sinks under the resulting irritation.

The appearances presented in the bodies of those who die from the effects of this poison are pretty uniform. In the birds, rabbits, guinea-pigs, and dogs, experimented upon by Dr. Mitchell, extravasation of blood and softening of the tissues in the neighborhood of the bite were almost invariably observed; the brain and spinal cord were more or less injected; the heart was distended and flabby; the lungs were sometimes engorged; and the intestines were occasionally ecchymosed. In several instances, the kidneys were filled with blood, and exhibited all the evidences of acute congestion. The ureters and bladder contained sanguineous urine. The blood in the heart and vessels was dissolved, and of a dark color.

The genus *trigonocephalus* includes several species, of which the water moccasin, or cotton-mouth, and the copperhead, are the most important. They have no rattles, but the upper jaw is armed with poisonous fangs, and their bite is said to be very deadly. The cotton-mouth snake is met with extensively in the Southern States, its northern limit being the Pedee River in North Carolina. Professor Holbrook states that it is the terror of the negroes about the rice plantations, being more dreaded by them than the rattlesnake, which only attacks when irritated, whereas the water moccasin makes war on everything that comes within its reach.

Of the genus *elaps*, the only species, according to Dr. Holbrook, known in this country, is the *elaps fulvius*, whose body, twenty inches in length, is of a beautiful red color, surrounded with black rings, margined with yellow. Its upper jaw is armed on each side with a permanently erect poisonous fang. It is found chiefly in the Southern States, in sweet-potato fields, and is so gentle in its habits as to be regarded as almost harmless.

The most noxious serpent in the East Indies is the *cobra di capello*, the

spectacled or hooded snake, of which there are a number of varieties, all distinguished for their venomous properties. The effects of its bite are very similar to those which follow the bite of the rattlesnake, only that they are in general somewhat more tardy, and accompanied by less swelling. The poison is of a semi-transparent, yellowish appearance, not unlike olive oil. It has been known to kill a large dog in less than twenty minutes; and in the case of the keeper at the Zoological Gardens in London, who was bitten by a cobra on the root of the nose, death occurred in ninety-five minutes. The internal viscera were found, on dissection, to be intensely congested, and the blood, which was dark, alkaline, and fluid, emitted a peculiarly acid and sickening smell.

In Europe, the common *viper* is the most venomous serpent known. It is uncommon in England, but exists in considerable numbers in France, Spain, and Italy, as well as in several of the more northern States of the Old World. The poison, which has a yellowish oily appearance, may be swallowed almost with impunity, provided there is no abrasion upon the mouth. It is most active in hot weather, killing small birds and animals almost instantly. Applied to the human subject, it causes acute pain and diffuse swelling, followed by a puffy, œdematous state of the subcutaneous cellular substance, and a livid and vesicated condition of the skin. The general symptoms, which seldom manifest themselves under three-quarters of an hour to an hour, bear so close a resemblance to those produced by the wound of the rattlesnake as to render it unnecessary to describe them.

A great deal has been written concerning the *treatment* of wounds inflicted by venomous serpents, and yet it is remarkable that we have not a solitary remedy upon which any reliance can be placed. The fact that so many articles have been recommended as specifics clearly shows that these lesions are often so slight as not to require any treatment at all, the unpleasant effects generally passing off spontaneously in a few hours, either because the poison has not been introduced in sufficient quantity, or because it has not been sufficiently noxious to produce any serious harm. The first thing to be done, as far as the part is concerned, is to constrict the limb as tightly as possible, a short distance above the wound, which is then to be instantly excised and cupped, the glass being retained as long as the blood is disposed to flow, when the surface should be well washed with the dilute tincture of iodine, the same remedy being thoroughly applied to the skin over the whole extent of the swelling. Subsequently, warm water-dressing, medicated with laudanum and acetate of lead, will form the most suitable application.

The practice of sucking the wound is of great antiquity, and we find that there have been men, from time to time, in different parts of the world, who have made it their special occupation. The *Psylli*, of Africa, and the *Marsi*, of Italy, acquired great celebrity for their skill in this particular branch of business, and the custom still prevails among many of the Indian tribes of this continent. The operation, however, cannot be performed with safety if there be any abrasion upon the lips or in the mouth, and should therefore always give way to the cupping glass.

Professor Brainard, of Chicago, has suggested the practice of injecting a solution of iodine under the skin for the purpose of destroying the poison. The only objection to the procedure is the difficulty of administering the remedy, such accidents nearly always happening in places remote from the apothecary and the surgeon.

Pain must be relieved, and the strength supported by morphine and alcohol, the latter being given, in any of its more common forms, to the utmost possible extent compatible with the patient's power of endurance. Whiskey seems to be the great remedy among the mountaineers of this country, for this class of wounds, and there can be no question, from what has appeared

in the public prints upon the subject, that it is entitled to great consideration. The treatment should be rapidly pushed to gentle inebriation, though such an occurrence is seldom to be looked for when there is such marked depression of the general system as so often attends this lesion. Ammonia might, perhaps, be advantageously combined with the alcoholic remedies, for there can be no doubt that it must, under such circumstances, be productive of benefit, whether we regard it merely as a stimulant, or as a neutralizer of the poison. When there is excessive prostration, along with great gastric irritability, enemata of brandy and laudanum should be employed. Olive oil has been highly recommended as an antidote against snake bite; but, there is no reason to believe that it possesses any such virtues. In the East Indies, the Tanjore pill formerly enjoyed great celebrity in the treatment of wounds inoculated with the poison of the cobra di capello and other noxious serpents, its efficacy being supposed to depend upon the arsenic which enters into its composition. Fowler's solution has also been much lauded for its supposed neutralizing qualities, especially of the poison of the fer-de-lance, a venomous serpent in the Island of St. Lucia; it is administered every three hours in doses of two drachms along with a small quantity of laudanum, until active vomiting and purging are induced. But none of these remedies are reliable, and my opinion is that no time should be wasted upon their exhibition.

In the former edition of this work attention was directed to the use of Bibron's antidote, as it has been called,—a mixture of bromine, iodide of potassium, and bichloride of mercury—as a means of neutralizing the effects of the poison of the rattlesnake; but it has been ascertained by Dr. Mitchell that it possesses no such properties; nor are arsenic and ammonia, or, indeed, any other known articles of the materia medica, endowed with such virtues. In regard to topical remedies, he found, experimentally, that iodine, injected subcutaneously, exerted a great influence over the local effects of the venom, but none in preserving life or defending the system at large. Some simple astringents also possess this power, and are as useful as iodine itself. Among the internal stimulants, he assigns, in common with all American practitioners, the highest position to alcohol, looking upon it, not as a chemical antidote, or neutralizer of the venom, but as a great supporter of the vital powers. When the patient is too weak, or too sick, to swallow, he recommends it to be given as an enema; and he also, in that event, advises the inhalation of hot alcohol, or even of ether, as a means of re-exciting the flagging powers of the system. When the patient has recovered from the immediate effects of the poison, quinine and a nutritious diet will be necessary, along with the spirituous stimulants, to aid restoration.

Finally, it may be observed, in regard to the so-called antidotes for snake-bite, that the remedies which have, from time to time, been invested with this virtue, doubtless owed their temporary reputation to the fact that the cases in which they were used were cases of a comparatively slight character, which would probably have recovered as well, or nearly as well, without as with their use. The history of surgery certainly warrants this conclusion.

3. WOUNDS INFLICTED BY RABID ANIMALS.

There is a peculiar disease among man and animals known by the name of hydrophobia, its characteristic symptoms, at least in the human subject, being a dread of water, as the term by which it is generally designated literally signifies. It is due to the influence of a particular poison, generated by certain animals, and capable of propagating the disease by inoculation. Of the nature of this poison all we know is that it is contained in the saliva, and that, after having remained latent for some time in the wounded part, it is

absorbed and carried into the system, where it produces the peculiar effects by which the malady is distinguished.

That the *virus* of hydrophobia resides in the saliva, or in the saliva and other secretions of the mouth and fauces, is a circumstance which has been fully established by experiments upon inferior animals. Thus, Dr. Zine inoculated a dog, cat, hare, and cock, with the saliva of a rabid dog, and readily induced the disease. Similar results followed the investigations of Dupuy, Youatt, and other veterinary surgeons. The former of these writers rubbed a sponge wet with the saliva of a mad dog upon the sore of a sheep, which subsequently perished from hydrophobia; and the latter communicated the affection from one brute to another by means simply of a silk thread, impregnated with this fluid and used as a seton. While hydrophobia, however, may be readily propagated in this manner, we are ignorant as to the precise source of the poison, whether, although it is contained in the saliva, it is really secreted by the salivary glands, or whether it is derived from the mucous membrane of the mouth and fauces. The former supposition is certainly the more plausible of the two, but the fact could only be verified by taking the fluid directly from one of these organs; an experiment which, so far as I am aware, has never been made.

There are certain animals which have the faculty of generating the poison of hydrophobia spontaneously; they belong chiefly, if not exclusively, to the canine tribe, and consist of the dog, wolf, fox, jackall, and badger. The cat is commonly supposed to possess a similar power, but this is still an unsettled question. Man and other animals do not produce the virus spontaneously, but are susceptible of the disease, and, with the exception of man, are probably all capable of propagating it when under its influence. Breschet repeatedly provoked the malady in dogs by inserting the saliva of rabid horses and asses; and several cases have been reported of human beings having suffered from the bite of rabid horses and pigs. It is uncertain whether hydrophobia can be communicated from one person to another. In the case of Mr. Wheeler, a dresser in Guy's Hospital, London, who was bitten by a rabid patient, no ill effects followed, and I know of no well authenticated instance of the disease having been induced in this wise. Rabbits and similar animals, as well as fowls, soon die from inoculation with this poison, without exhibiting any of the ordinary symptoms of hydrophobia.

The *inoculation* in hydrophobia is usually effected by a tooth, which, however, need not necessarily penetrate the true skin, numerous cases having occurred where the disease was communicated by the slightest scratch, or abrasion. One instance has been reported where death was produced by the licking of a wart upon the face, by a little poodle supposed to be laboring, at the time, under rabies. It is, indeed, not improbable that the disease may be communicated merely by the contact of the saliva of a hydrophobic animal with sound skin and mucous membrane. It is also supposed to be possible that a mother may transmit the affection to her infant through her own milk. Cases now and then occur which lead to the suspicion that the disease may be induced by dogs and other animals not actually mad, but simply enraged; whether this, however, be a fact or not remains to be proved. Finally, experiments have been performed which go to show that the morbid saliva may be administered internally with entire impunity.

The period of *latency* of this disease varies from a few weeks to several months. In 89 cases, analyzed by Dr. Blatchford and Dr. Spoor, of Troy, the average period was about seventy days, the minimum in 23 cases was thirty days and under, and the maximum in 6 cases was upwards of two hundred days. In the only two cases of hydrophobia that I have ever seen, the disease appeared, in one, at the end of four weeks, and in the other at the end of nine months from the date of the inoculation. According to John

Hunter, the extremes range from thirty days to eighteen months. An English writer, Dr. Bardsley, refers to an instance where the disease did not show itself for twelve years, but such a statement must be received with great allowance. The period is generally considerably shorter in animals than in man, and in very young persons than in adults.

Although a considerable period always elapses between the inoculation and the appearance of hydrophobic symptoms, yet it is extremely probable that the virus is speedily absorbed into the system, though some time is necessary to develop its zymotic properties. What countenances this view of the subject is that nearly all the other known poisons, when brought in contact with the living tissues, are promptly absorbed, so as to make, sooner or later, their peculiar impression upon the constitution. The poison of the rattlesnake is taken up almost instantaneously, and the probability is that the same is true with respect to the poison of smallpox, measles, scarlatina, and other zymotic affections. A certain period, however, is necessary, in every case, to enable the poison to explode upon the general system, or, in other words, to multiply itself, and extend its influence. With regard to the virus of rabies, it is certain that the disease is often developed within the usual period, after the most prompt and complete excision of the bitten parts.

Many persons are bitten by rabid animals who yet never contract the disease, the virus having either been exhausted before the rencontre takes place, or, what is more probable, having been wiped off by the clothes in the act of inflicting the wound. In this way more than half of those bitten occasionally escape with impunity; but, on the other hand, it sometimes happens that nearly every one is effectually inoculated. It is not impossible that idiosyncrasy may exert an important influence in the production of the disease. It is well known that this is true of other zymotic poisons, and it is therefore reasonable to suppose that it may also hold good of this. Out of fifty dogs that had been inoculated by Dr. Hertwich, of Berlin, with saliva taken from a rabid animal of the same species, not one in five was infected.

Hydrophobia occurs at all *ages*. It has been observed in infants at the breast, in children, and at every period of adult life. In the Transactions of the American Philosophical Society are the particulars of a case in a man of seventy-three. Women are equally as subject to the disease as men, and, if they suffer less frequently from it than they do, it is simply because they are less exposed to the attacks of rabid animals. It prevails in all countries, in all climates, and at all seasons of the year. Northern Europe, however, has furnished a greater number of cases than perhaps any other part of the world. It is also frequent in England; and, as a general rule, it is more common in northern than southern regions. Throughout the West Indies it is comparatively rare, although the number of dogs there is unusually great as compared with the number of inhabitants. Hydrophobia is more common in Canada and New England than in the Southern States of the Union.

The *symptoms* of rabies necessarily divide themselves into local and constitutional; or those furnished by the wounded part, and those afforded by the system, after the absorption of the specific virus.

The wound inflicted by a rabid animal generally heals as kindly as any similar wound made by a sound animal; the scar, perhaps, remaining a little red and tender, as it usually does after an ordinary bite, but exhibiting no other peculiarity, and the system being perfectly free from disease. By and by, however, when the period of incubation is about to draw to a close, the part begins to itch, burn, or smart, and soon becomes sore and irritable, hot, numb, or rigid, pain darting through it in different directions, and sometimes extending to a considerable distance beyond the site of injury, as from the hand up to the shoulder, or from the foot to the knee or groin. Sometimes a red line can be traced in the direction of the lymphatics. Occasionally,

though rarely, the cicatrice has been known to open afresh. Almost simultaneously with the local affection evidence of general indisposition appears. The patient feels unwell; his head aches; his sleep is disturbed by unpleasant dreams; he feels melancholy and depressed; and he has occasional attacks of chilliness, with a highly impressible state of the system. The poison is now fairly at work, and in a few hours—generally from ten to twenty-four—explodes with frightful violence. The period of latency is passed; the disease has reached its second stage; the dread of water and the difficulty of deglutition have declared themselves; in a word, hydrophobia is fully established. The patient, on attempting to drink, is suddenly seized with spasm in the throat, and finds that he is unable to swallow a particle of fluid; he tries and tries, but every effort is only succeeded by a renewal of suffering, and presently he dashes away the cup as if it were charged with some deadly poison, unwilling again to bring it to his lip. Tortured with thirst and a sense of dryness of the mouth, he will rather endure his discomfort than subject himself to the dreaded spasm. Should he succeed in forcing down a little water, he will be instantly seized with suffocative cough, convulsive tremors, and lividity of the face, compelling him to jump up in bed, and to pant for breath. The painful sensations are usually referred to the throat, and are often accompanied by a feeling of constriction in the chest, difficulty of respiration, a disposition to sigh, and a frequent desire to clear the mouth and fauces, which soon become clogged with an inordinate secretion of thick, viscid saliva and mucus, which greatly aggravate the patient's suffering. At this stage of the disease, and generally, indeed, before it has reached this point, there is superadded to the previous distress a remarkable susceptibility to atmospheric impressions, the slightest contact of cold air being a source of profound torture, producing a sense of suffocation, and even violent convulsions. The agony thus occasioned is sometimes much greater than that caused by the attempt to swallow fluids. The least opening of a door, the slightest motion of a fan, or even the smallest whiff of air directed from the attendant's mouth upon the body, instantly brings on a paroxysm of this kind. Light and noise too are always offensive; and hence the patient usually insists upon his room being kept dark, quiet, and closed. The mind, at this stage, is peevish and fretful; and nothing that can be done can please the sufferer, who, in consequence, often quarrels with his best friends. At times his imagination is completely perverted; he fancies that he hears noises and sees objects that have no real existence; he gets out of bed, walks about the room, screams, or gesticulates, very much like one affected with delirium tremens.

In the last stage, which is characterized by an aggravation of all the previous symptoms, the countenance has a haggard and distressed appearance, horror and anxiety being depicted on every feature; the eyes have a wild and glaring expression; the tongue is perfectly dry and parched; the strength is much impaired; the voice is hoarse and shrill, almost like that of a dog; the respiration is short and panting; more or less delirium is present, often amounting to complete mania; and the pulse, small and feeble, beats from one hundred and thirty to one hundred and sixty in the minute. Thus the disease progresses, paroxysm after paroxysm recurring until the frame is worn out by exhaustion, death usually taking place suddenly in a fit of suffocation. Occasionally a slight calm is experienced a few hours before the fatal event; the spasms almost completely subside, the power of swallowing returns, the mind becomes clear, and the patient, perhaps, sinks into a tranquil sleep. The duration of the attack varies from eighteen hours to a week, the average being about three days.

In a case of hydrophobia which I attended in 1842, the patient, a young man of about twenty-one years of age, was attacked precisely four weeks

after having been bitten in the left hand by a rabid dog. When I was called in, the disease was in its second stage, well-marked symptoms having appeared the previous day. The difficulty of swallowing and the morbid sensibility of the skin were present in a high degree. Every effort at drinking, nay, the very mention of fluid of any kind, and the attempt to raise the glass to the lip, caused violent convulsions; the countenance was flushed and tumid; the eyes red and suffused; the mouth parched; the throat stopped with viscid mucus; the pulse frequent and rather strong; the respiration hurried; the thirst and restlessness intense; the mind exceedingly peevish and irritable; and the sensibility of the skin so exalted that the slightest approach of a current of air, inappreciable by any one else, produced the most horrible torture. The inability to bear light and noise was also very great. The hand felt numb and painful, though the wound had not reopened. These symptoms gradually progressed, increasing steadily in severity, until towards the end of the third day from the attack, when the young man expired in a state of complete exhaustion. The pulse, during the latter stage of the malady, was exceedingly irregular, and upwards of one hundred and fifty in the minute; the breathing was short and panting; and the mind was excessively agitated and distressed, but clear and intelligent, except when the patient was on the verge of a convulsion. The voice was not materially affected.

It is impossible to mistake hydrophobia for any other disease. The dread of water, the difficulty of deglutition, and the dread of cold air, are always sufficiently diagnostic of the affection, even when no history of it can be obtained.

The *dissection* of persons dead of this disease has thrown no real light upon its seat and pathology. In the case of a young man of twenty-four, who died in 1840, nine months after he had been bitten on the hand, and whose body I assisted in examining, no lesion whatever could be detected, by the closest scrutiny, anywhere. The mouth, fauces, pharynx, and œsophagus, the larynx, trachea, and bronchial tubes, where disease might naturally be supposed to exist, under such circumstances, were perfectly free from morbid appearances. The brain and spinal cord, the lungs, stomach, bowels, and other viscera, were in as natural a condition as I ever saw them in any case. Occasionally, especially in protracted instances, the membranes of the brain have been found congested, and the ventricles partially filled with serum. The stomach, œsophagus, and pharynx have also been found inflamed; and several dissections are mentioned where pus was discovered in some of the larger joints. Very little reliance, however, it seems to me, should be placed upon the statements that have been published upon the subject, especially when we consider the loose manner in which most of them are drawn up, and the fact that comparatively few men are competent to make accurate dissections of dead bodies.

The *prognosis* of hydrophobia is always bad, the disease invariably ending fatally. If there is a case of recovery, of a reliable character, upon record, I am not aware of it. I know that a number of instances have been published in which the patient is said to have gotten well, but there is not a single one, so far as I am acquainted with them, that can withstand the test of scientific scrutiny.

The period at which death occurs is, in general, very short. The average in 72 cases, analyzed by Dr. Blatchford and Dr. Spoor, was three days. In 120 cases, analyzed by Dr. J. L. Smith, of New York, 65 perished in from one to two days. In some instances, the disease proves fatal during the first twenty-four hours, while in others this event does not happen until the tenth day, although when postponed so late it necessarily creates some doubt in regard to the true nature of the case.

In the *treatment* of this variety of poisoned wound, reliance must be placed solely upon preventive measures; for, as has just been seen, when the disease is once developed, there is no possible chance of doing anything more than mitigating the suffering, and even that only in a slight degree. If, as I have supposed, it be true that the poison is speedily absorbed after being brought into contact with the living tissues, the importance of promptly dislodging it cannot be too forcibly impressed upon the attention of the practitioner. As soon, therefore, as such a case is presented to his notice, the injured part should be thoroughly excised, care being taken to embrace a portion of the sound tissues. The flow of blood is then to be encouraged with a cupping glass, retained for some time, when the raw surface is well cleansed, and immediately cauterized with nitrate of silver. If the teeth of the rabid animal have penetrated between two bones, as, for example, when the bite has been inflicted upon the hand, excision must be performed with increased care, otherwise a portion of virus will be almost sure to be left behind. In such a case it might become a nice question to determine whether the operation should not be made to include a portion of the bones also; for almost any local sacrifice is justifiable to secure immunity from so horrible a disease. It would seem from the observations of Mr. Youatt and Mr. Blane, two eminent veterinary surgeons, that there is no remedy which so certainly neutralizes this poison as nitrate of silver. The former of these writers, whose opinion is entitled to the greatest respect, on account of his large experience in the treatment of canine madness, has repeatedly employed this article, under these circumstances, in his own case, and such is his confidence in its virtues that he regards it in the light of a specific. His plan is to cleanse the parts well in the first instance with soap and water, and then to use the caustic most thoroughly, previously enlarging the wound, if necessary. If I were so unfortunate as to receive such an injury upon my own person, I should certainly feel more confidence in my escape, if the wounded parts had been excised and cupped prior to the cauterization.

Excision should also be practised when the injured part has been neglected, or imperfectly removed in the first instance, it being well known that the individual may escape the constitutional effects of the disease even after the wound has partially reopened. But even if there were no reasonable hope of preventing the occurrence of the disease by this procedure, it should, nevertheless, be practised, if for no other reason than that it will have a soothing effect upon the mind of the poor sufferer. Everything calculated to allay his fears and contribute to his happiness is justifiable under such trying circumstances. If the symptoms of hydrophobia, however, are already developed, neither such an operation, nor even the amputation of the limb above the site of injury, will be of any service.

When the poison has reached the system, and has evinced its explosive effects, no treatment, however judiciously and perseveringly conducted, can be of any avail as a curative agent. The experience of two thousand five hundred years fully attests the truth of this statement. There is hardly an article of the *materia medica*, potent or impotent, vegetable or mineral, that has not been used, singly or combinedly, for the cure of this disease, and yet, as was mentioned in a previous paragraph, there is not one solitary instance, of a reliable kind, upon record, where any beneficial result followed its exhibition. I need not, therefore, recount the various methods of treatment spoken of by authors, as this would only be a waste of time and space. Nor shall I say anything of internal prophylactics, experience having shown that there are no such remedies in hydrophobia.

To relieve the frightful suffering from the disease, chloroform and ether, either alone, or variously combined with each other; morphia in large quantities in the form of enemata; the application of steam conveyed to the

patient's body as he lies in bed; and the exclusion of cold air, noise, and light from the apartment, constitute the most reliable means. General bleeding, the hot bath, and tartar emetic, so much vaunted by some, will only, as a general rule, expedite the fatal issue, without affording any decided mitigation of the suffering. Opium is of no use, even if given in enormous quantity, as the stomach does not appear, in this disease, to have the power of dissolving it. If anodynes are exhibited at all internally, they should be used in the form of morphia, laudanum, or black drop. Dr. Physick, with a view of relieving the difficulty of breathing, and preventing suffocation, advised laryngotomy, but I am not aware that it has ever been practised, or, if practised, that it has ever done any good. It certainly could not cure the disease, and it admits of doubt whether it would even moderate the spasm.

Hydrophobia in the Dog.—In concluding the subject of hydrophobia, a few words may be said respecting the character of this disease as it occurs in the dog, as it is important for the practitioner to be able to judge of the probability of his having been mad in the event of his having bitten a human being.

How the disease originates in the dog, one of the animals in which it is generated spontaneously, is not ascertained. It has been supposed that sexual abstinence, the use of filthy and unwholesome food, too close confinement, and extremes of heat and cold, constituted so many causes of the malady; but it is obvious that, although this may be true, yet our knowledge at present amounts to nothing but conjecture, which further and more carefully conducted observation alone can either verify or disprove. The average period of incubation is about forty days, the minimum being a fortnight, and the maximum three months and a half.

The early symptoms of rabies in the dog are thus graphically described by Mr. Youatt: "In the greater number of cases," he remarks, "there are sullenness, fidgetiness, and continual shifting of posture. When I have had opportunity, I have generally found these circumstances in succession. For several successive hours perhaps he retreats to his basket or his bed. He shows no disposition to bite, and he answers the call upon him laggardly. He is curled up, and his face is buried between his paws and his breast. At length he begins to be fidgety. He searches out new resting-places; but he very soon changes them for others. He takes again to his own bed; but he is continually shifting his posture. He begins to gaze strangely about him as he lies on his bed. His countenance is clouded and suspicious. He comes to one and another of the family, and he fixes on them a steadfast gaze as if he would read their very thoughts. 'I feel strangely ill,' he seems to say: 'have you anything to do with it? or you? or you?' Has not a dog mind enough for this? If we have observed a rabid dog at the commencement of the disease, we have seen this to the very life." Delirium is an early and characteristic symptom; the dog sees imaginary objects, and often springs at them with a furious dart; he is restless and excessively irritable, gazing wildly around, and snapping at everything within his reach. The saliva is secreted profusely, and collecting at the corners of the mouth, the animal makes frequent attempts to detach it with his paws; his appetite is strangely perverted, and he will sometimes greedily devour horse-dung, or even his own excrements; the voice is changed in its character, being generally hoarse, and more or less shrill: the eyes are singularly bright; and the thirst is intense and insatiable, the dog drinking frequently, and having no fear whatever of water, as is the case with the human subject.

The disease is now in full force, and tending rapidly to a fatal issue. The muscular powers being greatly exhausted, the animal finds it difficult to sustain himself upon his limbs; he reels and staggers about like a man in a drunken fit; his tail is depressed, and the tongue protruded; the eyes have

lost their brightness, and are of a dull, glassy appearance; the respiration is hurried and panting; finally, worn out by his suffering, the poor creature dies, either from convulsions, or from sheer exhaustion, the duration of the attack varying from three to five days. The power of communicating the infection exists, according to Youatt, in all the confirmed stages of the disease, and continues even for twenty-four hours after the death of the animal.

4. GLANDERS, FARCY, OR EQUINIA.

The horse, ass, and mule are capable of spontaneously generating a disease, which, although it affects the whole system, expends itself with peculiar force and virulence upon the mucous membrane of the nose, causing violent inflammation and a copious discharge of thick, fetid matter. It is accompanied by a pustular eruption of the skin; and the name by which it is generally known is glanders, from the fact that it is always associated with disease of the maxillary glands and of the lymphatic ganglions of the ear and neck. There is a form of the affection which is characterized by the development of small tumors beneath the skin in different parts of the body, varying from the size of a pea up to that of a hazelnut, of a spherical shape, very hard, almost immovable, and generally exquisitely painful to the touch. When very numerous, they give the surface a remarkably tuberculated appearance. To this disease the term *farcy* is commonly applied; and an attempt has been made by several writers to establish for it a distinctive character. Others, on the contrary, assert that it is identical with glanders, differing from it only in its location, or in the character of the structures in which it appears. This view of the case derives confirmation from the fact that the two affections often coexist, which would hardly happen if they did not possess a strong natural affinity for each other.

It has been observed that the animals in which this disease arises spontaneously are generally half-starved, over-worked, and of broken constitution. Whatever, however, the cause may be by which the affection is originally engendered, it is certain that it is both contagious and infectious, and that the strongest and most healthy animals will often speedily contract it when exposed to its influence; confinement in damp and ill-ventilated stables, especially if underground, powerfully predisposing to its occurrence. It was at one time thought questionable whether the disease could be propagated by atmospheric agency; but multiplied observation long ago fully settled that point. It would seem, indeed, that the air of an infected stable, after all the wood work, pavement, and plastering have been completely replaced, and every possible precaution used in regard to cleanliness, is capable of reproducing the disease in all its former severity.

The fact that glanders may occur in the human subject was first enunciated by Mr. Muscroft, in the *Edinburgh Medical and Surgical Journal*, in 1821. The case which he therein reports was that of a man who had accidentally inoculated his hand in cutting up for the kennel a horse that had died of this disease; violent symptoms soon showed themselves, and he expired in great agony at the end of a week. Since that time a number of similar examples have been recorded by other observers, thus indisputably establishing the transmissibility of glanders from animals to the human subject. As yet no facts had occurred proving that the affection might be communicated from one human being to another, or from man to beasts. In 1840, however, a case of this kind took place at St. Bartholomew's Hospital, London, which conclusively settled the question. The patient, a knacker, died of glanders, and the nurse who attended him took the disease and also perished from it.

These facts regarding the transmissibility of glanders from animals to man, from man to man, and finally from man to beast, are of great pathological

interest, and serve to inculcate the indispensable necessity of caution on the part of the professional attendants and nurses in their intercourse with individuals laboring under this horrible disease; since the smallest particle of the specific virus coming in contact with an abraded surface, or even the mere inhalation of the infected air of the patient's apartments, may give rise to the malady.

In the equine tribes of animals, glanders may be propagated by *inoculation* with the pus and mucus of the pituitary membrane, the fluids being inserted under the skin with a lancet, or rubbed upon the greasy heel of the horse. It may also be produced by applying these secretions to the mucous lining of the nose; and a curious case has been reported of its having been caused by introducing balls of farcied matter into the stomach. An experiment performed by Mr. Coleman, the distinguished veterinarian, shows that the blood of a glandered animal transfused into the carotid artery of a sound one, will rapidly engender the malady in its most virulent form.

The period of *latency* of this disease is generally very short, rarely exceeding two or three days. It is probably a little longer in the human subject than in animals, but the difference, if any, is very slight. It has already been seen that the first case that ever occurred, so far as is ascertained, in the human subject, terminated fatally at the end of a week from the time of the inoculation. The first local evidence of the disease is generally some swelling and tenderness of the maxillary glands and inflammation of the mucous membrane of the nose; sometimes the one, and at other times the other, taking precedence.

The *symptoms* of glanders naturally divide themselves into constitutional and local. Shortly after the inoculation has taken place, the patient begins to feel unwell; his head, back, and limbs ache; chilly sensations, alternating with flushes of heat, creep over his body; sleep and appetite are impaired; the strength sensibly diminishes; the joints are stiff and sore; the spirits are depressed; the stomach is irritable; and the bowels are costive. After the lapse of thirty-six to forty-eight hours, sooner or later, a severe and protracted rigor generally occurs, followed by violent fever and profuse perspiration; an evidence that the stage of incubation is passed, and that the poison has gained full admission into the system. The symptoms now rapidly assume a typhoid character. The pulse becomes quick, frequent, and tremulous; the tongue is dry and brownish; sordes accumulate upon the gums and teeth; the voice is weak and often husky; the respiration is short, panting, and accompanied by a sense of constriction across the chest; the surface is bathed with fetid, clammy perspiration; the thirst and jactitation are excessive; the urine is scanty and high colored; the alvine evacuations are slimy and excessively offensive; the mind wanders; and the pains are atrocious.

Coincident with these phenomena are marks of serious disease of the mucous membrane of the nose, which is highly inflamed, and the seat of a copious, viscid, and irritating discharge. Excessive pain and soreness exist in the forehead, over the frontal sinuses, evidently from an extension of the inflammation to the lining membrane of those cavities; and for the same reason there is generally great uneasiness in the throat and larynx. The nose and cheeks soon become hot, swollen, purple, excoriated, and exquisitely painful; the discharge from the nostrils assumes a bloody, purulent character, and is both copious and disgustingly offensive; the eyelids are infiltrated and nearly closed; and the features are hideously disfigured. About the tenth or twelfth day hard pustules make their appearance on various parts of the body, especially on the trunk, face, genital organs, and inside of the limbs, resembling those of smallpox, and attended with profuse fetid sweats. Occasionally they are accompanied by black bullæ, which, breaking, discharge a thin, sanious fluid, and bring into view gangrenous spots, varying from the

size of a three cent piece to that of a quarter of a dollar. In some cases, again, numerous tubercles appear in different situations, interspersed among the pustules, or pustules and vesicles; they are generally small, of a roundish shape, hard, and exceedingly painful; as the disease proceeds, they give way on the surface, and exude a thin, ichorous fluid. The lymphatic ganglions of the groin, axilla, and other regions, frequently participate in the disease, becoming enlarged, tender, and painful; the lungs are also apt to suffer, and, indeed, it is not uncommon to see serious involvement of various viscera.

As the disease progresses, the prostration rapidly increases; the fever displays a more malignant character; deep coma supervenes; and the body exhales a horribly offensive odor, almost characteristic of the disease, and strongly denotive of the dissolved state of the blood and the putrescent nature of the secretions.

The period at which death occurs varies from eight or ten days to four or five weeks. In a majority of the reported cases, the disease terminated fatally before the eighteenth day; some of the patients died as early as the end of the first week, while a few lived until after the fiftieth day.

When glanders pursues this rapid course it is said to be acute, and chronic when it is more tardy. In the former case, the local symptoms usually precede the general, frequently setting in within a few hours after the absorption of the virus. The inoculated part becomes red and tender, and the epidermis is soon elevated into a vesicle, or pustule, from which the inflammation rapidly extends along the lymphatic vessels as high generally as the glands of the groin or axilla. The swelling is excessive; the limb is stiff and numb; and the areolar tissue, infiltrated with sero-albuminous exudation, before long becomes the seat of numerous abscesses. In the more severe cases, black spots appear upon the surface, indicative of the existence of gangrene. Sometimes the local disease begins in the lymphatic ganglions of the groin or axilla, from which it spreads over the corresponding side of the trunk and even over the whole limb.

In contemplating the progress of this disease; it is impossible not to be struck with the resemblance it bears to that of a dissection wound. It evidently belongs to the hemotoxic class of affections, consisting essentially in a disorganized condition of the blood and solids, paralyzing and crippling the heart and brain, and thus bringing about that typhoid condition of the system which forms so prominent a feature of the complaint.

Dissection always discloses the existence of serious lesions in the nose and internal organs. The pituitary membrane, of a deep purple or livid hue, is coated with tough, viscid secretions, studded with tubercles, ulcerated at some points, and gangrenous at others; the nose is occasionally nearly eaten away; and large cavities generally exist upon the cheeks. The frontal sinuses, larynx, and bronchial tubes are livid and excessively congested; and the lungs often contain abscesses, occupied by ill elaborated matter, looking more like aplastic lymph than genuine pus. The heart is commonly softened. The mucous coat of the stomach and bowels is diminished in consistence, discolored, and sometimes studded with minute tubercles, similar to those observed in the nose. The pustules which exist beneath the skin and in the cellular tissue among the muscles, bear a great resemblance, in the nature of their contents, to metastatic or multiple abscesses; they contain no real pus, at least not in their earlier stages, but a dense, solid fibrinous matter, strikingly like that so generally found in pyemia and other forms of blood-poisoning.

The *diagnosis* of glanders is, in general, sufficiently easy. An inexperienced practitioner, deceived by the aching pains and soreness of the joints and limbs, might possibly mistake it in its earlier stages for rheumatism; but the occurrence of secondary symptoms would soon dispel the illusion. From

the effects of a dissection wound it may be readily distinguished by the peculiar discharges from the nose, and by the character of the cutaneous eruption. The history of the case, too, will furnish important diagnostic data, and should therefore always receive due consideration. The fact that the patient has nursed or examined a glandered horse or person, will generally of itself afford strong presumptive proof of the true character of the attack. In the latter stages of the disease, the nasal discharges, the existence of pustules, abscesses, and gangrenous spots, and the horribly fetid exhalations from the body, are signs which it is impossible to mistake.

The character of the *prognosis* in this disease may be gathered, in great measure, from what precedes. The acute form of the disease is nearly always fatal. Of fifteen cases, collected by Rayer, one only recovered. The danger in chronic glanders, on the other hand, is much less. Thus, of ten cases, mentioned by the same writer, seven recovered and three died.

The *treatment* of this affection is preventive and curative. The former consists in the adoption of proper measures for destroying the poison as speedily as possible after the inoculation. With this view the affected or abraded surface should be freely washed by holding it for a considerable length of time under a concentrated stream of water, and then thoroughly cauterized with acid nitrate of mercury, or some other active escharotic, or, what is better, effectually excised. If the operation be impracticable, and the wound is of a punctured nature, it should at once be enlarged, and then brought fully under the influence of some caustic, otherwise a portion of the poison lurking deep in the wound may escape its contact, and thus be absorbed into the system. If a person is known to have died of glanders, the safest plan for the practitioner is to avoid a post-mortem examination, especially if there are any abrasions, however slight, upon his hand and fingers.

The curative treatment, if it deserve such a name, has hitherto been entirely unavailing. Bleeding, both local and general, purgatives, tonics, and stimulants, have proved alike useless. Obviously our chief reliance must be upon the employment of supporting measures, especially quinine, carbonate of ammonia, tincture of the chloride of iron, and brandy, given in large and frequently repeated doses, in combination with liberal quantities of morphia, with a view both of allaying pain and controlling gastric irritability. Infiltrated fluids and abscesses should be promptly evacuated, and the affected parts wrapped up in flannel wrung out of saturnine and anodyne lotions. The nose should be frequently injected with tepid water impregnated with creasote, or tannate of iron; liquid chlorinated soda should be freely sprinkled upon the body and bedclothes; the apartment should be constantly ventilated; and the utmost attention should be paid to cleanliness. To these means should be added, in chronic cases, change of air, or residence near the sea-coast.

5. WOUNDS INOCULATED WITH A PECULIAR SEPTIC POISON GENERATED IN DEAD ANIMAL BODIES.

a.—*Dissection Wounds.*

Wounds contracted in the examination of dead human bodies are named dissection wounds, and are deserving of special attention from the severe effects they are capable of producing. These injuries generally occur in the form of punctures, abrasions, or slight incisions, and would, in general, be altogether unimportant if it were not for the fact that they are often inoculated with a peculiar poison, septic in its character, and therefore liable, if absorbed, to contaminate both the part and system. The instruments with which they are usually made are the scalpel, tenaculum, and needle, especially

the latter, as it is very apt to prick the fingers in sewing up dead bodies. Not unfrequently the inoculation is effected through the medium of a pre-existing abrasion, or scratch, of the presence of which the person may, at the time, be perfectly unconscious.

Of the *nature* of the poison which produces these severe effects nothing whatever is known. It is supposed that it is generated a short time before death, during the act of dying, or soon after dissolution, and that it is dependent for its development upon a vitiated state of the blood, though that state has not been pointed out. The idea is certainly plausible, supported as it is by the circumstance that the poison is generally most virulent when it is communicated by persons dead of puerperal fever, erysipelas, carbuncle, pyemia, carcinoma of the liver, and other kindred affections. Once formed, it becomes, like the virus of chancre, independent of the source whence it was derived. A good illustration of this fact was afforded me, a few years ago, in the person of a young cutler, who, in sharpening a case of dissecting instruments for me, which had not been used for nearly five months, slightly pricked one of his fingers. The consequence was that the hand and arm soon became exceedingly painful, as well as a good deal swollen, a characteristic red line extending up as high as the axilla, the glands of which were also in a short time involved in the disease. Nearly a month elapsed before he recovered from the immediate effects of his injury. A prick of the finger received in cleaning bones has sometimes been followed by severe suffering, and even loss of life. It is generally supposed that fresh bodies are more liable to convey the poison than such as have been kept for some time. This, however, is not always true; for in a subject which had been on hand for nearly a month, and which I dissected, in 1827, with Dr. Temple, of Virginia, that gentleman came very near losing his life from a little puncture which he received at the end of that time. It is worthy of remark that the body was that of an old female, who had perished from the effects of tertiary syphilis, as was apparent from the extensive disease of the skull and other portions of the skeleton, and that the attack of my friend was one of extraordinary severity.

Violent effects sometimes follow the dressing of wounds, in consequence of the contact of foul and irritating discharges, and several instances are upon record where surgeons have lost their lives from this cause. Similar results occasionally occur during the removal of cancerous growths, from inoculation with the secretions of the affected structures. The health of Professor Dudley, of Lexington, suffered seriously for several years from the inoculation of the hand with the matter of an encephaloid tumor during the amputation of an arm, performed for the purpose of getting rid of the disease. Dr. Physick met with a case where death occurred from the effects of a slight scratch with the shell of an oyster, received in the act of opening the animal.

The period of *latency* of this poison is usually very brief, or, more properly speaking, only a short time elapses before the occurrence of well-marked symptoms; for it is extremely probable that it begins its peculiar operation upon the inoculated structures almost immediately after its introduction, although its explosive effects may not manifest themselves nearly so soon. Generally they do not come on before the end of the second day, or the commencement of the third. In one case—the most remarkable, in this respect, on record—the symptoms were quite severe within the first twelve hours, and the patient died in forty hours from the receipt of the wound. In the case of Dr. Temple, above alluded to, violent indisposition ensued in less than thirty-five hours from the time he pricked his thumb. The accident happened late on a Saturday night, and on the following Monday morning, on his way to the college, he was taken so ill that he was obliged immediately to return to his room, which he did not leave again for nearly two

months. In the case of young Kissam, a medical student of New York, related by the late Dr. Godman, violent symptoms supervened in less than fifteen hours, although death did not occur until the fifth day. On the other hand, the patient occasionally remains free from suffering for a comparatively long period, as in the instance of Mr. Newby, an English surgeon, who punctured himself in opening the body of a child dead of enteritis, where no serious inconvenience was experienced until the commencement of the fourth day.

There is no question that some persons are peculiarly prone to suffer from this poison. I am acquainted with a physician who was formerly much engaged in pathological researches, who rarely opened a dead body without having a dissection boil upon his hand, thumb, or finger. Occasionally the consequences were more serious, the disease extending up the arm, along the course of the absorbents, as high as the axilla. Disordered health, hard study, general debility, mental anxiety, and other causes, no doubt, powerfully predispose to the development of the disease. A student who has for weeks inhaled the foul atmosphere of the dissecting-room, taken little exercise, and sat up late at night, eating, perhaps, withal, very heartily, will be much more likely to contract the disease, and to suffer severely, if he wound himself, than one who has taken better care of himself.

Symptoms.—The usual point of departure of this disease is the inoculated part, from which it rapidly spreads in every direction. A smarting, stinging, or burning sensation is generally the first circumstance which attracts attention. Upon looking at the part, it is found to be covered with a little whitish vesicle, perhaps hardly the size of an ordinary pin's head, filled with serum, and resting upon a hard, reddish base, extremely sensitive on pressure. When this vesicle breaks, as it usually does in twenty-four hours, a small ulcer is exposed, having a foul base, and discharging a thin, sanious fluid. The pain by this time is generally very distressing, burning, and pulsatile, depriving the patient of appetite and sleep; the sore enlarges; the swelling augments; and the surface feels exceedingly hot, tense, heavy, and numb. Generally a red line is seen extending from the seat of the inoculation along the arm to the axilla, marking the course of one of the absorbent vessels. As the poisonous influence spreads, the whole limb becomes enormously enlarged, pitting on pressure, and exhibiting a dusky, erysipelatous appearance. With this increase of swelling there is a proportionate increase of pain, which now amounts to torture; the limb feels like a mass of lead, and is completely deprived of the power of motion. In bad cases the inflammation extends to the top of the shoulder, the axilla, and even to the corresponding side of the trunk.

Such is the ordinary course of the disease; but cases occur where the order of the symptoms is reversed, the poison exploding in the axilla, and thence extending up the neck and down the side, the arm being, perhaps, almost free from inflammation, and there being no appearance, or only a very slight appearance, of disease at the seat of inoculation. The swelling, which sometimes reaches as low as the crest of the ilium, is, at first, of a doughy character, and of a pale pinkish hue; but it soon becomes hard, and assumes the peculiar erysipelatous blush already described as belonging to the more common variety. The pain is generally exquisite from the beginning, and is sometimes of itself sufficient to crush the system, before sufficient time has elapsed for the formation of the characteristic pustule. Such cases, which are always fraught with danger, have been known to terminate fatally in a few days.

It is not every case of inoculated dissection wound that gives rise to general symptoms; on the contrary, in the great majority of instances, the affection is altogether of a local character, being confined to the immediate neighbor-

hood of the original injury, diffused over the hand and wrist, or, it may be, limited to a few absorbent vessels, as seen by the red lines extending up the limb. Under such circumstances the patient may feel a little unwell, have some headache, and want of appetite, or suffer from chilliness and aching of the limbs, but there will be no serious disturbance of the general health. This will, however, be sure to occur, if the virus has gained full admission into the system, the symptoms showing themselves, on an average, in from twelve to twenty-four hours. The patient, at first, has merely a feeling of depression, or faintness, with a sense of chilliness, pain in the head, and slight derangement of the digestive organs. This prodroma is speedily succeeded by violent rigors, alternating with flushes of heat, nausea and vomiting, excessive restlessness, intense thirst, an increase of cephalalgia, a haggard, woe-begone state of the countenance, and indescribable despondency. The tongue is coated, the respiration hurried, the skin dry and hot, and the pulse sharp and frequent, but feeble. The bowels are either constipated, or, as more frequently happens, harassed with diarrhœa.

The disease, in its worst forms, soon reaches its crisis, the system rapidly falling into a typhoid state. During this downward course the symptoms above described become more and more marked; the tongue dry and brown; the pulse quick and tremulous; the countenance sallow and withered; the skin yellow and covered with clammy sweat; and the suffering indescribably severe. Delirium always sets in at an early period, and is a prominent symptom throughout. Death occurs in a few days to a few weeks, according as there is overwhelming exhaustion, or depression from gangrene and metastatic abscesses.

The appearances discovered on *dissection* are variable. When the case has run its course very rapidly, the internal organs may, apparently, be entirely free from disease, or there may be evidence of slight effusion into the chest, with an engorged condition of the lungs, the affected structures themselves being somewhat infiltrated with serum and lymph. Under opposite circumstances, there will generally be marks of inflammation of the arachnoid membrane, of the pleura, lungs, and peritoneum, with, perhaps, deposits of pus in the larger joints, among the muscles, and in the subcutaneous cellular tissue. The parts more immediately involved in the morbid action will be found to be enormously distended with the ordinary products of inflammation, highly softened at some points and greatly indurated at others, with here and there an abscess, and, perhaps, a gangrenous spot.

The *prognosis* of this affection may be deduced, in some degree, from the preceding remarks. When the disease is strictly local, much suffering may be the consequence, but ultimate recovery will be certain, the part immediately affected becoming, perhaps, withered and completely useless, as often happens when the lesion is seated in a finger. In the very worst cases death may occur in less than forty-eight hours, from the empoisoned condition apparently of the nervous system, with little or no evidence whatever of local disease. In another class of cases, also very bad, the patient may live five or six days, and then perish from the violence of the resulting inflammation; or he may linger on for weeks and months, abscess after abscess forming in the limb, on the side, or in other regions of the body, and finally die from constitutional irritation; or, lastly, he may, after having been for a long time on the very brink of the grave, struggle through the disease, and in the end make a good recovery, or he may remain permanently weak, and crippled in some internal organ.

Some persons are a long while in recovering from apparently very trifling accidents of this kind, depending either upon some idiosyncrasy, or upon some derangement of the general health. I myself formerly suffered a great deal in this way. On one occasion my thumb, which had been accidentally

pricked in examining the body of a woman dead of phthisis, remained sore for fifteen months; and a former colleague of mine, Professor Rogers, of Louisville, once had an affection of this kind upon one of his fingers which troubled him for upwards of three years. When the disease is thus protracted, the probability is that disorder of the digestive organs is essentially concerned in nursing its latent embers.

Treatment.—The treatment is preventive and curative. As soon as a wound of this kind has been received, the part must be most thoroughly washed, first with warm water and castile soap, and then by holding it under a stream of cold water, suction being at the same time performed with the mouth. If the wound be very small, or valvular, the best plan will be to dilate it, as a preliminary step, in order to facilitate the extraction of the poison. Whatever method be adopted, the operation is completed by effectual cauterization with the acid nitrate of mercury, inserted into the wound by means of a small pointed stick of wood. In the absence of this article, which I prefer to everything else for the purpose, use may be made of nitrate of silver, butter of antimony, hydrochloric, nitric, or sulphuric acid, or a saturated solution of equal parts of alum and nitre. Persons who are in the habit of suffering from dissection wounds should always employ some precautionary measures in examining dead bodies, such as anointing the hands well with pomatum, lard, tallow, or simple cerate, and even wearing thin leather gloves, any fluids that may be present being previously removed by an assistant. Fortunately, since the introduction of chloride of zinc injections now in such common use in our schools, suffering, in any form, from dissection wounds is much less common than formerly. In the Jefferson Medical College, no case of a serious character has occurred since this article first began to be used by Dr. Wallace, the able demonstrator of anatomy. The pupils of the other schools of this city have, I believe, been equally exempt.

If the case has been neglected, or if, in spite of the precautions here mentioned, a vesicle forms at the site of the wound, this should be at once opened by a free incision, when, bleeding having been encouraged by immersion in warm water, the part should be thoroughly cauterized with the nitrate of silver, or wet with the dilute tincture of iodine, an ectropic effect being still hoped for, though not likely to be attained. Warm water-dressing with laudanum is then applied, and the patient must take a brisk cathartic, keep quiet, and live light, watching the progress of events. If the disease extend, the indications will be to limit its action as much as possible, and to sustain the system under the approaching struggle. In view of the inevitable typhoid tendency, all exhausting remedies must be carefully withheld, especially the lancet and active purgation. If nausea and vomiting are present, a mustard and salt emetic, or an emetic of ipecacuanha is administered, and the bowels and secretions are regulated by mercurial laxatives, aided, if there be high fever, by tepid sponging of the surface, and the use of the neutral mixture. To relieve the excessive pain and restlessness, opium must be given in large and sustained doses, united, if there is much dryness of skin, with a little antimony or ipecacuanha. The distressing headache which so often attends the disease must be treated with cold applications to the scalp, the hot foot-bath, and the exclusion of light and noise; but anodynes will, in general, afford more ease than anything else. If inflammation of the arachnoid is threatened, a few leeches may be applied to the temple, or a blister to the nape of the neck. The moment typhoid symptoms appear, the proper remedies will be milk punch, quinine, iron, and ammonia. In the more terrible forms of the disease, commencing with violent pain in the axilla, side, and shoulder, these means should be used at once, in large quantity, especially the brandy, with the hope of neutralizing the poison, and thus arresting its zymotic tendency. Although we know nothing of the nature of this poi-

son, yet it is not at all improbable, judging from the good effects which are said to attend the employment of alcohol in the treatment of snake bite, that brandy and other spirituous liquors might be of great service in dissection wounds. The suggestion, at any rate, seems to me to be worthy of attention. Their beneficial effects might possibly be increased by the free use of carbonate of ammonia; certainly by that of anodynes.

As it respects the parts more immediately concerned in the disease, the best remedies, after the first ten or twelve hours, will be the warm water-dressing, medicated with laudanum and Goulard's extract, acetate of lead, or hydrochlorate of ammonia, preceded and accompanied by the dilute tincture of iodine. Lint wet with oil of turpentine and laudanum sometimes affords great comfort. Blisters and nitrate of silver are objectionable, their vesicating effects interfering with other applications. Leeches are occasionally productive of great relief, but they are not to be used, except in very robust subjects, and in the early stage of the affection. When there is much œdema, the pressure of the bandage will be useful. Tension is relieved, and matter evacuated, by free and timely incisions.

Covering the parts thickly with strong mercurial ointment, along the whole track of the inflamed lymphatic vessels, is sometimes useful in arresting the spread of the morbid action, and promoting the absorption of effused fluids. Dr. Wallace speaks in terms of high commendation of this mode of treatment, and the facts which he has communicated to me warrant me in saying that it is worthy of fair trial in the early stages of every case of the disease likely to come under the notice of the practitioner.

The secondary effects of this class of injuries are removed by change of air, attention to the secretions, tonics, iodide of potassium, and cod-liver oil. In obstinate cases, a mild course of mercury may be necessary. The most eligible topical remedies are evaporating spirituous lotions, or lotions of acetate of lead, Goulard's extract, or hydrochlorate of ammonia. Sometimes a deep and free incision will afford more prompt relief than anything else.

b.—*Malignant Pustule.*

This is a disease of the cutaneous and cellular tissues, commencing in the form of a little vesicle, and rapidly terminating in gangrene, its cause being a septic virus generated by horned cattle laboring under murrain. The French surgeons usually describe it under the name of *charbon*, and in many parts of Europe it is vulgarly known by the term Persian fire, or malignant pimple, the former having reference to the horrible pain which attends it, the latter to its destructive tendency.

The disease is met with in various sections of the Union, though it appears to be less common here than in Europe. Cases of it have occasionally been noticed in this city and its vicinity, and I have myself seen it in Kentucky, where, as well as in Ohio, Illinois, Tennessee, Mississippi, and Louisiana, murrain sometimes prevails as an epidemic. In the latter State it caused great havoc, in the summer of 1851, among the stock of the parishes of St. Mary and Vermilion, carrying off an immense number of cattle, as well as a considerable number of horses and mules, among the latter of which it first broke out. Hogs and dogs that ate of the carcasses took the distemper, and soon died of it. Several cases occurred in which the disease was communicated to the human subject by the green carrion fly. During my residence at Louisville four cases of the malady came under my observation, all having been contracted in flaying and eviscerating cows dead of murrain. Three of the cases were males.

In Europe, malignant pustule has hitherto been chiefly observed on the continent, particularly in France, Holland, Switzerland, and Germany. The

inhabitants of Great Britain appear to be nearly exempt from it; at least we may so infer from the fact that hardly any allusion is made to the disease in any of their works. In France it is said to be very common in Lorraine, Franche-Comté, Burgundy, Provence, Lyonnais, and some of the other southern regions, although no part is wholly exempt from it. It appears to be rare at Paris, but frequent at Marseilles, showing that locality is favorable to its production.

The disease is most common upon the hands and face, because these parts, being habitually exposed, are most liable to inoculation. Persons who work among hides, both green and dry, tanners, butchers, shepherds, blacksmiths, and veterinary surgeons, are most liable to its attacks. It is often contracted by common people in flaying and eviscerating animals dead of murrain. It has also occurred from introducing the hand into the rectum and vagina of a cow laboring under putrid fever. Cases have been observed where the virus was conveyed by insects from the diseased brute to man. I have already alluded to the fact that it may be communicated by the green carrion-fly. It would seem that certain parts of an animal, as the hair and wool, retain the poisonous matter for a long time, and even after they have been most thoroughly washed and cleansed. Dr. Bourgeois refers to the case of a man in which the disease was apparently produced by picking the horse-hair taken out of an old sofa. A very common way in which it is contracted is by handling dry hides. Even tanned leather is said to be capable of communicating the affection. It has been conjectured that it might be contracted by eating the flesh of brutes dead of murrain, but we know of no facts that justify such a conclusion. Whether it can be conveyed from one human being to another, or from man to the inferior animals, is also undetermined.

What the nature of the *poison* is which produces this disease, or when, where, and how it is developed, is a question which we have no means of solving. It is evidently of a zymotic character, like the virus of smallpox and chancre, and is generated by most of our domestic animals, especially cattle dead of murrain, its occurrence being less frequent in the horse, mule, ass, and sheep. It is also probable that it may be generated by birds, as the hen and turkey. In a case which occurred a number of years ago in Kentucky, and of which I have collected the particulars, the disease was contracted by three persons in picking and eviscerating several buzzards with a view of extracting their oil. Both the hands and forearms of each individual were inoculated. Violent local and constitutional symptoms showed themselves by the end of the second day after the operation, the parts becoming excessively swollen and painful, and covered with numerous vesicles, which, upon bursting, exposed ill-looking ulcers, discharging a thin sanious fluid, and remaining open for many weeks. The inflammation reached up to the axilla, the glands of which were enormously enlarged, some of them finally suppurating. Recovery took place only after a long time, and after great suffering, reducing the patients to the very verge of the grave. It is difficult to say whether, in these cases, the poison was actually generated by these birds, or merely conveyed by them through their feathers. However this may be, the facts involved in them are of much interest.

Symptoms.—The period of latency of the disease is very brief, generally, perhaps, not exceeding a few hours. The first distinguishable evidence of the operation of the poison is a small reddish point, not larger than a pin's head, and the seat of a burning, itching sensation, attended with a desire to scratch. Gradually spreading in size, it is speedily followed by a little vesicle, filled with a thin, turbid serum, which, in its turn, is soon replaced by a pustule of a yellowish, brownish, or reddish color, according as it contains pure pus, or pus mixed with blood. Around the pustule is a distinct areola,

not unlike that of smallpox; the part is exquisitely painful, hard, and circumscribed, allowing itself to be raised up from the subjacent structures. Continuing to extend, it becomes gradually more and more prominent, and at length acquires a base equal to the diameter of a twenty-five cent piece, half a dollar, or even a dollar. Meanwhile the pustule bursts, revealing a foul, gangrenous ulcer, discharging a sanious, fetid, irritating fluid, sometimes quite abundant. Long before the disease has reached this crisis, the affected limb is enormously swollen, stiff, numb, heavy, and exquisitely painful, the inflammation often reaching as far as the shoulder, and seriously involving the axillary glands. The number of vesicles is variable; in one of my cases there was only a single one; in another there were two, one on the hand and the other on the forearm; in the third there were five; and in a fourth the whole arm and hand were literally covered with them, their number amounting to several hundred. When numerous, they are always proportionably small, not exceeding the diameter of a currant or a split pea.

When the disease is seated in the face, the swelling is generally so great as to give rise to the most hideous distortion, it being almost impossible to distinguish one feature from another. The eyelids are closed and distended like bladders, the lips are several times the natural thickness and hardly movable, the cheeks are enormously puffed out, and the natural line of demarcation between the jaw and neck is completely effaced. The face, in fact, looks more like a dark, shapeless mass than a human countenance. When seated here, the malady is apt to extend to the throat, causing great swelling of the palate and tonsils, attended with immense difficulty of deglutition and respiration, and sometimes followed by suffocation.

The constitutional symptoms are those, in the first instance, of general *malaise*, or uneasiness, with a feeling of depression and foreboding of evil. Presently high fever sets in, preceded and accompanied by rigors; and then, in a very few days, the patient sinks into a low typhoid condition, commonly attended with low muttering delirium, loss of sleep, and excessive restlessness. Death often follows in three or four days from the first manifestation of the disease; but sometimes it does not take place under a week, and in a few rare cases not before the end of a fortnight. The patient's habits and state of health at the time of the inoculation, the quantity of matter absorbed into the system, and the nature of the treatment, all, doubtless, exercise an important influence upon the issue of the case. As a general rule, however, it may be stated that few recoveries occur under any circumstances.

Dissection has hitherto thrown no light upon the nature of this disease. The internal organs, especially the lungs, are generally considerably engorged; and in a few rare instances metastatic abscesses have been found. The affected limb is usually distended with serum and lymph, the latter of which often exists in large quantity, giving the parts their characteristic hardness, and exhibiting occasionally, here and there, a greenish, gelatinous appearance. In one case I discovered several depôts of blood. If the patient survive sufficiently long, abscesses will be found in the subcutaneous cellular tissue, or evidences of purulent extravasation. The inflammation seldom extends deeply among the muscles, being apparently limited by the aponeuroses. The axillary glands are sometimes much enlarged, softened, discolored, and infiltrated with various kinds of fluids. In the immediate neighborhood of the vesicles the parts are of extreme density, cutting with a grating noise very much like fibro-cartilage. Doubtless the veins and absorbents are implicated in the disease, but in what manner, or degree, has not been ascertained. There is usually, after death, a tendency to rapid decomposition.

Treatment.—The treatment is prophylactic and curative. As soon as it is ascertained that an individual has been inoculated, the part should be im-

mediately cut out, after which it should be well washed with warm water, to encourage vascular disorgement, and then still further drained by the cupping-glass, these means being followed by thorough cauterization with dilute acid nitrate of mercury or the solid nitrate of silver. Or, instead of this, the part is destroyed with the Vienna paste, or the hot iron. When early and effectual riddance has been neglected, or found impracticable, the treatment must be conducted upon general principles, by mild, soothing, and supporting measures. All sanguineous depletion, both by the lancet and leeches, active purgation, and other debilitating means are avoided, as calculated, inevitably, to hasten the fatal crisis. The secretions, always seriously deranged in this disease, are rectified by small doses of calomel, the excessive pain is allayed by full doses of morphia, and the system is sustained by the liberal use of brandy, quinine, and other stimulants. The limb, placed in an elevated position, is wrapped up in light flannel cloths, wrung out of a tepid solution of lead and opium, and if there be much tension and throbbing, early and free incisions are practised to afford vent to the effused fluids. Sometimes great comfort is experienced from the employment of an emollient cataplasm, covered with laudanum and olive oil. Feter is allayed by the chlorides, which may also sometimes be advantageously given internally. Should convalescence take place, the cure must be promoted by nutritious drink and food, and change of air.

CHAPTER X.

EFFECTS OF INJURIES UPON THE NERVOUS SYSTEM.

UNDER this head may be included the more immediate effects of injuries, as nervous depression, or shock, and traumatic delirium, as it has not inaptly been termed. These effects may succeed to almost any lesion, however trivial or complicated, their production being greatly influenced by the temperament, habits, age, and idiosyncrasy of the individual; and they deserve the most careful study, inasmuch as they are frequently followed by the worst consequences. The subject of tetanus might properly be included under the present division, but as this disease occasionally arises without any external injury, the consideration of it will be postponed until I come to speak of the affections of the nerves.

SECT. I.—PROSTRATION, COLLAPSE, OR SHOCK.

Shock may be defined to be a depression of the vital powers, induced suddenly by external injury, and essentially dependent upon a loss of innervation. It bears, in effect, the same relation to the nervous system that syncope does to the vascular; in the one case, the result is caused by a diminution of nervous fluid, in the other by a diminution of blood; in both, the consequence is more or less prostration, with perturbation of body and mind, extremely variable both as to intensity and duration. When nervous shock is severe, it may instantaneously terminate in death, as so often happens in falls and blows upon the head; more generally, however, after having continued for an indefinite period, it passes into reaction, the powers of life gradually coming up, as the different organs and the general system regain their nervous fluid. The most severe and fatal cases of shock are generally those that supervene upon direct injury to the great nervous centres, as the brain and spinal cord; no less disastrous effects occasionally succeed blows upon the epigastric region, in consequence of the violence thus inflicted upon the solar plexus of nerves. In some of these and other similar instances life is destroyed with the same rapidity as by lightning, the nervous fluid being instantaneously annihilated without the individual being rendered conscious of his doom. Such cases have their counterparts only in those frightful hemorrhages in which, a large artery, as, for example, the aorta, being divided, the patient perishes in a few seconds from loss of blood. The blood has long been known by physiologists as the vital fluid, so necessary has its integrity always been regarded to the well-being of the system and the maintenance of healthy action. But it is certainly not the only fluid entitled to this distinction; the nervous fluid is both more subtle and more important as a life preserver. When blood flows away in a mighty and overwhelming torrent, the person dies, and life is then said to be destroyed, as it certainly is, by the excessive sanguineous drainage. But in shock, the same effect may happen, and yet the body be literally surcharged with blood, not a single drop perhaps

having been spilled in the accident causing the fatal result. Thus, of the two fluids, the nervous is, in every respect, the more important, because the more essential to life; and its disturbance is therefore a more frequent cause of death.

It would be out of place in a work on surgery to inquire into the nature of the nervous fluid, or to attempt to settle the question, so often propounded, whether there really is any fluid of this kind at all. Such an investigation belongs more properly to physiology; but there is no sensible practitioner who has not occasion daily to lament, in the exercise of his profession, his want of knowledge of the functions of the nervous system, and I feel sure that cases of disease and accident are constantly permitted to slip through our hands simply because of our forgetfulness that there is such a thing as a nervous fluid. No one is unmindful that a patient has blood, that a certain quantity of this fluid is necessary to the maintenance of health and life, and that, like the solids, it is subject to a thousand diseases, often of themselves sufficient to cause death. Unfortunately, we can never acquire any intimate knowledge of an agent so subtle as the nervous fluid; like the electric, or galvanic, which it is supposed to resemble, we can know it only by its effects.

Shock may be produced by a great variety of *causes*, some of a bodily, others of a mental character; some external, others internal. It may be purely nervous, or partly nervous and partly hemorrhagic, that is, dependent upon the conjoined loss of the nervous and sanguineous fluids. The nature and extent of shock are greatly influenced by the state of the general health at the time of the accident, the amount of the injury, the importance of the part more directly assailed, and, also, in an especial manner, by the idiosyncrasy of the individual. There are some persons, soldiers, for example, of the most undoubted courage, men who would not hesitate to face the mouth of the cannon, who fall into a state of the most profound prostration from the most trifling accident; who turn pale and tremble like a leaf; whose minds are perfectly bewildered, and who are, as it were, completely stunned, from injuries so insignificant as not to affect, in the slightest degree, ordinary persons. Such an occurrence can only be explained by a reference to idiosyncrasy; and it has its counterpart in those persons who, although extremely plethoric, faint from the slightest loss of blood, or even from the mere sight of that fluid. There are other persons, on the contrary, whom hardly any accident, however severe, can shock; they are insensible to pain; their nervous system is obtuse; nothing affects them, either bodily or mentally; a severe blow may stun them, but the effect is transient; in a few minutes they are completely restored to consciousness and power. Here, again, is an example of idiosyncrasy, a peculiarity of organization; in the former case, the individual is all nerve, all sensibility; in the latter, all blood, all muscle. But it is not only the nervous and irritable that suffer from shock; the fat and corpulent are prone to be affected by it from the slightest causes, and hence such persons seldom make good subjects for the knife; they bear the loss of blood badly, and are extremely liable to perish from erysipelas and pyemia, in consequence, as it appears to me, rather of loss of nervous fluid than from any toxic state of the blood, or blood-poisoning, properly so-called. There are some individuals whom the slightest operation will kill; touch them, and they are sure to die; they are destitute of life-power, and incapable of resisting the slightest shock. The fainting produced by the pricking of a needle and the introduction of a bougie affords a familiar illustration of shock from trivial causes.

Among the external causes of shock deserving of particular notice, on account of their crushing effects, are injuries upon the skull and spine, such as are produced by a fall or blow; gunshot, railway, steamboat, and factory wounds; dislocations and fractures; violent sprains, burns, and scalds; and

some of the more severe operations, as the extirpation of enormous tumors, and the amputation of the larger limbs, even when not attended with any considerable hemorrhage.

Severe shock is frequently produced by internal causes. One of the most familiar examples of this kind is afforded in perforation of the bowel, consequent upon typhoid fever, and followed by extravasation of fecal matter. The moment this takes place, the shock is immense; if the patient had been struck severely on the head, it could not be more so; in some cases it is so overwhelming as to destroy life in a few hours. The pain which attends the passage of a gall-stone, or of a urinary concretion, is often followed by similar results; extravasation of urine may be mentioned as another example. Many a woman has perished from shock induced by severe labor; and the excessive prostration consequent upon apoplectic seizures is familiar to every practitioner.

Mental shock is often extremely severe, and is occasionally followed by the worst consequences, especially when it occurs during the progress of a severe illness, or after a severe surgical operation. Fright is perhaps the worst of the causes of mental shock. The effect of terror, in suddenly exhausting the nervous power, is well illustrated by the history of those persons, who, being sentenced to be bled to death, actually died on hearing water trickling into the basin, which they supposed to be blood issuing from their veins, after the arm had been slightly pricked, although no vessel had been opened. It is related of Desault that he one day lost a patient, about to be lithotomized, from sheer fright. The man, who was very cowardly, fainted and died under the impression that the operation was progressing, when this distinguished surgeon was, in fact, only tracing the line of the intended incision on the perineum with his nail. A sick, bedridden person, in danger of being burnt to death, has been known to perish from shock, brought on by excessive mental trepidation. The receipt of disagreeable news, the sudden loss of property, and, in short, violent mental emotion of almost any kind, may give rise to similar effects.

Mental and corporeal shock are often combined; and, when this is the case, it is not uncommon to see the former predominate, in a very marked degree, over the latter. The soldier on the field of battle may suffer from bodily shock induced by a severe wound; he may feel that he is badly hurt, but still he is sanguine of recovery, and cheerfully and manfully bears up under his affliction. The surgeon examines his wound, and perceiving its grave character, informs him that it will probably cost him his life. Instantly the case assumes a different aspect; the system is overwhelmed with perturbation and excitement; the vital powers are depressed to the utmost; and death takes place perhaps several days sooner than it would otherwise have done.

The *symptoms* of shock, although extremely variable, are generally such as attend syncope from loss of blood, or concussion of the brain, which is itself only a form of nervous depression, or expenditure of the vital forces. If the accident has been slight, the effect will be that of a moderate stun, that is, the patient will experience some degree of mental confusion, look pale, and feel weak and tremulous; objects will appear dark to him, and he will probably reel, if not fall. Presently, however, especially if he lies down, reaction will take place, and in a short time he will recover both his mental and physical powers, so as to be able to converse, act, and walk in the same manner as before he was hurt. When the injury has been severe, the effect upon the nervous system will of course be proportionably greater. The patient, unable to support himself, falls to the ground, often as he does so inflicting serious violence upon his person. Consciousness, special sensation, and volition are perhaps completely abolished; the countenance is deadly

pale, the respiration is slow and feeble; the pulse is small, fluttering, and, at times, altogether imperceptible; the extremities become rapidly cold; and the surface is soon bathed with an abundant clammy sweat. Gasping and sighing, with convulsive tremors, are often present, and, in general, but too clearly denote the serious character of the lesion. Not unfrequently there are involuntary discharges from the bowels, with nausea and even vomiting.

The duration of these symptoms is subject to no little diversity; at times they pass off in a few minutes, or, at farthest, in a few hours; at other times, they last for several days, and even then perhaps they do not disappear entirely, one or more hanging on for a considerably longer period. When the shock is very severe, death may occur instantaneously, or the case may linger on for some time in a state of doubt and uncertainty, with, now and then, an attempt at reaction, and at last prove fatal. Instances occasionally occur in which, after tolerably complete reaction has been established, the system sinks again into a partial state of collapse, the vital forces having evidently not sufficient stamina to maintain the action of the brain and heart. Such cases are very apt to end fatally, generally within the first twenty-four hours after their commencement.

Reaction, after shock, is denoted by a gradual, or more or less rapid resumption of the functions of the different organs, which awake, so to speak, from their slumber, and spring back again into life and happiness. One of the first evidences of this change is a return of the color of the face, with an increase of the heart's action, as indicated by the state of the pulse, which is not only stronger and fuller, but more steady and regular; the respiration is more free and open; the surface becomes warmer and dryer; the sphincters again obey the will; and the mind regains its self-possession and power of action. Often the first symptom of reaction, after severe shock, is vomiting, followed by complete clearance of the contents of the stomach, itself generally a favorable sign, as it is denotive of a return of muscular power.

There is a form of shock which has been called, not inaptly, insidious, as the symptoms are generally of a masked character, and are therefore well calculated to deceive both the patient and practitioner. The person, although severely injured, congratulates himself upon having made an excellent escape, and flatters himself that he is not only in no danger, but that he will soon be well; in fact, to look at him one would hardly suppose, at first sight, that there was anything serious the matter with him; the countenance appears well, the breathing is good, the pulse is but little affected, except that it is too soft and frequent, and the mind, calm and collected, possesses its wonted vigor, the patient asking and answering questions very much as in health. But a more careful examination soon serves to show that deep mischief is lurking in the system; that the machinery of life has been rudely unhinged, and the whole system profoundly shocked; in a word, that the nervous fluid has been exhausted, and that there is not enough power in the constitution to reproduce and maintain it. The skin of such persons soon assumes an icterode, or sallow, cadaverous appearance, feeling at the same time doughy and inelastic; the extremities become deadly cold; the pulse makes a desperate effort at seeming excellence, but is, at best, weak and tremulous; there is little or no pain; and the patient is altogether too composed and tranquil for the amount of injury he has sustained. The system does not seem to be conscious of what has occurred; its sensibilities are blunted, and hence it is incapable of suffering. Nature, to use the language of Hunter, does not feel the injury.

The countenance, in this form of shock, has often a peculiar melancholy expression, as if foreshadowing the fatal event; a sad smile plays upon the lip, and illumines the lower part of the face, while the upper part, on the contrary, wears a gloomy aspect, in striking contrast with the other. The

forehead, as the patient looks at his attendants, especially if he has just been roused from sleep, is strongly knit and wrinkled, giving it a scowling and sinister air. As the case progresses, the brain gradually sinks into a comatose condition, the signs of prostration become more pronounced, and death finally occurs from mere exhaustion, life, under such circumstances, seldom lasting longer than three or four days.

The *treatment* of shock must be conducted with two objects in view; the first is to promote reaction, and the second to moderate supervening inflammation, for to prevent it altogether is by no means always possible.

To recover a patient from shock, he should immediately be placed recumbently, everything tight or constricting should be removed from his person, free access of cold air should be provided, cold water should be dashed upon the face, smelling bottles should be held near the nose, and sinapisms should be applied to the extremities and precordial region. If the case be unusually severe, and apprehension is entertained for the patient's safety, stimulating injections should be thrown into the rectum, and turpentine rubbed along the spine. If deglutition is practicable, brandy and water should be given, but in attempting to convey this or any other fluid into the stomach, great care must be taken, otherwise the liquid may descend into the wind-pipe, and so cause strangulation. The most prudent plan, under such circumstances, is to introduce the drink with a spoon, the mouth being previously forced wide open, and a powerful effort made to excite the patient's attention by hallooing loudly into one of his ears. If he cannot swallow, no attempt should be made at compulsion, but, for the reasons just mentioned, the effort should at once be discontinued.

In the milder cases of shock, the most simple treatment will often suffice to bring about reaction; as, for example, the recumbent posture, a drink of cold water, and the use of the fan and smelling bottle. The blood and nervous fluid soon resume their wonted channels, and the vital forces rapidly regain their supremacy.

In the mental form of shock, a soothing word, or an assurance of absence of danger, will frequently go farther in promptly effecting restoration than the most powerful stimulants, steadily and regularly administered. Persons suffering from this variety of prostration are frequently much more frightened than hurt, and promptly regain their animation and self-possession when they are told that their injuries are altogether of a simple, trivial character, devoid of all danger, both present and future.

Occasionally reaction is sadly interfered with by an overloaded and oppressed stomach, as when the accident has occurred soon after a meal. In such cases, the patient often lies in a state of deadly pallor, with more or less retching, for hours, before he can shake off the oppressive burden. The indication obviously is to assist nature in her efforts at emesis, by the administration of a dose of alum, ipecacuanha, or sulphate of zinc, or, what, perhaps, is better, under such circumstances, equal parts of common salt and mustard. Serious lesion of the brain is hardly to be considered as a contra-indication to such a course, when it is recollected that the digestive powers are completely suspended, and with what difficulty reaction takes place when the stomach is oppressed by a heavy meal.

The foolish and reprehensible practice of bleeding persons laboring under the exhaustion of shock, once so common, has become completely obsolete. No surgeon should do anything without a reason, and it is therefore difficult to perceive what could ever have induced a procedure so contrary both to physiology and good sense. In the opinion of the vulgar, there are no cases in which it is not proper, immediately after such an accident, to draw blood from the arm; but assuredly no practitioner would yield his judgment to such an erroneous view, and perform an operation that might speedily prove

destructive to his patient. Fortunately, whenever such an attempt is made by the ignorant and thoughtless charlatan, the blood generally refuses to flow, and consequently no harm is done.

The second indication is to moderate the resulting inflammation. To do this, much may be accomplished in the way of prevention, by letting on the reaction gradually; avoiding, on the one hand, the undue use of stimulants, and, on the other, cautiously interposing antiphlogistics as occasion may arise for their exhibition. Proper allowance is made for the apparent violence of the symptoms, the excitement without power; the struggle may be furious, but will in all likelihood be brief, for if the previous depression has been at all severe the flame will ere long cease of its own accord, or readily yield to the influence of very simple means, such, for instance, as sponging the surface frequently with cool or tepid water, and administering a little morphine and antimony, aided by rigid abstinence, and perfect tranquillity of mind and body. Bleeding should be practised only in young and plethoric subjects, with a tendency to serious inflammation of some important internal organ, and where, consequently, the fire is real, and not merely apparent. The opposite course often exerts a most pernicious influence upon the patient's recovery; impairing his vital powers, and preventing the system from keeping up a due supply of healthy nervous fluid, so conducive to the restoration both of the part and system. As the secretions are commonly materially deranged in all cases of severe shock, early and effectual means should be adopted for their correction and improvement; a gentle mercurial purge will often admirably fulfil the indication, and render any further use of this class of remedies unnecessary. The diet for the first few days should consist mainly of animal broths, aided, if necessary, by milk punch, or wine whey, and cautiously followed by food of a solid and more substantial character. Starvation, in cases of severe shock, is not to be thought of. Such a course cannot be too pointedly or too forcibly condemned, as it is contrary alike to sound sense and the dictates of an enlightened experience.

Anodynes are always borne well after severe shock, and should be administered early and freely, to allay vascular action and tranquillize the nervous system. The most suitable article will be morphine, or the ammoniated tincture of opium, either alone, or conjoined with valerian; the latter remedy being especially serviceable in nervous, hysterical persons. If the vital powers flag sensibly after the occurrence of reaction, recourse must be had, in addition to anodynes, to quinine, carbonate of ammonia, and brandy, liberally and diligently administered. Determination to internal organs is met by leeches and blisters.

SECT. II.—TRAUMATIC DELIRIUM.

One of the most unpleasant effects with which the surgeon has to contend in the treatment of wounds and other injuries, as well as after surgical operations, is the occurrence of delirium, at a period, too, perhaps, when everything is apparently progressing in the most favorable and gratifying manner. All of a sudden, the nature of the case undergoes a remarkable change for the worse; the horizon, just a moment before perfectly calm and serene, like the summer's sky, is almost instantly overcast by a dark, lowering cloud; the system is thrown into nervous tremors, and the mind, agitated with disagreeable forebodings, is absorbed in some peculiar fancy, in which the patient imagines himself pursued by his enemies, or annoyed by persons peeping at him through the keyhole of his door, making grimaces at him through the window, or concerting measures for his destruction. Great diversity obtains in respect to the manner in which the disease is ushered in.

In some cases the symptoms are apparently of a hysterical character, the patient laughing and talking in a loud, boisterous, and incoherent manner; or perhaps indulging in unmeaning jokes about the nature of his disease, the way in which he was hurt, or the conduct which he exhibited during the operation he has undergone. In another class of cases, by no means uncommon, he is completely absorbed in his business; he harnesses his horses, hitches them to the carriage, and swears at them because they do not move to please him. In some cases, again, he is seized with a species of religious phrensy; he prays and sings, and utters pious exclamations. Occasionally, he labors under some demoniacal delusion; he fancies that the devil has possession of him, and that he is about to be carried to the infernal regions. Finally, there are instances in which the patient is sadly annoyed by the idea that he is pursued by snakes, dogs, or rats, or that some horrible reptile is trying to creep into his throat. In short, there is no end to these delusions, which are often as ludicrous to the observer as they are distressing to the patient, to whom they are always a source of severe suffering, not less so than if they were real.

The cause of these symptoms is not always apparent. In the great majority of cases, they are produced, either directly or indirectly, by the inordinate use of alcoholic spirits, suddenly interrupted by the occurrence of a severe injury, attended, it may be, by dreadful shock, or copious hemorrhage, thus greatly increasing the susceptibility of the nervous system to external and internal impressions. It is not necessary for their development that the individual should have been a habitual drunkard; they often show themselves nearly as readily if he has merely been a free drinker without having carried the use of liquor to the extent of intoxication. On the other hand, they occasionally occur in persons of the most temperate habits, who have perhaps never used alcohol in any form, or for any purpose whatever. Dupuytren, who first called attention to this variety of the disease, has given it the name of nervous delirium, and in the paper which he has published on the subject he has reported a number of cases in which it supervened upon various kinds of injuries and operations, some of them of a very trivial character, or such as usually produce no unpleasant results of any description, the patient rapidly recovering from their effects. It cannot be doubted that, in these cases, the affection is generally of a purely nervous nature, arising from the effects of the commotion inflicted upon a delicate and highly susceptible constitution. Under such circumstances, it is often mixed up with the effects of shock, rendering it difficult, if not impossible, to distinguish them accurately from each other. All practical surgeons have frequent opportunities of witnessing such cases. So far as my observation extends, I am not aware that any class of injuries is entirely exempt from the disease; sometimes the most trivial scratch, or contusion, is followed by it. Corpulent persons, who generally bear injuries and operations very badly, are particularly prone to this form of delirium. Burns and scalds, railway lesions, lacerated wounds, and compound fractures may be enumerated as among the more powerful causes of the disease. It has been thought that children are less liable to suffer from nervous delirium than adults and elderly subjects; but this is certainly not true; on the contrary, such is the susceptibility of the system at this tender age to physical and mental impressions, that the slightest accident is often sufficient to develop it. If women are less frequently affected than men, it is simply because they are less exposed to the various exciting causes of the disease. There is certainly every other reason why they should suffer quite as much as men, if indeed not more.

Nervous delirium generally comes on within the first twenty-four or forty-eight hours after the application of the exciting cause; it may last for a variable period, but rarely longer than five or six days, and may terminate either

in health, or in death, according to the gravity of the injury that has produced it. Its leading symptoms are a confused, wandering, or flighty state of the mind, with excessive vigilance; incoherency of speech and manner; absence of fever; an open, moist state of the skin; and little or no excitement of the pulse. The eyes have generally a wild expression, and the patient is easily disturbed by noise and light, as well as by the presence of his attendants. The appetite is usually impaired, the bowels are costive, the urine is scanty and rather high-colored, and the feet are disposed to be cold. If the patient be spoken to, he is generally readily roused, but soon lapses into his former condition.

Nervous delirium, properly so called, is easily distinguished from delirium tremens by the absence of tremors, which form such a striking feature in the latter disease as to be characteristic. In delirium tremens the limbs are in a constant trembling condition; the symptom comes on early in the attack, and always lasts until the effects of the disease are nearly worn off. When the delirium is fully developed, the hands and fingers are incessantly in motion, the patient carrying them to his mouth, face, and head, as if he were desirous of swallowing something, or removing some imaginary object from his person. The countenance is usually flushed, the eyes are deeply injected, the pulse is small, frequent, and quick, and the mind is roused with difficulty. Added to these circumstances is the history of the case, which generally affords valuable, if not conclusive, information respecting the patient's habits prior to his attack.

Delirium tremens, the result of alcoholic stimulation, is an extremely common occurrence after all severe operations and injuries, and is one of the most serious causes of their mortality. Hence operations should never, if possible, be performed upon this class of persons so long as they can be put off, or without due preparation of the system; special care should also be taken to avoid shock and loss of blood, as these are two of the most powerful predisposing causes of the disease.

It is well known that persons addicted to the immoderate use of opium and tobacco are liable to suffer from a peculiar form of nervous delirium after severe injuries and operations, characterized by excessive wakefulness, and a sense of indescribable wretchedness, with a bewildered and confused state of the mind, from which it is sometimes extremely difficult to rouse them, so as to induce them to take their necessary food and medicine. It is not improbable that the excessive use of coffee and tea may, in persons of a very nervous, excitable temperament, produce similar effects.

In general, as was previously intimated, traumatic delirium usually sets in at an early period after the application of the external injury that provokes it; sometimes, however, the patient, perhaps contrary to expectation, goes on exceedingly well for some considerable time, happily surmounting the primary effects, but suffering severely from the secondary, the consequence commonly of profuse, unhealthy, and exhausting suppuration. Again, instances occur in which he may have several attacks of this nervous suffering, with a variable interval of from several days to several weeks, during which the mind may be perfectly clear and tranquil, the patient bearing up manfully under his disorders, sanguinely and fully anticipating none other than the most favorable termination.

Traumatic delirium, however induced, or in whatever manner it may present itself, is often extremely difficult of management. In its worst forms, the mind is frequently so completely disordered as to render confinement of the patient with the strait waistcoat an indispensable item of the treatment. This is the more necessary when, as sometimes happens, the patient is disposed to tear off the dressings from his wounds, to commit suicide, or to hurt his neighbors and nurses. There is a remarkable circumstance which

has been noticed by all practitioners in this class of persons; I allude to their utter indifference to pain. So great is this, in many instances, that they will not only uncover their wounds, but absolutely take a sort of pleasure in handling and picking them. Dupuytren refers to the case of an old man who, having been operated upon for strangulated hernia, tore away the dressings from his groin, and composedly squeezed his bowels, his friends all the while thinking he was getting on most admirably, such was his calm and quiet demeanor as he lay in bed.

One of the most important indications, then, is to set a careful watch over the patient, in order that he may not do any harm either to himself or others; in wounds and fractures the most perfect quietude is generally necessary, and the greatest pains should therefore be taken to secure it to the fullest extent, for whatever has a tendency to disturb and fret the parts will be sure to act as a cause of additional excitement. Moral force alone will be of no avail; the patient can neither reason correctly himself, nor comprehend the reasoning of those about him. Hence if medicine does not promptly effect the object, the only resource is the strait jacket, applied of course with proper care, so that while, on the one hand, it shall not be so loose as to frustrate the intention of its use, it shall not, on the other, be so tight as to occasion injurious constriction; a circumstance which, although a matter of paramount importance, is not always, as I well know from experience, as scrupulously attended to as it should be by nurses and practitioners.

The next indication is to tranquillize the nervous system, and induce sleep, or, in other words, to get rid of the redundant excitement. To fulfil this indication, recourse must be had to anodynes, administered in such doses as shall most promptly and effectually bring about the desired result. The patient must sleep before he can obtain relief; the early interposition, therefore, of suitable treatment is a matter of primary importance, attacking and routing the disease, as it were, in its very incipency, ere yet it has taken firm hold of the system. The best remedy will be found to be opium, either in the form of morphia or of the acetated tincture, given in full and sustained doses, in combination with a sufficiency of tartar emetic to prevent vascular excitement and promote perspiration. Solid opium is objectionable, as it takes a long time to dissolve in the stomach, and often excites instead of tranquillizing the nervous system. Tartar emetic will always be found to be a most valuable adjuvant. In the milder cases, the disease frequently promptly yields under the influence of a small quantity of laudanum, as from fifteen to twenty-five drops, in half an ounce of camphor-water and a drachm of the compound tincture of cardamon, repeated every two or three hours. Dupuytren was in the habit of employing laudanum as an injection in this disease, giving from ten to twenty drops with a small quantity of water, and frequently repeating the dose, until he succeeded in accomplishing his purpose. He asserts that the medicine thus administered often exerts a much more prompt and happy effect than when given by the mouth; and the result of my own experience amply corroborates the truth of the statement. As a preliminary measure, the rectum should be well cleared out with an ordinary enema.

When opium and its preparations cannot be borne, an excellent substitute will occasionally be found in hyoseyamus, lupulin, aconite, belladonna, and Indian hemp; aided by the cool shower-bath, followed by dry frictions, or, what will generally answer quite as well, and be more convenient, sponging of the surface freely and repeatedly with tepid, cool, or cold water. When the delirium is furious, leeches should be applied to the temples, or a large blister to the nape of the neck, and cold to the scalp, previously divested of hair. As a temporary expedient, and an auxiliary for allaying the violence

of the spasms, the judicious inhalation of chloroform will be of service. General bleeding will rarely be proper in any case, whether of nervous delirium or delirium tremens. In nervous, hysterical females, the free use of assafœtida and of valerianate of ammonia often answers better than almost anything else.

When the patient has been a habitual drunkard, or when the delirium can be distinctly traced to the effects of the sudden withdrawal of alcoholic stimulation, the dictates of common sense, not less than the results of sound experience, indicate the propriety of a resumption of the accustomed drink, or a resort to an appropriate substitute. Much judgment will of course be necessary under such circumstances, lest the remedy be carried too far, causing thereby additional excitement and vigilance instead of composure and refreshing sleep.

CHAPTER XI.

SYPHILIS.

SECT. I.—GENERAL CONSIDERATIONS.

THE term syphilis is applied to a class of diseases which, commencing in the genital organs in the form of a sore of a specific character, may, and often do, invade the lymphatic ganglions of the groin, the cutaneous and mucous tissues, and finally also the bones, cartilages, and fibrous membranes, leaving upon each and all of them, as well as upon the system at large, a peculiar and distinctive impress. These different parts, however, do not all suffer at one and the same time; on the contrary, it would seem to be necessary that the poison upon which the infection depends should lie for a certain period in the tissues in which it has been deposited in order to enable it to prepare itself for further action. Thus, in the first instance, the operation of the poison is strictly local, the sphere of its influence being limited to the genital organs, or to these organs and the lymphatic ganglions of the groin. After having lingered here for some time, varying, on an average, from four to six weeks, the cutaneous and mucous surfaces begin to suffer; and at a still later period, that is, from six to eighteen months, the bones, cartilages, and fibrous textures are attacked. In this manner are produced three distinct groups of syphilis, known, respectively, as primary, secondary, and tertiary, depending upon the peculiar modifications of the specific poison to which the malady owes its origin.

It is not my intention here to enter into an account of the history of the origin of syphilis; such an undertaking, besides involving an immense amount of research—ethnological, literary, and biblical—would be entirely out of place in a treatise of this description, limited as it is to the practical details of surgery. I may remark, however, that, in my opinion, it is great folly to regard the disease as of modern origin. If the records of antiquity could be fully explored, it cannot be doubted that we should discover the most satisfactory and irrefragable evidence of the existence of syphilis in the most remote periods of society, now aggravated and now kept in abeyance, according to the habits and morals of the various races of mankind, and the nature of the climate of the countries in which they dwelt. If the history of the inner life of Sodom and Gomorrah could be laid open to our scrutiny, it would furnish a page to the history of prostitution as loathsome and disgusting as any afforded by the vilest and most depraved cities of the present day, either in the Old World or in the New.

Syphilis is peculiar to man. Numerous experiments have been performed, by inoculation, upon almost all the domesticated animals, but in no instance whatever has the poison produced any specific effect. The little puncture made with the lancet in the operation became temporarily inflamed, but the impression soon passed off, and the parts rapidly recovered their natural condition. If, in the monkey, the inoculated surface assumed somewhat more of the appearance of a chancre than in the other classes of animals

subjected to trial, it was, nevertheless, not characteristic, and it is certain that no case has ever been reported where the insertion of the matter was followed by constitutional symptoms.

The disease never arises spontaneously, but is always the result of inoculation with a peculiar *poison*, known as the poison of syphilis or of chancre. Of the precise nature of this poison we have no knowledge; we only know it by its properties, or by the effects which it is capable of exerting upon the economy when brought in contact with it under circumstances favorable to its development. Thus, observation and experiment have shown that it always produces a disease similar to itself, the resulting sore or ulcer yielding a virus, in every respect identical with that which furnished it in the first instance. Like the poison of smallpox, it is a peculiar poison, capable of reproducing itself, and of multiplying itself by zymosis. The smallest, inconceivable atom, brought in contact with an appropriate surface, will speedily develop a disease which, if permitted to progress, may occasion the most horrible consequences, both local and constitutional, and so contaminate the solids and fluids as to render it transmissible from the parent to the offspring. As a little yeast may impregnate a large mass of dough, and cause a ferment that shall affect every particle of gluten entering into its composition, so a little syphilitic virus, so minute as to be utterly inappreciable by our senses, may affect the whole system, and poison every avenue of life and health. Zymosis having fairly commenced, it is impossible, in any case, unless proper means be adopted to counteract it, to say when it may cease, or what may be its ultimate effects.

The pus which contains the syphilitic virus, and which therefore serves as a vehicle for its propagation, does not, so far as can be ascertained, differ from pus supplied by ordinary inflammation, either in its physical, chemical, or microscopical characters. Thus, it may be thick and yellowish, serous, ichorous, or plastic; bland or acrid; acid, alkaline, or neutral; pure, or mixed with adventitious matter; and, lastly, perhaps even animalcular, although this point is not fully settled. The specific property of the virus is not destroyed for a number of weeks, if the pus with which it is combined is preserved in a well-corked vial; resembling, in this respect, the virus of vaccinia and variola. It is rendered inert, however, by chemical agents and also by gangrene of the tissues which have been inoculated with it.

The infecting virus does not seem to have any particular predilection for age, sex, temperament, or occupation; all are alike liable to be affected by it. Previous disease does not prevent its action. It produces its peculiar impression most readily when applied to a clean ulcerated surface, an abrasion, or a recent wound; but inoculation may take place independently of these circumstances, simply from the introduction of the virus into a mucous follicle, which thus serves to entangle and retain it until its structure is brought thoroughly under its influence. When the part to which the virus is applied is perfectly healthy, several days may elapse before it becomes impregnated; or it may even escape entirely, the matter which contains it either not being able to penetrate its surface, or being wiped off before the occurrence of absorption. For the same reason a person thus situated may communicate the poison to another so as to give rise to a chancre, while he himself experiences no ill effects. Such a result not unfrequently happens in women, in consequence of the matter of syphilis lodging in the folds of the mucous membrane of the vagina, from which it is afterwards transferred to the virile organ in the act of copulation.

The syphilitic virus may be communicated in various ways; first, by sexual intercourse, which is by far the most common; secondly, by unnatural connection, giving rise to chancres of the anus and perineum; thirdly, by the body and bedclothes of the person; fourthly, by surgical instruments and

dressings; fifthly, by chamber-pots and water-closets; and sixthly, by the fingers of the affected individual. In this manner a patient may inoculate his lips, nose, eyelids, or any abraded, raw, or open surface upon any portion of the body. In this way, too, accoucheurs sometimes inoculate their fingers in examining women laboring under chancre of the vulva, vagina, or uterus.

It is still a mooted point whether the virus of syphilis begins to act the moment it comes in contact with the living tissues, or whether, after having been absorbed by them, it remains there in a state of latency, as is supposed by some to be the case in inoculation in hydrophobia. Without attempting to decide this question, for which our data are perhaps still insufficient, it is reasonable to infer that the effects vary, in different cases and under different circumstances, according to the structure of the inoculated surface, the natural susceptibility of the part, the purity and quantity of the poison, and the degree of the resulting inflammation. It is well known that a tolerably distinct chancre is sometimes formed within the first twenty-four hours after an impure connection, whereas at other times this result does not follow under a week. The average period may be stated at from three to six days. My opinion is that the actual latency of the virus is very short, and that, like other zymotic poisons, it begins to act, although imperceptibly to us, within a very brief space after it has been inserted. The probability of this conclusion is strengthened by what occurs in artificial inoculation, an operation which is usually performed upon the skin of the inner surface of the thigh.

SECT. II.—PRIMARY SYPHILIS.

Primary syphilis consists, as already stated, of chancre and bubo: that is, of an ulcer of the genital organs, and of a swelling of the lymphatic ganglions of the groin, often eventuating in suppuration and other bad effects. So long as the disease is limited to these structures it is strictly of a local character; but when it passes beyond them, so as to affect the system, it becomes constitutional.

1. CHANCRE.

If a small quantity of matter be taken from the surface of an ulcerating chancre, and inserted with the point of a lancet into the substance of the skin, just beneath the epidermis, the earliest effect, manifesting itself within the first twenty-four hours, will be a little reddish speck, looking very much like a flea-bite, and denotive of very slight inflammation, such, for example, as might be supposed to result from any little puncture independently of the operation of any specific virus. During the next twenty-four hours, the part exhibits the appearance of a minute papula, or little swelling, somewhat elevated above the surrounding level, and encircled by a faint, narrow, rose-colored areola. From the third day to the fourth the papula assumes the form of a vesicle, the epidermis being raised by a drop of whitish, pearl-colored serosity; the inflammation is more considerable, and the areola is of larger size and of a deeper hue. At the end of this period the vesicle is transformed into a pustule; that is, the inoculated part becomes filled with pus, its centre is gradually depressed, and the areola acquires its most distinctive features. From the fifth to the sixth day the structures immediately around the seat of the disease undergo a remarkable change; hitherto they had been quite soft, or, at most, only somewhat œdematous, but now they are observed to become indurated from the deposition of plastic matter, and to feel, when pressed between the thumb and finger, like a mass of fibro-cartilage, or tolerably firm cheese, the sensation partaking at the same time of

an elastic character. Having assumed this character, the sore is possessed of the requisite properties for supplying infecting matter, of which, up to this moment, it was destitute. At the expiration of the sixth day, the pustule begins to turn dark, its contents solidify, and a firm, thick scab forms, composed of several strata, and having the shape of a truncated cone, with a depressed apex. Should the scab now fall off, or be accidentally removed, a large, deep ulcer will be exposed, having an excavated appearance, as if it had been scooped out with a punch, its edges being steep and slightly ragged, its bottom incrustated with a layer of grayish, aplastic lymph, and its base hard, firm, and slightly elastic like fibro-cartilage. The discharge is generally of a thin, sanious, or ichorous nature, without any of the properties whatever of laudable or healthy pus. The ulcer thus formed constitutes what is termed an indurated chancre, or, from the faculty it possesses of contaminating the system, the infecting chancre. It is also not unfrequently called the Hunterian chancre, from the fact that it was first accurately described by Mr. John Hunter in his treatise on the venereal disease. From what has been said, it will be perceived that, although the poison doubtless begins to act at an early period after inoculation, yet it requires some time before it can produce a true syphilitic sore, and that the local disease itself consists of several well-marked stages, running, however, gradually into each other; the first distinct evidence of its presence being a papula, the second a vesicle, and the third a pustule, followed by a hardened base and an excavated ulcer, bathed with infecting matter, which is capable of contaminating the constitution, fluids as well as solids.

Although a chancre may occur on any part of the body, yet as it is by far most common on the genital organs, it is here that it has been studied with the greatest care and attention. Its most common sites are the head of the penis and prepuce, the vulva, vagina, and uterus. The disease may also attack the urethra in both sexes, especially in the male, although the occurrence is very uncommon. Any portion of the head and foreskin of the penis may be affected, but of the former the corona, or rather, the gutter just behind the corona, and the surface on each side of the frenum are most liable to be involved, from the circumstance that these parts are particularly apt to retain the infecting matter; for the same reason the free extremity of the prepuce is very prone to suffer. A severe chancre occasionally forms on the body or root of the penis. In the female the disease sometimes occurs on the perineum, on the outer surface of the labium, and around the anus.

A chancre upon the mucous surface of the genital organs does not always pass through the same regular stages as a chancre upon the skin from artificial inoculation. On the contrary, it frequently begins as an ulcer, in consequence of the matter having been brought in direct contact with an abraded surface, or a scratch, and in this case the evolution of the disease is always peculiarly rapid and well-marked. At other times, again, it commences as a boil or an abscess. This form is most common when the inoculation has taken place from the matter having insinuated itself into the orifice of a mucous follicle. Under such circumstances, the gland swells and becomes softened, and is soon after destroyed by ulcerative action. Moreover, it is important to remember that the vesicular and pustular stages above described may have passed by unnoticed, and that, consequently, when the sore is first inspected, it may possess all the characters of a well-defined chancre. No general symptoms precede or usher in the local disease, whatever may be the form in which it begins; all that the patient experiences is a slight sensation of heat, some itching, and an increase of the sensibility of the part which is about to become the seat of the infection.

Chancre presents itself under two *varieties* of form, the indurated and the non-indurated or soft, all other distinctions being now abandoned, on the

ground that, whatever differences of appearance the sore may exhibit, they are solely and entirely of an accidental character, and therefore altogether independent of the nature of the syphilitic virus. It is impossible, in the actual state of the science, to determine why one person should have a hard chancre and another a soft chancre. In the adjudication of such a question it will not do to invoke the existence of a corresponding number of poisons; to do so would be to destroy the unity of the disease, and to invest the subject with inextricable confusion. The most philosophical course, in the absence of facts, is to assume that there is really only one virus, but that this virus is capable of being so modified in its character, by local and constitutional causes, or by internal and extrinsic circumstances, as to produce effects apparently the very opposite of each other in different individuals. How else can we explain the occurrence of indurated and non-indurated sores upon the genital organs? The laws of disease have their irregularities and anomalies not less than the laws of health; exceptions meet us everywhere, and it would indeed be very singular if they should be altogether wanting in syphilitic affections. In the production of the two varieties of chancre here alluded to, some powerful modifying circumstances must be in operation, shaping, influencing, and controlling the result. Smallpox, scarlatina, measles, and other eruptive diseases are subject to remarkable departures from the natural standard, and yet no sensible pathologist would for an instant suppose that every new feature exhibited by these affections was indicative of the existence of a new poison. The modifying cause, whatever it be, may exist in the inoculated structures, in the peculiar nature of the pus containing the specific virus, in the specific virus itself, or in the state of the constitution, or in all these circumstances combined.

M. Ricord has recently published some very singular statements in regard to the peculiarities of these two varieties of chancre, which, if they shall be ultimately verified by the observation of others, would almost necessarily lead to the conclusion of the existence of two separate and distinct varieties of syphilitic poison. Thus, he positively affirms, on the strength of a large clinical experience, that the indurated ulcer alone is an infecting ulcer, that is, a chancre capable of furnishing a fluid which, if conveyed into the system, may contaminate the solids and fluids in such a manner, and to such an extent, as to give rise to secondary and tertiary accidents. The non-indurated chancre, on the contrary, he regards as a purely local affection, often troublesome, it is true, but always free from the risk of invading the constitution in anywise whatever. My observations would lead me to infer that, while there really are two varieties of chancre, the indurated and the soft, as described by the French syphilographer, they do not by any means possess the properties which he ascribes to them. The hard chancre is unquestionably most frequently followed by constitutional symptoms, but to maintain that it is so exclusively is what, I am sure, no experienced practitioner will admit. So far from giving my adhesion to such a doctrine, I have had the most unequivocal evidence, in numerous instances, of the infecting properties of the soft chancre. Indeed, I am satisfied that some of the very worst cases of secondary and tertiary syphilis that I have ever been called upon to treat have been cases of this description; originating generally in very small sores upon the head of the penis or prepuce, perfectly soft in their consistence, very superficial, manifesting no disposition to spread, and soon completely disappearing. Such chancres not unfrequently exist without the knowledge of the patient, their discovery being, perhaps, purely accidental. It is doubtless this form of ulcer which has given rise to the absurd notion, not yet entirely exploded, of the possibility of the formation of bubo without the precedence or concomitance of chancre.

The characters of the indurated chancre may be deduced from the account

already given of artificial inoculation of the skin, which affords its best type. In order, however, to contrast its features with those of the soft chancre, it may be well here to reproduce the description of the principal phenomena which mark its progress.

The *indurated chancre*, fig. 82, is usually rounded or somewhat oval, and from the diameter of a split pea to that of a five cent piece. Its surface is hollow, as if scooped out, and incrustated with a layer of lymph, of a dirty grayish color, and very firmly adherent. The edges of the ulcer are hard, slightly elevated, and inclined a little slopingly from within outwards. The base is well-defined and remarkably hard, feeling, if pressed between the thumb and finger, like a button of fibro-cartilage, or, to employ the comparison of Benjamin Bell, like a split pea, set in the tissues immediately around the chancre. The induration begins to form about the end of the fifth day, and generally attains its maximum by the end of the tenth or twelfth. The

Fig. 82.

Indurated chancre.

amount of induration of the base varies; in general, it will be found to be less on the prepuce than on the head of the penis, the nature of the affected tissues doubtless influencing the result; and it usually lasts some time after the chancre is completely cicatrized, a circumstance, as will appear by and by, of great practical moment.

The indurated chancre, if not generally solitary, is certainly so, on an average, in nearly five cases out of six; for I find that, of 848 cases observed by Fournier, Clerc and Hammond, 185 only were multiple. Occasionally, though rarely, the number ranges from two to six, or even as high as nineteen, as in an instance witnessed by Fournier.

It has no distinct areola; its march is indolent; and it furnishes a thin, serous, sanguinolent, or ichorous fluid, small in quantity, and difficult of inoculation. Hence, unless the matter come in contact with a raw surface, or a surface well adapted for its absorption, a second chancre seldom arises during the progress of the primary one. Another feature of the indurated chancre is its extreme liability to infect the lymphatic ganglions and the general system, few persons, if any, escaping contamination after it has reached maturity.

The *soft chancre*, also generally of a rounded form, but less regularly so than the hard, is much more common than the latter, and is often multiple, from three to six or eight occasionally occurring in the same subject. It is particularly apt to show itself at the free margin of the prepuce, and at, or just behind, the corona of the penis. Several often arise simultaneously, and others are liable to form during their progress from fresh inoculation, or the mere contact of their own secretion with the surrounding parts. The surface of the soft chancre is superficial, flat, uneven, and coated with a grayish, whitish, or dirty drab-colored deposit. In some cases it has a worm-eaten appearance. Its edges, when seated on the head of the penis, are steep and abrupt, as if made with a punch, but on the prepuce they are generally overhanging, sloping or shelving, extremely ragged, and less closely identified than those of the hard chancre with the neighboring structures. The base of the chancre is entirely free from induration. The only exception to this is where irritating applications have been used, causing an increase of inflammation with plastic deposit.

The soft chancre generally manifests a disposition to spread, and, in persons of a broken constitution, often takes on phagedenic action. It furnishes an abundance of purulent fluid, which is highly infectious, and therefore readily inoculable, thus accounting, as already stated, for the multiplication

of ulcers during the progress of the disease, one sore being added to another in consequence of the dissemination of the matter over the surrounding surface. The soft chancre is frequently, but not generally, followed by bubo, the disease being usually limited to one ganglion, which, becoming inflamed and swollen, rapidly suppurates, and, in time, forms a large ulcer, the matter, like that of the chancre to which the bubo owes its origin, being at first inoculable, and capable, in turn, of producing a soft chancre. Finally, the soft chancre often affects the system, giving rise to secondary and tertiary symptoms; attacks of this kind, however, are less common than in the indurated variety, though the effects are frequently not less deplorable.

The period during which a chancre retains its specific character varies. Occasionally, though rarely, it loses its infecting properties in ten days or a fortnight. The average time, however, is much longer; and, on the other hand, an instance sometimes occurs where the specific poison continues to be formed for many consecutive months. As a general rule, it may be stated that no patient is safe so long as the ulcer is not in a granulating condition. The observations of Ricord tend to show that one attack of indurated chancre effectually protects both the part and system against a second attack, the syphilitic poison thus resembling, in its habits, the poison of smallpox; the soft chancre, on the contrary, exercises no such influence, one attack affording no immunity against another. My own experience leads me to believe that this conclusion should be received with great reserve.

The two varieties of chancre now described are liable to be modified in their appearances, progress, and modes of termination by local and constitutional circumstances, among which the most important are the want of cleanliness and the degree of the concomitant inflammation, the habits of the individual, the state of the general health at the time of the inoculation, and the occurrence of intercurrent diseases. The influence which these several causes are capable of exerting is, in many cases, so great as to change the whole outward feature of the existing ulcer; hence those numerous divisions and subdivisions of chancre which, even up to the present moment, disfigure the nomenclature of syphilis, and which have tended so much to embarrass the progress of our knowledge. It is impossible for this disease to observe the same uniform course in every instance; alterations are inevitable, and must often occur despite the utmost caution both of the patient and his attendant. In this respect, a chancre holds the same relation as an ordinary ulcer, presenting one appearance to-day and another to-morrow; now highly inflamed, and now almost free from irritation; at one time in a healing condition, and at another ready to commit the most destructive ravages. Out of these appearances, or varieties of appearances, have sprung the so-called inflammatory, diphtheritic, phagedenic, and sloughing chancres, with several others which it is unnecessary here to mention. Such occurrences constitute complications of disease rather than species and varieties, for they are liable to take place in all sores whatever their character, whether simple or malignant, specific or common. There is reason to believe that in syphilis the specific poison may sometimes undergo such a radical change as to adapt it, in an especial manner, for the production of these differences in the appearances of the local affection. Promiscuous intercourse with badly diseased women, particularly if these women are foreigners, and receive the embraces of a considerable number of men in rapid succession, would seem to be a powerful predisposing cause of these accidents. It was observed by the surgeons who accompanied the British army into Portugal, that many of the soldiers who had connection with the native prostitutes suffered severely from phagedenic and gangrenous ulcers, while the residents of the country experienced very little trouble, and usually soon recovered from the effects of the disease. The French soldiers, during Bonaparte's campaign in Egypt, suf-

ferred in the same manner. Similar phenomena are frequently witnessed in the inmates of the houses of ill-fame in crowded cities. Thus, in London, in Swan Alley, a narrow lane, celebrated as the residence of the humblest class of prostitutes, half-starved, badly clothed, nearly constantly intoxicated, and having frequent intercourse every day with filthy lascars and other vagabonds, many of the cases of chancre assume the worst possible type, running rapidly into phagedenic action, and often causing frightful ravages and even loss of life. Examples of a like kind came under my observation in this city, in 1827, 8, and 9, in the Philadelphia Almshouse, and in the numerous brothels which then existed among the low blacks and whites south of Pine Street.

All chancres are inflammatory affections, and it is only therefore when the concomitant action assumes a grave type that it can be regarded as unnatural. Under such circumstances, the characteristic symptoms consist of inordinate pain and swelling of the parts more directly involved in the disease, accompanied by an increase of discoloration, and an unhealthy aspect of the ulcer, which is the seat of a thin, ichorous discharge, more or less abundant, and generally a good deal irritating. Morbid erections are frequent, the prepuce is disposed to be œdematous, and the whole organ appears to be enlarged, especially the anterior extremity. When the inflammatory action transcends certain limits, it may pass into gangrene or destructive ulceration, as occasionally happens in common ulcers of the leg, and from similar causes, especially from excessive indulgence in the use of ardent spirits, loss of sleep, bad air, an impoverished diet, and improper courses of mercury. Or, the overaction may be brought on by a plethoric state of the system, and a neglect of the requisite depletion. I have seen gangrene and phagedenic ulceration of the genital organs of both sexes occur at a very early period, in consequence, apparently, merely of too active a course of treatment soon after the establishment of the disease, and such cases are sometimes characterized by extraordinary rapidity of progress, the suffering parts being, as it were, overwhelmed by the disease.

Gangrene, as a consequence of chancre, is more apt to invade the prepuce than the head of the penis, and, what is remarkable, the upper portion of this muco-cutaneous pouch is more frequently affected than the lower or lateral. Occasionally both structures are attacked simultaneously, or, if one suffer first, the other is soon attacked also, and in this manner the whole organ may gradually be involved, dropping off perhaps ultimately near the scrotum, or at its attachments to the pubic bones. The occurrence of gangrene is announced by a blackish spot, preceded and accompanied by a burning, smarting pain, and by an aggravation of all the other inflammatory symptoms. The system is extremely feverish, the pulse is frequent and irritable, sleep and appetite are impaired, or, more commonly, entirely destroyed, and the patient is often slightly delirious. When the prepuce alone suffers, the whole of it may slough off, or, what is not unusual, it may be perforated at one or more points, the largest opening perhaps admitting the head of the penis, as seen in fig. 83. A common effect of gangrene, consequent upon chancre, no matter where situated, is the destruction of the specific poison, thus effectually preventing inoculation of the system, provided that had not previously taken place.

Fig. 83.

The sloughing sore, the prepuce almost gone; the glans going.

announced by a blackish spot, preceded and accompanied by a burning, smarting pain, and by an aggravation of all the other inflammatory symptoms. The system is extremely feverish, the pulse is frequent and irritable, sleep and appetite are impaired, or, more commonly, entirely destroyed, and the patient is often slightly delirious. When the prepuce alone suffers, the whole of it may slough off, or, what is not unusual, it may be perforated at one or more points, the largest opening perhaps admitting the head of the penis, as seen in fig. 83. A common effect of gangrene, consequent upon chancre, no matter where situated, is the destruction of the specific poison, thus effectually preventing inoculation of the system, provided that had not previously taken place.

Phagedena is a rare complication of chancre, especially in the better classes of subjects; it is analogous, in its worst forms, to hospital gangrene, and is most liable to show itself in persons whose constitution has been ruined by intemperance and other debilitating influences. As already stated, it sometimes oc-

curs as an endemic, and is then probably induced by a foul state of the atmosphere, as when the disease breaks out in the crowded wards of public institutions; or by some peculiar modification of the syphilitic poison, greatly heightening its virulence, as when it takes place in soldiers after having cohabited with foreign prostitutes. The morbid action deports itself variously; in general, it extends rather slowly, but continuously, gradually but effectually eroding the parts, and thus widening the breach as well as deepening it. Or, it may be that, as one portion of the chancre heals, another spreads. Or, the action may be very acute, extending with extraordinary rapidity, and committing excessive ravages in an almost incredibly short time. Or, lastly, the erosion may be conjoined with gangrene, the textures dying both molecularly and in mass. The phagedena may begin soon after the appearance of the chancre, or it may manifest itself, as is most generally the case, at various periods of its progress. It may occur upon any portion of the genital organs, but is most common upon those parts of the mucous surfaces which are most plentifully supplied with follicles. In the male it is most liable to appear in the gutter upon the head of the penis, or at the point of reflection of the prepuce. The under surface of the penis, at the side of the frenum, is another favorite site, and when chancre occurs here it is almost certain to destroy this fold of mucous membrane.

The appearances of the acute and chronic forms of phagedenic chancre are illustrated in figs. 84 and 85.

The phagedenic complication is sometimes followed by grave hemorrhage, the erosive action laying open an artery of considerable size, as the dorsal artery of the penis, from which blood may issue in such quantities as to induce severe, if not fatal, exhaustion. The scarlet hue of the fluid and the saltatory character of the

stream will at once indicate its source. In some cases it oozes from the ulcerated surface from many points, as water oozes from a sponge.

Chancres sometimes assume a *serpiginous* form, the erosive process, as the term implies, creeping about in different directions, generally in circles or semi-circles, one portion of the sore being perhaps cicatrized while the other is steadily advancing at the opposite point. The ulcer, although generally superficial, occasionally penetrates to a considerable depth, and, as its course is usually chronic, it often results in serious mutilation. Its surface, incrustated with grayish or drab-colored lymph, is bathed with ichorous fluid, and its edges are steep, ragged, and more or less everted. The serpiginous form of chancre is most common in persons of strumous constitution, especially such as are predisposed to phthisis, scurvy, and herpetic affections. It is generally remarkably obstinate, occurs almost exclusively in the skin, and manifests no disposition to burrow.

When a chancre is covered with a thick layer of lymph, it constitutes what the French syphilographers have called the *diphtheritic* chancre; such an occurrence is very common in all ill-conditioned specific ulcers upon the genital organs, and is always denotive of an unusually irritable and inflamed condition of the part, the action of which altogether transcends the healthy limits, nature being incapable of converting the deposit into granulations,

Fig. 84.

Fig. 85.

Chronic phagedena; with great surrounding hardness.

and so throwing it off in the form of a slough, or as an effete substance. A considerable effusion of lymph is often observed in connection with the indurated chancre, but the soft chancre is by no means exempt from it.

Diagnosis.—The diagnosis of chancre is often difficult and sometimes impracticable, particularly in its earlier stages, before the disease has assumed its more distinctive features. The affections with which it is most liable to be confounded are herpes, eczema, balanitis, and simple excoriations, fissures, or abrasions, the result of friction and other accidents.

Herpes, as will be seen in its appropriate place, is an eruption of the prepuce and head of the penis, appearing in the form of little vesicles, hardly as large as the head of a pin, occurring in groups, closely set together, of a whitish color, and resting upon a florid base, with which they form a striking contrast. They are most frequent on the inner surface of the prepuce, in persons of red hair and tender skin, and often appear in successive crops, none of which last longer than six or eight days. They are characterized by a sense of itching and a slight serous discharge, manifest little disposition to extend, and usually promptly yield to very simple treatment. The resulting ulcer is always free from induration.

Chancres never put on the appearance of herpes. The only approach to it is where the specific ulcers are seated in the mucous follicles, but in this case their circular form and excavated character will always serve to distinguish them from common sores.

Eczema is also an eruptive disease, but the little vesicles are more minute and diffused than in herpes, and there is also usually a greater amount of local irritation, the parts being swollen, hot, red, and itchy. When these vesicles burst, a thin watery fluid escapes, followed by the development of little delicate scales. The affection is apt to become chronic, and then little crevices generally form, increasing the irritation, and furnishing an acrid, sero-purulent, sanious, or ichorous discharge. Eczema is most common on the prepuce, and is often particularly conspicuous at the free border of this mucocutaneous covering. A careful examination of the affected parts, the history of the case, and the co-existence of the disease with eczema elsewhere will always lead to a correct distinction between this affection and chancre.

It is probable that an inexperienced practitioner might mistake an incipient balanitis for a chancre, but no one who has ever seen the two diseases could possibly commit such an error. In balanitis the inflammation is generally widely diffused, often, indeed, over the whole surface of the prepuce and head of the penis, and the discharge is not only profuse but of a thick mucopurulent nature from the very commencement. There is no circumscribed ulceration as in chancre, and, indeed, no tendency whatever to destruction of tissue. These characters will always serve to prevent the disease from being confounded with chancre, which, whether indurated or soft, invariably presents itself as a distinct and well-defined ulcer.

Simple ulcers, abrasions, or excoriations are liable to appear upon the prepuce and head of the penis, and may, unless great caution is exercised, be mistaken for chancres. They may proceed from a great variety of causes, as want of cleanliness, friction of the pantaloons, injury received during connection, and intercourse with filthy females, especially such as are habitually the subjects of profuse and acrid discharges. However induced, such ulcers are always very superficial, and display no disposition to extend in depth, although they may spread considerably in diameter. The discharge which attends them is of an ichorous character, and they are usually surrounded by an inflammatory border, which is not the case in chancre. The most important diagnostic feature, however, by far, is that such ulcers always very promptly disappear under the most simple remedies, attention to cleanliness, with a cooling lotion and a mild aperient, generally sufficing to effect a cure in a few days.

The site, size, shape, appearance, and course of chancre, considered separately, afford no reliable diagnostic evidence; but viewed collectively they are of great importance as means of discrimination. Thus mere site and size are of no consequence, because a chancre may, like a common sore, occur on any portion of the penis and be very diminutive, as when, for instance, it occupies a mucous follicle; but if, in addition to this, the ulcer is found to be excavated, to have a foul diphtheritic bottom, to pursue a chronic course, and to resist the ordinary means of cure, it is quite impossible to mistake its character; we conclude that it is specific, and nothing else. The indurated chancre is too well marked not to be recognized; it may, it is true, not be so easy to do this during the first few days of the disease, but it is altogether impossible to be deceived when the sore has attained its proper development, the hardened base to which it owes its name being then of itself sufficient to settle any doubts respecting the diagnosis.

The history of the case often affords valuable information. If the patient is a married man, or if he has any other motive for concealment, he will be likely to deny that he has had impure connection, and even insist upon it that the sore on the penis is non-specific. Under such circumstances, it is not necessary to try to convict him of falsehood; the surgeon examines the parts, and if he finds any suspicious looking ulcers, he will be very apt to conclude that they are syphilitic, and this opinion will be strengthened by the very denials of the patient, especially if he is noted for his gallantries. Young unmarried men usually treat their attendants with entire candor, generally specifying with great particularity the time of the impure connection, and evincing no little anxiety to afford them all the light they can with a view of settling the diagnosis. We must, therefore, on the one hand, not believe that a man has not been exposed to infection simply because he says so; and, on the other, it must not be taken for granted that every sore that may be found upon the penis is of a specific nature.

Finally, in all cases of doubt the groins are to be examined with reference to the existence or non-existence of bubo. In the ordinary non-specific affections, above described, the occurrence of ganglionic enlargements is extremely rare, and when it does happen it usually appears early in the attack, the bubo being small in extent, at the same time that it is comparatively transient. In chancre, on the contrary, bubo seldom comes on before the end of the third week, and the swelling, besides being generally considerable, is always persistent, frequently passing into extensive suppuration and ulceration.

When the above means of diagnosis fail, which will seldom be the case if we are careful, the only other resource is inoculation, a small quantity of the suspected matter being inserted, upon the point of a lancet, in the skin on the inside of the thigh. If the operation is speedily followed by a vesicle, and this, in its turn, by a pustule, with a well-marked areola, there can be no doubt whatever respecting the true nature of the disease. Inoculation, if properly executed, cannot deceive, and is, therefore, after all, the only true and reliable test, although there are few surgeons of experience who will not, as a general rule, be able to determine the diagnosis without its aid.

Treatment.—The treatment of chancre must be conducted with a twofold object; the prevention of the absorption of the specific poison into the system, and the rapid and effectual healing of the sore. If the poison be permitted to enter the lymphatic vessels, constitutional contamination will be inevitable, and the result of such a vice may be a long train of evils, which may continue during the rest of the patient's life, and, if he be married, even show themselves in his offspring.

The prevention of the absorption of the virus constitutes what is called the *abortive* treatment, and should be an object of earnest solicitude in every case of the disease. Observation has proved that, if the specific character of a

chancre can be effectually eradicated before the end of the fifth day from the inoculation, the constitution will completely escape contamination, the chancre being up to this time a purely local affection. The matter secreted by the indurated chancre, which is the more common, although, as has been seen, not the only source of infection, does not possess any specific properties prior to this period, or, if it do, it does not appear to be amenable to absorption until the part has acquired a certain degree of development, of which the hardened and circumscribed base forms a most important and characteristic element. Up to this time it is almost certain that the matter may, by proper management, be prevented from reaching the system, and exerting any deleterious impression upon it; but it is not equally certain that this procedure may not occasionally secure such immunity after this period, from the poison being unusually long delayed in the chancre, or, what is tantamount to this, from an indisposition on the part of the absorbents to carry it into the system. Hence, if there be no decided contra-indications, growing out of the existence of severe inflammation, or inordinate size of the sore, the patient should have the benefit of the abortive treatment even after the lapse of the first week or ten days, although the chances of success will then undoubtedly be much diminished, as far as the security of the system is concerned.

The abortive treatment is mainly of a local nature. The best plan of getting rid of the chancre is to dissect it out from the parts upon which it rests with a pair of forceps and a delicate bistoury, being careful to cut sufficiently widely around the diseased structures, so as to embrace the whole of them in the incisions. The operation requires some skill, but it is soon over, and, although a little painful, is rarely attended with any bleeding. Some caution is necessary, especially when the chancre has existed for an unusual length of time, to avoid inoculation of the wound; a circumstance which might readily happen if the surface of the sore were permitted to come in contact with it. When the excision is completed, the part is to be treated with mild measures, like any common wound, and will generally heal in a very short time.

If the patient be averse to the employment of the knife, or if the nature of the case be such as to induce the belief that excision cannot be effected without the danger of inoculating the raw surface, an attempt must be made to accomplish the object by means of escharotics. For this purpose several articles are in common use among the profession. The one most generally selected is a piece of nitrate of silver, cut to a very delicate point, and inserted into the ulcer, or broken vesicle, being held there until the infected tissues are brought thoroughly under its influence. The objection to this substance is its insufficiency; for, whether it acts simply as a neutralizer of the poison or as a destructive of the tissues, it is equally certain that it is generally unreliable, and hence it ought never to be used in a case of such a serious nature. The article to which I have long given the preference, on account of its superior efficacy, is the acid nitrate of mercury, prepared according to Bennett's formula, and applied either pure or variously diluted, according to the exigencies of each particular case. A good average strength is one part of the acid to double that quantity of water, applied with a piece of soft wood, the end of which is smooth and well rounded off. Such a contrivance is much better than a probe wrapped with lint or cotton, as the fluid can thus be brought in contact with the infected surface in a more concentrated and efficient manner. In order to prevent the solution from diffusing itself too widely, the parts should be previously well wiped, and immediately after bathed in pure water, or some weak alkaline lotion. The most suitable dressing will be an emollient poultice. When an escharotic is required, it is always better to make one free application than a number of imperfect ones.

When the acid nitrate of mercury is not at hand, the cauterization may be effected with almost any of the mineral acids, especially the nitric and hydro-

chloric. Some surgeons are in the habit of using caustic potassa, while others give a preference to the Vienna paste. Ricord has lately recommended a powerful caustic, composed of sulphuric acid and powdered vegetable charcoal, united in the proper proportions to form a semi-solid mass. Of this a thin layer is applied to the chancre and the parts immediately adjacent, upon which it soon dries, forming a black adherent crust, which, on dropping off, as it usually does in eight or ten days, leaves a healthy granulating sore, rapidly followed by cicatrization. The objections to the carbo-sulphuric paste are the extreme pain which it produces, and its tendency to spread too far over the sound tissues.

Conjointly with these local measures, it is necessary that the patient should be kept perfectly quiet for a few days, that his diet should be very light and non-stimulant, and that the bowels should be moved with some mild aperient. At the end of this time, unless there is evidence of undue inflammation, he may get up and go about his business.

The abortive treatment having failed, or the time having passed for its successful employment, the question necessarily arises, How shall the case be managed in order to secure a prompt and satisfactory result? Supposing the chancre to be one of a simple character, unaccompanied by severe inflammation, the treatment ought to be of a correspondingly simple nature, all harsh and irritating applications being studiously avoided, inasmuch as they never fail to do harm, and thus retard recovery. From neglect of this precaution many a sore upon the genital organs that would, if gently managed, disappear in a few days, is often protracted for weeks, if not months, to the great detriment both of the part and system. Young practitioners, in particular, are apt to fall into this error; their experience being limited, and their knowledge of the disease being derived from books rather than from clinical observation, they think they cannot do too much, and the consequence is that they fret and worry the sore until it places itself, so to speak, in a state of open rebellion, resenting all measures, local and constitutional, that are used for its cure. Instead of this, none but the most soothing means should be adopted, the object being to coax the disease, not to force it into terms.

One of the first and most important points to be attended to, in every case, is cleanliness. This is best secured by frequent ablutions, or, what is preferable, by immersion of the penis repeatedly during the twenty-four hours in tepid water, containing a little common salt, acetate of lead, or chloride of soda. If the chancre be concealed by a tight and inflamed prepuce, free use should be made of the syringe, as it will be impossible to effect retraction to an extent sufficient to accomplish the purpose. In the intervals of these local baths, which, while they serve to keep the parts nice and clean, contribute materially to the reduction of the concomitant inflammation, the ulcer should be kept constantly covered with a small piece of patent lint, wet with a weak solution of tannin and opium in compound spirits of lavender, yellow wash, or the dilute ointment of the nitrate of mercury, in the proportion of one part to six or eight parts of simple cerate. The tannin and opium constitute an excellent remedy, exerting at once an astringent and soothing influence, greatly promotive of healthy action. They form the principal ingredients of the aromatic wine, so much used in the French hospitals, and their efficacy has been well attested both in public and private practice everywhere. The yellow wash is also a very valuable remedy, but to obtain all the good which it is capable of yielding it should be employed very weak, as one-eighth of a grain of the mercury to the ounce of water, the strength being increased if it be found necessary on account of the slow progress of the case. The officinal preparation is much too strong and irritating, and must therefore be scrupulously abstained from. In my own practice I have derived great benefit

from the ointment of the nitrate of mercury, diluted as above mentioned, and applied either alone or in union with tannin and opium. In fact, there is no remedy which has done better or more efficient service in my hands than this in the treatment of simple chancre. I am aware that by many all greasy articles are denounced as being injurious, in consequence of their alleged tendency to become decomposed and rancid. Such objections, however, can only be considered as having any force when these applications are too long continued, or when there is a want of attention to cleanliness, the secretions being allowed to accumulate unduly, so as to promote putrefaction. All this may be readily obviated by changing the dressings every five or six hours, and taking care that the ointment shall always be very fresh.

There is one important rule which applies here with as much force as in the case of common ulcers, and that is to vary the dressings whenever they are found to be unproductive of benefit, making them now weaker, now stronger, adding new ingredients, or omitting old ones, or changing the remedy altogether. Much of the success, in every case, will depend upon the care with which this rule of practice is carried out.

When the parts begin to granulate, the simplest dressings generally suffice; such as common ointment, Turner's cerate, diluted with five or six times its bulk of fresh lard, or merely a bit of dry lint carefully interposed between the contiguous surfaces. The latter application often promotes cicatrization with remarkable rapidity.

When the head of the penis is swollen and painful, it must be kept constantly buried in an emollient poultice, made of powdered elm bark or ground linseed, and frequently changed. Or, instead of this, the warm water-dressing may be used, its efficacy being increased by the addition of laudanum and acetate of lead. It need hardly be added that the organ should be incessantly maintained in an elevated position, just as any other part of the body in a state of inflammation.

Constitutional treatment is important, and must therefore claim due attention, however simple the sore. Perfect quietude of mind and body is indispensable in every case. The effects of any disturbance of this kind are sure to be promptly seen in the aspect of the sore and the character of the secretion. The diet must be plain and simple, animal food and stimulants being carefully avoided; the bowels must be kept open by cooling purgatives; and, if need be, free use must be made of the saline and antimonial mixture. Venesection will rarely be required, and then only in very plethoric subjects. If the local trouble be considerable, leeches may be applied to the groins or the inner surface of the thigh, care being taken to cover the bites, when the flow of blood has ceased, with collodion, in order to prevent their inoculation from the accidental contact of the chancrous matter. These animals should never be applied to the penis itself, much less to the parts immediately affected, as their secretions could hardly fail to come in contact with the little wounds, and so propagate the disease. If the ulcer belongs to the indurated variety, or if it be followed by a suppurating bubo, a moderate course of mercury will be proper; but as this is a subject which will come up for consideration by and by, it will not be necessary to enlarge upon it here.

Chancre, complicated with undue inflammation, phagedena, gangrene, or excessive inactivity, requires some modification of treatment, adapted to the peculiar conditions of the part and system which are always present under such circumstances, and which may, therefore, be regarded, in the true acceptance of the term, as so many exciting causes of the morbid action. It is only by bearing in mind the intimate relation subsisting between the local disorder and the state of the constitution, and the influence which they re-

ciprocally exert upon each other, that the practitioner may hope to treat these epiphenomena with any immediate prospect of success.

When chancre is accompanied by severe *inflammation*, as denoted by the swollen, discolored, and painful condition of the parts, and the feverish state of the system, recourse must at once be had to the vigorous employment of antiphlogistics, for the purpose of moderating, as promptly as possible, the violence of the disease. Bleeding at the arm, active purgation, light diet, and the use of antimonials, with absolute rest in the recumbent posture, cooling, anodyne, and mildly astringent lotions to the ulcer, and an emollient poultice or the warm water-dressing for the head of the penis, constitute the chief remedies in such an emergency, and must be carried to an extent compatible with the powers of the system. Pain and morbid erections are relieved with opiates, administered in full doses. By these means the disease is soon brought under subjection, when it is to be managed in the same gentle manner as the milder forms of chancre already described.

When the ulcer assumes a *phagedenic* character, manifesting a disposition to spread more or less rapidly both in depth and diameter, the principal addition to the treatment, required in chancre complicated with undue inflammation, consists in the increased amount of opium employed to soothe the part and system, which are generally excessively irritable in this variety of morbid action, and can only be successfully quieted by the most liberal use of this article. If the skin be hot and arid, the pulse excited, and the face flushed, the opium should be combined with antimony, or some cooling diaphoretic, so as to produce a decided determination to the surface. The diet and bowels must receive due attention; all stimulants must be avoided; and the mind and body must be maintained in the most tranquil condition. If mercury has been given, its use is at once to be abandoned, experience having shown that, under such circumstances, it not only produces great harm, but that in many cases it is the principal cause of the phagedenic action.

The local applications should all be of the blandest kind, consisting of warm water-dressing or emollient poultices, and of lint steeped in mucilage of gum arabic, or an infusion of elm bark, with the addition, to each ounce of fluid, of from two to three drops of nitric acid and one drachm of the vinous tincture of opium. If the disintegrating action is very rapid, the ulcer should be touched freely with a solution of the acid nitrate of mercury, or a piece of solid nitrate of silver, its surface being kept constantly covered in the interval with the medicated lotion just mentioned. In some cases nothing will arrest the erosive tendency so speedily as a weak solution of sulphate of copper, in the proportion of from half a grain to a grain to the ounce of water, with the addition of from four to six grains of tannin and opium.

The phagedenic form of chancre, however, does not always occur in the strong and robust; the system may be, and often is, in an adynamic condition, requiring tonics and stimulants instead of depressants. The constitution, degraded perhaps by long suffering or by all kinds of intemperance and starvation, must be brought up by quinine and iron, with porter, ale, or milk punch, a nutritious diet, and change of air, particularly if the patient be the inmate of a crowded and ill-ventilated hospital. The dissipated and enervated residents of large cities are particularly prone to suffer from phagedena during the progress of chancre, and the practitioner, therefore, cannot be too much upon his guard how he depletes this class of individuals. What is needed in such a state of the system is perfect tranquillity of mind and body, as secured by the liberal exhibition of anodynes, and a better condition of the blood, to enable the part to institute a more salutary action.

If *gangrene* set in, the treatment must vary according to the concomitant state of the system, independently of any consideration growing out of the

presence of the specific virus. The question should simply be, is the action on the part of the system too high or too low? If the former, antiphlogistics will be indicated, and should be promptly employed, although not without a certain degree of restriction, lest the powers of the constitution should suffer from the effect, and thus promote the spread of the disease. Bleeding and purgation must be used warily; the practitioner must measure his ground and feel his way. The excitement may only be apparent, not real; and may, consequently, shortly subside, either spontaneously, or under very simple remedies. Most likely the action is typhoid from the beginning, or, if not, it soon will be; hence, instead of a depletory, a corroborative course will be necessary, similar to that in ordinary gangrene in other parts of the body, our chief reliance, so far as constitutional means are concerned, being upon quinine, ammonia, brandy, camphor, and opium, with jelly and rich animal broths.

As it respects the part itself the indications are, first, to arrest the gangrenous action, and secondly, to promote the separation of the eschars. To fulfil the first of these objects, the affected structures are freely painted with the dilute tincture of iodine and wrapped up in an emollient poultice, medicated with laudanum and acetate of lead, while the dying tissues are well mopped with the acid nitrate of mercury, or brought under the full influence of the solid nitrate of silver. If any constriction exist, such as that produced by a tightened and retracted prepuce, it must be promptly relieved with the knife. The detachment of the sloughs may be promoted artificially, or, if not too large, be intrusted entirely to nature's efforts; at all events, all harsh interference must be carefully avoided. Feter is allayed by the chlorides.

The sloughs having separated, the next object is to invite the development of healthy granulations; and for this purpose the most available remedies will be found to be the nitric acid lotion, with tincture of opium, the ointment of the balsam of Peru, the aromatic wine, or the dilute ointment of the nitrate of mercury, with the warm water-dressing or an emollient cataplasm, as a general covering to the affected structures.

Chancre attended with deficient action—the *indolent* sore of some syphilographers—demands for its successful management a careful investigation of the nature of the exciting cause of this particular state of the part before recourse be had to direct treatment. In general, it will be found to depend upon some defect of the system, by correcting which the ulcer will speedily assume a healthy appearance, throwing out florid granulations, furnishing thick, laudable pus, and cicatrizing along its margins. Or it may be that the obstacle is of a strictly local nature, caused by want of cleanliness, by an undermined condition of the sore, or, finally, by the presence of a thick, semi-organized layer of lymph, firmly adherent to the surface of the chancre. Whatever it may be, it should, if possible, be promptly rectified; the constitution, if at fault, is improved, and the part is treated with special reference to the promotion of the granulating process. Particular attention is given to cleanliness, the hardened and shelving edges are trimmed off with the knife, and the incrustated surface, freely cauterized with the nitrate of silver or acid nitrate of mercury, is kept constantly covered with blue ointment or some stimulating lotion.

The indolent form of chancre is frequently accompanied with an indurated base, which often continues a considerable period after the ulcer has become completely cicatrized, and constitutes a variety of primary syphilis peculiarly dangerous on account of its liability to be followed by constitutional symptoms. The idea now almost universally prevails that no person is safe from constitutional contamination so long as the part remains in this condition. It is an incontestable evidence that the specific virus still lingers at the original seat of the infection, and that, like a smothered fire, it may spring

up at any moment into a full blaze, re-exciting ulceration, and endangering the system. It is to this form of chancre, more particularly, that mercurialization is applicable, very few patients thoroughly recovering without it. The manner in which it should be conducted has given rise to much discussion, and is deserving of special attention.

My own opinion is that the more simple and gentle the *mercurial* course is the better. It should be carried just far enough to affect the gums, and no further. The object is not to cause profuse salivation, as was the wont of the older surgeons, but merely to produce slight soreness of the mouth, as an evidence of the constitutional impression, and to maintain this impression, in an equable, uniform manner, until the local affection has completely disappeared. The preparation which I usually prefer is calomel, in doses of from one to two grains three times a day, in union with a little opium, or, if there be dryness of the surface, with morphia and ipecacuanha. Blue mass is also a valuable article, and may often be employed as a substitute for the calomel, especially in the young and delicate. As soon as the medicine has produced a slightly salivant effect, or soreness of the gums, it is to be discontinued, or given in smaller doses and at longer intervals. If the desired result be slow in coming on, the treatment may be aided by mercurial inunction, from one to two drachms of the blue ointment being rubbed on the inside of the arms and thighs morning and evening.

I prefer calomel, blue mass, and mercurial ointment to the more modern preparations of mercury, chiefly for the reason that they are less liable to gripe, and also because they are more certain and reliable in their effects. Iodide of mercury, the article usually resorted to by modern practitioners, nearly always causes intestinal irritation, and is, as I know, from ample experience, generally very tardy and unsatisfactory in its action. The bichloride, so valuable in the tertiary form of syphilis, is not a reliable medicine in chancre, except, perhaps, in cases of extraordinary chronicity, in which I have sometimes given it with much benefit, in doses varying from the twelfth to the eighth of a grain every eight hours.

Mercury must not be employed, in any form, in the treatment of primary syphilis, if there be fever, or general excitement of the system. In such a case the patient must be subjected to a certain amount of preliminary treatment, consisting of rest, abstinence, purgation, and the use of salines and antimonials. A similar course is to be followed in phagedena and gangrene, or even when there is merely an unusually irritable state of the constitution. Exhibited under such circumstances, the mineral never fails to produce mischief, by increasing the local and general derangement. The great art of administering mercury in this and other diseases is to know when and how to give it; never to employ it sakelessly, or simply because it is mercury, but to give it for a good reason; and in order to do this properly a great deal more judgment is required than is generally imagined. Upon the manner in which the article is used in primary syphilis will, in great degree, depend the future welfare of the patient.

There can be no question that primary and even secondary syphilis are often curable without mercury. Every practitioner meets with instances where none but the most simple means are necessary to attain this object promptly and satisfactorily. For the last twenty years I have rarely given this mineral in any case of these two forms of the affection; and, although tertiary symptoms have occasionally supervened upon this mode of treatment, I have, on the whole, had no cause whatever to regret it, but quite the contrary. The value of the non-mercurial treatment was fairly tested, in hundreds, if not thousands, of cases, by the British surgeons, during the Peninsular wars, and their results, as published by some of their most enlightened and reliable brethren, prove, in the most irrefragable manner, that primary syphilis may

generally be effectually relieved by ordinary antiphlogistic means. It was found that the average period occupied by the treatment of chancre unaccompanied by bubo, without mercury, was twenty-one days, a little more than twice this period being required when the sore was followed by bubo. On the other hand, the cases that were treated with mercury required, for the cure of the chancre, an average of thirty-five days, and for the chancre and bubo fifty days. The results of the practice of certain hospitals are equally corroborative of the value of this treatment. Thus, in the various hospitals of Sweden, of 20,000 cases treated with mercury, the number of relapses amounted to thirteen and two-thirds in the hundred; whereas, in a like number of cases treated by the simple method, the proportion of relapses was only seven and a half. In the Hamburg Hospital, out of 1649 patients, of both sexes, 582 were treated with mercury, and 1067 without mercury; the mean duration of the cure in the former was eighty-five days, and of the latter, fifty-one days. At Strasbourg, 5271 persons were treated without mercury, with hardly any relapses and secondary affections.

The above results are greatly in favor of the non-mercurial plan of treatment; and they deserve the more attention because it was formerly believed that the primary disease, when so relieved, is more liable to be followed by constitutional symptoms than when the patient gets well without the aid of the mineral. Finally, another fact developed by the British observers, and one repeatedly noticed in private and hospital practice since, is, that when mercury is exhibited in undue quantities, and especially in states of the system not properly prepared for its reception, the constitutional contamination is apt to be of the very worst kind, a sort of mercurio-syphilitic diathesis being established, which, in its remote effects, is more unrelenting and irradicable than the original disease, however severe.

If *hemorrhage* arise during the progress of chancre, no time should be lost in arresting it; the patient may be already much exhausted by previous suffering, and a slight drainage of this kind might therefore prove eminently prejudicial to his recovery. When the blood issues unmistakably from an open orifice, it should at once be secured by ligature or the compressing forceps, a sufficiency of tissue being included in their bite to insure safe maintenance. If, on the contrary, it proceeds from many points, the ordinary styptics will generally suffice for its arrest, especially if the system be promptly brought under the influence of opium.

The morbid *erections* which so often accompany chancre, and which generally so much impede the reparative process, must be treated in the same manner as in gonorrhœa; by the liberal use of anodynes by the mouth or rectum, and by soothing topical applications, either warm or cold, as may be most grateful to the part and system. If hemorrhage be present, they must be controlled at all hazards, on account of their tendency to tear open the bleeding vessels.

Phymosis, complicating chancre, must not be interfered with, unless it act constrictingly, threatening destruction of the prepuce and the glans by mortification. In this event, the parts must be freely divided upon the grooved director, the edges of the incision being immediately cauterized with nitrate of silver or acid nitrate of mercury, to prevent inoculation. In ordinary cases, the tightened foreskin is permitted to retain its place, cleanliness and medication of the ulcer being effected by means of the syringe, as already stated.

Paraphymosis is occasionally present, perhaps to a perplexing and even dangerous extent. The constriction produced by it may be such as to cause excessive œdema of the prepuce, and great engorgement, if not severe swelling, of the head of the penis; inducing a condition of things which, if not speedily relieved, may eventuate in extensive gangrene. These effects may

be brought about whether the chancre be situated on the glans or on the retracted prepuce, and, for the reason just mentioned, always demand prompt attention. An attempt should be made to restore the parts by manual efforts, aided by chloroform, to give the surgeon more perfect command over his movements. This failing, the only alternative is to divide the stricture, care being taken afterwards to keep the wound well coated with collodion.

Chancre of the Urethra.—Chancre occasionally attacks the urethra; probably much oftener than is generally supposed, although its relative frequency to chancre of the prepuce and head of the penis has not been determined. The fact that this disease is liable to occur here was not known, even to the most enlightened syphilographers, until within a comparatively recent period, and hence it is not surprising that many of them should have considered gonorrhœa as capable, in some cases, of giving rise to secondary symptoms. The chancre being concealed in the urethra, the discharge which attended it was regarded as being exclusively the product of gonorrhœa, and the ignorance which existed upon the subject would probably never have been removed if it had not been for the practice of inoculation. The numerous experiments which have been performed upon the subject have proved, beyond the possibility of doubt or cavil, that gonorrhœa is a mere local affection, and that, whenever any constitutional syphilitic phenomena occur as a consequence of a urethral profluvium, those phenomena are due, not to the effects of gonorrhœa, but to those of a urethral chancre.

Chancre of the urethra is generally situated just behind the meatus, or in that portion of the tube which corresponds with the glans; I have, however, repeatedly met with it on the lips of the external orifice; and in the case of a young gentleman, recently under my care, I found a well-marked indurated chancre at least two inches behind the anterior extremity of the tube. The disease occasionally, though very rarely, extends over nearly the whole of the urethra, as far back as the neck of the bladder.

The period of latency of chancre of the urethra is much longer than in the ordinary form of the disease, which, on an average, does not exceed four or five days; here, on the contrary, it is rarely less than three and a half or four weeks. The reason of this would seem to be that the specific virus, being entangled in one or more of the lacunæ of the tube, is incapable of exciting the same rapid influence as when it is brought in contact with an abraded surface upon the head of the penis. Moreover, it is extremely probable that only a very small quantity of the poison generally finds its way into the urethra, and that, consequently, it has great difficulty, not merely in effecting a secure lodgment, but in so multiplying itself as to enable it to produce ultimately an explosive effect upon the mucous and submucous tissues. The urine, passing along the tube soon after the intromission of the specific fluid, will, in general, either wash it entirely away, or, combining with it, effectually neutralize its properties.

The discharge attendant upon chancre of the urethra is generally less copious than in ordinary gonorrhœa; it is also more thin, and of a lighter color, unless the accompanying inflammation is unusually severe, when it may be both profuse and of a thick, bloody character, or thick and yellow with a greenish tinge. There is generally some degree of scalding in micturition, though hardly ever as much as in gonorrhœa, and the site of the chancre is nearly always indicated by a sense of hardness, or a kind of lump easily distinguished by the thumb and finger. When the disease affects the anterior extremity of the tube, it is not uncommon to find great induration of the whole head of the penis with a red and phlogosed appearance of its mucous covering, and considerable tumefaction of the prepuce. Morbid erections are not only frequent but often very painful and troublesome. The disease is usually chronic, and rarely gives rise to fever, although it is liable to be fol-

lowed by secondary and tertiary symptoms. Bubo is not one of its ordinary effects; but a certain amount of contraction of the urethra nearly always is.

The *diagnosis* of chancre of the urethra is often difficult. It is certainly easy enough when the ulcer is situated at the lips of the meatus, or just behind the orifice, the separation of the edges of which will then bring it fully into view, or, at all events, to an extent sufficiently satisfactory. When located farther back, its existence becomes a matter of doubt; for, although the induration which accompanies it may be very distinct, yet as a similar condition may be present in gonorrhœa, in consequence of the development of an abscess, or the escape of a drop of urine into the submucous cellular tissue, no useful deduction can be drawn from it. Perhaps the most valuable rational symptoms are, the unusual latency of the poison, or the extraordinary length of time which intervenes between the impure connection and the outbreak of the disease, the remarkable obstinacy of the attack, resisting, as it generally does, all the various methods of treatment which are commonly directed for the cure of gonorrhœa, and, lastly, the slight scalding in micturition, and the frequent variation in the nature of the discharge, which is now scanty, thin, and serous, and now profuse, thick, and yellow. The only real diagnostic character, however, is furnished by inoculation, which should be promptly resorted to in all cases of doubt on account of the selection of a proper and efficient course of treatment.

The *treatment* of chancre of the urethra is to be conducted upon general anti-syphilitic principles. The remedies which prove so serviceable in gonorrhœa are entirely inert here, except in so far as they may be instrumental in diluting the urine and depriving it of its acrimony. When within reach gentle cauterization with nitrate of silver will be beneficial, and, in obstinate cases, hardly any other direct application will be of much avail. In the intervals of the cauterization, or, in the more intractable forms of the disease, throughout the treatment, different kinds of injections must be used, especially weak lotions of sulphate of copper, tannin, and opium, acetate of lead, bichloride of mercury, and iodide of iron. If the sore be seated near the meatus, the opposite surfaces should be kept apart with a tent medicated with the dilute ointment of the nitrate of mercury; or a small bougie smeared with this substance may occasionally be introduced. If marked induration exist, early but gentle mercurialization must be employed, both as a means of promptly curing the chancre, and of protecting the system from contamination.

Chancre in the Female.—Chancre in the female is most common upon the vulva, in the vagina, and upon the uterus, the relative frequency of the occurrence being in the order here stated. The perineum also sometimes suffers. The inferior portion of the vagina is much more liable to be affected than the superior, but both this part of the tube and the uterus are not nearly as often the seat of the indurated, or true Hunterian chancre, as was at one time supposed, owing probably to the fact that the infecting matter which covers the sore of the penis is wiped off during coitus before the organ has effected full penetration. The nature of the ulcer is easily recognized by its excavated shape, its steep, irregular edges, its foul, unhealthy-looking bottom, and its indurated base. In chronic chancre of the uterus, the hardness is generally wide-spread and most characteristic, the neck and mouth of the organ being almost of a stony consistence, deeply engorged, and of a florid hue.

The soft or non-indurated chancre is much more common than the indurated, the two varieties of sore following, in this and other respects, the same laws in the female as in the male. The former is often multiple, and may acquire a large size; the latter, on the contrary, is usually single, and almost always very small, its dimensions rarely exceeding those of a five cent piece. Both classes of ulcers are frequently the seat of excessive pain, especially

when they attack the vulva and the inferior portion of the vagina. Their march is generally chronic, and their presence can only be satisfactorily determined by careful ocular inspection. In regard to their diagnosis, the surgeon must be guided principally by the history of the case, the character of the patient, and the appearance of the ulcers. When the ordinary means of discrimination fail, inoculation must be practised.

In the treatment of chancre in the female, the same general rules are to be observed as in the treatment of chancre in the other sex. Absolute rest in the recumbent posture, active purgation, the saline and antimonial mixture, anodynes, diaphoretics, the warm bath, and light diet constitute the principal constitutional remedies. The most important topical means are frequent injections of cold water, or cold water impregnated with some mild anodyne and astringent articles; canterization with the solid nitrate of silver or the dilute acid nitrate of mercury; and isolation of the sores by tents of patent lint, medicated with aromatic wine, lotions of tannin and opium, yellow wash, or some slightly stimulating unguent, especially the dilute ointment of nitrate of mercury. In obstinate cases, especially in the indurated chancre, a mild course of mercury will be necessary.

2. BUBO.

Bubo is an enlargement of one or more of the lymphatic ganglions of the groin. It may proceed from a great variety of causes, tending to irritate and inflame the lymphatic vessels leading to these glands; thus it may be occasioned by gonorrhœa, excessive sexual indulgence, fatigue from protracted exercise, injury of the inferior extremity, or the presence of a boil upon the nates, thigh, or perineum. Such swellings are particularly liable to occur in young subjects of a scrofulous temperament, in whom they often arise from the most trivial causes, and generally disappear without much, if any, treatment; the concomitant inflammation being usually very slight and seldom passing into suppuration. The syphilitic bubo, on the contrary, is a specific disease, the result of inoculation with the matter of chancre, and capable of furnishing a secretion similar to that by which it was itself produced. An open syphilitic bubo is, in fact, a chancre, and nothing else. Hence, like the latter, it constitutes merely a form of primary disease; for so long as the poison is limited to the glands of the groin there cannot, of course, be any true contamination of the system. It is only when it passes beyond this point that its operation can become general; up to that period syphilis is essentially a local affection.

The true syphilitic bubo rarely arises until the end of the second week, or the beginning of the third from the appearance of the original sore; cases sometimes occur at an earlier period, as the seventh or eighth day, and, on the other hand, the attack may be postponed until the close of the first month. Some authorities, Puche among the rest, would have us to believe that the disease may occasionally not show itself until after the lapse of three years. Such a statement, although apparently credited by respectable authorities, is too ridiculous to be seriously entertained by any one. Nature undoubtedly constantly deviates from her established laws, but it is impossible to suppose that she could be guilty of so great a departure as such an occurrence as this would imply. We must rather conclude that the fault lies in a want of correct observation than in such a flagrant violation of the laws of syphilis.

Bubo may follow either the soft or the indurated chancre, but in order to do this it is necessary, as a general rule, that the sore should be free from phagedena and gangrene, or, indeed, from severe inflammation of any kind, inasmuch as the absorption of the specific virus and its transmission to the

groin are accomplished with great difficulty when the parts are overpowered by disease. An active, open state of the ulcer, and the smallest conceivable amount of inflammation in the structures immediately around, are, other things being equal, the conditions which are the most favorable to the development of the true syphilitic bubo. Considerable diversity exists in respect to the aptitude with which the two varieties of chancre produce bubo, as well as in regard to the characters of the bubo itself. Thus, the indurated chancre is always followed by bubo, the swelling, which usually involves several ganglions, being hard and chronic, and partaking more or less of the character of the parent sore, without much disposition to suppurate, although it is sure eventually to contaminate the constitution. The pus, moreover, which occasionally forms, is not generally specific, and is for the most part of a thin, ichorous nature. The soft chancre, on the other hand, is only now and then followed by bubo; the disease, which attacks only one gland, always runs its course very rapidly, and soon terminates in the formation of an abscess, the fluid being both abundant and readily inoculable.

However produced, the specific bubo will generally be found to occur on the same side as the chancre. Thus, if the ulcer exist on the right side of the penis, the right groin will be the one to suffer, and conversely. Now and then an exception to this rule is met with, depending, probably, upon an interlacement of the lymphatic vessels, those of the right side passing over to the left, and the reverse. A bad form of bubo occasionally occurs at the root of the penis, or upon the pubes, caused by the presence of an infected ganglion.

Both sexes are liable to syphilitic bubo; but males suffer much more frequently than females, owing to the difference in the arrangement of the lymphatic vessels, those of the former passing in a much more direct manner than those of the latter from the seat of the disease. In chancre of the uterus and upper part of the vagina bubo is uncommon, and the same law holds good in chancre of the urethra in men.

The relative proportion of bubo to chancre has not been settled; while the indurated form of the disease is very generally followed by swelling of the inguinal glands, soft chancre does not perhaps produce such an effect oftener than in one case out of four.

An opinion has extensively prevailed during the last twenty years, or more, that a bubo may form in the groin without the intervention or antecedence of a chancre, in consequence of the direct absorption of the specific poison from a mucous or cutaneous surface. It is maintained by the advocates of this doctrine that such an effect is possible, because, as they allege, bubo and even constitutional symptoms occasionally occur without any evidence whatever of their having been preceded by primary ulcers upon the genitals. They assume that the matter in which the poison is entangled, or held, as it were, in solution, may be absorbed by the mucous or even the cutaneous surface of the penis in the same manner, and upon the same principle, as morphine, atropine, and other articles of the materia medica, and that, being subsequently conveyed by the lymphatic vessels to the groin, it is capable of infecting its glands in such a way as to form a true syphilitic bubo. Hence, the disease has been called the primary non-consecutive bubo, or, to use a French phrase, *bubon d'emblée*. The existence of this variety of inguinal enlargement was admitted by several of the older writers on syphilis, especially by Astruc and Swediaur, and has been dwelt upon at much length by Ricord and his disciples. Many of the most experienced practitioners, however, in all parts of the world, positively assert that they have never met with it, and, as for myself, I am quite sure that no instance of the kind has ever fallen under my observation. My belief, therefore, is that the occurrence is a mere chimera, explicable on the supposition that the chancre

which precedes it is so small and evanescent as to elude detection. It is certain that such slight and transient ulcers often do appear on the genital organs of both sexes, and that, notwithstanding they do not attract any attention either on the part of the patient or his attendant, they are yet not unfrequently followed by the worst forms of constitutional contamination.

An excellent observer, Dr. Bumstead, of New York, in his able work on venereal diseases, in speaking of this subject, makes the following very apposite remarks:—"The existence of a bubon d'emblée, secreting inoculable pus and capable of infecting the constitution, is entirely inconsistent with our present knowledge of venereal diseases, and cannot now, as formerly, be admitted. The reported cases of this character are very far from being conclusive."

Varieties.—Bubo, like chancre, is susceptible of a great variety of forms. Thus, it may, after having progressed a certain distance, remain stationary, perhaps even several months, manifesting no decided disposition either to advance or to recede. Conjoined with this indolent, passive, or inactive state is generally a certain degree of hardening, such as we so often observe in the chronic indurated ulcer upon the head of the penis. Such a swelling is always to be dreaded on account of the disposition which the specific poison has to lurk in the substance of the affected glands, from which, in time, there is great danger of its being conveyed into the system, so as to give rise ultimately to secondary and tertiary symptoms. The bubo, in fact, is a hot-bed, not merely for the temporary lodgment of the virus, but for its zymotic operation, and its gradual extension to other and more important structures.

In another class of cases the enlarged glands, taking on inordinate inflammatory action, pass into *suppuration*, the matter usually collecting in a solitary abscess, of an ovoidal shape, and from the volume of an almond up to that of a goose's egg. When the disease assumes this form, it generally runs its course with considerable rapidity, being characterized by severe constitutional disturbance, such as rigors, fever, and headache, and by intense local suffering, the pain being of an aching, throbbing character, the swelling great, the heat excessive, and the discoloration of a dusky livid red. If the matter, which is generally of a thick, yellowish appearance, intermingled with blood and cellular sloughs, be not promptly evacuated, it is apt to burrow among the neighboring tissues, causing extensive sinuses, which it is often extremely difficult to heal, and which occasionally lay open most important structures. In neglected cases I have seen such an abscess, more than once, pass high up over the abdomen, and low down upon the front of the thigh. In the indurated bubo, the result usually of an indurated chancre, the secretion is generally comparatively scanty, and of a thin, ichorous, sanious, or sanguinolent nature. Whenever the quantity of matter is unusually large, it may be assumed that it is furnished by the cellular tissue in which the affected glands are wrapt up rather than by the glands themselves.

When the contents of the abscess have been discharged, whether spontaneously or otherwise, the disease takes the name of an open or *ulcerated* bubo, a state in which it may remain, with very little change, for an almost indefinite period. The discharge from such a sore, which is always situated above Poupart's ligament, and which inclines from above downwards and inwards, may partake more or less of the character of laudable pus, or it may, as most generally happens, be thin, ichorous, and irritating, its quantity varying from several drachms to upwards of an ounce in the twenty-four hours. How long it may retain its specific properties is unknown. The edges of the sore exhibit very much the same appearances as those of a common chancre; thus, they may be very steep, hard, and ragged; everted,

inverted, or undermined; thick or thin; pale, reddish, dusky or purple. The bottom is usually incrustated with a dirty, greenish, or yellowish pultaceous substance, with here and there a small, fiery looking, exquisitely sensitive granulation. Sinuses often extend from the main ulcer in different directions, and it is not uncommon, when the destruction has been at all extensive, to see some of the affected ganglions lying in a partially detached state at the bottom of the sore, perhaps adhering merely by a few shreds of cellular tissue.

An ulcerated bubo may take on *phagedenic* action, extending more or less rapidly in different directions, just as in the case of a chancre occurring in an unhealthy constitution. This epiphenomenon may show itself soon after the swelling has been laid open, or not until after the lapse of several weeks or months. It is usually characterized by severe pain, by a thin, profuse, sanious discharge, and by a foul pultaceous state of the sore, along with an irritable condition of the system, want of appetite and sleep, and disorder of the alimentary canal.

Finally, a syphilitic bubo may become the seat of *gangrene*; sometimes before ulceration sets in, but usually not until afterwards. Such a termination is most apt to occur in the lower classes of patients, the inmates of cellars, prisons, almshouses, and other filthy places, and often produces the most frightful ravages, causing extensive destruction of the skin and cellular tissue, as well as, in some cases, of the muscles of the abdomen. The symptoms are generally very severe, and the disease often proves fatal, the sufferer, meanwhile, forming a most loathsome and disgusting object.

Diagnosis.—Syphilitic bubo is liable to be confounded with bubo from other causes, and hence it is by no means always easy to determine the diagnosis, desirable as it is that there should be no mistake upon a subject of such practical moment. There are a few points in connection with these two classes of swelling which are deserving of attention as means of discrimination. In the first place, the surgeon must carefully consider the history of the case. If the bubo be of a syphilitic nature it will not, as a general rule, come on until the end of the second week from the primary disease, and in many instances, indeed, not until a considerably later period. In the common bubo, on the contrary, the swelling usually supervenes within a short time after the exciting cause has begun to act. Thus, a boil upon the nates, or a corn, bruise, or other injury of the toe, is usually followed by a bubo within the first three or four days after the local affection has sprung up. Secondly, useful information may be obtained from the duration of the swelling. A syphilitic bubo usually lasts a number of weeks, often, indeed, several months; an ordinary bubo, on the other hand, generally promptly disappears with the exciting cause that induced it. Thirdly, the specific bubo often suppurates and ulcerates; the common bubo seldom, if ever, and then only in persons of a scrofulous and broken constitution. Fourthly, the matter of the syphilitic bubo is often inoculable; of the common, never. Finally, the syphilitic swelling is always situated above Poupart's ligament, affecting mostly only one gland; the non-syphilitic swelling, on the contrary, is usually situated below that band, or partly below and partly above, and generally attacks several ganglions, though rarely in an equal degree.

The scrofulous bubo occurs only in persons of a scrofulous diathesis, mostly in children prior to the age of puberty. It commonly affects a considerable number of glands simultaneously, and they remain enlarged for a long time, being very hard and lobulated, and slowly tending to suppuration. The matter is of a yellow-greenish hue, and collects in several little abscesses, which, bursting, leave ill-conditioned ulcers, with thin, bluish, undermined edges, and a thin, sanious, irritating discharge, destitute of inoculable properties. The bulk of the swelling is usually situated beneath Poupart's

ligament, at the upper and inner part of the thigh; and traces of strumous disease generally occur in other parts of the body.

Treatment.—The treatment of bubo must be conducted upon the same general principles as that of chancre, of which, as already stated, it is simply another form. If the disease be seen early, before there is much inflammatory action or any decided tendency to suppuration, the abortive treatment will come in play, consisting of the free application of tincture of iodine, and of concentrated compression, either with a truss, or a series of linen pads and the spica bandage. There are few cases of incipient bubo which can resist the combined influence of these remedies, if properly managed. If the compression, in the efficacy of which I have great confidence, proves painful, it must be moderated, or altogether pretermitted for a time. Occasionally the treatment is advantageously preceded by the application of leeches.

If the disease has already made considerable progress, iodine and compression will probably prove insufficient, and then more active measures will be required. Of these, the most efficient is the formation of an eschar upon the most prominent portion of the swelling by means of the Vienna paste, applied as in making an issue, or a solution of bichloride of mercury, in the proportion of twenty grains to the ounce of alcohol. The skin having been previously elevated by a small blister, a compress wet with the lotion is firmly bound upon the raw surface, and retained for two hours, when it is replaced by an emollient poultice or the warm water-dressing. The pains produced by this application are excessive, and hence the paste usually deserves the preference, especially as it does not possess any special therapeutic advantages. The new action created by the caustic neutralizes or overwhelms the pre-existing, and rapidly destroys the specific disease.

When suppuration is threatened, or inevitable, the process should be expedited by the usual means, aided by recumbency and a relaxed position of the lower extremity. As soon as fluctuation is observed, the parts are freely divided, even if the matter be deep-seated, in order to give full vent to the confined fluid. A tent is kept in the opening to prevent closure of its edges. The incision should always be made in the direction of Poupart's ligament. If the bubo is chronic and indurated, the operation is sometimes attended with considerable hemorrhage, chiefly, however, of a venous nature, and consequently easily arrested by pressure and quietude. When the suppurative process is very slow and imperfect, as it sometimes is, especially in the variety of bubo just mentioned, the most appropriate application is a large blister, retained sufficiently long to produce thorough vesication, and dressed with an emollient poultice. When the accumulation of pus is very large, it has been proposed to effect its evacuation, not by incision, but by a number of punctures, on the ground that the procedure would be less destructive to the integument than the more common operation. I have not, however, found such a result to obtain in my own practice. On the contrary, the skin and cellular substance are generally so much detached and impoverished as to render it impossible to preserve them with any reasonable prospect of their ultimate reunion. Hence, I am always in favor of a free division; nor do I hesitate afterwards to remove such portions of integument as may seem to act obstructingly to the reparative process by overhanging the surface of the ulcer, and interfering with its medication. If sinuses form, they must be laid open in the usual manner: fungous granulations are repressed with escharotics, as sulphate of copper and nitrate of silver, or, what is better, the scissors. If the constitution is impaired by protracted suffering and confinement, tonics and change of air will be required; and in all cases proper attention is paid to the diet, the bowels, and the secretions. Should phagedena or gangrene supervene, the same line of treatment will be demanded as under similar circumstances in chancre. The chronic indurated bubo will

rarely yield in a satisfactory manner until the system is brought gently under the influence of mercury.

SECT. III.—SECONDARY SYPHILIS.

1. GENERAL CONSIDERATIONS.

The term secondary is employed to designate that group of morbid phenomena which manifest themselves after the occurrence of primary syphilis, the period of their evolution varying, on an average, from five to eight weeks from the first outbreak of the disease. The structures which are most liable to suffer are the cutaneous and mucous, and these may be attacked either simultaneously or consecutively, or one may suffer and the other escape, according to the condition in which they may happen to be at the time of the contamination.

Secondary syphilis is always preceded by chancre, for there is no reason to believe, as has been stated elsewhere, that the specific virus ever finds its way into the system by direct imbibition, or without the intervention of a breach of continuity of some kind or other. This fact is too well established to admit of any doubt. Bubo, however, does not always precede it; in many cases, in fact, the inguinal glands remain completely intact, and yet the constitutional symptoms may be of the very worst character, occurring, perhaps, early after the primary disease, and exploding with peculiar virulence upon the cutaneous and mucous tissues. It would be interesting, in a practical point of view, if we could determine the relative frequency of secondary symptoms and bubo, or how often in a given number of cases constitutional syphilis occurs with involvement of the inguinal glands, and, on the other hand, how often bubo exists without being followed by consecutive derangement. For the solution of this question, however, there are, unfortunately, no sufficient data. As was previously stated, the indurated chancre is nearly always succeeded by constitutional involvement, occurring early in the disease, and generally giving rise to the most serious, if not to positively irremediable, effects. It has lately been insisted upon by certain authorities that the soft or non-indurated chancre is solely a local affection, and therefore never followed by any specific vice of the general system. In this doctrine I cannot agree, for I can see no reason, on general pathological principles, why an ulcer which furnishes an infectious virus, as the soft chancre is well known to do, should be capable of inoculating certain tissues and not others; why, in other words, it should be able to reproduce itself locally, and yet not be able to affect, implicate, or contaminate the constitution. To assume the possibility of such an occurrence would be, as has been remarked elsewhere, to suppose that there are two distinct poisons, a view which is contrary to all reason, science, and analogy, and therefore altogether untenable. But the observant practitioner is not driven to the adoption of so absurd a conclusion; he appeals to his personal experience, and is satisfied that he has repeatedly seen the very worst cases of secondary symptoms succeed to the soft chancre. I am sure it has repeatedly fallen to my lot to witness such effects, and I therefore regard this doctrine as a most pernicious one, calculated as it is, if practically followed, to throw the surgeon off his guard, and thus prevent him from adopting a suitable treatment for the relief of his patient.

Secondary symptoms often come on before the primary have disappeared; a chancre, indeed, may, so to speak, be in full bloom, and continue to furnish an abundance of specific virus, and yet the constitutional disease have already made considerable progress, the skin being perhaps covered with eruptions, the throat inflamed or ulcerated, and the tongue affected with tubercles, thus

showing thorough contamination both of the solids and fluids. Or, the chancre may have become cicatrized, but remain hard and tender, more or less of the specific poison lurking in the affected tissues, ready to ferment and break out anew from the most trivial causes. Or, the original sore may have got entirely well, but the bubo be still in action, either as an indurated swelling, or as an ulcer with more or less discharge. Or, lastly, and as is perhaps most commonly the case, the secondary complaint does not display itself until some time after the primary has completely disappeared, and the patient has perhaps imagined himself perfectly well.

It is generally impossible to determine, in advance, what effect a chancre may exert upon the system; or, in other words, whether it will be likely to lead to constitutional contamination. There are certain circumstances, however, which, like coming events, cast their shadow before them, and thus serve to enable the attendant to form at least a plausible conjecture, if not a positive conclusion, in respect to the future condition of the system. These circumstances may be arranged under the following heads:—

1st. It is now generally, if not universally, admitted that the indurated chancre is nearly always followed by secondary symptoms; often, if not usually, coming on before the primary sore is completely healed, and producing a degree of contamination which it is extremely difficult, if not impossible, to eradicate completely from the system. The constitution, once affected, nearly always retains the peculiar impress which it has received from the virus, in so much that the disease is probably capable of being propagated from parent to offspring during a series of generations.

2d. The non-indurated chancre, if multiple or of great extent, will, other things being equal, be more likely to give rise to constitutional involvement than a single sore, especially if superficial and of small size.

3d. The site of the chancre probably exerts some influence upon the production of secondary symptoms. Thus, there is reason to believe that a specific ulcer seated upon the inner surface of the prepuce, or at the free border of this muco-cutaneous fold, will be more likely to lead to contamination of the system than a chancre on the head of the penis, owing probably to the greater activity of the absorbent vessels in the former than in the latter. A chancre of the urethra is rarely followed by constitutional infection.

4th. Constitutional involvement is also influenced by the duration of the chancre. It has been conclusively shown that if a chancre, even if it pertain to the indurated variety, be cured or removed before the end of the fifth day from the time of the inoculation, there is, as a general rule, no risk whatever of systemic contamination; and it is perfectly reasonable to suppose that the chances of absorption of the specific virus will be much diminished, in every case, whatever may be the nature or site of the sore, in proportion to the shortness of its duration. Hence the absolute importance of getting rid of such a sore in the most summary and thorough manner.

5th. The state of the patient's health greatly influences the production of secondary syphilis. If he be stout and robust, and, in every respect, well conditioned, both as it concerns his solids and fluids, the poison will be much less likely to be conveyed into the system than if he be feeble and exhausted by disease, or laboring under a strumous or scorbutic cachexia.

6th. The kind of treatment also produces a marked effect upon the occurrence of a syphilitic diathesis. There is no doubt at all that, as a general rule, secondary symptoms are much more liable to declare themselves if mercury be given for the primary disease than when the cure is accomplished without it. The results of upwards of 80,000 cases, treated by the simple method in various parts of the world, conclusively establish this fact.

7th. The degree and character of the inflammatory action accompanying the chancre often greatly influence the occurrence or non-occurrence of con-

stitutional symptoms. When the inflammation is unusually severe, or of a highly phagedenic type, absorption will be kept in abeyance, and the system escape contamination. Gangrene, supervening early in the progress of the chancre, always prevents the absorption of the specific virus.

Finally, it is not improbable that the occurrence of secondary accidents is materially influenced by individual peculiarity or idiosyncrasy. It is well known that some persons contract primary syphilis with great difficulty, and, on the other hand, there are some who can never touch an infected female without being inoculated. The same is true of secondary syphilis. Thus, one man whose penis is literally covered with chancres may escape constitutional contamination entirely, while another, who has only a small sore precisely of the same kind, may suffer very severely. There must be great individual peculiarities in regard to the susceptibilities to the action of this poison, otherwise it would be impossible to account for the remarkable diversities which characterize the evolution and course of this disease in different persons.

Secondary syphilis is not *contagious*, thus showing that the specific virus, after it has fully entered the system, undergoes changes which essentially modify its properties and disqualify it for the production of an inoculable disease. I am aware that a contrary opinion has been held by some very eminent authorities, and that the experiments of Vidal, Cazenave, and others, with the pus of syphilitic ecthyma, would seem to countenance such a view; but it is impossible not to believe that these distinguished syphilographers, in their zeal to promote the interests of science, were deceived by accidental circumstances connected with the state of the system of those who were the subjects of their researches, causing it to give rise to an appearance similar to, but by no means identical with, that of a chancre or an infectious pustule. Indeed, if such an occurrence were possible it would manifest itself constantly during the progress of secondary syphilis in consequence of the secretions coming in contact with raw surfaces upon the skin and mucous membranes.

But, although secondary syphilis is not contagious, it is *transmissible* from the parent to the offspring, probably not merely through one but through many generations, the result declaring itself in a great variety of affections, and often proving destructive to the new being, sometimes before birth and other times not until afterwards. The very stream of life is poisoned, and all those who partake of it are destined to suffer from its effects, this being at least one way in which "God visits the iniquity of the fathers on their children, down to the third and fourth generation." The very fact that the disease is transmissible shows that the whole system of the individual is impregnated with the specific poison, every globule of blood and every particle of solid matter being impressed by it. It is this pervasive, universal influence that has led to the opinion, now very general on the part of the best educated members of the profession, that constitutional syphilis is seldom, if ever, completely eradicable. Once implanted in the system, its germ is probably indestructible.

Secondary syphilis is usually ushered in by well-marked *constitutional* phenomena. Generally some days—frequently as many as eight or ten—before there is any evident local disease, the patient feels conscious that he is unwell, or that there is something wrong about him; he is in a state of *malaise*, or in that uncomfortable condition in which a man is neither well nor yet decidedly sick. Prominent among these symptoms is his mental dejection; he is gloomy and desponding, indulging in unpleasant forebodings, and unable to apply himself to business; his countenance assumes a dull, muddy appearance; his hair becomes dry and rough; his limbs and joints feel sore and stiff; his appetite is indifferent; the bowels are inclined to be costive; the urine is scanty and high-colored; exercise soon fatigues; and the sleep, disturbed by fre-

quent dreams, is unrefreshing. Gradually, after the lapse of a few days, or, it may be, all of a sudden, the patient is seized with chilly sensations, or actual rigors, followed by high fever, or by fever and profuse sweats. The attack, which constitutes what is called *syphilitic fever*, is manifestly an effort of the system to eliminate the specific poison, and the tissues upon which it usually explodes are, as was previously stated, the cutaneous and mucous, together with the posterior cervical ganglions, the morbid phenomena of the former exhibiting themselves in various eruptions, and of the latter in ulcers of the throat and tubercles of the tongue. The iris may also be enumerated as liable to suffer from secondary involvement.

2. AFFECTIONS OF THE SKIN.

The syphilitic affections of the skin, the *syphilides*, as they have been termed by Alibert, manifest themselves under at least six varieties of form, the exanthematous, scaly, vesicular, pustular, tubercular, and papular. Of these, however, the last three, in consequence of the lateness of their appearance and the severity of their character, may be regarded rather as appertaining to the tertiary order of phenomena than to the secondary. Of the other three, two are not unfrequently coincident with the primary disease, although, in general, they do not show themselves until some time afterwards. The syphilitic eruptions nearly always pursue a chronic course, are more or less circular in their form, and always exhibit a characteristic copper color, especially in their earlier stages; for, after they have existed for some time, they are very apt to assume a grayish, muddy, or bronze appearance, owing to some modification in the coloring matter of the skin. Although occurring upon all parts of the cutaneous surface, they are usually most conspicuous upon the forehead, nose, cheek, back, and shoulder, together with the inside of the arm and thigh, and are followed or attended by thin, grayish scales, hard, thick, greenish scabs, narrow, superficial cracks, or well-marked ulcers.

Syphilitic cutaneous diseases can generally be easily distinguished from ordinary skin diseases; first, by the history of the case, especially the existence or absence of chancre; secondly, by the concurrence of lesions of the cutaneous and mucous textures; thirdly, by the copper color of the affected surface, the eruption, scale, or pustule being itself either of that complexion, or surrounded by a more or less distinctly defined border of it; and, lastly, by the total absence of itching in syphilitic affections, whereas that symptom is of very common occurrence in ordinary cutaneous maladies.

1. In the *exanthematous* form, the spots are of a dark copper color, of a circular shape, and from the size of a dime to that of a twenty-five cent piece, the intervening surface being of a muddy, dusky aspect. Although they sometimes cover nearly the whole body, yet they are generally most prominent on the trunk and extremities; they are never confluent, do not disappear under pressure, and usually pass off with a slight desquamation of the cuticle. There is a variety of this eruption in which the spots are of much smaller size, more irregular in shape, and of a brighter red, the color resembling that of a new copper coin. From this circumstance, and from the eruption being often somewhat confluent, like measles, it is generally known by the name of *roseola*. In neither of these forms is there any actual elevation of the skin.

The syphilitic exanthem often comes on before the disappearance of the primary disease, sometimes suddenly, and without any decided premonitory symptoms; at other times gradually, and with considerable pyrexial disturbance. As the eruption fades it loses its reddish tint, and assumes a dingy, dirty, dusky, or grayish aspect. Its duration varies from ten days to three or four weeks. Its gradual disappearance, and its coincidence with chancre,

bubo, cervical adenitis, and other marks of syphilis, either primary or secondary, together with the absence of local distress, as itching and smarting, readily distinguish it from measles and other cutaneous affections.

2. The *scaly* variety of syphilis generally appears without any febrile disturbance, from six to ten weeks after the primary disease; it is always remarkably chronic, lasting frequently for months together, and is commonly associated with ulceration of the throat and palate, iritis, and affections of the bones and joints; forming, in this case, a kind of connecting link between the secondary and tertiary stages of the constitutional malady.

The eruption manifests itself, as the name implies, in distinct scales, or thick and hardened portions of epidermis, of a dull, opaque, grayish appearance, resting upon a copper-colored base. It generally appears in separate patches, which, although they may occur on all parts of the cutaneous surface, are, nevertheless, most common on the forehead, scalp, face, forearms, palm of the hand, and sole of the foot, in the latter of which they often acquire a remarkable thickness. Each individual spot is from three to twelve lines in diameter, of a rounded shape, ordinarily isolated, rough, and somewhat elevated beyond the adjoining level. The scale is hard, whitish or grayish, and slightly adherent; the skin underneath has a tendency to ulcerate, or to form cracks and fissures, and when, by this means, its integrity is destroyed, the affected surface becomes covered with a thick, dry, brownish crust. When the part has cicatrized, a whitish spot, somewhat depressed at the centre, marks the original site of the disease.

3. The *vesicular* variety of syphilitic disease is of very uncommon occurrence; it is, in fact, by far the rarest of all the syphilides. It usually begins coincidently with the latter stages of the primary sore, or soon afterwards, in minute, circumscribed pimples, scattered over different parts of the body, to which soon succeed small vesicles, occupied by a transparent, serous fluid, and surrounded by a reddish, copper-colored areola. Their progress is slow, and their contents are either absorbed, or they harden into thin scales, or scabs, which, falling off at different intervals, leave the part of a dingy, yellowish hue. The vesicles, which exist in distinct groups, are occasionally, though rarely, so numerous as to cover nearly the whole surface of the body. In general, they are most common on the neck, chest, and extremities, especially the superior, their occurrence on the face and head being very infrequent. They usually coincide with syphilitic disease of the throat, and nodular pains in the bones and joints; a circumstance which, together with their copper-colored base, readily distinguishes them from ordinary vesicles.

4. Syphilitic *pustules* consist of circumscribed elevations of the skin, occupied by pus, or sero-purulent matter, and possessing a strong tendency to terminate in ulceration. Although they occasionally co-exist with the primary disease, they seldom appear until a long time after, and therefore generally appertain to the third order of symptoms, their presence being always denotive of profound constitutional contamination. Their size and figure are subject to considerable diversity. Sometimes they are as large as a hazel-nut; but ordinarily they do not exceed the volume of a pea, and in many cases they do not attain even that size. In their shape they are conical, oval, pyriform, rounded, or flattened, with a minute central depression; and there are few instances in which these different varieties do not co-exist. Their number is often immense, hundreds being scattered over a small extent of surface; and, as they form successively, they may be seen and studied in every stage of their development. Each pustule reposes upon a hard, copper-colored base, and is apparently of a very complex structure, though its precise character is undetermined.

After remaining for a short time, the contents of the pustule escape, congregate, and form hard, thick scabs, of a dark color, pretty firmly adherent, and

sometimes circularly furrowed. In the more simple cases, the scabs soon fall off, leaving merely a chronic induration, a livid, dusky, or grayish stain, or a small cicatrice; in the more severe forms of the disease, on the contrary, deep, circular, characteristic ulcers are exposed, with a foul, grayish bottom, and a hard, purple, and well defined margin. In cases of the latter description, the scabs are frequently renewed, and are finally succeeded by round, indelible scars.

There are two varieties of syphilitic pustules, the one, termed the *psudra*, occurring in groups, and the other, the *phlyzations*, disposed separately, without any tendency, as is sometimes the case with the other, to become confluent. Willan and some other dermatologists have described them under the generic appellation of syphilitic *ecthyma*. It is the matter furnished by these pustules that has been erroneously supposed by Vidal, Cazenave, and a few other observers, to be capable of transmitting secondary syphilis by inoculation.

The pustular form of syphilis is not unfrequently associated with the tubercular and papular, but rarely with the roseolar and squamous. Severe constitutional disturbance is generally present, and, indeed, the suffering may be so great as to destroy life, the health being gradually undermined by the excessive pain and irritation of the eruption and its sequelæ.

5. In the *tubercular* variety of syphilis, the most formidable, if not also the most frequent of all, the eruption consists of small, red, copper-colored eminences, varying in size between that of a mustard-seed and an olive. Of a rounded, flattened, or conoidal shape, they are either isolated, assembled in groups, or arranged in perfect circles; they are smooth and polished, produce little or no pain, and become covered, in a short time, with a dry, scaly incrustation, which is generally reproduced as fast as it falls off.

In the more aggravated forms of this variety of syphilis, the tubercles are inordinately large, prominent, of a deep violet hue, from three to six lines in length, and encircled by a well-marked, copper-colored areola. After continuing thus for some time, varying from a few months to several years, they inflame, suppurate, and are finally replaced by deep, foul, painful, irregular ulcers, reposing upon a hard, purple base. The thick scab which usually covers these erosions is repeatedly renewed, showing, whenever it is detached, that the sore is extending its ravages. When the tubercles are numerous, the ulcers, running together, often acquire a frightful size, and, on healing, leave disfiguring cicatrices.

6. *Papular* syphilis is characterized by the occurrence of small, hard, solid elevations, containing no fluid, and terminating almost always in desquamation, seldom in ulceration, or in the formation of scabs. There are two varieties of the affection, one of which is acute and primary, the other chronic and secondary.

In the first variety, the eruption appears simultaneously on different regions of the body, and is completed in about forty-eight hours from the time of its invasion. The papulæ are extremely small, disjointed, or grouped, of a red copper color, and of a slightly conical shape, being surrounded, here and there, by violet areolæ, which are often confluent, and give the surface a characteristic yellow tinge. Ulceration rarely attacks these papulæ; they disappear in a short time, and are followed by a furfuraceous desquamation of the cuticle.

In the other variety, the eruption is developed in a slow and successive manner, being announced by small yellow spots, which are particularly numerous on the forehead, scalp, and extremities. The papulæ, which are of a light copper color, are larger than the preceding, flat, of the size of small beans, grouped, and devoid of an areola. In time, the summit of each elevation becomes covered with a dry, grayish pellicle, which is regenerated as fast as

it desquamates, until the disease finally entirely subsides. Meanwhile, the skin between the agglomerated papulæ undergoes important changes; it assumes a dingy yellowish color, has a dry, shrivelled aspect, and is the seat of a constant exfoliation of the cuticle.

Treatment.—The treatment of secondary cutaneous syphilis may be divided into common and specific, the first being of a general antiphlogistic character, while the second has for its object the neutralization or destruction of the virus upon whose action the affection more particularly depends, and which, so long as it continues, exposes the system constantly to new outbreaks of the disease. In general, it will be found to be advantageous to begin the treatment with antiphlogistic remedies; for, although they may not always, or perhaps even very frequently, eradicate the poison, yet it is unquestionably true that the salutary impression which they make upon the system, by ridding it of its impurities, and restoring the secretions, greatly paves the way for the more prompt and efficient operation of any specific measures that may afterwards be deemed advisable. A disregard of this rule is probably one of the chief reasons why the mercurial treatment of syphilis is so often followed by severe tertiary symptoms, the system not being properly prepared, by a course of dieting, baths, purgatives, and other remedies, for the reception and beneficial action of the mineral.

Syphilitic fever should be combated upon the same general principles as any other kind of sympathetic fever. If the symptoms run high, as indicated by the state of the pulse and skin, and the patient is young and plethoric, blood may be taken from the arm, and the saline and antimonial mixture be directed, the bowels having been previously opened by a brisk cathartic. The action of the medicine should be promoted with tepid drinks, and, if there be much pain and aching in the back and limbs, a Dover's powder, or an anodyne and diaphoretic draught will probably be necessary. The duration of the fever is usually very short, the disease often yielding to very simple measures.

When eruptions appear upon the skin, the treatment which I usually adopt is the *antimonial*, having found it to answer an excellent purpose in a great majority of the cases of the disease that have fallen under my observation. The quantity of tartar emetic to be given at each dose must vary from the fourth to the eighth of a grain, repeated every three, four, or five hours, according to the influence of the remedy, decided nausea being hardly ever desired. The object is to produce only a sedative and alterant effect. It may be administered by itself, as in the milder forms of secondary cutaneous affections, or be variously combined with other articles, as sulphate of magnesia, when there is constipation, aconite, when there is much arterial excitement, or morphine, when an anodyne and diaphoretic action is desired. The salutary operation of the medicine will be greatly promoted by the daily use of the tepid bath, by diluent drinks, and by the strict observance of the antiphlogistic regimen.

How tartrate of antimony and potassa acts in producing its salutary effects in secondary syphilis of the skin has not been determined. It is not improbable that it may, as mercury is supposed to do, neutralize the poison of the disease, by divesting it of its zymotic qualities; or it may act simply as an eliminator, by furnishing an outlet for the poison through the various emunctories, upon all of which this medicine is known to exert more or less influence.

Tartarized antimony, then, according to my experience, is the great remedy upon which our reliance is mainly to be placed in the treatment of secondary syphilis, especially of the skin, and, also, although in a less degree, of the mucous membrane. If the remedy fail, or the disease prove rebellious, recourse must be had to mercury, given in the same manner, and with the

same restrictions, as in the primary form of the disease. The use of the latter medicine may, I am satisfied, be limited to a very narrow circle of cases of secondary syphilis, and it will be found that, whenever it becomes necessary, its action will be immensely promoted by the previous employment of tartar emetic.

3. ALOPECIA.

During the progress of syphilis it occasionally happens that the hair of the scalp falls off, constituting what is technically called alopecia. The accident generally comes on within the first six or eight weeks from the appearance of the primary sore, with which, consequently, it is not unfrequently coincident, and usually occurs in circular disks, of variable size, and of a well-marked copper color, similar to the eruptive syphilides. The affection is commonly partial, showing itself, as just stated, in distinct patches, of which several may exist simultaneously, or as fast as one gets well another may succeed, and thus the affection may proceed until it has travelled over the greater portion of the scalp; or, instead of this, nearly all the bulbs may suffer at once, and the hair drop off in great numbers, leaving the head ultimately nearly completely bare. When the system is, as it were, saturated with the specific virus, not only the hair of the scalp, but also of the beard, the eyebrows, and the rest of the body may drop off. I have seen two well-marked cases of this universal alopecia, both occurring in young men who had been the subject of indurated chancre upon the head of the penis; in one the desquamation was associated with roseola and sore throat, and was never followed by a reproduction of hair anywhere. The patient, after having lingered for several years under the exhausting effects of rupia and nodes, died in a state of marasmus. In the second case, the alopecia was succeeded by syphilitic sarcocele; and in this the hair, in time, was regenerated upon the scalp, although it always remained stunted, and was remarkably coarse, stiff, and sparse.

The first sign of baldness usually consists in a loss of the soft and glossy state of the hair, which becomes dry, stiff, and brittle, breaking off very easily in combing the head. After a little while it is observed to fall off in great abundance; and if the scalp be now examined it will be found to be remarkably harsh and scurfy, and to be covered with muddy, dingy, or dusky, copper-colored blotches, generally of a circular shape, and apparently, though not in reality, somewhat elevated above the adjoining surface. Fever occasionally accompanies the affection; and pains in the bones and joints, apparently of a rheumatic nature, generally characterize the progress of the case. Regeneration of the hair, partial or complete, may usually be expected, even under apparently the most adverse circumstances.

Baldness, as an effect of syphilis, is a grave occurrence, and the practitioner cannot be too eager in his attempts to arrest it. The first thing to be done is to cut off the hair, not too closely, but just sufficiently to admit of the requisite attention to cleanliness and medication. Shaving of the scalp is not necessary in any case, however severe. The treatment, directed more especially to the relief of the diseased hair-bulbs, must be essentially of a stimulating character, the object being to impart tone and vigor to the whole of the affected surface. In the more simple cases mild lotions of alcohol and spirits of hartshorn, eau de Cologne and compound spirits of lavender, or alcohol, glycerin, oil, and tincture of cantharides, either in equal, or in different proportions, may be used, according to the desired strength of the particular preparation. Another excellent wash is a solution of tannin and sulphate of copper in equal parts of spirits of wine and water, six grains of the former, and half a grain of the latter being used to the ounce of fluid. The applica-

tion should be made twice in the twenty-four hours, the friction being performed with the hand and fingers, and steadily continued until there is a glow upon the surface. The scalp should be washed every morning with warm water and Castile soap, and well combed immediately after to promote cleanliness and dislodge dandruff.

If soreness of the scalp exist, or if there be eruptions, papules, tubercles, or numerous dry and adherent scales, the most eligible application will be a pomade of simple cerate and of the ointment of the nitrate of mercury, in the proportion of seven parts of the former to one of the latter, mixed with a few drops of the oil of jasmine and a little Cologne water, and thoroughly rubbed into the roots of the hair night and morning. Along with these means special attention should be paid to the state of the system, and if the case threatens to be obstinate, or if the alopecia coexist with an indurated, indolent, or badly-healed chancre, measures should be adopted to bring the patient as promptly as possible under the gentle influence of mercury.

4. SYPHILITIC ABSCESES.

The subcutaneous cellular tissue is occasionally the seat of what might be termed the syphilitic abscess. It belongs to the third order of symptoms, and presents itself as a multiple affection. In the few cases that have fallen under my observation the abscesses were scattered over the body in immense numbers, being particularly abundant on the anterior portion of the trunk and on the inside of the arms and thighs. Their volume varies from that of a currant to that of a pea; they rest upon an indurated base, and are generally grouped rather closely together. Their contents are of a white, yellowish appearance, and of a somewhat tough consistence, partaking very much of the character of a mixture of pus and aplastic matter. The progress of the disease is usually very tardy; the general health is a good deal disordered, and the abscesses are very slow in reaching the surface. In fact, under the use of iodide of potassium and mercury most of them gradually disappear without breaking.

5. CERVICAL ADENITIS.

The posterior cervical ganglions generally suffer at an early period of the constitutional involvement, becoming enlarged and somewhat tender, though never very painful, and rolling, when pressed upon with the finger, like so many little elastic balls under the integuments. The swelling is generally most conspicuous in the glands situated along the upper two-thirds of the posterior border of the sterno-cleido-mastoid muscle, and along the root of the hairy scalp, extending frequently as far outwards as the mastoid process on each side. It is essentially of a chronic nature, often lingering for many weeks, and never terminating in suppuration. Diagnostically considered, this species of adenitis, from the constancy of its presence, is of great value, but from the want of practical tact to detect it, it is extremely liable to be overlooked by the surgeon. The number of glands involved seldom exceeds two or three, and in many cases the disease is apparently limited to a single one. Its occurrence is most common in young subjects, and it occasionally manifests itself at so late a period of the disease that it may then be considered as belonging rather to the tertiary than to the secondary order of symptoms.

Cervical adenitis generally readily disappears under the treatment directed for the relief of other secondary affections. The enlarged glands may be rubbed twice a day with ammoniated liniment, or painted with dilute tincture of iodine. If much induration exist, the most eligible remedy will be gentle mercurial inunction.

6. AFFECTIONS OF THE MUCOUS MEMBRANES.

Secondary syphilis of the mucous membranes generally declares itself within a short time after the cure of the primary sore, and sometimes even before this has completely disappeared; existing at one time in association with secondary affections of the skin, and at another, and perhaps more commonly, independently of them. From four to eight weeks is the average period of the evolution of the disease when it attacks these structures. What strikes one as very remarkable is the extent of surface over which it may spread, there being no visible portion of the mucous membranes where it has not been observed. The parts, however, which are most prone to suffer are the tonsils, palate, pharynx, tongue, cheeks, and lips. It rarely extends into the windpipe. No dissections of a satisfactory nature have been made tending to show that the lining membrane of the stomach and bowels ever participates in the morbid action, but it is certain that well-marked signs of the malady have been repeatedly witnessed at the anus, as high up as the first inch or inch and a half from its verge, and of such a character as to be altogether unmistakable. In the male they sometimes appear upon the foreskin and head of the penis, while in the other sex they are liable to occur upon the vulva, the vagina and uterus. Their presence has not been detected in the respiratory and urinary organs, and is therefore altogether a matter of conjecture, only to be settled by future observation. From the remarkable relations existing between the skin and mucous membranes, and the fact that syphilitic affections of the former are liable to occur in all parts of its extent, it is not improbable that the latter may suffer in the same manner, though perhaps not in an equal degree, some portions almost entirely escaping, while others are peculiarly prone to receive and harbor the specific virus.

Secondary affections of the mucous tissues occur in various forms; at one time, or in one place, as an erythematous disease, at another, as an elevation or tubercle, and again as a distinct ulcer, crack, or fissure; depending, doubtless, upon some peculiar modification of the structure of the suffering part, some change in the action of the poison, or some idiosyncrasy of the individual. In the mouth and throat, where these affections are most common, it is not unusual to notice their coexistence, mere inflammatory redness with or without plastic deposit going on at one point, ulceration at another, and the formation of a tubercle at a third.

Syphilitic *erythema* is observed chiefly in the throat, affecting the arches of the palate, tonsils, uvula, pharynx, and perhaps the root of the tongue. In rare cases it extends to the roof of the mouth. It may present itself as a diffused inflammation, or in the form of distinct patches, generally of a circular or oval figure, and from the size of a gold dollar to that of a twenty-five cent piece, the intervening surface being apparently quite healthy. The color, in the early stage of the disease, resembles that of a new copper coin, but it gradually loses its bright, fiery hue, shading off into dark bronze, in proportion as the morbid action declines. In cases of long standing and unusual severity, the discoloration is of a deep flesh-color and conjoined with marked thickening of the mucous membrane, and a tendency to ulceration. Deposits of lymph are not uncommon upon the inflamed surface, even when the disease is not at all active; occurring in small aphthous-looking specks, in patches of considerable size, or in circular rings, more or less firmly adherent, and of a pale orange tint.

This affection, which bears the closest resemblance to erythema of the skin, generally exists without the consciousness of the patient; there being no soreness in the throat or difficulty of deglutition, and no constitutional disturbance. All is quiet and passive, and the disease is perhaps discovered

altogether by accident. It of course denotes only a very slight taint of the system. It is apt to appear within the first four or five weeks after the primary sore, and consequently not unfrequently before this is healed.

Ulcers of the throat assume various appearances, and involve different structures, but particularly the tonsils and the back of the pharynx, affecting these parts either separately or conjointly. They occur principally in two varieties of form, the excavated and superficial.

The excavated ulcer looks, as the name denotes, as if it had been made with a punch, or dug out of the tissues with a sharp instrument. Its edges are steep, everted, and ragged, like those of the Hunterian chancre; and they are surrounded by a hard inflammatory, copper-colored base. The surface is usually incrustated with greenish, muddy, or yellowish lymph, which gives it a foul, unhealthy aspect. The discharge is thin and ichorous. The excavated sore is always most distinctly marked on the tonsils, where it sometimes acquires an immense size, and is generally accompanied by extensive inflammation of the surrounding parts. It is often seen during the progress of the primary disease, especially the indurated chancre, and is liable to be associated with some of the earlier forms of cutaneous eruptions, particularly the exanthematous and scaly.

The superficial ulcer is often multiple, several frequently occurring together, either in close proximity, or scattered over the inflamed surface. Its appearance is either that of an abrasion, or of a cavity with well-defined, ragged edges, rather sharp, and often somewhat undermined; its surface being covered with a white or yellowish tenacious and adherent lymph: the parts around, although red and irritated, are free from induration. The most common sites of this variety of sore, which now and then assumes a serpiginous character, are the arches of the palate, uvula, and pharynx. It generally comes on early after the absorption of the specific virus, and often coexists with the primary sore.

Secondary syphilitic ulcers of the throat are liable to take on phagedenic and gangrenous action, in the same manner as primary sores, and apparently from similar causes, the state of the system and mode of life of the patient mainly contributing to change their character. In consequence of the superaddition of this action, extensive destruction of the soft palate may result, followed by difficulty of deglutition and important alterations of the voice. Ordinary syphilitic ulceration of the throat, even when considerable, is not always attended by well-marked local and constitutional symptoms; the disease, in fact, is often remarkably insidious in its approaches, and may therefore have made great progress before its presence is even suspected. The excavated form of the affection is generally accompanied with extensive swelling, pain and difficulty in swallowing, and more or less febrile disturbance. When the tonsils are the seat of the lesion the tumefaction may be so great as to cause serious obstruction to respiration.

Small ulcers, crevices, and fissures, of a secondary nature, are sometimes met with on the lips, especially at the corners of the mouth, the inside of the cheeks, and the tongue; generally superficial, indisposed to spread, and attended with but little uneasiness and discharge. Occasionally they have abrupt edges and a hardened base. Their diagnosis must necessarily be difficult, the only reliable sign being their co-existence with other marks of syphilis, either primary or consecutive.

Mucous tubercles are most commonly found upon the tongue, the lips, and the inside of the cheeks, where they occur as slight elevations of the mucous surface, generally of an irregular oval or elongated shape, and of a whitish hue, as if the secretion of the part had been discolored with nitrate of silver or partially coagulated albumen. Upon taking hold of the swelling with the thumb and finger it is felt to be more or less hard, not unlike an indurated

chancre, and is generally quite tolerant of manipulation, even firm pressure rarely causing any decided pain. The size of the spots is variable, ranging from that of a pea up to that of a twenty-five cent piece; they sometimes exist in considerable numbers, and then they occasionally become confluent. If unrestrained, they may give rise to ulceration, generally of a deep, excavated character, the edges of the sore being steep and callous.

This variety of syphilitic affection finds its analogy in the condylomatous excrescences which are so liable to form about the anus and perineum, in consequence of the action of the syphilitic virus. As it usually comes on without any pain, its discovery is often purely accidental. The most reliable diagnostics are the peculiar color and feel of the affected part above referred to, and the coexistence of syphilis in other localities, particularly the throat and skin. Not unfrequently traces of the primary disease will be found either in an open sore, or in the indurated cicatrice of a recently healed chancre.

Treatment.—These mucous affections being all of a kindred character, their treatment must be conducted upon the same general principles. If the patient be at all plethoric, antiphlogistics will probably be necessary, blood being taken either by the lancet or by leeches from the vicinity of the inflamed parts, and the depletion followed by active purgation and the use of the antimonial and saline mixture, rendered anodyne and diaphoretic by the addition, to each dose, of a small quantity of morphia. Light diet and perfect quietude are enjoined. In the milder cases of these diseases the most simple constitutional means will generally suffice, no drain upon the system of any kind being necessary. The most suitable local remedies are nitrate of silver, acid nitrate of mercury, and nitric acid, either pure, or variously diluted, and applied at longer or shorter intervals, according to the exigencies of each particular case. The solid lunar caustic is generally to be preferred when there is no breach of continuity, the affected surface being touched with great care and gentleness once every forty-eight hours, some mildly astringent gargle, or simple mucilaginous fluid, being employed in the intervals. When the part is ulcerated the caustic must be used more boldly, as well as oftener; though, under such circumstances, I usually give a decided preference to the acid nitrate of mercury, applied by means of a stick of soft wood, the end of which, being well rounded off, enables us to deposit just enough and not any too much of the fluid, as is so apt to happen when we employ a mop. Not only the sore but also the inflamed surface around should be treated in this way, and the application, in bad cases, should be regularly repeated every twenty-four hours until there is a very decided improvement in the disease. I have found that hardly any secondary ulcer of the throat, palate, or tongue can withstand such a remedy beyond six or eight days, while in many cases it yields in a much shorter time. As soon as the reparative process begins, the acid is used less frequently and in a more dilute state. When the acid nitrate is not at hand, a good substitute will be furnished by nitric acid.

The gargle which I usually prefer in ulcerated sore throat is the pyroligneous acid, in the proportion of from one to two drachms to half a pint of water, well sweetened with honey, and used five or six times in the twenty-four hours. Weak solutions of subacetate of copper and tannin, of nitric acid, and of chlorinated soda also answer an excellent purpose.

Mucous tubercles generally yield to a few applications of the solid nitrate of silver, aided by astringent gargles, suitable purgation, and light diet. Similar means will usually suffice for the cure of superficial abrasions, excoriations, and fissures of the lips and cheek.

Mercurialization only becomes necessary in particular cases. In general, the remedy is called for when there is an excavated ulcer, or an ulcer possessing an extraordinary degree of indolence, or indolence and induration. The simple, superficial sore rarely requires such a remedy; and it is of course

withheld when there is a tendency to phagedena or gangrene in a broken, anemic state of the system. Under such circumstances tonics, a generous diet, and nutritious drinks take the place of the mineral.

SECT. IV.—TERTIARY SYPHILIS.

1. GENERAL CONSIDERATIONS.

When the specific poison has deeply penetrated the system, and become, as it were, inlaid in its different structures, as well as thoroughly commingled with the blood, the effects which it produces constitute what is denominated tertiary syphilis, an order of sequence first distinctly asserted by Ricord, and now generally recognized by surgical teachers. The boundary line, however, between the secondary and tertiary groups of phenomena is not always well defined, the former affections often running, by gradual and insensible gradations, into the latter; an occurrence which cannot be too strongly impressed upon the mind of the reader, on account of its great practical importance. It is generally understood that those symptoms of the disease which show themselves before the fifth or sixth month from the commencement of the primary sore should be classed under the head of "secondary syphilis," while those which come on subsequently, or after this period, are considered as appertaining to the third order of phenomena, or "tertiary syphilis," the average period of their evolution ranging from six to eighteen months, although in very many instances they do not occur until a number of years after the appearance of chancre, or chancre and bubo. Thus, I have repeatedly seen tertiary symptoms manifest themselves, for the first time, from twelve to eighteen years after the primary disease, the poison having lain all this time, like a hidden spark, in the economy. Once fairly roused, however, into activity, it extends through the system with great rapidity, completely overwhelming it in its progress, and exploding, with peculiar force, upon certain tissues, textures, or organs, these structures having apparently a kind of elective affinity for it.

The textures which are particularly prone to suffer in tertiary syphilis are the skin, mucous membranes, periosteum, bones, fibro-cartilages, aponeuroses, tendons, and testicles. All parts of the economy, however, are involved in the contamination, and it is extremely probable that, in the worst cases, hardly any organ or structure entirely escapes. The affections of the internal viscera, however, although alluded to by many of the older syphilographers, have only of late attracted serious attention, and hence the amount and nature of their participation in this poisoning process have not been satisfactorily ascertained. Enough, however, has been determined to produce conviction that the changes in the lungs, brain, heart, liver, and other organs are often of a grave character, liable to be followed by the worst results, because so insidious are their approaches and progress that even their existence is hardly ever suspected during life, to say nothing of the impossibility of arresting them by any known treatment, or combination of remedies. The most common of these internal lesions, which have, strangely enough, been termed secondary, are foul, ragged-looking abscesses, with imperfectly elaborated contents, softening and pulpy degeneration, and tubercular deposits. Attention has not yet been sufficiently directed to the alterations of the ovaries of females who die of tertiary syphilis; but from the resemblance which exists between these organs and the testes, both in structure and function, and from the fact that the latter are so often involved in the disease, it is highly probable that it will be found, as our pathological researches are extended, that they frequently seriously participate in the morbid action.

Tertiary syphilis is not invariably preceded by secondary symptoms ; on the contrary, there are many cases where the disease passes directly from the first to the third order of phenomena, the structures usually implicated in the secondary attack escaping entirely. Again, it is well known that tertiary syphilis is not always preceded by bubo.

Tertiary symptoms are most liable to occur in persons of intemperate habits, and of a broken dilapidated constitution, with an impoverished state of the blood. A scrofulous or scorbutic condition of the system also acts as a predisposing cause.

The nature of the chancre doubtless exerts considerable influence upon the production of the disease. Thus, there can be no hesitation in affirming that tertiary syphilis is more apt to follow an indurated than a non-indurated chancre. The duration of the primary disease is also to be taken into the account ; it being reasonable to suppose that a chronic chancre, which retains its specific poison, will be more likely to give rise to constitutional syphilis than one that is acute or rapidly healed.

Finally, the occurrence of tertiary symptoms is influenced by the nature of the general treatment. It is well known, as stated elsewhere, that when the primary sore has been treated without mercury there is much less likelihood of the development of remote constitutional symptoms than when this remedy has been used, especially when its effects have been carried to an inordinate extent, as evinced by profuse salivation. The occurrence of tertiary syphilis, under such circumstances, is not only probable, but the chances are that, if it do break out, it will show itself in the very worst form, by establishing a sort of mercurio-syphilitic diathesis, which it is extremely difficult, if not impossible, to eradicate completely from the system.

The immediate development of tertiary syphilis is often remarkably influenced by the habits and state of health of the individual. It is impossible to say how long the specific virus might lie dormant in the system if the subject of it were entirely free from the prejudicial influences of surrounding agents. Exposure to cold is usually accused of being one of the most common exciting causes of the complaint, and yet it is notorious that the inhabitants of the South Sea Islands and other tropical regions are extraordinarily prone to all kinds of constitutional syphilis. There can be no doubt, however, that the poison is often fanned into activity by the hardships of our northern winters and by a residence in damp cellars, or moist, ill-ventilated, underground apartments, especially when this mode of life is conjoined with all kinds of dissipation and intemperance, loss of sleep, and an impoverished diet. Although it is extremely probable that no state of the system, however near it may approach to the normal standard, can ever entirely prevent the development of tertiary syphilis, when once the poison has taken possession of it, yet there can be no doubt that an individual so circumstanced will, other things being equal, be much less likely to suffer than one who is differently situated, or who gives himself up to the unbridled indulgence of his passions.

The matter furnished by ulcers, abscesses, and suppurating surfaces, consequent upon tertiary syphilis, is not inoculable ; the specific virus has been completely changed in its properties, and no case has ever occurred where it was capable of infecting the tissues of a healthy person by direct contact. It is also believed that the disease is not hereditarily transmissible ; but although this be true in the ordinary sense of the term, yet it is extremely probable that the offspring of such an individual are, if not actually imperfectly developed, naturally predisposed to various kinds of cachectic affections, particularly to scrofula and scurvy, by which life is rendered miserable and often cut off prematurely, the constitution being unable to endure the hardships incident to ordinary pursuits.

The *prognosis* of tertiary syphilis is always grave. Whatever form it may assume, it is extremely difficult to dislodge it effectually from the system, or to effect a radical permanent cure. Relapses are of constant occurrence from the most trivial exposure, or the least disorder of the digestive organs, and few patients, however skilfully they may have been treated, are afterwards ever entirely free from rheumatic pains, proneness to cold, and stiffness of the joints. In fact, although recovery undoubtedly occasionally does take place, yet in most cases the constitution remains in an enfeebled and crippled condition, remarkably subject to attacks of other diseases.

Tertiary syphilis often proves fatal, although not nearly as frequently as prior to the discovery of the use of iodide of potassium, death generally occurring from local irritation and constitutional exhaustion. Many of those who recover are horribly disfigured, some from pock marks, some from the loss of the nose and palate, and some from ankylosis of a joint.

2. SYPHILIS OF THE THROAT AND MOUTH.

Tertiary affections of the throat and mouth are by no means uncommon; they supervene at an indefinite period after chancre, and manifest themselves in characteristic ulcers, which, if permitted to go on, gradually spread to the palate and maxillary bones, which, together with the soft parts, are sometimes destroyed to a most frightful extent, the buccal and nasal cavities being perhaps laid into one immense cavern. In some of these cases large portions of the alveolar process of the maxillary bone are necrosed, followed by the loss of many of the teeth, and a similar fate may be experienced by the ascending process and ungual bone, thus implicating and endangering the lachrymal sac and its canals. The nature of the disease is readily ascertained by ocular inspection and the altered state of the voice.

Tertiary syphilis of the *tongue* generally appears in the form of ulcers, or fissures, the latter of which are sometimes of enormous extent and depth, reaching far into the substance of the organ. Specific ulcers are usually situated upon the side of the tongue, at or near its middle, and exhibit the characteristic features of venereal sores in other structures, having a deep excavated form and a foul surface, with marked induration of the base, the parts feeling, on being pinched, like a mass of fibro-cartilage. Only one such cavity generally exists; when large and irritable, it may give rise to swelling of the lymphatic glands at the base of the jaw. The history of the case, the foul, excavated character of the sore, and the existence of syphilitic disease in the throat, nose, or other parts of the body, will always distinguish the lesion from other affections.

The following case will convey a good idea of syphilitic fissures of the tongue:—Frederick Saxe, a blacksmith, aged twenty-eight years, presented himself at the Clinic of the Jefferson Medical College in July, 1857. His tongue, which was of the natural length and breadth but much increased in thickness, and excessively hard at the sides, especially the left, was covered with numerous fissures, of varying size and depth, overhung by steep indurated edges, which at first sight concealed them almost completely from view. The largest groove, which resembled a deep furrow, extended along the centre of the organ, from a short distance in front of the root to within a few lines of the tip, its depth being nearly half an inch. The bottom of each fissure had a clean, smooth appearance; the mucous membrane of the tongue generally was somewhat redder than natural, but there was an entire absence of pain and even soreness under rough manipulation. The starting point of the disease seemed to have been the throat, which had been inflamed for a long time; the uvula had become elongated, and had been cut off weeks ago. The arches of the palate and tonsils were still a good deal discolored and con-

gested. The tongue had been in its present condition for the last three months, having resisted various kinds of treatment, without the disease apparently manifesting any tendency to spread. A small painful node existed on the right tibia, and there was a vesicular eruption with some itching on the face. The man denied that he had ever had syphilis, but the history of the case and his present condition clearly proved that he was mistaken, or tried to deceive me. He rapidly recovered under the internal use of iodide of potassium with bichloride of mercury, and the local application, every other day, of the solid nitrate of silver.

3. SYPHILIS OF THE NOSE.

Syphilitic disease of the nose, or syphilitic ozæna, as it is occasionally called, is another tertiary symptom, depending upon ulceration of the pituitary membrane, and the several bones of the nasal fossæ, including not unfrequently the proper bones of the nose. The morbid action, which is generally associated with marks of a constitutional taint in other situations, usually sets in at a very remote period after the primary sore, and lingers on obstinately for many years, notwithstanding the best directed efforts to arrest it, until it has caused the most extensive havoc, piece after piece dying and dropping off until every one has disappeared. When the proper nasal bones are involved, the whole organ, bridge, cartilage, and skin, may be destroyed. The disease is attended with an abundant fetid and bloody discharge, and the voice has a peculiar characteristic, muffled twang.

The septum of the nose is very prone to suffer in this form of syphilis, giving way, first, at the cartilaginous structure, and afterwards at the osseous. The consequence is that the part is perforated by an opening of variable size and shape, with sharp, irregular edges, which have a constant tendency to spread until the greater portion of the septum is destroyed. A similar effect sometimes follows scrofula, and considerable difficulty may therefore attend the diagnosis. The chief points of distinction are the history of the case, and the fact that the ulcerative action is generally much more rapid in the former than in the latter disease.

4. SYPHILIS OF THE LARYNX.

Syphilis of the larynx seldom comes on until a long time after the primary disease, and may therefore justly be classed among the tertiary phenomena. In most cases, indeed, it does not declare itself before the end of the second year, and often not until much later. It is generally, but, I think, erroneously ascribed to an extension of disease from the palate, tonsils, and pharynx, by continuity of structure; on the contrary, there is reason to believe that it is usually an independent affection, commencing in the larynx, and thence sometimes passing into the throat. However this may be, its coincidence with syphilis in other parts of the body, particularly of the skin, bones, and fibrous membranes, sufficiently stamps its character, and renders it easy of diagnosis.

The disease, beginning in inflammation, soon terminates in ulceration, which often continues for months and even years together, the erosive action being at one time stationary, or on the very verge of healing, and at another steadily advancing. Confined originally to the mucous membrane, it at length invades the arytenoid cartilages, the vocal cords, and even some of the muscles of the larynx. Portions of the thyroid cartilage occasionally perish, and a not uncommon occurrence is the partial destruction of the epiglottis. In some of the cases of this disease that have come under my observation, nearly the whole of this fibro-cartilage was eaten away, nothing

but a thick, narrow, stump-like remnant being left to cover the glottis, as illustrated in fig. 86, from a preparation in my private collection. The cricoid cartilage rarely participates in the disease.

The ulcers are seldom numerous, unless they are follicular, when the affected surface may literally be studded with them; in general, we do not

Fig. 86.

Syphilitic ulceration of the larynx.

find more than one or two, which are then pretty large, both as it respects their depth and superficial area. They are of a circular or oval shape, with indurated edges and a foul bottom, and, in the more severe and protracted cases, they sometimes penetrate very deeply, opening, perhaps, externally. Such an occurrence is most likely to happen when there is extensive destruction of the thyroid cartilage.

Occasionally the mucous membrane, instead of being ulcerated, is the seat of granulations, or syphilitic warts, of a red, fleshy appearance, and from the size of a small pin-head to that of a mustard-seed, their number varying from half a dozen to fifteen or twenty; they are usually most conspicuous around the vocal cords, and apparently consist in a hypertrophous condition of the mucous crypts which naturally exist in the interior of the vocal tube.

The symptoms of syphilitic disease of the larynx are generally well marked, particularly when it has made considerable progress, or when it presents itself in the form of ulceration. Besides the wan, emaciated, and cachectic appearance of the patient, which is itself almost sufficient to point out the nature of the affection, there is a hoarse, husky, characteristic state of the voice, which, in time, is reduced to a mere whisper, and eventually completely

lost. The larynx feels tender on motion and pressure; deglutition is difficult and painful; and the slightest vocal exertion is productive of severe suffering. Cough is always present, frequently to a most harassing extent; and in attempting to swallow fluids the patient is frequently seized with symptoms of impending suffocation. The matter which is expectorated is excessively fetid, often bloody, and occasionally mixed with fragments of cartilage, its quantity being frequently very copious. As the disease progresses, the local and constitutional irritation increases; the emaciation becomes extreme; the sweats are copious; and the patient at length dies completely exhausted, the immediate cause of his death being, perhaps, inanition, suffocation, or hemorrhage from the sudden giving way of an artery of considerable size. Long before this event, however, the lungs, pleuræ, and bronchial tubes become seriously involved, and thus serve materially to hurry on the fatal crisis.

5. SYPHILIS OF THE EYE.

Iritis belongs to the more advanced stages of syphilis, being usually associated with tubercular, papular, or pustular eruptions, rupial sores, nodes, and rheumatism of the bones, and ulceration of the throat, palate, and nose. It is characterized by a fixed and contracted state of the pupil, which is generally filled with lymph and displaced upward and inward; by the appearance, upon the anterior surface of the iris, of reddish-brown tubercles, or minute yellowish abscesses; and by severe nocturnal pains, situated deep in the eye, forehead and temple. The disease commonly attacks both organs,

either simultaneously or successively, and always rapidly extends to the other structures, as the cornea, choroid, and retina, involving them in its ruinous consequences, few persons recovering without loss of sight. As allusion will again be made to this affection in the chapter on the eye, no further notice need here be taken of it.

In April, 1858, Dr. Addinell Hewson read before the Pathological Society of Philadelphia, the history of a case of supposed syphilitic *retinitis*, in a stout man, thirty-one years of age, who had contracted primary syphilis upwards of two years previously. He had subsequently labored under loss of flesh and strength, alopecia, and sores on the skin, afterwards followed by violent pain in the left temple, and dimness of vision in the left eye. There had been no iritis. Under the ophthalmoscope, the lens and vitreous humor appeared to be perfectly clear, but the retina was defective in translucency and of a dirty tint, its surface being extensively sprinkled with small white, yellowish-white, or reddish points, of a globular shape, and strongly resembling the condylomata of syphilitic iritis. The optic nerve was changed in color, and the vessels of the retina were somewhat varicose.

6. SYPHILIS OF THE EAR.

Syphilis of the ear is uncommon. Patients of a broken-down constitution and of intemperate habits are most liable to suffer. The disease frequently comes on in the form of sudden deafness, attended with aching pain, and evidently consists of inflammation of the tympanic membrane, which, upon inspection, is found to be red and abnormally vascular, and, in time, to become more or less opaque. If the morbid action be not soon arrested it may eventuate in ulceration, followed by complete destruction of the membrane, and permanent deafness. In the worst forms of the disease, the Eustachian tube, the middle ear, and even the petrous portion of the temporal bone become involved.

The diagnosis is usually sufficiently easy, the most reliable points being the coexistence of syphilis in other parts of the body, the comparative slightness of the pain, which is much less than in ordinary myringitis, and the amenability of the disease to specific treatment. The affection evidently appertains to the earlier tertiary group.

Syphilis of the ear must be managed upon the same general principles as syphilis of other organs. The great remedies are mercury and potassium, aided by leeches, blisters, and mildly astringent injections.

7. SYPHILIS OF THE SKIN.

Ulcers of the skin, or rupial sores, may be a sequence of secondary syphilis, but in general they are among the more remote effects of the tertiary form of the disease, coming on, in most cases, several years after the primary affection. They usually coexist with nodes and rheumatic pains, or with ulceration of the throat, nose, and larynx, or with all these ailments combined, and are nearly always preceded by scaly eruptions, pustules, papules, or tubercles. Persons of a broken, infirm, and cachectic constitution are their most common subjects, and those in whom they commit the greatest ravages.

Much diversity exists in regard to the situation and character of these cutaneous ulcers. They are most frequently found on the extremities, especially the inferior; they are also sufficiently common on the forearm and elbow, and on the scalp, forehead, and temple. Their size ranges from that of a split pea to that of the crown of a hat, their shape being usually circular or oval, although sometimes it is extremely irregular from two adjoining sores being connected or running into each other. The edges are nearly always

callous, everted, and more or less ragged; the surface is excavated, covered with a greenish, pultaceous matter, and exquisitely sensitive; while the discharge, which is often very profuse, is thin, ichorous, and offensive, frequently excessively so. It is not often that we notice anything like a distinct, well-defined areola; such an occurrence is seen only in rare cases, but in most instances there is marked inflammation with redness and induration in the parts immediately around. The largest of these ulcers generally occur on the shoulder, side, and buttock, and it is amazing what an immense size they may attain. Numerous small ulcers of this kind occasionally exist in groups, giving the surface a peculiar worm-eaten appearance. In some cases, again, the ulcers have a serpiginous arrangement; in another class of cases they are, perhaps, very much undermined; and now and then two large ulcers are connected together by a sort of cutaneous bridge. In fact, there is no end to the diversities of their configuration. Finally, they may be quite superficial, or so deep as to involve the subjacent cellular tissue, and even the fasciæ, muscles, tendons, and bones.

Rupial ulcers often continue for an indefinite period, sometimes partially cicatrizing, now spreading, now indolent or stationary. From local causes, as well as constitutional, they may take on almost any kind of action; when the patient is in an exhausted, irritable condition, they are very apt to become severely inflamed, and to assume a phagedenic, sloughing character, spreading often with immense rapidity, both in diameter and depth. The system generally actively sympathizes with these sores; the skin is dry and hot, the pulse small, quick, and frequent, the appetite impaired, the sleep destroyed, and the loss of flesh and strength excessive. The patient has an old, superannuated, care-worn look, with all the signs of a deep-laid syphilitic cachexia. The scars left by the healing of these ulcers are abnormally white, and retain for a long time a remarkable hardness, with a tendency to constant furfuraceous desquamation. They are sometimes very rough, and prone to reopen from the slightest causes.

The *diagnosis* of syphilitic ulcers is generally sufficiently easy, the only affection with which they are liable to be confounded being the common non-specific sore. There is generally an appearance about a specific ulcer of the skin which at once stamps its character. In the first place, it is generally circular or oval, and of an excavated shape, with hard, everted edges, and a foul surface, destitute of granulations and of healthy discharge; the surrounding surface is indurated, and generally somewhat discolored, the tint often resembling that of copper. Secondly, the sore is often multiple, occurring in groups, and also on different parts of the surface; a circumstance which is generally of itself sufficient to denote its nature; for the ordinary ulcer is usually solitary, and is most common on the lower extremity. Thirdly, the disease of the skin nearly always coexists with syphilitic disease in other structures, especially the periosteum and bones. Finally, the effects of the treatment afford important aid in doubtful cases; ordinary ulcers disappearing, or soon assuming a healthy, granulating appearance, under simple anti-phlogistics, rest, and light diet, whereas specific ulcers always require the use of iodide of potassium and mercury, the latter often both internally and externally.

These syphilitic affections of the skin are admirably illustrated in fig. 87. The diagnosis is unmistakable.

The syphilitic eruptions are sometimes attended with *onychia*, or inflammation of the matrix of the nails, the latter of which gradually become dry and black, and eventually drop off, leaving a foul, excavated, painful ulcer, with hard, steep edges, and a very fetid, ichorous discharge. If the morbid action be very severe, or if it be not soon arrested, the matrix will be completely destroyed, when there can of course be no reproduction of the nail; most

commonly, however, a part of its substance survives, and afterwards makes a feeble effort at the formation of a new nail, which, in general, however, is merely an ill-shaped, stumpy, horn-like excrescence, altogether different from

Fig. 87.

Syphilitic rupia.

the original structure. The diagnostic signs of the disease are the copper-colored appearance of the surface immediately around the ulcer, and marks of syphilis in other regions of the body. The lesion occasionally does not appear until many months after the primary sore, thus bringing it, properly speaking, under the head of tertiary symptoms.

8. SYPHILIS OF THE OSSEOUS SYSTEM.

Affections of the periosteum and bones belong to the latter order of tertiary syphilis, and they may declare themselves in various forms, of which the most important are nodes, or soft tumors, inflammatory hypertrophy, exostosis, caries, and necrosis. These affections may come on at any time after the eighteenth month from the date of the primary sore, but in the great majority of cases they do not show themselves until after the lapse of at least twice that period. They are most liable to occur in persons of a scrofulous and cachectic constitution, and in those whose health has been destroyed by habitual intemperance, constant exposure, and deficient alimentation, leading to an impoverished state of the blood and protracted derangement of the secretions. The idea is now generally prevalent that diseases of the periosteum and bones, especially in their more severe forms, are, in great measure, limited to those persons who have undergone severe courses of mercury for their cure; and in this opinion the results of my experience induce me fully to concur. Of the many cases of tertiary syphilis of the osseous tissue that have fallen under my observation nearly all had taken mercury in large quantity, and the few who had been treated without that remedy had suffered comparatively little, except where there was a marked strumous diathesis, which never fails, I think, to aggravate the effects of the ingrafted disease. It would thus appear, at first sight, that this metal, by combining with the specific poison, was capable of essentially modifying its action, if not of forming a new virus, more potent and destructive than the original. But it is not necessary to have recourse to such an explanation; it is sufficient to know that the action of mercury, when carried to an inordinate extent, is a most powerful depressant, the effect of which is felt, for a long time, by the whole system, by the blood not less than by the solids. A species of physical degradation of the entire organism is thus engendered, which cannot fail to predispose it, in no slight degree, to the injurious operation of morbid agents, whether acting within the system, or impressing it from without, through the medium of the cutaneous and mucous surfaces. Instead, therefore, of supposing that a new poison, or a sort of a syphilitico-mercurial virus, is formed under these circumstances, it will be found to be more in accordance with the established facts of pathology to conclude that the frightful ravages so often committed in tertiary syphilis, after the inordinate use of

mercury, upon the osseous tissue, are the result, exclusively, of the deteriorating influence of this metal upon the general system, whereby the more feebly organized structures, as the bones and their investing membrane, are rendered peculiarly prone to a bad form of inflammation, which, if not early checked, often leads to the most serious consequences.

Tertiary syphilis is met with only in certain bones, chiefly in the superficial, or in those least protected by soft parts, as the tibia and fibula, the ulna, clavicle, and bones of the skull, nose, palate, and upper jaw. In rare cases, almost every piece of the skeleton is involved, either simultaneously or successively; some in nodes, some in caries, some in necrosis, and some in exostosis.

Nodes occur chiefly upon the tibia, ulna, and skull, particularly the frontal and parietal bones. They present themselves as circumscribed, semi-solid swellings, of an ovoidal shape, somewhat elastic to the touch, and from half an inch to an inch and a half in diameter. So far as we are able to determine, they always begin beneath the periosteum, upon the surface of the bone, as an inflammation, which is soon followed by the deposition of a remarkably gummy substance, of a light, turbid, or greenish hue, and of the nature of cacoplastic lymph. In many cases this is the only substance found in the swelling; in others, however, it contains, in addition, a considerable quantity of serum or of pus, or the gummy matter may be entirely absent, and the tumor be occupied by an imperfectly elaborated pus. The periosteum and bone, at the seat of the node, are both inflamed, softened, and ulcerated; and as the tumor extends, the superincumbent structures, participating in the morbid action, become red and painful, and ultimately yield at the most prominent point, thus allowing the pent-up fluid an opportunity of escaping, although generally in a very imperfect manner, and not without severe suffering.

A node is essentially an abscess of the fibrous and osseous tissues, the consequence of a specific inflammation, and occupied by an imperfectly elaborated pus, or a mixture of pus and plasma. Its course is always chronic, and the pain which attends it is peculiar, being of an intermittent, neuralgic character, subject to violent nocturnal exacerbations. The general health is always disordered, and, if the swelling is large, considerable constitutional disturbance is apt to be present. In many cases, nodes co-exist in different pieces of the skeleton. The skull is sometimes studded with them.

A node may not only ulcerate, but also mortify; and after it has become an open sore, it may take on an almost endless variety of morbid actions, incident to syphilis in other structures. Thus, it may be excessively irritable, be invaded by phagedena or gangrene, burrow extensively among the surrounding tissues, be complicated with serious disease of the osseous tissue, or, lastly, be indolent and indisposed to heal.

Caries of the bones is most commonly met with in the long bones of the extremities, as in the tibia and ulna, in the skull, and in the palate, maxillary, nasal, turbinated, and ethmoid bones, together with the vomer; in all of which it is not unfrequently conjoined with *necrosis*, whole pieces dying and sloughing away, so as to cause the most frightful mutilation and disfigurement. These ravages are generally most conspicuous about the countenance, especially when the disease attacks and destroys the proper bones of the nose, which then cave in, and cause that remarkable flattening of the face so characteristic of the effects of tertiary syphilis. In many cases the turbinated bones, the ethmoid, and vomer are separated, so as to convert the nasal fossæ into one immense cavity; and instances occur where, in consequence of the destruction of the palate and maxillary bones, the mouth and nose communicate with each other. In the long bones of the extremities, the caries and necrosis are generally superficial, the dead portions coming

away in the form of exfoliations, the central parts of these pieces seldom participating in the morbid action to an extent sufficient to cause their destruction.

The adjoining cut, fig. 88, from Druitt, affords a graphic illustration of caries of the bones of the skull, which, as in a case that came under my observation many years ago, are sometimes completely riddled, so as to give them, throughout, a cribriform appearance.

Fig. 88.

Syphilitic caries of the skull.

Syphilitic *hypertrophy* of the osseous tissue is extremely common, and sometimes involves the greater number of pieces of the skeleton; the bones, however, which are most liable to be attacked are the tibia, fibula, femur, ulna, radius, and cranium. The lesion occurs either as an exostosis, or as a diffused swelling, which, when it affects the whole length and thickness of a bone, assumes the name of general hypertrophy. The mode of formation of a syphilitic exostosis presents nothing peculiar, and need not, therefore, claim any special attention; it evidently takes its rise in a deposit of plasma, which serves as a nidus for the future growth, the ossific process passing through the same phases as in the natural skeleton. The tumor is usually knobby and irregular, with a broad base, and a rough scabrous surface. In cases of long standing, it is nearly always of a hard, ivory consistence.

The more common variety of hypertrophy is the diffused or general, of which the best specimens are usually seen in the bones of the leg, thigh, and forearm, which are often nearly twice the natural thickness and of extraordinary weight and firmness. A section of such a piece, seen in fig. 89, from a specimen in my cabinet, shows that the spongy substance has been com-

Fig. 89.

General syphilitic hypertrophy of the femur; internal structure.

pletely, or almost completely replaced by solid osseous matter, that the medullary canal has been obliterated, and that the compact structure has acquired a closeness of texture almost equal to that of ivory. The Haversian tubes are for the most part obliterated, or greatly changed in their size and shape, and the outer surface of the bone, as seen in fig. 90, is remarkable for its roughness, its appearance bearing a striking resemblance to that of a worm-eaten tree. The skulls of persons laboring under tertiary syphilis are sometimes astonishingly hypertrophied. In a specimen, presented to me several years ago by Dr. Cochran, of Louisiana, the cranial bones are

throughout at least half an inch in thickness; the different pieces are completely fused together without any trace of suture or of diploe, and their consistence and density are almost equal to those of ivory.

Fig. 90.

General syphilitic hypertrophy; external characters.

The *periosteum* is variously affected in syphilitic diseases of the bones; in the more inflammatory lesions it is generally very vascular, soft, and spongy, at the same time that it is considerably thickened, and easily detached from the subjacent surface. In hypertrophy, especially the diffused form, the principal alterations are thickening and induration, with a tendency, here and there, to ossification. Instead of being easily separated from the affected bone, as it is in the more acute affections, the membrane always adheres to it with extraordinary firmness.

The various syphilitic affections of the bones, but especially diffused hypertrophy, are all attended with more or less disturbance of the general health, and deep-seated, excruciating pains. These pains, from the fact that they are always worse at night, have earned for themselves the title of *nocturnal*, although they are rarely entirely absent even in the day; they are also frequently called syphilitic rheumatic pains. They are generally of a dull, heavy, aching, or gnawing character, and begin to increase in severity the moment the patient becomes warm in bed; they may continue all night, or go off in a few hours, but while they last the patient has no sleep or comfort of any kind. Not unfrequently they are of a neuralgic nature; excessively keen, darting, and coming on in nightly paroxysms. While they exist, the affected bones are generally exquisitely tender and intolerant of manipulation.

9. SYPHILITIC ORCHITIS.

Syphilis of the testicle must be classed among the tertiary symptoms, since it rarely comes on until a long time after the primary sore. The average period, in the cases that have fallen under my notice, was from two to four years; but it not unfrequently happens that the enlargement does not show itself until after the lapse of eight, ten, or even twelve years. It is usually associated with syphilis of other parts of the body, particularly the bones, joints, throat, nose and skin, the latter of which is often extensively ulcerated and otherwise disordered. These complications, which are seldom entirely absent in any case of syphilitic orchitis, are especially liable to occur when the tertiary affection breaks out long after the primary one, and they are always denotive of an infirm cachectic state of the system, induced by long suffering, neglect, or bad treatment, or all these causes combined.

The disease almost always involves both testicles, either simultaneously or successively, although seldom in an equal degree; and, as it proceeds, it is sure to extend to the epididymis, so that, in time, the two structures form one inseparable mass. The swelling is characterized by extraordinary weight and hardness, the affected organ resting upon the hand like a heavy solid body, and requiring constant support to prevent it from causing a sense of

dragging. When the disease has reached its maximum, the testicle is often six or eight times the normal bulk. The surface of the swelling is variable, though in general it will be found to be rather smooth, or but slightly knobby. The induration is uniform, except when there is, as not unfrequently happens, an accumulation of water in the vaginal tunic, in which case the corresponding portion will be soft and fluctuating. The spermatic cord usually participates in the disease, being unnaturally hard and thickened. When the disease is of long standing, the affected structures lose their normal characters completely, either at particular points, or throughout, the seminiferous substance being replaced by fibrous tissue. In the worst forms of the malady tubercular deposits occur, which, breaking down and disintegrating, lead to the formation of unhealthy abscesses, and, when these discharge their contents, to the establishment of fungus.

Syphilitic sarcocele is always a remarkably tardy and painless disease. It is only, as a general rule, when there is much water in the vaginal tunic, constituting the complication called hydrosarcocele, and causing constant pressure upon the inflamed and degenerating tissues, that the patient will be likely to suffer much, and then chiefly at night and in damp states of the atmosphere. When the swelling is very large, considerable inconvenience is usually experienced from the weight and bulk of the organ. The subjects of this form of syphilis are always thin, pale, and anemic, the appetite is greatly impaired, the strength is wasted, and the sleep is interrupted by nocturnal rheumatism. Their whole appearance, in fact, is indicative of a worn-out, miserable state of the system. When both organs are extensively diseased, the individual must necessarily be impotent. A remarkable feature of this form of syphilis is its tendency to recur, perhaps again and again, after being apparently relieved by treatment.

Syphilitic orchitis can always be easily distinguished from common orchitis; first, by the tardy, indolent, and persistent character of the swelling; secondly, by the simultaneous, or successive involvement of both organs; thirdly, by the co-existence of syphilitic disease in other parts of the body, especially of nodes, and ulcers of the skin, nose, and throat; fourthly, by the gradual but certain destruction of the textures and functions of the testicle; and, lastly, by a careful consideration of the history of the case, particularly of the character of the patient. In obscure cases, before resorting to extirpation, the surgeon should make a faithful trial of anti-syphilitic remedies, otherwise he may have occasion to lament his rashness.

The subjoined case, which I treated at the Clinic of the Jefferson Medical College, in the winter of 1857, affords an excellent idea of the nature, progress, and termination of syphilitic orchitis, with the changes experienced by the affected organ. It was drawn up by Dr. S. W. Gross.

A man, aged 29, had a fungus of the right testicle, which had commenced four months previously, as a small pustule on the scrotum. He had contracted chancre and bubo nine years before, and was laboring at the time of his admission under syphilitic rheumatism, ulceration of the tibia, and a slight eruption upon the face. The right testicle began to enlarge, and to become hard and painful three years ago. The left organ was also diseased, but in a less degree. The general health was much impaired. The fungus, above alluded to, was about the size of a half dollar, and the seat of an offensive, ichorous, and profuse discharge, as well as of severe pain, especially at night. Being satisfied, from a careful examination, that the organ was hopelessly destroyed, I had no hesitation in removing it. The dissection verified the correctness of my diagnosis. The tubular structure was completely annihilated, a fibrous substance, of a pale yellowish color and dense consistence, occupying its place. At the posterior part of the epididymis was an abscess, about the volume of a small hickory-nut, filled with a tough, yellowish, cheesy-looking

matter, bearing a close resemblance to tubercular deposit. The wound soon healed, and under the use of iodide of potassium and bichloride of mercury, aided by a nutritious diet, the patient rapidly improved in health and spirits. A year previously to this, I performed a similar operation upon a middle-aged man, who had also labored for a long time under tertiary syphilis. The fungus was of large size, and the testicle was completely degenerated into fibrous tissue. Whenever syphilitic orchitis is of long standing, whether it is accompanied or not by fungus, it will generally be found that its tubular substance is irretrievably destroyed.

10. CONDYLOMATOUS GROWTHS.

Condylomata of the skin, or of the skin and mucous membrane, usually described by the French syphilographers under the name of mucous tubercles, occasionally arise as a consequence of venereal contamination. They consist in the development of various sized excrescences, of a flat and rather broad appearance, occurring either in groups or in isolated tubercles, and dependent essentially upon a hypertrophied condition of the integuments. It is difficult to assign to this disease its precise rank in the order of syphilitic phenomena, or even to affirm, with certainty, that it is always plainly of a syphilitic character. There are not wanting surgeons of great eminence who do not hesitate to assert that these condylomata may be produced by the contact of gonorrhœal matter, or by acrid vaginal and other secretions not specific in any way. On the other hand, it has been alleged that they pertain, not to one form of syphilis, but to all three, now following chancre, now secondary syphilis, and now tertiary. As for myself, I am inclined to regard them as of a constitutional character, depending upon the absorption of the syphilitic virus, and displaying themselves at a period more or less remote from the primary sore; as belonging, in fact, rather to the third order of phenomena than to the second, and under no circumstances whatever to the first. The idea of the constitutional origin of these bodies is strongly corroborated by the acknowledged fact, that they always require a course of constitutional treatment for their permanent eradication.

These excrescences are sometimes a result of hereditary syphilis. Of this rare occurrence, I have witnessed not less than five cases. The first was a boy, eight years old, whose father had himself had a similar affection several years previously, in consequence of tertiary syphilis, attended with nodes and a scaly eruption. The tubercles existed in great numbers around the anus, and upon the lower part of the perineum, and could not possibly have been better characterized; the child was pale and somewhat emaciated, but there was no other evidence of constitutional contamination. The mother had given birth to three infected infants, two before, and the other at the full period; the former were cast off dead, and in a putrid condition, and the latter died at the age of three months from marasmus, the whole body having been covered with scaly eruptions, which were particularly conspicuous on the forehead, hands, and feet. All the other cases were equally well marked.

The most common sites of condylomata are the scrotum, vulva, perineum, anus, and buttocks, as exhibited in fig. 91. They also occur, though unfrequently, on the penis, and in the folds of the thigh, in the axilla, and in the ear. They seem to have a particular predilection for parts which are habitually hot and moist; for it is there that they are not only most frequently found, but that they acquire their greatest and most rapid development. Their size and shape are very various. Thus, they may not be larger than a pin-head, or a mustard-seed; but on the other hand, they often acquire the volume of a filbert, and even of a small almond. In shape, they are usually flat with a broad base, though not unfrequently the free portion is much

larger than the adherent, a circumstance which gives the growths a pediculated aspect. When they occur in groups, as is very apt to be the case, they often coalesce, forming thus considerable masses, tuberculated on the surface,

Fig. 91.

Condylomata.

irregular in shape, of a reddish color, and of a firm, fibrous consistence. The largest and worst of these tumors always occur at the margin of the anus, and on the perineum, vulva, and other parts which, from the contact of the opposing surfaces, are habitually subjected to friction, heat, and moisture, which, as already stated, are greatly conducive to their development. In these localities, the tumors are always humid, exhaling a thin, muco-purulent fluid, often quite abundant, and always excessively fetid. In those parts, on the contrary, where they are more exposed to the air, they are dry, insensible, of a darkish color, and partially incrustated with scabs.

Condylomata often coexist with other evidences of a syphilitic taint, especially affections of the bones, rupial sores, tubercles, and scaly eruptions. Their course is variable; sometimes steadily onward, at other times stationary, and now and then even retrogressive. Exercise and friction always irritate them, causing them to become sore, and sometimes so exquisitely sensitive as to deprive the patient of the power of locomotion. When they are large and numerous, the discharge is generally copious and almost insupportably offensive. They are rarely accompanied by febrile symptoms.

It has been supposed that the discharge furnished by these excrescences is contagious, and, consequently, capable, by inoculation, of producing a similar disease. A great deal of plausible testimony has been adduced in favor of this opinion, by surgeons holding the highest position as observers and men of talent; but the notion has always appeared to me to be untenable, on the ground that these bodies, being always the result of a constitutional vice, are not capable of yielding any specific virus. When they coexist with chancre, the occurrence of infection during sexual intercourse is easily explicable.

The diagnosis of condylomata cannot be mistaken. The situation of the excrescences, their peculiar shape, their chronic character, and their fetid secretion all serve to give them a distinctive character. Corroborative testimony is often furnished by the history of the case and the coexistence of syphilis in other parts of the body.

TREATMENT.

The treatment of tertiary syphilis reposes upon broad, scientific, and philosophical principles, and may therefore generally be pursued with a positive certainty of affording great relief, if not of ultimately effecting a radical cure. Even the worst cases may usually be immensely benefited in a very short time under the modern system of treatment; and I have repeatedly seen patients, apparently on the very verge of the grave, who had not enjoyed a comfortable night's sleep for years, and whose bodies had been sadly deformed and racked by pains, raised to health and usefulness by a few doses of medicine. The remedy to which we are indebted for these wonderful effects is the *iodide of potassium*, which, if there be such a medicine as a specific, is unquestionably entitled to that distinction. Experience has shown that it is capable of performing for tertiary syphilis what quinine is for intermittent fever, or arsenic for neuralgia. It is the remedy *par excellence* in tertiary syphilis; a modern discovery of stupendous consequence to the human race; a remedy without which it would be impossible to treat this disease with any prospect whatever of success in almost any case, however simple. Let me not, however, in making these broad statements, be misunderstood. I do not wish to assert that iodide of potassium is absolutely infallible; like quinine and other great remedies, it occasionally disappoints expectation; but we may safely claim for it a degree of certainty which no other article of the materia medica possesses, as an antisyphilitic agent in the tertiary stage of this affection. I therefore ask for it, as has been done by many others, an undoubted confidence in its efficacy, and a fair trial of its use.

The exhibition of iodide of potassium may usually be commenced without any preliminary treatment; it is only when there is great disorder of the secretions that any preparation of the system will be necessary, and then it need not generally extend beyond a single dose of purgative medicine, and the administration of a full anodyne. The proper mode of exhibition is that of solution in distilled water, either alone, or with some bitter infusion or tincture, as hop, gentian, or quassia, such a combination being particularly desirable in the event of a gentle tonic being required. The dose of potassium has been a prolific source of dispute. Long experience has taught me that, while less than ten grains will rarely do much good, there are few cases in which more than this quantity is really ever needed. I have therefore found this to be a good average dose, repeated three times a day, at intervals of eight hours, the most favorable period for the administration being soon after eating. When a rapid effect is required, as when there is unusual urgency of the symptoms, an additional dose may be given, but this will seldom be necessary. I have occasionally exhibited twenty, twenty-five, and even thirty grains at a dose thrice daily, but the effect, instead of being gratifying, has generally disappointed me, the medicine seeming to act as an irritant rather than as a calmative, as it always does when it agrees perfectly with the system. I have never given drachm doses of the article, as is done so often by others, and I should regard such practice as altogether unmeaning, if not positively prejudicial. We cannot take the disease by storm; the treatment must be chronic, in conformity with the malady which it is intended to cure; hence it requires patience, regularity, and perseverance rather than a display of strength and heroism. The remedy must not be abused. The practitioner should be intent upon accomplishing a certain amount of good every day, until he succeeds in eventually expelling the implacable foe effectually from the system. Conducted upon this plan, a most rapid and decided amendment generally occurs; the sleep, appetite, and strength daily improve;

the countenance loses its wan, cachectic appearance; and in less than a fortnight, often indeed in less than a week, the patient looks and acts like a new being, his whole condition, physical and mental, evincing the astonishing change wrought by the medicine.

Iodide of potassium, especially when given in large doses, occasionally signally disagrees with the system, rendering it necessary either to suspend its use altogether, or to administer it in a modified form, or in smaller quantity. The most common effect which it induces is an irritable condition of the air-passages, with a sense of fulness in the head and frontal sinuses, a thin watery discharge from the nose, more or less sneezing, vascular injection of the conjunctiva, and a general feeling of discomfort, the symptoms strongly resembling those of a rather severe coryza. This effect sometimes declares itself after the exhibition of only a few doses of the medicine; at other times it does not appear until after the lapse of eight or ten days, or until the system has been pretty well saturated with it. In some cases, depending evidently upon a strong idiosyncrasy, the smallest quantity almost is sufficient to produce excessive discomfort, and an invincible repugnance to the further use of the remedy. Among the more uncommon effects to which the iodide of potassium may give rise are, gastric irritation, diarrhœa, salivation, glossitis, vesicular eruptions of the skin, excessive diuresis, hemorrhagic discharges from the urethra and vagina, and cerebral excitement not unlike that occasioned by alcoholic drinks.

The best mode of counteracting these disagreeable effects of the medicine is to combine it with an anodyne, as a small quantity of morphia, or from five to ten drops of acetated tincture of opium with each dose. In some cases I have found the free use of strong hop tea to answer the purpose, while in others a mere diminution of the dose was sufficient. I do not remember an instance in which I have been compelled, on this account, to abandon the use of the article altogether.

The length of time during which the potassium should be continued must, of course, vary in different cases and under different circumstances, and does not therefore admit of any definite statement. In the great majority of cases it should be exhibited for many weeks and even for a number of months, with an occasional intermission of three or four days, in order to afford the system a short respite, which is always found eminently beneficial whenever a medicine has to be used chronically. An invariable rule with me is to continue the remedy for several weeks after all disease has apparently vanished; and afterwards to give it for eight or ten days at a time at intervals of a month, on the same principle that we administer quinine periodically and for a long time, for the radical cure of intermittent fever.

Iodide of potassium may sometimes advantageously be combined with carbonate or muriate of ammonia, the two articles being given in solution, in equal proportions, thrice a day. An eminent Italian practitioner, Dr. Gamberini, of Bologna, recommends, as a substitute for iodide of potassium, iodide of sodium and iodide of ammonium. The latter preparation has lately been very frequently employed by Professor Blackman, of Cincinnati, and, as he informs me, with the most gratifying results. He prescribes it in doses of about five grains, three times in the twenty-four hours, using along with it, when there is much emaciation, cod-liver oil and generous diet.

Although I have no hesitation in declaring that iodide of potassium alone will often cure tertiary syphilis, yet I am quite satisfied, from personal experience, that its efficacy is generally remarkably augmented by the addition of a small quantity of *mercury*. Indeed, so thoroughly am I convinced of the decided superiority of this course that I have of late years almost invariably employed it, thus greatly abridging the treatment, and much more completely eradicating the disease. The plan is particularly beneficial when the affection

is of long standing, when it has deeply penetrated the system, as shown by the existence of nodes, nocturnal pains, and ulcers upon the skin, and when the patient has been fruitlessly subjected to frequent courses of the iodide alone. An infirm, broken state of the system is no bar to the use of mercury in this mode of combination; on the contrary, it often affords the medicine an opportunity for its best display.

The form of mercury which I prefer, and to which I have become much wedded, is the bichloride, which is readily made soluble by the iodide, and may be given in doses varying from the eighth to the sixteenth of a grain three times a day. I usually begin with the twelfth of a grain, gradually increasing the quantity, if necessary, on account of the obstinacy of the case, to the eighth or sixth of a grain, which should rarely, if ever, be exceeded in any case. The effects of the remedy are of course carefully watched, the slightest tendency to ptyalism being a sign for its suspension, or, at all events, its more guarded use. In general, I have found it beneficial to continue the mineral until there is slight tenderness of the gums, with a metallic taste in the mouth, and to keep up this action afterwards for several weeks by repeating the dose occasionally as the effect begins to flag. In short, chronic mercurialization is wished for, not acute, which never fails to do harm, sometimes immense and irreparable. After the mercurial course has been sufficiently persisted in, the cure may be completed by the iodide of potassium, now given by itself, and perhaps in reduced doses, simply to maintain a slight constitutional impression.

When the bichloride disagrees, which, however, is seldom the case, a good substitute, although of inferior value, will be found in the blue mass, the gray powder, or the protiodide. Donovan's solution, a compound of mercury, iodine, and arsenic, may sometimes be advantageously exhibited, the dose being from six to eight drops three times a day. It often proves serviceable in relieving rheumatic pains and swellings of the bones and periosteum. When the system is much dilapidated, the object is best attained by inunction, fumigation, or the vapor bath, the remedy, when thus introduced, acting often much more beneficially and kindly than when administered by the mouth.

The topical application of mercury is particularly to be commended when the syphilitic disease is of unusually long standing; when the surface is covered with irritable, painful, and intractable sores; when there is deep involvement of the bones, as declared by the existence of nodes, diffused swellings, or caries and necrosis; or when the system is greatly exhausted by protracted suffering, want, and exposure, or long and injudicious courses of mercury by the mouth. Thus employed, its effects frequently display themselves in the most striking and efficient manner, in the rapid and extraordinary improvement that follows in the character of the several local affections and the condition of the general system.

The article which is usually employed for *inunction* is the simple mercurial ointment, from a drachm to a drachm and a half being rubbed upon the inside of the thighs and arms once a day until the constitutional effects of the medicine become apparent by the state of the gums, breath, and saliva. I usually add a small quantity of powdered camphor, with a view of rendering the ointment more soluble, and thereby facilitating its introduction into the skin. The friction should be very thorough, and be continued until the ointment has disappeared from the surface.

Mercurial *fumigations* may be conducted in a very simple manner, and with hardly any expense. All that is necessary is a large comfort, long enough to extend from the floor to the patient's neck, to which it is carefully secured with a piece of tape, so as to prevent the fumes from escaping into the room and entering the sufferer's lungs. For want of this precaution, suffocation

has occasionally occurred, as in an instance which took place, many years ago, at the Louisville Hospital, in a man affected with tertiary syphilis. Or, instead of this, the body may be surrounded with a cloak of oil-cloth. The patient, completely stripped, is seated in a large arm chair, or upon a stool, beneath which is placed the fumigating apparatus, consisting of a common dinner plate, and a spirit lamp, arranged in such a manner as not to endanger the safety of the person. The mercurial preparation usually employed is the red sulphuret, of which from half a drachm to a drachm is put upon the plate prior to the ignition of the lamp. The operation, which should not be repeated oftener than once a day, lasts from ten to twenty minutes, at the end of which the patient should retire to bed, and cover himself well up in order to maintain the perspiration usually so auspiciously begun during the fumigation. Great prostration, however, may follow this sweating process, and hence care should be taken not to carry it too far, or to renew it too frequently. The length of time during which the fumigation should be continued must depend upon circumstances; in general, it will not be short of two or three weeks.

Another mode of employing mercury topically is by a combination of fumigation with steam, constituting what Mr. Langston Parker, of Manchester, terms the *mercurial vapor bath*. It is applied after the same method as ordinary fumigation, with this difference, that, while the cinnabar or sulphuret is volatilized by means of a spirit lamp, the steam of hot water is conveyed from a boiler under the patient's mantle as he sits in his chair.

I can testify from considerable experience to the beneficial effects of these two methods of mercurialization, having effected some very extraordinary cures with them after all other rational means of treatment had failed. I recollect, in particular, the case of a young gentleman of Arkansas, who was under my charge, in 1855, on account of tertiary syphilis of many years' standing, attended with an enormous amount of rupial action of the skin, one of the sores being fully as large as a dinner plate, and with an infirm, cachectic state of the system, who was promptly cured, comparatively speaking, by daily fumigations with sulphuret of mercury, conjoined with the frequent use of the tepid bath, a nutritious diet, and stimulants, after a great variety of other means had been fruitlessly employed. My impression is that this mode of treatment is not sufficiently appreciated by the profession of this country. It certainly deserves the highest encomiums. When there is much disorder of the secretions, derangement of the alimentary canal, or a feverish state of the system, a short course of preliminary treatment will generally be necessary before commencing the fumigation process, as this will greatly augment its efficacy. In all cases the object should be to bring the mercurial vapor as fully as possible in contact with the syphilitic sores.

Simple and medicated *baths* often prove serviceable in tertiary syphilis, not only as means of cleanliness, but by the direct soothing and healing influence which they exert upon the part and system. They are particularly beneficial in rupial ulcers and in rheumatic pains of the bones and joints. The emollient bath, prepared by mixing a basinful of thick gruel, or twice that quantity of wheat bran, with a suitable quantity of tepid water, generally proves most grateful. The common salt-water bath, or a bath containing a small quantity of carbonate of potassa, or chloride of sodium, is an excellent detergent and stimulant in the foul ulcers of the skin and bones so common in the advanced stages of syphilis. Occasionally the water may be advantageously impregnated with bichloride of mercury, from three to ten grains of the salt being added to the gallon of fluid, and the immersion continued for at least twenty or thirty minutes. Much caution, however, is required, especially when the surface is considerably denuded, otherwise severe pyalism may arise. Baths containing nitric, hydrochloric, or acetic

acid, are sometimes used, though of late they have gone much out of vogue, chiefly, perhaps, because they are inconvenient, and liable, if proper care be not taken in their preparation, to cause severe pain.

Besides mercury and the other means above mentioned, there are certain remedies which, although usually considered as being merely auxiliary, are, nevertheless, of great consequence in a curative point of view in the treatment of syphilis. At the head of these may be placed a properly regulated diet, tonics, sudorifics, and anodynes, which deserve the greatest attention in every case of the disease.

It is impossible to insist too strongly upon a well regulated *diet* in the treatment of this affection, when it is recollected how much its progress and virulence are influenced by the exhausted and impoverished condition of the system which generally attends it in its more advanced stages. No medicine can possibly produce its full and legitimate effects under such circumstances, without the aid of good, wholesome, and easily digestible food, stimulating drinks, especially brandy and whisky, and an abundance of fresh air. The blood must be enriched and the solids rebuilt before it will be possible to eradicate the specific virus from the system.

Tonics are nearly always indicated; and quinine with iron will usually be found to answer better than any other combination. The bitter extracts, as gentian and quassia, are generally of no account, except in so far as they may conduce to improve the appetite. Occasionally benefit accrues from the use of some of the acids, particularly the nitric and hydrochloric, either alone or conjointly, and diluted with a large quantity of water. Formerly, powerful anti-syphilitic properties were ascribed to these articles, but it is probable that all the good they do is solely dependent upon their tonic virtues, and not upon any agency they possess in neutralizing the syphilitic poison. When much emaciation exists, with want of assimilative power, or a feeble digestion, there is no article which holds out greater promise of usefulness than cod-liver oil, given in doses suited to the state of the stomach and the general condition of the system.

Sudorifics have long held a high rank in the treatment of syphilitic affections, under a supposition, at one time quite rife, that they aided in carrying off the venereal poison, thus ridding the system of its noxious influence. Without conceding to them such a virtue, which they certainly do not possess, there is no question as to their general usefulness in all states of the economy attended with obstructed perspiration, so often present in the advanced stages of syphilis, particularly when there is serious involvement of the skin. The object for which such medicines are usually prescribed may be readily obtained by the warm, hot, or steam bath, assisted by tepid drinks, and various kinds of diaphoretics, as Dover's powder, antimony and morphia, and similar articles. Some caution is necessary in the use of sudorifics, lest injurious debility be induced.

But of all the auxiliary remedies now described, the most important, in every respect, are *anodynes*; their employment is absolutely indispensable, and it is therefore impossible to assign to them too high a rank. They are, up to a certain stage of the treatment, of more consequence even than food and drink. The patient is not only not able to sleep, but his body is literally racked with pain and surcharged with irritability. To look for any substantial improvement, under such circumstances, from ordinary remedies, would be worse than idle; it would be absurd. The first thing to be done is to quiet the system and induce sleep; and to accomplish this, anodynes must be exhibited in large and sustained doses, a grain of morphia, or its equivalent of solid opium, laudanum, or black drop being given every eight or twelve hours, according to the effects of the article. The manner in which anodynes are borne, in the worst forms of tertiary syphilis, is often astonish-

ing, and can only be explained by the irritable condition of the nervous system.

I have not made any reference to *sarsaparilla* in the enumeration of the above remedies, simply because I am not sure that its employment in my hands has ever been productive of any appreciable benefit. Whether this has arisen from bad luck, or from the use of an inferior article, it is not in my power to affirm; I may state, however, that I have employed it in every form and mode of combination in which it is used in this and other countries, and am therefore inclined to believe that it has been invested with virtues which do not belong to it, or which are due mainly, if not solely, to its associate ingredients.

Finally, persons laboring under tertiary syphilis should live in a pure, dry atmosphere, and be well protected against cold. When it is remembered how easily the disease is provoked by exposure to cold, and by living in damp, underground, and ill-ventilated apartments, the importance of attention to this injunction cannot fail to be fully appreciated. The body should be well covered with flannel, both in summer and winter, and the patient should not be permitted to sit in the draught.

The above general treatment is applicable, to a greater or less extent, to all forms and cases of tertiary syphilis whatever; it is only necessary, therefore, in concluding this branch of the subject, to refer to the topical measures, and to such modifications of treatment as are likely to grow out of the anatomical relations of the individual structures and organs liable to suffer from this disease.

There are certain rules of treatment which are applicable to all local affections, whatever may be their site or extent. Thus, the surgeon does not hesitate to remove dead bone, open abscesses, trace out sinuses, divide fasciæ or aponeuroses, and trim off the ragged, undermined and impoverished edges of cutaneous ulcers, so as to place them in a more suitable condition for speedy reparation. All this is self-evident, and only requires mention to secure attention. Cleanliness is of paramount importance in all cases, as it contributes not merely to personal comfort, but also, in a powerful degree, to recovery. Fætor is allayed by the free use of the chlorides.

Ulcers, fissures, eruptions, papules, and tubercles of the *skin* often get well with very little topical treatment; simply, in fact, under the use of iodide of potassium, or potassium and mercury, with attention to cleanliness and other hygienic observances. When much inflammation is present, with a foul appearance of the part and a tendency to spread, the dilute tincture of iodine will come in play, with emollient cataplasms, or the warm water-dressing, simple or medicated. Touching the sores lightly once a day, or every other day, with dilute acid nitrate of mercury or the solid nitrate of silver, generally astonishingly promotes the cure. Unguents are not always as bad as they have been represented to be in these cases. I have often employed them with excellent effect, especially the opiate cerate, the balsam of Peru ointment, and the ointment of the nitrate of mercury, mixed with six or eight times its bulk of simple cerate. The mercurial ointment, much diluted, and mixed with opium, often makes an excellent dressing in the indolent form of rupial ulcer.

Syphilitic *onychia* is, strictly speaking, a rupial ulcer, and should therefore be treated in the same manner as similar sores elsewhere. If abscesses form under the nail, they must be punctured; and if the nail die, it must be removed, or trimmed, if it overhang and injuriously compress the diseased parts.

The topical treatment of tertiary ulcers of the *throat*, mouth, and tongue is restricted principally to applications of the acid nitrate of mercury and solid nitrate of silver, made at first once a day, and subsequently every third,

or fourth day, according to the condition and progress of the sore. Weak gargles, or washes of acetic acid, tannin and sulphate of copper, chlorinated soda, or of the cyanuret of mercury, in the proportion of from ten to sixteen grains of the salt to a pint of some bland, mucilaginous fluid, as linseed tea or infusion of elm bark, may be employed three or four times a day in the intervals.

In the treatment of syphilis of the *nose*, our chief reliance is upon injections of weak lotions of iodide of iron, sulphate of copper and tannin, tincture of myrrh, and chlorinated soda, particularly the latter, as it imparts not only a healthy stimulus to the affected surfaces, but effectually allays fetor, so distressing and disgusting in this class of nasal complaints. Mercurial preparations are, as a general rule, improper, being extremely prone to pass into the stomach, and thus occasion salivation; but for this they would often be most beneficial. In using injections for the nose, a large syringe with a long, perforated nozzle is required, the object being to bring the fluid in contact with every portion of diseased structure. They should not be repeated more frequently than thrice a day, and especial care must be taken that they do not distress by their severity. In fact, an injection of the nose should never smart beyond a very few minutes, and then only in a very slight degree. If it pains longer, it is an evidence that it is too severe to be beneficial.

If the affected parts are within reach, regular and steady medication may be effected with lint smeared with some suitable ointment or wet with some slightly stimulating lotion. In all cases the nasal cavities should be frequently inspected with a view to the early detection and removal of dead bone.

In syphilis of the *larynx* direct medication may be attempted by means of the mop wet with a weak solution—from ten to twenty grains to the ounce—of nitrate of silver, introduced once every third or fourth day, the patient being at the moment partially under the influence of chloroform so as to render the parts more passive, and, consequently, more tolerant of the operation, which is otherwise very apt to prove a complete failure. When the disease is extensive or the case urgent, as when there is deep ulceration with excessive difficulty of deglutition and frequent spasm of the muscles, or œdema of the glottis, nothing short of laryngotomy will suffice, and should be had recourse to without delay. Direct medication may then be made with acid nitrate of mercury or with any other article that may seem expedient. If warty excrescences be present, they may be clipped off with the scissors, repullulation being prevented by escharotics or sorbefacients. Dead cartilage is removed in the usual way.

The great remedy for syphilitic *iritis* is mercury pushed in such a manner as to produce a most rapid and decidedly salivant effect. No time is to be lost; the treatment must be prompt and earnest, with a view to the one result, or the eye is lost. If the patient be young or plethoric, blood is freely taken from the arm or by leeches and cups from the temple. Opium is given to allay pain and prevent the mercury from running off by the bowels.

Affections of the *bones* and periosteum of the extremities are treated upon general antiphlogistic principles. The local pain and swelling are often immensely benefited by tincture of iodine, leeches, and blisters, although in very many instances they readily yield to the internal exhibition of iodide of potassium and mercury. A node should not, as a general rule, be opened so long as it is very small, and unproductive of serious annoyance; when the reverse, however, is the case, it should be freely incised, and so also if it be the seat of distinct fluctuation, denotive of the existence of matter. A good rule, under such circumstances, is to make the knife graze the bone, imperfect division of the parts being generally worse than useless. If the resulting ulcer be slow in healing, it should be well blistered, or dressed with mercurial

ointment, or some stimulating and anodyne lotion. Sometimes the pain and tension of a node may be promptly relieved by subcutaneous incision, effected by means of a delicate bistoury, carried about in different directions and in such a manner as also to divide the periosteum. Necrosed bone must be removed as soon as it is sufficiently detached to admit of its easy separation; while carious bone must be scraped and otherwise managed to put it in a condition capable of undergoing reparation. Diffused hypertrophy rarely requires any other than constitutional remedies. Exostosis, properly so called, is usually free from mechanical inconvenience; should it act obstructingly, the best remedy will be the saw or pliers.

Syphilitic *sarcocoele* is treated, topically speaking, upon the same general principles as swelling of the testicle from gonorrhœa, by rest of body and elevation of part, leeches, astringent and anodyne fomentations, and mild mercurial inunctions. When the enlargement is indolent and rebellious, strapping may be employed, either with common adhesive plaster, mercurial and ammoniac plaster, or the plaster of Vigo. The cure is often retarded in these cases by the presence of a considerable quantity of serum in the vaginal tunic, compressing and irritating the diseased organ. The proper remedy is a free incision, or repeated punctures. If abscesses and fungus form, they should be treated in the ordinary manner.

When the testicle is fungous, ulcerated, and completely disorganized, the only resource is removal, no treatment, either general or local, proving of any service in such a case. But, before so serious an operation is ventured upon, it should always be understood that the organ is really, and not merely apparently, past recovery.

The treatment of *condylomatous* growths must be conducted upon general and local principles. It is true, topical means alone will often cure them without difficulty; but to effect permanent riddance constitutional treatment is generally indispensable. The most efficacious remedy, for this purpose, is the iodide of potassium in union with the bichloride of mercury, administered as in tertiary syphilis, the diet, bowels, and secretions being at the same time suitably regulated. The specific treatment should be prolonged, in a modified manner, for several weeks after all disease has apparently disappeared, the object being to break up all tendency to recurrence.

In regard to the topical treatment, cleanliness is a matter of primary importance, hardly less on account of the attendants than of the patient himself. Free use must be made of tepid water, impregnated with the liquid chlorinated soda, and applied by means of a sponge or syringe; if there be much discharge, the dressings and the bedclothes should be frequently sprinkled with the solution. Another important element of treatment is perfect rest with isolation of the affected parts, their contact having, as stated previously, a tendency to foster growth and secretion. To repress the tumors, various remedies may be used, the best of which is chromic acid, applied once in the twenty-four hours, until they are shrivelled and dried up, as they generally will be in a few days. Nitrate of silver, nitric acid, and acid nitrate of mercury, so commonly recommended, are all extremely severe, besides being very uncertain. In the intervals of the applications, the excrescences should be kept well covered with some desiccating substance, such as three parts of prepared chalk to one of carbonate of zinc, calomel, or dry lint. Under this management rapid improvement soon follows; the tubercles becoming dry, shrivelled, and less sensitive. In the minor cases, prompt relief generally follows the application, several times a day, of pulverized savin, with a small quantity of tannin and a minute portion of sulphate of copper, or equal parts of powdered savin and alum. Great attention should be bestowed upon cleanliness for a long time after the excrescences have disappeared.

SYPHILIS IN THE INFANT.

Infants are subject to syphilis, and there are two modes in which they may become infected. First, they may suffer from direct inoculation, and, secondly, the disease may be communicated by either parent; by the father in the act of copulation, or by the mother during the process of pregnancy. It has also been supposed that a child may be contaminated by the milk of an unsound nurse, but if this be true, the facts have not been presented in such a light as to induce general conviction of their accuracy.

Direct, primary syphilis may be contracted, as, indeed, it most generally is, by a child in its passage through the soft parts of the mother, by the surface of the body coming in immediate contact with a chancre in the vagina, or on the vulva, or, at all events, with the secretions of such a sore. In this manner an eye may become inoculated, or the mouth, or, in short, any mucous surface that may entangle and retain the specific virus sufficiently long to admit of its absorption; for in so young a subject as this it is probably not necessary that there should be any actual solution of continuity in order to produce the effect, the mucous tissues being so delicate, and the lymphatics so active as to enable the poison to enter these vessels by direct imbibition. When the disease attacks the skin, however, it is generally, if not always, the result of direct inoculation from the matter being brought into contact with an abrasion on its surface. A nurse having a chancre upon her nipple may impart the virus to the infant's lips in the act of suckling, but such an occurrence, although possible, must be extremely uncommon.

In whatever manner the infection is caught, the resulting disease pursues the same course as when it occurs in the adult, whether from sexual intercourse or artificial inoculation. The child may perish from the local irritation, or, if it survive the primary affection, it may afterwards suffer from constitutional syphilis, the impression manifesting itself in cutaneous eruptions, mucous tubercles, sore throat, ulceration of the nose, and rheumatic pains in the bones and joints.

In the great majority of cases of infantile syphilis, however, the disease is communicated either through the seminal fluid of the father, in the act of procreation, or by the mother through her blood after the ovum has taken up its residence in the uterus. That the contamination may occur in both these ways has been incontestably proved by numerous observations, conducted with such care as not to admit of any reasonable doubt. The semen is a living fluid, and in a man laboring under constitutional syphilis the probability is that every spermatozoon is completely impregnated with the specific poison; hence it is only necessary that it should be mixed with the material furnished by the mother in order to produce thorough vitiation of the new being. Thus, the very fountain of life is poisoned in the very act of conception, and it is therefore not surprising that all its sources should participate in the evil thus inflicted.

The time at which a female with secondary symptoms may communicate the poison to her offspring cannot be accurately stated. The probability is that it is very short. This is proved by the circumstance that such a woman frequently aborts within a few months after conception, evidently in consequence of the deleterious effects of the virus upon the fœtus. I suppose that the contamination is coeval with conception, occurring at the moment of the commingling of the two seminal fluids; for if it be assumed, as we have a right to do from the facts of the case, that the male can communicate the poison in this manner, why should a similar faculty not be ascribed to the female? She, too, furnishes a fecundating substance—a seminal liquor—

which can no more escape contamination when her system is affected with secondary syphilis than the seminal fluid of the male. In both cases, the blood, the source of life, growth, and nutrition, is completely poisoned, and hence all its products, whether solid or fluid, must necessarily participate in the evil effects to which such a state must give rise. But in the female these effects must be still greater than in the male; the whole function of the male, in the process of reproduction, consists in the deposition of a certain amount of semen, perhaps a solitary spermatozoon, while the female is also obliged not only to furnish a fluid, but after conception has occurred, she is compelled to nourish the new being, the most intimate connection being established between them by means of the placenta.

It has been alleged that a healthy child, or a child born of healthy parents, may be infected by a nurse affected with secondary syphilis; the milk being tainted, and capable of communicating the disease. Of the possibility of such an occurrence I entertain, I confess, great doubt; my own practice has certainly not afforded me any examples of it, while it has fallen to my lot to see several cases where the converse was the fact, healthy children having sucked infected women, and yet they remained perfectly sound.

It has been a contested point whether a child, laboring under constitutional syphilis, can infect its nurse by communicating the disease through the nipple, and the question, as might have been expected, has been answered differently by different writers. Those who have espoused the affirmative side of the question, rest their assertion upon the result of personal observation, the most reliable testimony of all, one would suppose, in a controversy of this kind; but it is not to be forgotten that observation is fallacious, and that all men, however competent to practise medicine and surgery, are liable to be deceived by their patients, especially in relation to venereal affections. Not only do the abettors of this doctrine assert the possibility of this mode of transmission, but they go further and allege that a nurse so affected has, in turn, infected her own offspring. In a case related by Mr. Hunter, and upon which great stress is usually laid by authors, it is stated that the diseased infant, in this way, successively inoculated three wet nurses, two of whom afterwards conceived, and were delivered of syphilitic children. Now, instead of looking upon this case in this peculiar light, I should be inclined to infer one of two things, either that this diseased child had had a chancre upon its lip, or, what is more probable, that the three nurses had all been previously infected.

Those, on the other hand, who contend that such a mode of contamination is impracticable, base their conclusions upon the fact that the matter of secondary syphilis is destitute of inoculable properties, no well authenticated case, or one entirely free from objection, having yet been observed of the transmission of the disease through its intervention. Now, if this be true, as undoubtedly it is of the adult, it ought to be equally true of the infant; and hence, although the child should have a specific sore upon the lip or tongue, and the mother a fissure, crack, or ulcer upon the nipple, yet, inasmuch as the secretion of the former is innocuous, no constitutional contamination can be caused by its contact with the exposed surface of the latter.

There is another question which closely connects itself with the preceding, and it is this: Is there any evidence, of a positive kind, that a husband laboring under secondary syphilis may communicate the disease to his wife through the agency of the semen? So far as I am aware, there is none, and yet the affirmative side of the question has met with some very warm advocates. It is absurd to believe that this fluid, when injected into the vagina and uterus, is ever absorbed, even supposing that it were retained for a considerable length of time, which, however, it rarely, if ever, is. There is certainly no satisfactory proof of such an event, and we must, therefore, at least for the

present, reject it. It is different when impregnation occurs. Here, as already seen, the semen mixes directly with the corresponding fluid of the female, to which it at once imparts its deleterious properties, thereby effectually tainting the new being in the very act of its creation.

Hereditary syphilis is generally a grave disease; for, unless it be judiciously treated, it nearly always proves fatal. A great majority of the neglected cases terminate in abortion, the foetus often perishing as early as the end of the third month, and from thence on death may occur at any period up to the full term of gestation, the child being usually thrown off in a putrid and horribly offensive condition. The number of successive abortions is sometimes remarkable; in one instance, communicated to me by one of my own patients, it amounted to thirteen, the woman never having brought forth a healthy infant. Cases of three and four successive abortions have repeatedly come under my observation. Now and then a woman will abort several times in succession, and then be delivered of an apparently healthy child; I say apparently healthy, for, although the new being may be perfectly plump and fat, and exhibit all the outward signs of the most perfect integrity, yet generally, in a very few weeks, it is found to present unmistakable marks of decay and disease. The first thing that is usually noticed is that it loses flesh and strength, becoming gradually thin and puling, and looking as if it had been withered by the sudden drying up of its juices. The skin has a dingy, muddy, shrivelled appearance, and hangs about in loose, soft folds. The countenance is shrunken, wan, and ghastly, and resembles that of a man of seventy-five or eighty, instead of that of an infant a few weeks old. The voice is husky; the respiration is snuffling; the throat is sore; the gums are red and spongy; the lips and anus are fissured; and the body is covered with copper-colored eruptions, usually of the scaly kind, and intermixed with tubercles. Purulent ophthalmia is not uncommon, the inflammation usually coming on within two or three days after birth, and generally ending in total blindness. In some cases numerous superficial ulcers are found upon the surface, attended with a thick, tenacious discharge, and a hard, reddish, characteristic base. The hair often drops off in large quantity, both on the scalp and on the rest of the body. The well-developed node and orchitis are of rare occurrence in infantile syphilis. Death, under such circumstances, is seldom protracted beyond the first three or four weeks after birth. Occasionally, the child may reach the end of the second or third year, and in a few instances life is prolonged until after the period of puberty, the individual having a stunted, sickly growth, and being the subject of deep ulcerations of the throat, palate, nose, and skin, with, perhaps, caries of the bones of the extremities, and stiffness of some of the principal joints. Such, in a few words, is an account of the most common effects of this direful form of the disease. Few children recover, and those who do are doomed to drag out a miserable existence, generally amidst the most loathsome and disgusting deformities.

Infantile syphilitic eruptions are liable to be mistaken for some of the more common affections of the skin incident to early childhood, and the *diagnosis* is not unfrequently envired with no little difficulty in consequence. In obscure cases, our chief reliance is to be placed upon the history of the attack, and other concomitant circumstances. From three to four weeks after birth is the average period of the appearance of the cutaneous affections, the sole of the foot, the buttock, scrotum, face, chest, and inside of the thigh and arm being the parts originally involved. The surface immediately around the eruptions is of a coppery or reddish-brown color, a condition very different from what is observed in ordinary diseases, especially eczema, lichen, prurigo, and lepra, with which they are most liable to be confounded. Besides this, which is always a most important symptom, diagnostically considered, the

general appearance of the infant shows that it has received a severe shock; it is thin and emaciated, and progressively fails to an extent, and in a manner altogether unusual in common cutaneous maladies. The old, withered and shrivelled look of the child is almost, of itself, characteristic of the disease; the snuffling is another important element in the discrimination of the case, and too much stress cannot be laid upon the mottled, dingy, or muddy state of the skin. The history of the case will usually show that the parents have been the subjects of syphilis, or that they are actually suffering under it at the time.

Much stress has recently been laid upon the condition of the teeth as a diagnostic sign in hereditary infantile syphilis, attention having been first directed to the subject by Mr. J. Hutchinson, of England. The disease occurs chiefly in connection with, or as a result of, specific stomatitis, and displays itself more particularly in the upper incisors, although the lower incisors and even the canine teeth occasionally participate in the morbid action. The first evidence of the disease is generally a dirty, dingy or light brownish appearance of the enamel of the central and afterwards of the lateral incisors, which soon begin to soften and crumble away, the child ultimately becoming edentulous. Both sets of teeth are cut prematurely as well as very irregularly, as it respects their position in the jaw; and, unless the constitutional taint is early eradicated, the permanent are doomed to share the same fate as the temporary, although they are destroyed less rapidly.

The characteristic appearances of infantile syphilitic teeth are well illustrated in the annexed sketches, figs. 92, 93, borrowed from Mr. Erichsen.

Fig. 92.

Syphilitic temporary teeth.

Fig. 93.

Syphilitic permanent teeth.

Treatment.—The treatment of infantile syphilis must be prophylactic and curative. If the mother be suspected to be laboring under a constitutional taint, as she justly may be if she has had several consecutive abortions or miscarriages, or if she is in infirm health, with eruptions upon the skin, a plentiful discharge from the vagina, and an ulcerated condition of the neck of the uterus, she should be promptly put upon a course of mercury and a properly regulated diet, in order to prevent the ill effects of the contaminated state of her blood upon the fœtus, and thus enable the latter to attain its full growth, and the full period of gestation. The mercurial course should be chronic, not acute, and as gentle as possible, lest it should excite abortion; and in most cases it will be beneficial to associate the metal with the iodide of potassium and some preparation of iron, with a view to a tonic effect upon the general system, which, as already stated, is usually in an impaired and cachectic condition, and therefore requires great attention to bring it up to its normal level. The diet should be mild and nutritious, the clothing should be warm, and the patient should have the full benefit of fresh air.

As soon as the child is born it should be taken from its infected mother, and confided to a sound wet-nurse, as an appropriate diet is absolutely essential to its preservation. If no suitable wet-nurse can be obtained, it should have an abundant supply of fresh cow's milk, or, what is better, of

the milk of the ass, which approaches nearer to the human milk, in some of its more important properties, than that of any other animal. The body and limbs should be well protected with flannel, and frequent recourse should be had to the tepid bath, impregnated with bran, or mucilage, especially if there be eruptions, fissures, or ulcers upon the skin. An abundant supply of pure air will be indispensable. The fact is, too much attention cannot be paid, in every case, to the observance of the rules of hygiene. Cod-liver oil will prove a valuable adjuvant in all cases where it agrees with the stomach.

The most important internal remedy is mercury, and it is here that this article often displays its effects to the greatest advantage in neutralizing the specific virus. If any one should doubt the efficacy of this medicine, as an antisypilitic agent, his scepticism will soon vanish if he will take the trouble to watch the progress of the treatment and the good results that will follow it. If it is not positively a specific, it approaches as nearly this property in this disease as anything well can, quinine in intermittent fever hardly excepted. The form of exhibition is the bichloride, in doses varying from the fortieth to the fiftieth of a grain three times in the twenty-four hours, dissolved in distilled water, or, when there is need of a tonic, in a few drops of Huxham's tincture of bark. This should be steadily continued, with now and then a few days' intermission, for a number of weeks, not only until all disease is apparently gone, but for a considerable period after; and it will be well for the sake of the more complete eradication of the poison, to recur to the remedy occasionally until the child is several years of age. When the disease proves obstinate, the bichloride may generally be advantageously conjoined with the iodide of potassium, from the fourth to the eighth of a grain being given with each dose of the salt, according to the age of the child. When the body is covered with sores, pustules, or tubercles, a gentle course of mercurial fumigation will be advisable, but great care must be taken not to carry it to such an extent as to induce debility or to suffocate the child. Mild dressings may be used in the intervals, and of these the best will be very weak preparations of oxide of zinc or of the nitrate of mercury, in the form of unguent.

Cases sometimes occur where the bichloride of mercury does apparently either no good, or where it proves positively prejudicial; under such circumstances trial may be made of mercury with chalk, or, what is preferable, because not liable to cause gastro-intestinal irritation, of inunction with mercurial ointment, from half a drachm to a drachm being rubbed upon the inside of the thigh once a day, the surface being kept constantly covered with a piece of flannel. The treatment is continued for several weeks, until all evidence of the disease has disappeared.

SYPHILIZATION.

Within the last few years, attention has been directed, in various quarters, to the subject of *syphilization*, or the cure of syphilis by inoculation with the virus of chancre. As early as 1844, Dr. Turenne, in attempting to transfer syphilis from man to the monkey, was struck with the fact that, when the inoculation was repeated a number of times, the tissues to which the matter was applied were at length rendered completely insusceptible to its influence. To the condition thus obtained, he applied the term *syphilization*. Supposing that the treatment might be advantageous to the human system, he accordingly instituted some experiments upon men, but the results of his observations were not given to the profession until after the publication of the

memoir of Dr. Sperino, of Turin, in 1851. In this memoir numerous experiments are detailed, going to show that constitutional syphilis may be successfully cured by repeated inoculation. More recently the subject has engaged the attention of other observers, especially of Dr. Boeck, of Norway, the results of whose labors have been widely disseminated through the medical press of Europe and America. I am not aware that any experiments upon syphilization have been performed in this country.

According to Dr. Boeck, syphilization is justifiable at all periods of life, but it should only be resorted to after the development of secondary symptoms; for, as long as the disease is in its primary stage, inoculation would be improper, as no one can positively determine beforehand whether the constitution will become tainted or not. The earlier the treatment is commenced, the better, and the effect will always be the more prompt and decisive, when the patient has not been subjected to any previous mercurial course, which renders the system more stubborn to its influence, and more prone to relapses.

The inoculation is performed with the virus of chancre, and it is immaterial whether the matter be taken from the indurated or the non-indurated sore. The parts selected for the operation are the trunk and the inside of the thighs and arms. In a few days pustules will form, the matter of which must be inserted into the skin, until no further effects result, when the virus of the primary sore must again be employed, and the same course be pursued as before, until it is found that no further impression can be made upon the system. It will sometimes require the use of a new virus five or six times, before complete constitutional immunity can be secured. The symptoms, as a general rule, begin to abate in from four to six weeks, but it may take a whole year before the disease is perfectly eradicated. It will be found, upon every repetition of the inoculation, that the pustules and ulcers become less and less, and, also, that they gradually lose their specific appearance and character.

In regard to the value of this treatment, it is obviously impossible, at present, to form any definitive conclusions; further observation alone can enable us to do this. The practice is, to say the least, exceedingly filthy and disgusting; a circumstance which, added to the tediousness of the cure, will probably serve as an effectual bar to its general adoption. Besides, a surgeon may, in consequence of its employment, render himself liable to prosecution and heavy fine, as in a case which recently occurred in France.

CHAPTER XII.

GENERAL DIAGNOSIS.

DIAGNOSIS is the art of distinguishing and identifying diseases and accidents, or, in other words, of determining their seat, nature, and effects. Its study is of paramount importance to every practitioner, and he should therefore omit no opportunity of improving his knowledge of it. Its value, practically considered, has been felicitously expressed by Louis, the illustrious secretary of the French Academy of Surgery. "The science of diagnosis," says he, "holds the highest rank among the different branches of the healing art, as it is at once the most useful and the most difficult. The discernment of the peculiar character of each kind of disease and of its different species constitutes the source of all curative indications. Without a clear and exact diagnosis, theory must always be at fault, and practice frequently uncertain." It is by his knowledge of diagnosis that the practitioner acquires a command over disease which he who is destitute of it can never attain. It should therefore form the great object of his inquiry in every case of disease and accident; for to be able to locate and define their seat and character is almost to be able to cure them. To be incapable of doing this is literally to grope about in the dark; or to be tossed to and fro, like a mariner without a helm, upon an ocean of uncertainty. To disentangle truth from error; to give to disease "a local habitation and a name;" to distinguish one injury from another; and to base upon the knowledge thus derived a proper course of treatment, calculated to restore the sufferer to comfort and health, are among the highest attributes of the practitioner, and require an amount of talent, tact, and experience such as few men possess.

The very first thing that a surgeon does when he is called to a case of disease is to set up an inquiry into its true nature; to ascertain where it is situated, or what structures it involves; how it has been brought about; what progress it has made; and what are its essential characteristics, or in what particulars it differs from other lesions. In order to do this with any tolerable degree of success, it is necessary, in many cases, literally to interrogate every important organ and tissue of the body, with a view of ascertaining which of them are more directly implicated in the disorder, which are free from suffering, and which are affected only sympathetically. Such a step is generally indispensable when the lesion is of spontaneous origin, or when it arises without any appreciable cause. When the converse is the case, a less elaborate examination will usually suffice to supply the requisite light. Not unfrequently the nature of the complaint is perceived at a glance.

SECT. I.—EXAMINATION OF THE PATIENT.

To examine a patient well, so as to elicit all the light that may be necessary to a thorough comprehension of the nature of his malady, requires generally great tact and an extensive knowledge of morbid and healthy anatomy, physiology, pathology, and animal chemistry, not to say anything of micro-

scopy, now so much employed as a means of diagnosis. Any one may make a superficial investigation, and in the more ordinary cases such a mode of procedure may perhaps be all that is required; but under opposite circumstances, where everything is shrouded in obscurity, nothing short of the most patient and elaborate exploration will usually answer the purpose. Knowledge and tact alone, however, will not insure success; they may go very far, it is true, in enabling the practitioner to solve the mysteries of a case, but unless they are aided by a nice faculty of observation, and by a just sense of discrimination, he will never be able to analyze and group the facts presented to him in such a manner as to render them fully available when he comes to apply his therapeutic agents. Unfortunately, however, the power of observation is a rare gift, which few possess, and still fewer use to advantage. Surgeons, like physicians, have eyes, but they do not always see, and ears, but they do not always hear. Another fault, of which, unfortunately, too many, even among the most sagacious and best informed, are frequently guilty, is the hasty manner in which examinations are made, and, hence, no wonder that so many disgraceful and fatal blunders are daily committed by men who, if they would only give themselves proper time, might see disease as clearly as if they were looking at it in a mirror. Hasty examinations commonly lead to hasty deductions, and hasty deductions to hasty generalization and slovenly practice. All practitioners do not of course require the same amount of time to arrive at a correct judgment respecting the diagnosis of their cases; some literally jump at conclusions; others reach them only by a slow and tedious process of examination and induction. Of the two, the latter are generally the safest practitioners.

The object of an examination is often seriously interfered with, if not entirely frustrated, by the want of co-operation of the patient, in consequence of his timidity, his want of intelligence, or the perverseness of his disposition. Much adroitness is therefore often required to bring out the desired result; fully as much as the lawyer is obliged to expend in the examination of a witness who is incapable of appreciating the responsibility of his position, or of making a proper use of his knowledge. To gain the confidence of a patient is one of the first duties of a practitioner, as this is often necessary not only to a full development of the history of his case, but to its successful management. A gentle word, an agreeable tone, a winning manner, are well calculated to effect this result, and are attributes of the highest value, the more so as but few persons in our profession possess them.

Age, occupation, climate, and habits of life, being so many circumstances calculated to modify morbid action, should be among the first objects of inquiry at the bedside of the sick. There are many diseases which occur only at particular periods of life. Thus, scrofula is most common in children, scirrhus in elderly persons, chronic enlargement of the prostate in advanced age. The influence of occupation in the production of disease is well shown in hemorrhoids, varix, and ulcers of the legs, and, to go no farther, in necrosis of the lower jaw in persons engaged in the manufacture of lucifer matches. Gout, rheumatism, pneumonia, and pleurisy are most common in northern latitudes, while dysentery, hepatitis, and fever are most frequent in southern. Individuals of dissipated habits are particularly prone to erysipelas, boils, and carbuncles, and are often attacked with delirium tremens, when they become the subjects of severe injuries, as lacerated wounds, fractures, and dislocations.

Particular inquiry should be made into the previous history of the case; whether there is any hereditary predisposition to disease; whether the suffering organ was ever similarly affected before; how the present attack came on, how long it has been in progress, and what have been its chief symptoms. A careful examination of this kind cannot fail to elicit important and valuable

information, which, if properly applied, may go far in saving the patient's life, or in cutting short his disease.

A knowledge of the *causes* of a disease often throws valuable light upon their diagnosis. Thus, the knowledge that a youth affected with urethritis recently had connection with a lewd female, at once leads to a proper comprehension of the nature of the case; and in the same manner important aid may be obtained in deciding between a specific and a non-specific ulcer on the head of the penis. The diagnosis of a malignant pustule upon the hand is generally determined at a glance by a surgeon of experience; but one of an opposite character will hardly arrive at such a result without being told that the patient a few days previously was engaged in flaying a cow, or in handling green hides. During the existence of endemic and epidemic diseases, all persons brought within their influence are liable to their attacks, and the similarity of the symptoms is consequently sufficient to stamp their character. The knowledge that pyemia frequently follows upon severe injuries and capital operations is of the greatest value to the practitioner, as it enables him at once to interpret correctly the symptoms which attend that peculiar affection, the nature of which was so long a mystery.

In accidents, a knowledge of the manner of their occurrence is often a matter of great moment in a diagnostic point of view. Thus, if a man, in the act of falling from a considerable height, has alighted upon the vertex, and is immediately rendered insensible, and particularly if he remains in that condition for a long time, the inference is strong that the base of the skull is fractured, and that he will perish from the effects of the lesion, although there may be no apparent injury upon the portion of the head which received the blow. In railroad accidents the leg may be severely hurt, and yet not sufficiently so to account for the extraordinary depression of the system; inquiry discloses the fact that the body was violently compressed between the car and a post, and a more thorough exploration leads to the discovery of rupture of the spleen, liver, bowel, or bladder; a circumstance which at once establishes the diagnosis, and prevents the patient from being subjected to useless amputation.

When the patient is unconscious, whether from disease or accident, valuable information respecting the nature of the affection may often be obtained from his nurses and friends; or, in the latter case, from the by-standers, who thus become important witnesses of what transpired at the moment in regard to the manner in which the injury was inflicted, the previous state of the intellect, and the condition of the person immediately consequent upon the receipt of the lesion.

In the more obscure cases of diseases and accidents, the diagnosis can be arrived at only after the most patient, thorough, and systematic examination; a random exploration will be worse than useless. Every organ must be questioned, and even then it is often extremely difficult to determine what the lesion really is. In my own examinations I usually begin with the alimentary canal, from which I pass on, successively, to the abdominal and pelvic viscera, the lungs and their envelops, the heart, brain, and spinal cord, and, finally, the external surface, carefully noting everything of importance as I proceed. In this manner, it is difficult for any serious disease to escape detection, if the practitioner is at all endowed with the faculty of correct observation.

EXAMINATION OF THE DIFFERENT ORGANS.

In general, very useful diagnostic information is afforded by the state of the *tongue* in surgical affections. In traumatic fever, abscesses, rheumatism, and gout, the organ is usually unnaturally dry, and covered with a thick, white

fur, at the same time that its tip and edges are abnormally red. A narrow, pointed, or acuminate appearance of the tongue is also frequently observed under these circumstances, especially in young subjects. In profuse hemorrhages, the tongue is generally very pallid, soft, flabby, and indented at the edges. A dry, brownish, and tremulous state of this organ, with difficulty of protrusion, is generally denotive of the existence of a typhoid condition of the system, and, in connection with other symptoms of exhaustion, is to be regarded as an unfavorable occurrence. It is the kind of tongue which commonly attends gangrene, malignant erysipelas, and the latter stages of traumatic fever.

The appearances of the tongue sometimes afford useful hints respecting the state of the digestive apparatus, and even of the general system. Thus, aphthæ upon this organ, or small ulcers scattered over its surface, are usually denotive of chronic gastric disorder, or derangement of the stomach and liver, by correcting which the disease promptly vanishes. In constitutional syphilis, the existence of mucous tubercles upon the tongue affords at once a satisfactory solution of the nature of the complaint. The presence of an excavated ulcer upon this organ, or upon the tonsils, with a copper-colored border and a foul bottom, is generally equally diagnostic of a contaminated state of the system.

A thick and tumid upper *lip* is generally denotive of a scrofulous taint of the system, or of a vitiated state of the alimentary canal depending upon the presence of worms, and disorder of the hepatic and follicular secretions. A cracked, chapped, or fissured state of the lower lip is often an accompaniment of general plethora, over-feeding, and gastro-enteric derangement. A pale prolábium is indicative of a deficiency of the coloring matter of the blood, and is generally an evidence of the necessity of tonics.

Useful information is sometimes derived from an examination of the *gums*. A red, spongy, and tumid state of them is usually denotive of a scorbutic diathesis, especially if it be conjoined with frequent bleeding and hemorrhagic spots in different parts of the body. An eroded appearance of the gums is generally indicative of an accumulation of tartar, while the presence of sordes is expressive of a typhoid state of the system.

Pain in the throat and difficulty of deglutition are evidences of tonsillitis, and of disease or mechanical obstruction of the œsophagus. A careful inspection of the fauces and the introduction of the probang usually readily determine the precise locality of the affection, as well as its nature. In the former case, the tongue is carefully depressed with the handle of a spoon, or a tongue-holder, the mouth being widely opened as the patient sits upon a chair in a strong light; in the latter, the surgeon, standing behind the patient whose head rests upon his chest, carries the instrument gently and cautiously along the tube until it comes in contact with the obstruction, which is not passed all at once, or forcibly, lest undue violence should be inflicted, perhaps eventuating in rupture or ulceration of the œsophagus.

No examination in any case of disease, if at all serious, whether surgical or medical, can be considered as at all complete without a thorough exploration of the condition of the *stomach* and *bowels*. When it is recollected that disorder of the secretions of these organs, the presence of irritating ingesta, or the accumulation of fecal matter, is frequently a source of disease in other parts of the body, as well as in these organs themselves, the importance of an attentive examination of them cannot be too much insisted upon. The insertion of the finger into the rectum, and the use of the speculum, often lead to the most useful knowledge of the condition of the anus and lower bowel. An examination of the alvine evacuations not unfrequently reveals important information in regard to the state of the liver, as the presence, absence, or

quality of the bile, and the action of the mucous follicles of the alimentary tube, and should never be omitted in any case of serious disease or accident.

Intellect.—The intelligence is often remarkably altered in disease and accident. Delirium and incoherency are common effects of all lesions attended with high arterial excitement. Their character, degree, and duration vary much in different cases, and are greatly influenced by surrounding and intrinsic circumstances, as the nature of our treatment, the intensity of the morbid action, the importance of the affected organ, and probably also by the idiosyncrasy of the individual. In general, as they are of a purely sympathetic character, they rapidly disappear with the excitement that induced them; coming and going perhaps several times in the twenty-four hours, especially during the vesperal and nocturnal exacerbations which are so liable to distinguish most febrile attacks, whether traumatic or idiopathic.

In organic disease of the brain and its envelops, on the contrary, a different order of things usually occurs. Here the delirium, once fairly begun, continues uninterruptedly, although it may be characterized by intervals of remission; and, as the morbid action progresses, it generally lapses into stupor, and this, ere long, into deep coma, which is but too often the immediate forerunner of dissolution. In compression of the brain, whether from extravasated blood, excessive congestion of the cerebral vessels, effusion of serum, or depression of the cranial bones, the intelligence is commonly completely abolished; the patient is deprived of all sensation and volition, and cannot be roused by the most powerful stimulants. He is, in fact, a mere automaton, dead to all surrounding impressions. If, from any cause, inflammation of the brain or of its membranes arise, the face soon becomes flushed, the eye suffused, the pupil contracted and impatient of light, the skin hot and dry, and the pulse quick, hard, and frequent. Delirium soon sets in; the mind becomes incoherent, and, although questions may still with some effort be answered rationally, yet the patient speedily lapses into his former condition, knitting his brows, tossing from side to side, withdrawing his hand from the attendant, muttering constantly, and falling gradually into a more unconscious state. Rigors generally occur early in the disease, and are always denotive of great danger. If effusion of serum, lymph, or pus take place to any considerable extent, convulsions and deep coma are sure to follow, soon terminating in death.

Countenance.—The state of the countenance is always a subject of inquiry with the intelligent practitioner. The mirror of the soul, it reflects, to a greater or less extent, alike the sensations of pleasure and of pain, of joy and of sorrow, and is thus capable of supplying important diagnostic indications in a great variety of diseases and accidents. To call attention to all the details which necessarily connect themselves with the study of the physiognomy under these circumstances, would be out of place in such a work as this, and I shall therefore content myself by referring to a few of the more frequent and conspicuous.

Excessive pallor of the countenance, especially of the prolabia, is generally denotive of great loss of blood, or of extreme shock of the nervous system. In the latter case it is often associated with a peculiar withered and shrunken expression of the features, reminding one sensibly of the decay of a leaf in autumn. In apoplectic affections of the brain, the face is turgid, flushed, and paralyzed on one side, thus causing serious distortion, the angle of the mouth being drawn to the opposite side, while the eyelid on the affected side has a drooping appearance, descending hardly half way over the ball. In general inflammatory fever, whether the result of accident or of internal causes, the countenance is red and tumid, the eye is suffused, and the ala of the nose is rapidly dilated and contracted by the hurried inspiration. When the breathing is much embarrassed, as when there is deep congestion of the lungs, or

mechanical obstruction to the entrance of the air, as when a foreign body exists in the larynx or trachea, the face is livid and often remarkably puffy, particularly when the affection is of long standing, and accompanied by œdema of the subcutaneous cellular tissue. All painful affections of these organs are characterized by an anxious expression of the features, attended by an unusual dilatation of the nostrils during each act of inspiration, and by a peculiar heaving movement of the chest. "In inflammation of the abdominal viscera," observes Dr. Marshall Hall, "attended with severe pain, the muscles of the face are in a state of continued contraction; the features are unnaturally acute, the forehead is wrinkled, and the brows knit. The nostrils are acute and drawn up; the wrinkles, which pass from them obliquely downwards, are deeply marked; the upper lip is drawn upwards, and the under one frequently downwards, so as to expose the teeth. The state of the features is aggravated on any increase of the pain from change of position or external pressure. When the abdominal pain arises from spasm, the muscles of the face are exceedingly contracted and distorted during the paroxysms of pain; but in the intervals of the paroxysms the countenance assumes a calm and placid aspect."

The diagnostic value of the Hippocratic countenance has long been recognized by practitioners. Its presence is always denotive of extreme danger, and is commonly associated with other symptoms of an untoward import, as twitching of the tendons, high delirium, a dry tongue, sordes on the teeth and gums, and excessive prostration. It consists in a peculiarly sharp, retracted, and withered appearance of the features, and generally attends the closing scenes of all typhoid states of the system, whatever may be their cause or character.

Voice.—The state of the voice often furnishes useful information respecting the nature of the lesions of the larynx and trachea. Its peculiarity in croup is well known, being either sharp and shrill, like the crowing of a young cock, or low, hoarse, and almost extinct, especially if the disease has made considerable progress. In œdema of the glottis, without being always hoarse, it is generally reduced to a mere whisper; and in thickening of the vocal cords and ulceration of the mucous membrane of the larynx, partial loss of voice, and ultimately complete aphonia, generally attend.

Respiration.—The respiration should always be attentively examined. In all acute diseases, attended with unusual vascular excitement, it is increased in frequency, short, and laborious. In pneumonia and pleurisy it is generally diaphragmatic, the intercostal muscles being almost completely quiescent, with hardly any perceptible elevation and depression of the ribs. The patient, alarmed and anxious, breathes with great difficulty, dilating his nostrils at every inspiration, and raising the shoulders and upper part of the chest, so as to draw in as much air as possible at each effort. In inflammation of the abdominal viscera, on the contrary, the diaphragm is nearly stationary, while the intercostal muscles are in full play, the act of inspiration being short and panting, lest the descent of the diaphragm should produce an aggravation of suffering by rudely compressing the affected organs. In affections attended with cerebral congestion, effusion of blood, or depression of the skull, the breathing is slow, labored, and irregular; often stertorous, and accompanied by a peculiar whiff. In spasmodic diseases of the respiratory organs, the inspiration is quick and imperfect, as if the patient was unable to dilate the chest, and is usually accompanied with a characteristic wheezing sound, often audible at a considerable distance, during expiration, which is, at the same time, labored, and protracted. Short, difficult, and anxious breathing, aggravated by muscular exertion, as in ascending a hill, or rapid talking, is generally denotive of hydrothorax, and of organic disease of the heart and great arteries.

Heart.—The diagnostic signs manifested by the heart and arteries deserve careful consideration. In examining the pulse, the exponent of the great central organ of the circulation, particular attention should be paid to its frequency, volume, and force, as these constitute the leading features by which the practitioner judges of the state of the system, or, in other words, of the character and effects of the morbid action. To do this properly requires not a little knowledge and experience, for nothing varies more than the condition of the pulse in health and disease. Hence it is not surprising that it should have been pronounced by one of the older physicians to be the most fallacious of symptoms.

Pulse.—In traumatic fever the pulse, as a general rule, is quick, frequent, and hard, and similar qualities usually characterize it in idiopathic affections. The increase in the number of its beats ranges from ten to thirty and even forty in the minute; they are performed with a peculiar sharpness and rapidity, and the blood is sent into the arteries with such momentum as to cause their coats to rebound under the finger, offering thus a decided resistance to its pressure. When this is the case, the pulse is said to be hard. Hardness, quickness, and frequency are often associated with fulness, especially in very plethoric subjects, laboring under intense inflammatory excitement; but such a coincidence is by no means always necessarily present; on the contrary, instances occur where the pulse is so exceedingly small and thready as to require some care to detect it. This is generally the character of the pulse in peritonitis, from whatever cause arising, and therefore affords valuable diagnostic information. In certain affections of the brain, as in compression, whether a result of apoplexy or external injury, the pulse is slow, full, and laboring, as if the heart were oppressed by a heavy load which it found difficult to carry or to shake off. The pulse after hemorrhage is strikingly peculiar, although it is not easy to define its character; it may be described as being very sharp, quick, and thrilling, as if the blood were sent into the artery with a kind of jerk, imparting thus a vibratory sensation to the finger. Once felt, it is impossible ever to forget it. An intermittent pulse is generally denotive of organic disease of the brain, or of the heart, lungs, or great vessels; sometimes, however, it appears to be the result altogether of functional disease, as dyspepsia, or gastro-intestinal irritation.

In examining the pulse with a view to its diagnostic value, it is to be remembered that it may be naturally slow or frequent, hard or soft, full or small, strong or feeble, depending upon idiosyncrasy, or the effects of previous or existing disease.

The time and mode of examining the pulse require some attention. As a general rule, the surgeon should not put his hand upon the wrist immediately after he has sat down by the side of the bed, as such a course would be likely to cause alarm, and thus lead to erroneous inferences. Nor should he use a watch for the purpose of counting it, especially if the patient be very sick and nervous, as this also might excite injurious apprehension. In fact, it is impossible to conduct the examination too carefully; for unless this be done, the intention of the practitioner will often be completely thwarted, simply in consequence of his awkwardness. At least two fingers should be placed upon the radial artery, and the application should be continued sufficiently long to enable him to determine fully the character of its beats, particularly their frequency, volume, and power of resistance.

Kidneys.—The renal secretion should claim particular attention in every severe case of accident and disease. A very superficial inspection will generally at once detect remarkable deviations from the normal standard, both as it respects the color, quantity, and consistence of this fluid, as well as any tendency it may manifest to the formation of deposits after having stood for some time in the receiver. But if a more thorough investigation be deemed

necessary, as when organic disease of the kidney is suspected, or with a view to the detection of the existence of any particular calculous diathesis, a more minute and elaborate examination, conducted with the microscope and chemical tests, will be required; and it need hardly be added that such a procedure generally calls for an amount of knowledge, skill, and experience such as few professional men possess. As this subject will receive special consideration in the chapter on the urine and its deposits, no further allusion to it need be made here.

Finally, the practitioner must not neglect to examine the state of the *skin*, noting particularly the character of its temperature, the presence or absence of moisture, the degree of its contractility, and any change of color it may have experienced; the condition of the limbs, as to the existence or non-existence of paralysis or injury; and lastly, the state of the genital organs, if, upon inquiry, there is reason to suppose that they are either the seat of the morbid action, or that they deeply sympathize in the disorder of other parts of the body.

SECT. II.—MENSURATION.

An examination of the dimensions of a part occasionally affords valuable aid in determining the diagnosis of its lesions. Such a mode of investigation is particularly serviceable in fractures and dislocations, in coxalgia, and in affections of the chest, especially in pleuritic effusions, so common after accidents and diseases.

The best contrivance for ascertaining the amount of shortening in an injured or diseased limb is the graduated tape, used by seamstresses and tailors, and inclosed in a metallic case, so as to admit of its being carried in the pocket. It is a yard in length by half an inch in width, and being composed of oil-cloth it is perfectly inextensible, thus rendering it admirably adapted to the object. In order to attain perfect accuracy of result, it is necessary that the sound and affected members should be placed as nearly as possible parallel with each other; for if there be the slightest variation in their inclination it must proportionably impair the value of the examination, if not completely destroy it. Thus, for example, in trying to ascertain the amount of overlapping of the fragments of a broken femur, the two thighs should not only be placed parallel with each other, but great care should be taken that they, as well as the buttocks, rest evenly upon the bed, table, or floor on which the patient lies. Finally, in order to perform the operation in the most unexceptionable manner, the additional precaution should be taken of maintaining the head, chest, pelvis, and extremities all in a straight line until the measurement is completed.

After the limbs and body have been adjusted as here described, two fixed points are selected, between which the tape is stretched. Thus, to take the thigh again as an illustration, the two proper points are the anterior superior spinous process of the ilium and the inner border of the patella. The distance between these two prominences having been ascertained upon the affected member, the tape is next stretched between the same points on the sound limb, the difference in the length between the two being the sum of the shortening of the injured bone. Where no fixed points can be obtained, a mark may be made upon the skin either with ink, or nitrate of silver.

The graduated tape may also be employed for measuring the diameter of a limb, as in disease of an important joint, or a suspected morbid growth. Or, instead of this, recourse may be had to the graduated compass of Mayor, which, however, notwithstanding its ingenious mechanism, really possesses no real advantages over the tape. This instrument consists of four

pieces, the central one, which is a flat rod, being marked by a scale of inches and lines.

Mensuration of the chest is often practised in pleuritic effusions, although such a means of diagnosis is seldom necessary in the hands of an intelligent and skilful surgeon, auscultation, percussion, and inspection being quite sufficient for the purpose in almost every instance coming under his observation. When more than ordinary care is desired, the graduated tape, extending from the middle of the sternum to the centre of the spine, will readily supply the requisite information.

The plumb-line is occasionally used for determining the existence of curvature of the spine; such an expedient, however, can only be necessary in the earlier stages of the malady, before marked deformity has set in. When the disease is fully established, such a mode of investigation would savor alike of affectation and stupidity.

A ready method of determining the angle of an object, as, for example, that of a broken bone, has been suggested by Malgaigne. It consists in applying a sheet of paper, by its edge, to the limb so as to represent its vertical axis. At the point where the axis changes its direction, the paper is so folded as to follow it exactly; the result will be that the salient angle thus formed will necessarily give the entering one caused by the fragments of the deformed bone. In order to determine the degree of this angle, a sheet of paper is folded in four, which "makes a right angle, or 90° ; folding again one of the sides affords an angle of 45° ; adding this angle of 45° to the unchanged right angle, gives an angle of 135° , and so on. Applying now this extemporaneous quadrant to the already ascertained angle of the fracture, we obtain, without trouble, or loss of time, as accurate an estimate as possible."

SECT. III.—ATTITUDE OF THE PATIENT.

The attitude of the patient and the position of the affected part are variously and often remarkably changed in diseases and accidents, and afford, in many cases, valuable diagnostic indications, not attainable in any other way. The study of the variations in the configuration of the body is of much greater moment, as a means of distinguishing different lesions, than is generally imagined, and has received less attention than its importance merits. In some affections, the diagnosis absolutely hinges mainly, if not entirely, upon the attitude assumed by the patient in consequence of the morbid action. We need only instance the peculiar distortion of the body in tetanus, caused by the continued and violent contraction of the muscles, drawing the trunk, in one case, powerfully forwards, in another backwards, and in a third to one side. No one that has ever witnessed this change of configuration can possibly mistake it in a similar attack; for there is no other lesion capable of producing it. In caries of the vertebræ, usually known as Pott's disease, and in lateral curvature of the spine, the result of irregular muscular action, the distortion of the body is characteristic. In coxalgia, the flattening of the hip, the elevation of the pelvis of the affected side, the retraction of the heel, and the effacement of the femoro-gluteal fold are among the most valuable diagnostic signs of the malady.

In diseases and injuries of the chest, the position of the patient is often highly characteristic. In inflammation of the lungs and pleura, attended with slight effusion, he generally lies either on the affected side, or else upon his back, not on the sound side, as the weight and pressure of the diseased organ would seriously impede respiration and excite violent coughing. In hydrothorax, with large accumulations on both sides, the patient is obliged

to raise his head and shoulders very much, or even to sit up in bed, in order to obtain the requisite supply of air. When he lies down, the effused fluid is diffused over a larger portion of lung, an occurrence which is instantly followed by increased difficulty of breathing, and by the necessity of a change of posture to prevent impending suffocation. "When out of bed, he is often observed to sit with the arms placed along the side, and the hands fixed and pressing forcibly on the chair or sofa on which he rests; in other cases he leans a little backwards, still supported by the arms and hands, which are pressed behind his back."

The attitude assumed by the patient in inflammation of the abdominal and pelvic viscera is generally very striking and characteristic. Unable to shift his position, he lies constantly upon his back, with his head and shoulders considerably elevated, the knees raised, and the thighs partially flexed, the object being to relax the abdominal muscles in the greatest possible degree, so as to take off their weight and pressure from the inflamed surface. In spasmodic affections, on the contrary, the position of the patient is altogether different; instead of observing dorsal decubitus, he lies at one time on this side, and then on the other, now on the back, and next on the belly; and instead of avoiding pressure he actually courts it, not feeling comfortable without it. Hence, he often doubles himself up, and twists and contorts his body in almost every possible manner, in order to obtain relief.

In stone of the bladder impeding the flow of urine, the attitude of the patient is frequently very singular. Sometimes he is compelled to assume a stooping posture; at other times he crosses or separates his legs, inclines his body to one side, lies down, rests on his elbows and knees, or lies on his back, and throws up his buttocks. In traumatic and other affections, attended with typhomania, retention of urine may be suspected, if the patient lies on his back with the limbs retracted. In acute inflammation of the kidney, the body is generally inclined a little forwards and towards the affected side, so as to relax the lumbar muscles, and take off any pressure they might otherwise exert upon the diseased organ.

The nature of an accident is not unfrequently revealed by the attitude of the part and body; sometimes by the one, sometimes by the other, and occasionally by both. Thus, the manner in which the patient inclines his head and supports his arm in fracture of the clavicle is so peculiar as to be absolutely, in great degree, pathognomonic of the nature of the lesion. Dislocations of the shoulder, hip, and other joints, are denoted by striking, if not characteristic, changes in the attitude of the body and limb. The existence of a fracture is often revealed by a peculiar change in the conformation of the affected member, consisting either in a marked shortening, or in a peculiar alteration in the axis of the part. The disease called wry-neck derives its name from the peculiar twist of the neck by which it is distinguished.

SECT. IV.—EXTERNAL CHARACTERS.

Important diagnostic data are sometimes furnished by the color, form, consistence, mobility, pulsation, temperature, crepitation, sensibility, or odor of a part, and by the spots, scars, or ulcers existing upon its surface. A mere glance at these different topics will serve to show their value as means of distinguishing morbid action, whether it be considered simply in reference to its nature, or its nature and degree.

Thus, as stated under the head of inflammation, the *color* of the diseased part may be scarlet, as in inflammation of the mucous membrane of the fauces; lilac, as in sclerotitis; grayish, or brick-colored, as in iritis. When the redness occurs in the form of a streak, extending up the arm or leg, it is

denotive of phlebitis, or of angeioleucitis. Diffuse discoloration characterizes erysipelas; circumscribed discoloration, boils and carbuncles. A scarlet hue implies great vascular activity, such as exists in acute inflammation; a purple hue, on the contrary, denotes partial stasis of the blood, which, if not soon arrested, may lead to gangrene.

Change in the *form* of a part may be caused by swelling, as in inflammation attended with effusion, or it may depend upon the presence of a new growth, or it may be the result simply of hypertrophy. In fractures it is caused by displacement of the ends of the fragments; in dislocations by the presence of the head of the bone in its new situation. In hernia, very striking changes generally attend the figure of the affected parts, especially when the protrusion is old and unusually bulky.

Extraordinary *consistence* of a part is indicative either of excessive induration from inflammatory deposits, particularly semi-organized lymph, or of the presence of a solid tumor, or a displaced bone. When the part is unusually soft, the alteration of consistence may depend upon the presence of pus, fluid blood, serum, or serum and lymph, and often requires the closest scrutiny for the successful detection of its precise character. Under such circumstances the history of the case frequently affords important diagnostic data, especially the age of the accumulation, and the presence or absence of inflammatory symptoms. If the part fluctuates distinctly, and is, withal, red, tender, or painful, the probability is that the alteration of consistence is due to the existence of pus; if, on the other hand, it be perfectly free from discoloration and uneasiness, although the undulation under pressure may be most perfect, the conclusion must be that the disease is either a chronic abscess, or else some serous or hematoid cyst.

The *mobility* of a part may be diminished or increased, thus throwing important light upon the nature of the case. As a general rule, it may be stated that it is lessened in dislocations, and augmented in fractures. The value of this symptom is well shown in diseases of the articulations, as well as in inflammation of other parts of the body, which, if at all seriously involved, have their mobility always proportionably diminished. In malignant tumors, loss of mobility of the morbid growth generally forms a prominent phenomenon in the advanced stage of the disease, in consequence of the firm adhesions that take place between it and the surrounding structures. A similar effect may be produced by the manner in which such tumors are bound down by the aponeuroses and muscles. In affections of the eye an alteration of the mobility of the iris often affords most important diagnostic information.

Abnormal *pulsation* in a part leads to the suspicion of the existence of aneurism, and this suspicion will almost be converted into certainty, if, in addition to this phenomenon, there is a peculiar thrill, with a vibratory sensation, and a decided diminution of the volume of the part upon the application of pressure to the cardiac side of the artery supplying it with blood. The mere fact of the existence of abnormal pulsation should put the surgeon upon his guard, in order that, by redoubling his efforts at a thorough exploration, he may not commit any errors of diagnosis; laying open, perhaps, an aneurism, when he supposes that he is dealing only with an abscess or a hygroma.

The surgeon occasionally meets with what is denominated *crepitation*, a rough, grating, or friction sound, of great value as a diagnostic in fractures, emphysema, and inflammation of the sheaths of the tendons. In many cases it may be both felt and heard. In fractures it is produced by rubbing together the ends of the broken bone, and is generally so distinct as to be completely characteristic of the nature of the lesion. In order to elicit it, a good deal of management is often necessary; but in general it will be suffi-

cient, after the ends of the broken bone have been fairly placed in contact, to grasp one piece firmly, and to hold it so while the other is rotated on its axis; or both fragments may be moved simultaneously in opposite directions.

The crepitation of emphysema is a kind of crackling sound, similar to what is produced by the rumpling of dry parchment, or by rubbing together numerous little dry, friable balls filled with air. The part, moreover, feels soft and puffy, and the contained air may be easily pressed from one spot to another.

Bony tumors of the antrum of Highmore and of the lower jaw, attended with great expansion and attenuation of their walls, occasionally emit, when pressed between the fingers, a peculiar crackling noise, similar to that of dry parchment. The sound thus elicited, however, is altogether different from crepitation, properly so termed, and its chief value consists in showing the alteration which the osseous tissue is capable of undergoing when it is subjected to long-continued eccentric pressure.

The crepitation attendant upon inflammation of the sheaths of the tendons is altogether different from the two preceding varieties, resembling the sound caused by rubbing dry starch between the fingers. When the disease is chronic it may sometimes be both heard and felt. It evidently depends upon the presence of plastic matter, and is most common about the wrist and ankle. This sound is often closely imitated in affections of the mucous bursæ, especially when they are pretty well distended with fluid, intermixed with flakes of lymph and fibrinous concretions.

A faint crepitating sound is sometimes produced by breaking up the clots of a sanguineous cyst, and rubbing the fragments between the fingers. The noise, when it does occur, is always most distinct at the base of the tumor, where most of the solid matter is necessarily collected.

An alteration of *temperature* in parts affected with disease is sufficiently common, and occasionally affords valuable diagnostic intimations. With what interest does not the surgeon watch the rise of heat in a limb after the ligation of its principal artery! A casual examination is generally sufficient for its detection; when more than ordinary nicety is required, recourse may be had to the thermometer. The intensity of the morbid action may sometimes be pretty accurately measured by merely observing the increase of its temperature. A sudden diminution of temperature, in a part previously in a high state of inflammation, may generally be regarded as an omen of unfavorable import, as it is denotive of the approach of gangrene.

An increase of the *sensibility* of a part is a frequent, if not an almost constant, occurrence in disease, especially when it is of an acute character. In ophthalmia, the slightest ray of light is a source of distress to the patient; in otitis, the ear is intolerant of sound; and in gastritis the stomach is oppressed by the smallest quantity of fluid, however bland, or however cautiously used. Parts, such as bones and ligaments, that are perfectly devoid of feeling in health, often become exquisitely sensitive in inflammation; and thus it is that the practitioner is not unfrequently enabled to detect the existence of morbid action in structures hidden from view, much better than he can in any other manner. The proper way of ascertaining the existence and amount of morbid sensibility is to make gentle and methodical compression, or to percuss the affected part, so as to communicate to it the vibrations of the whole hand, or, what is preferable, of one of the fingers.

When pain exists, a careful distinction should be drawn between that which arises from inflammation and that produced by spasm and neuralgia. In inflammation, the pain is steady and persistent, increased by motion and pressure, commencing with the morbid action, keeping regular pace with it, and gradually disappearing as the morbid action declines. In spasmodic affections, or colic, on the contrary, the pain is paroxysmal, or marked by

distinct intermissions; abrupt, both in its invasion and departure; relieved by pressure, and change of posture, and generally attended with flatulence of the stomach and bowels. In neuralgia, the pain occurs in transient and violent paroxysms, darts along the course of the affected nerves with the rapidity of lightning, and is usually accompanied by more or less tenderness of the part, without any distinct tumefaction, discoloration, or augmentation of temperature.

Finally, there are certain affections which may sometimes be readily diagnosed by a careful examination of the *cutaneous* surface, and that of the mucous outlets. Thus, if there are copper-colored eruptions upon the skin, and excavated ulcers on the fauces, or tubercles upon the tongue, cheek, or lip, no one could fail to conclude that the system was laboring under a syphilitic taint. Partial or complete destruction of the uvula, tonsils, or arches of the palate, would inevitably lead to a similar inference, especially if, added to this, there is evidence of actual disease. Scars upon the cutaneous surface, scattered irregularly about, large, deep, white, and permanent, are generally denotive of the former existence of *rupia*.

The character of an ulcer will sometimes lead to the detection of its cause, or to the state of the system which has induced its development. Last autumn a girl, aged fourteen, was brought to my Clinic at the Jefferson Medical College, on account of a large chronic ulcer seated in front of the leg, directly over the tibia; it had been in progress for the better part of a year, was excessively painful, and had resisted a great variety of local and constitutional remedies. Having brought the patient under the influence of chloroform, I scraped away a thick mass of semi-organized substance which formed the bottom of the ulcer, together with the carious and softened portion of the bone; and when she returned to me a week afterwards I was struck with the remarkable improvement that had taken place both in the part and system. Shortly after her visit, however, not less than five or six small unhealthy-looking ulcers, with thick, everted edges, and a foul, nasty surface, broke out around the old one, which by this time had also changed for the worse. Convinced that the disease was of a syphilitic nature, I placed the patient, without any further inquiry into the case, upon the use of iodide of potassium and bichloride of mercury, under the influence of which, and a nourishing diet, she rapidly regained her health and strength, with good sound cicatrices.

Thus it will be perceived that the diagnosis in this case, founded upon the appearance and obstinacy of the patient's ulcers, was confirmed by the result of the treatment employed for their cure.

SECT. V.—INSTRUMENTAL EXPLORATIONS.

There are certain affections whose character can be ascertained only by a careful examination with the aid of instruments, full access to them in any other manner being impracticable. The instruments mainly required for this purpose are the probe, bougie, sound, speculum, stethoscope, and exploring needle, each of which will therefore demand some notice.

Probe.—The probe, fig. 94, is chiefly employed for the purpose of exploring fistulous tracks and sinuses, the course of balls, and the presence of foreign bodies. It may therefore be considered as a highly valuable instrument, one which is daily and hourly brought into requisition by the surgeon in extensive practice. It is generally made so as to be flexible, being composed of silver, or other suitable metal; and varies in length, diameter, and shape according to circumstances. The ordinary pocket probe is about five inches in length, and of the diameter of a crow-quill, one extremity being blunt, the other somewhat pointed, or furnished with an eye. For exploring the lachrymal

passages a much more delicate instrument is required; the uterine probe, on the contrary, is very large; a long and rather stout instrument is generally

Fig. 94.

employed for ascertaining the existence of a foreign body in the air-passages after having opened the trachea, for tracing the course of a ball, and for exploring certain varieties of fistules and sinuses.

The *index finger*, when sufficiently long, and not too thick, is the best probe of all, as the information furnished by it is generally much more reliable than that supplied by a metallic instrument. It is particularly available in the examination of the vagina, uterus, and rectum, whether the object be to detect the presence of disease, malposition, or the existence of an extra-neous body.

The *rectal touch*, performed with the index finger, is constantly practised by the surgeon in sounding patients for stone in the bladder, with a view not only of ascertaining the presence of the foreign substance, but also for the purpose of determining its size and situation. Enlargement of the prostate gland, and the existence of calculi in its substance, can seldom be satisfactorily diagnosticated in any other manner. Displacements of the uterus, pelvic tumors, and malformations of the internal genital organs, are often promptly detected by the rectal touch; and there is no practitioner that does not employ the finger in suspected disease of the anus and lower bowel. The rectal touch can readily discriminate between a hemorrhoidal tumor and a carcinomatous growth, a polyp, a prolapsus of the mucous membrane, or a foreign body. The extent of the spasmodic contraction of the anus, which attends fissure of that outlet, is generally readily ascertained by the insertion of the finger.

The *vaginal touch* affords important information in relation to the diseases of the vagina and uterus. It is in this manner that the practitioner ascertains the existence of the various kinds of tumors that are liable to form in these organs, whether benign or malignant, and also the different displacements to which they are subject. A practised finger will readily detect a carcinomatous ulcer of the uterus, a rent in the vagina, and a calculus in the bladder.

Whatever instrument is employed, it should be well oiled and warmed, to facilitate its introduction, and great care should be taken to pass it along in as gentle and easy a manner as possible. If the parts requiring to be explored are inflamed and tender, it may be necessary, before undertaking the examination, to lessen the sensibility by preliminary treatment, consisting of soothing measures, otherwise it may be productive of severe pain and an aggravation of the disease. No general rules can be laid down respecting the position of the part or of the body during the examination, although it must be sufficiently obvious that this is a matter of paramount importance to a satisfactory result. In exploring fistulous tracks it is occasionally necessary to enlarge their orifice somewhat, in order to afford a more ready passage to the instrument or finger.

Bougie.—For ascertaining the condition of the mucous outlets of the body, as the urethra, œsophagus, and rectum, a bougie, which is but another name for a probe, is generally employed, the principle upon which the examination is conducted being the same as in exploring a part with the probe properly so called; that is, the instrument, which is either straight or curved, and composed of gum elastic or metal, is well oiled and warmed, and then care-

fully introduced as far as the seat of the obstruction, the distance between which and the external orifice is now determined by looking at the graduated scale upon the surface of the bougie, or by making a scratch upon it with the nail. The examination is completed by insinuating the instrument gently into the stricture, so as to measure its extent, and the degree of its resistance. The information thus elicited is generally of the greatest diagnostic and practical value.

Sound.—The instrument employed for exploring the bladder is called a sound, although it is in reality nothing but a probe, blunt pointed at the distal extremity, and a good deal curved, so as to adapt it to the course and shape of the urethra. It is composed of steel, being perfectly smooth, and of a round shape. Its object and mode of use will claim special attention in connection with the diagnosis of vesical diseases, which could not be established satisfactorily in any other way.

Speculum.—Of the value of the speculum as a means of diagnosis in affections of the vagina, uterus, anus, nose, and ear, it is unnecessary to say anything of a formal character, as it is fully appreciated by every sensible practitioner. Indeed, it is only surprising when we consider the great aid which we derive from its use that its employment should still be so much restricted, as it seems to be, in certain parts of this and other countries. Invented at an early period of the science, it was completely lost sight of for many ages, until it was re-introduced, about thirty years ago, to the notice of the profession by Recamier, who thus conferred an inestimable benefit upon the public.

The speculum is composed of polished metal, or of glass, and consists either of a cylinder, or of two, three, or four movable blades, secured by screws, and furnished with an appropriate handle. A wire speculum (fig. 95)

is sometimes used. For most purposes to which such an instrument is applicable the cylinder answers exceedingly well, and it possesses the additional recommendation of simplicity of construction, convenience, and cheapness. The valvular speculum, on the contrary, is a complicated contrivance, expensive, and liable to get out of order. Nevertheless, there are certain forms of disease, especially of the uterus, which hardly admit of satisfactory exploration by any other means. Whatever form of instrument be selected, it should be well oiled and warmed, and then carefully inserted into the cavity which it is designed to explore, the patient having been previously placed in the most eligible position for undergoing the examination. Unless the case is one of unusual urgency, the examination should always be put off until there is a clear day, as the light of the sun is far better, as well as more convenient, than an artificial one. In exploring the uterus, the touch should precede the introduction of the speculum, with a view of ascertaining the existence or non-existence of any displacement of that organ.

I have never found it necessary to use an oral speculum, an instrument occasionally met with at the cutler's shop. Making the patient take a full inspiration, while he holds his mouth wide open, will generally permit a thorough inspection of the tongue, cheeks, and fauces; where greater nicety is required the tongue may be depressed with the handle of a spoon, a spatula, or a tongue-holder, and the tonsils and arches of the palate separated by means of a director or a long probe.

Exploring needle.—The value of the exploring needle cannot be too highly appreciated by the practical surgeon, as he is obliged to use it in the examination of a great variety of external affections, the diagnosis of which does not admit of accurate determination in any other manner. On the other hand, however, there is reason to believe that there is no instrument, certainly none of its size, that is more frequently misapplied by the uninformed prac-

itioner, or one which may do a greater amount of harm when used without proper judgment and discrimination. Like everything else that is good, it is liable to abuse; a circumstance which cannot be too strongly impressed upon the mind of the young surgeon. I am sure I have seen immense injury and even loss of life produced by its careless and reckless use.

Numerous exploring instruments are in the hands of the profession; some of which, displaying great delicacy and ingenuity, seem to combine all the advantages that such contrivances are capable of affording, while others are extremely clumsy, and, consequently, very imperfectly adapted for the purpose they are designed to fulfil. The great fault with most of them is that they are too large, thus inflicting an amount of injury upon the affected part, which, especially in malignant diseases, is often followed by the most disastrous effects, causing, perhaps, not merely severe pain and hemorrhage, but such a change in the vital relations of the morbid growth as to lead to its rapid development, if not to the speedy destruction of the patient. I recollect seeing, some years ago, a tumor upon the hip of a lad, aged sixteen, which, after having been subjected to various examinations by highly respectable surgeons, was at length pierced with a large exploring needle. The swelling, which had been supposed to be nothing but a chronic abscess, and which for some time had been almost stationary, now rapidly increased in volume, ulcerated, and fungated, and in less than a fortnight destroyed life. Dissection showed that the morbid growth was one of the encephaloid kind, the activity of which had been greatly augmented by the changes induced in its vital relations by the injury done by the instrument. A large volume might be filled, if one had time, with a rehearsal of the mischief that has been committed by the exploring needle in the hands of careless and unscrupulous practitioners.

Exploring needles consist either of a solid cylinder or of a species of trocar and canula, sharp-pointed, fine, and perfectly smooth, so as to facilitate their introduction and easy management. They are made of various lengths and diameters, according to the depth, volume, and nature of the part to be examined. The annexed cut, fig. 96, represents an exploring needle, with a

Fig. 96.

lateral groove. The best instrument of the kind, according to my experience—one which answers every purpose in superficial affections, and which may always be used with the most perfect safety—is the ordinary cataract needle, spear-shaped, and sufficiently stout to prevent it from breaking. This is inserted into the most prominent portion of the tumor or morbid accumulation, with a sort of rotatory motion, the object being to condense, as it were, the edges of the opening to promote the escape of the contents of the swelling, which readily occurs, if they are of a fluid consistence, a drop of the liquid often adhering to the instrument, or resting upon the orifice of the little puncture. When the contents are of a semi-solid nature, or the tumor is very deep-seated, the needle should be larger, or, what is preferable, it should be replaced by a very small trocar, long enough to reach and penetrate the affected structures. Whatever instrument be used, it must not, on any account, be permitted to come in contact with any important vessels or nerves. When the swelling is of unusual bulk, it may be explored at several points of its extent at the same sitting. The little puncture made in the operation should be immediately closed with adhesive plaster or collodion. When the object is to exclude the entrance of air, the instrument may be

carried some distance between the integument and the swelling, so as to make the opening somewhat valve-like.

A needle, perforated in its entire length, has lately been recommended, on the ground of its superior efficacy in exploring deeply-seated disease, its great value consisting in the facility of discriminating between different kinds of fluids, or in reaching deeply-seated fluids without the admixture of the superficial.

Dr. Addinell Hewson, of this city, has invented an exploring instrument for the purpose of obtaining a small portion of a tumor, or morbid deposit, with a view to a microscopical examination of its structure, the tube which he employs for this object being furnished with a peculiar contrivance attached to the rod which slides in its interior. Such a procedure, it strikes me, is more ingenious than useful, as its disturbing influence upon the morbid mass can hardly fail, at least occasionally, to impart new life and energy to the affected tissues.

Ophthalmoscope.—Another instrument has lately been added to our diagnostic armamentarium; this is the ophthalmoscope, of which due mention will be made in the proper place. Whether the high expectations anticipated from its use will be fully realized time alone can determine.

Laryngoscope.—This is an instrument of very recent introduction into medical and surgical practice. It is intended, as the name implies, to assist in exploring the larynx, and the only objection to its employment is the difficulty of its application, few practitioners being possessed of the requisite degree of tact to use it to advantage.

Otoscope.—To Mr. Toynbee, of London, belongs the merit of introducing an instrument called the otoscope, which promises to be of great aid in the examination of the ear, with a view of determining its precise condition in cases of supposed disease. It is of very simple construction, as well as of easy application, and is likely to come into extensive use.

Stethoscope.—The use of the stethoscope, as a means of surgical diagnosis, is comparatively limited, and it might be altogether dispensed with by those who have a well practised ear, and are not averse to the employment of immediate auscultation, or the direct application of the ear to the affected parts. Lisfranc thought that the stethoscope might be advantageously resorted to for the purpose of detecting crepitus in deep-seated fractures; or, what is the same thing, in fractures covered by a large amount of muscular and other tissues, as, for example, in those of the neck of the thigh-bone in very fleshy subjects. Few occasions, however, can arise in which such a mode of exploration can be of any real service, and I am not aware that any of our more experienced practitioners ever employ the instrument with this object.

Laennec, long ago, proposed auscultation as a means of detecting the presence of calculi in the bladder. He thought that it would be particularly serviceable in ascertaining the existence of very small concretions, which, when struck with the sound, emit only a very indistinct noise; and he suggested that, under these circumstances, the stethoscope should be applied to the pubic or sacral region while the instrument was being freely moved about in the organ. The recommendation, however, has not met with any particular favor, and there are, I suppose, few surgeons who would feel inclined to cut a patient for stone on such slender evidence of its presence.

The chief value of auscultation, then, is restricted to the examination of diseases of the heart, pericardium, lung, and pleura; and to the investigation of certain lesions of the abdomen, uterus, and ovaries, simulating pregnancy, with a view to the detection of the foetal circulation. Dry tapping, as it has been emphatically called, would probably be of much less frequent occurrence, if the stethoscope were oftener employed in supposed dropsy in young unmarried females.

SECT. VI.—EXAMINATION OF THE DISCHARGES.

The discharges, normal and abnormal, from different parts of the body, often furnish the surgeon important diagnostic information. Thus, an habitual flow of tears over the cheek is usually denotive of disease of the lachrymal passages, and necessarily suggests the propriety of a careful examination of them with a view to the detection of obstruction. For a similar reason the surgeon is prompted to inspect the ear in otorrhœa, and the nose when it is the seat of muco-purulent profluvium. The very nature of the discharge informs him of the existence of inflammation, but how that inflammation is produced, whether by the presence of a foreign body, a piece of dead bone, or a polyp, is a question which can only be decided by the most careful scrutiny; requiring, perhaps, the employment of the syringe to wash away the secretion, and repeated inspection before the precise nature of the case can be satisfactorily made out. One of the most important symptoms of inflammation of the maxillary sinus is a flow of pus into the throat; but no surgeon can be certain that it proceeds from that cavity unless he has previously ascertained that there is no disease of the mucous membrane of the nose.

The character of the *sputa* has long been an object of study with practitioners on account of the useful information which they afford in regard to the existence of particular diseases. Such information is hardly of less value to the surgeon than to the physician, as it apprises him of the presence of lesions which forbid surgical interference, or place him in possession of useful data respecting the occurrence of pulmonary complications, so common after accidents and capital operations. The reddish streaks in the expectoration excite suspicion of the existence of pneumonia; the rust-colored sputa confirm that suspicion, and at once invest the case with its proper importance. The fetid putrilaginous matter coughed up in gangrene of the lungs is characteristic of that disease from whatever cause proceeding. In phthisis, after the occurrence of caverns, the expectorated matter is ejected in distinct rounded masses, with irregular and indented edges; it sinks in water, and is of a yellowish color, with various shades of ash and even green, and streaked with opaque specks. A discharge of blood by vomiting is denotive of hemoptysis when the fluid is of a scarlet color, and of hematemesia, when it is perfectly black. In affections of the throat, attended with thick mucous or muco-purulent secretion, the sputa are sometimes streaked with blood. The saliva in mercurial stomatitis has a characteristic odor, and the same is true of the discharge which accompanies gangrænopsis.

A thick yellowish discharge, more or less abundant, from the *vagina*, is indicative of inflammation of that canal, of the uterus, or of both, and the addition of blood may usually be regarded as an evidence of concomitant ulceration. In the virtuous woman such a profluvium is generally to be considered as the result of accidental causes; in the courtesan, on the contrary, it at once awakens a suspicion of the existence of gonorrhœa or chancre. In cancer of the womb, the disease is attended, in its earlier stages, by hemorrhage, and afterwards, when ulceration has set in, by a foul, purulent, or sero-sanguinolent discharge, more or less copious, and so excessively fetid as to indicate unmistakably the character of the lesion.

In the male, a discharge of matter from the *urethra* generally furnishes useful information respecting the character of the disease under which the individual is laboring. When the discharge is thick, yellowish, and abundant, it is denotive of gonorrhœa, or chancre, though in the latter case it is seldom very profuse; when thin, and lactescent, or like the white of an egg, it indicates the existence of gleet, or prostaticorrhœa. A large and sudden

discharge, especially when no profluvium precedes or follows it, is to be taken as an evidence of spermatorrhœa.

The presence of *spermatozoa* in hydrocele sometimes throws important light upon the source of the water. It has been ascertained that whenever the fluid contains animalcules of this kind, the disease is generally of an encysted nature; for, although they also occur in ordinary hydrocele, yet the circumstance is so uncommon that it must be regarded as altogether of an exceptional character.

Of the signs afforded by the *renal* and *urinary secretions*, as evidences of disease, either of a local or general character, proper mention will be made in the chapter on the affections of the urinary organs. Here I shall only add that a careful examination of these secretions is often a matter of paramount moment to the surgeon, especially when he is obliged to decide respecting the propriety of a severe operation, the result of which might be seriously compromised by the existence of organic lesion either of the kidneys, or of some other important viscera. Hardly any man, however reckless, would enter upon such an enterprise if the urine were loaded with albumen.

The existence of disease of the *anus* and rectum, and even the true nature of such disease, may often be satisfactorily inferred by the discharges furnished by these parts. A flow of pure blood, especially during defecation, is generally denotive of internal hemorrhoids; so also if there be frequent evacuations of thick, bloody mucus, either while the person is at the water-closet, or in the intervals of his visits. A narrow, compressed, or flattened state of the feces is indicative of mechanical obstruction, occasioned either by stricture of the rectum, enlargement of the prostate gland, or contraction of the anus. In ulcerated cancer of the lower bowel, the discharges are generally very profuse, of a muco-purulent nature, mixed with blood and mucus, and excessively fetid; in fact, characteristic of the nature of that horrible malady.

The matter of certain *abscesses* serves to point out their nature and situation, or their accidental communication with neighboring parts. Thus, in the mammary gland, the fluid may contain milk; in the liver, bile; in the kidney, as when an opening takes place externally, urine. Abscesses of the wall of the abdomen have been known to contain biliary calculi; of the joints, fragments of cartilage and bone. In acute abscesses, the contents are thick and yellowish; in chronic, or strumous, thin and slightly greenish, with an intermixture of small, opaque, whitish flakes, resembling grains of boiled rice.

The discharges accompanying *ulcers* generally afford valuable hints respecting the kind of action that is going on in them. Healthy granulating ulcers or wounds always yield a thick yellowish pus, possessing all the properties of laudable pus, as described under the head of Suppuration; when, on the contrary, their action is unhealthy, the discharge is thin and bloody, ichorous, or sanguinolent, and more or less irritating. In cancerous ulcers, the discharge is generally profuse, foul, devoid of pus globules, and excessively fetid. In ulcers of the bones, it is ichorous and irritating; never healthy, so long as there is any diseased osseous tissue.

The *odor* emitted by a part in a state of disease sometimes supplies important data for the diagnosis of a case. Most readers are familiar with the remarkable anecdote related of J. L. Petit. Travelling through Germany, this celebrated surgeon, while stopping at an inn to change horses, was struck with the odor of gangrene, which he distinguished from several others, hardly less offensive. Not understanding the language of the country, he made his wishes known to a female who showed him into an adjoining room, where he found a man apparently moribund from a mortified intestinal hernia. Happy in being able to render him some assistance, he carefully dressed the parts, and meeting, before he set out upon his journey, with a French physician, he instructed him in the future management of the case. Upon his

return, five months afterwards, he had the gratification to learn that the man had completely recovered his health without a stercoraceous fistule.

The odor attendant upon ozæna is characteristic; no one that has ever perceived it can mistake it. The contents of an abscess at the verge of the anus always emit a fecal smell; a peculiar fetor accompanies the formation of a urinary fistule, and no one can be deceived by the odor of the breath in salivation. In hospital gangrene the stench is so remarkable that, once noticed, it can never be forgotten, although it is so unlike everything else of the kind as to render it impossible to define or describe it. The odor which accompanies gangrene of the mouth of children is unmistakable. The diagnosis of ulcerated cancer of the uterus can often be established by the sense of smell alone. Large wounds in a state of profuse suppuration not unfrequently exhale a peculiar nauseous or sickening odor, in some degree characteristic of the action attending them. The pus of scrofulous lymphatic ganglion, for a long time pent-up, is sometimes horribly fetid. A smell, similar to that of a macerating tub, often attends abscesses depending upon caries of the spine. In all these cases, as well as in many others that might be adduced in illustration of the subject, it is probable that the peculiarity of the odor is due partly to the admixture of the natural secretions of the structures affected.

SECT. VII.—MICROSCOPICAL EXAMINATION.

The study of surgical affections has been much advanced of late years by the use of the microscope, the improvements in which during the last quarter of a century have been so important as to have actually established a new branch of science. Discoveries and investigations made by means of this instrument must be alluded to in connection with nearly every form of disease, and its aid will often be found essential to the complete study of particular cases occurring in practice. A concise description of the different varieties of microscopes, and their employment, will therefore not be out of place here.

The fundamental principle of all appliances for assisting vision is to be found in the refractive power of certain media upon rays of light. Glasses, generally of a lenticular shape, single or combined, are the media chiefly employed; either natural or artificial light being available for our purpose. The light is very commonly concentrated and intensified by means of lenses or mirrors.

The student should bear in mind that it is not the object which is magnified, but merely the image impressed upon the retina. The rationale of this enlargement may be briefly set forth as follows:—Let a single lens, convex on both sides, be used to examine an object so small as to be just perceptible at the ordinary distance of distinct vision, say nine or ten inches from the eye. The eye, the lens, and the object being in their proper relations to each other, the rays of light coming from the object will so converge in passing through the lens as to form a distinct image upon the retina; in other words, the object will be seen by the eye as if it were an object of much greater size, placed at the point of ordinary distinct vision. When this occurs, the object is said to be *in focus*. The space thus presented to the eye is called the *field*.

In a single lens the rays of light towards the circumference of the field are always prismatically colored to a greater or less degree, this being very marked in what is known as the Stanhope lens; and portions of the image will also be indistinct, from the fact that by such a lens all the rays are not brought to foci equally distant from the eye. These two phenomena are called, re-

spectively, *chromatic* and *spherical aberration*; they are to a great degree obviated in the Coddington lens, which is composed of a sphere of glass, having at its equatorial line a deep groove, filled with opaque matter, by which means the central aperture is limited.

Now, as was before stated, all our means for obtaining magnified views of objects are based essentially on the same optical principle, namely, the refraction of light. The microscopes ordinarily used are of the kind called *double*, which means that the image of an object, magnified by a lens or set of lenses, is again magnified before it reaches the eye. Here let it be distinctly understood that a *single* microscope may consist of any convenient number of lenses, provided they form but one set. The lens or set of lenses forming the first magnified image constitute the *object-glass*, and are so arranged as to obviate the chromatic aberration before alluded to. The *eye-piece* consists of a lens or *eye-glass*, by which the image transmitted by the object-glass is again magnified, and of another lens at some distance below the eye-glass, in order so to change the direction of the rays as to allow more of the object to be seen at once—in other words, to enlarge the field—whence it receives the name of *field-glass*; between these two glasses is placed a *stop* or *diaphragm*, with a central aperture, for the purpose of arresting the circumferential rays, and thus correcting both the spherical and the chromatic aberration. The eye-glass, diaphragm, and field-glass, fastened in their proper relative positions in a tube, thus constitute the *eye-piece*, which

fits accurately into another tube; at the lower end of which tube is secured the one holding the object-glass, and these three portions, the eye-piece, the object-glass, and the tube into which they both fit, constitute the *compound body*. In the manufacture of microscopes, the proper relation of all the parts is ascertained upon optical principles, that is, the instrument is said to be *corrected*; sometimes, in order to compensate for certain conditions, it needs *over-correction*, and sometimes, again, it needs *under-correction*. The compound body, thus constituted, itself fits into a tube connected with the stage of the microscope; this latter tube and the stage being either fixed vertically, or capable of oblique inclination by means of a cradle-joint. The *stage* just mentioned is a plate upon which the specimen to be examined is laid, as will be presently stated. The stand of the microscope is that portion which supports the stage and compound body; it must be somewhat heavy, so as to give firmness to the instrument. The annexed cut, fig. 97, represents an excellent pattern for a microscope; it is known as the "Smith and

Fig. 97.

Smith and Beck's large compound microscope.

Beck," and combines great strength and steadiness with facility of manipulation.

Objects are studied by transmitted or reflected light; in the former case a mirror is placed below the stage, which is of course perforated, and the mirror is movable around one or both of its horizontal diameters, so as to catch light from any required quarter, and throw it up through the aperture in the stage, and through the object, as in fig. 98. If reflected light is to be used, the opening in the stage is closed up, and a double convex lens, or "bull's eye," is employed to concentrate the light upon the object.

It is necessary in examining objects by transmitted light, to be able to limit the amount of light coming from the mirror; every microscope should therefore be provided with a diaphragm-plate below the stage. This is a metallic plate, perforated with holes of different sizes, so arranged as to pass in succession under the opening in the stage, when the plate is rotated.

The alteration or adjustment of the focus is variously performed in different microscopes. In some the compound body is acted on by two milled heads, one large, with a rack and pinion movement, named the *coarse* adjuster; the other smaller, with a screw movement, called the *fine* adjuster. In others the compound body is worked up or down merely with the hands, and the stage is made movable by means of a screw with a milled head.

Various methods are also adopted for moving the object so as to bring different portions of it into the field. Sometimes the fingers alone are used; sometimes a lever and universal joint, or a set of screws, acting upon the stage so as to carry it in any desired direction. Although very convenient, these appliances, as well as those for the adjustment of the focus, are not absolutely necessary, the fingers acquiring a great degree of dexterity by practice.

Nothing has as yet been said of the preparation of the specimen. The methods of doing this may be divided into two, according as the object is mounted *dry* or *wet*; the latter being the one almost exclusively adopted in our ordinary examinations, which are, moreover, almost always conducted by means of transmitted light. Generally a very small portion of the substance is placed on a glass slide, moistened with a drop of water, and covered with a strip of extremely thin glass. Some microscopists prefer to use, instead of water, a solution of gum, sugar, or phosphate of soda, of a specific gravity of about 1030; this is intended to prevent endosmotic changes in the tissue. When a liquid, such as blood, chyle, milk, or urine, or a mass composed of separate cells, is examined, it suffices to put on the fine glass cover, perhaps with a slight degree of pressure, to obtain a suitably thin layer for study. Fibrous textures require tearing apart with needles, and so also do the cells of certain growths, such as the epitheliomata. Bony and cartilaginous tumors, and also some glandular ones, are displayed to better advantage in thin sections.

Great importance should be attached, in all these researches, to the perfect

Fig. 98.

Arrangement of microscope for transparent objects.

cleanliness of the glass slides and covers, to the purity of the water or other liquid used, and to the freedom of the object from any foreign matters. Curious mistakes have sometimes been made from want of care in these respects; and, with a view of still further guarding against error, it is well for the observer to become acquainted with the shape and appearance of such impurities as are liable to be met with. Hairs, animal and vegetable, animalcules, air-bubbles, and portions of articles taken as food, are perhaps the most common of these.

Less fatigue is caused to the eye by the use of a microscope which can be inclined somewhat, than by one which is fixed in the vertical position; and it is important, for the same reason, that the habit should be acquired of so concentrating the attention upon the field of the instrument that the unemployed eye need not be closed; in this way much straining of both organs is avoided. Any one who uses the instrument frequently, will find it to his advantage also to employ the same powers as much as possible; thus enabling himself to estimate more accurately the comparative sizes of the elements brought under his notice, without the trouble of a calculation except where great exactitude seems called for. The best powers for habitual use may be chosen between 300 and 450 diameters; higher ones than these are very seldom necessary.

Certain chemical reagents are often applied to objects under the microscope, their effects in many cases affording valuable information as to structure and composition. *Iodine*, dissolved in water by means of iodide of potassium, turns starch blue. *Nitric acid* gives a marked yellow color to animal textures generally; either this or *hydrochloric acid* diluted, or a combination of the two, will remove the calcareous portion of bone or tooth. *Alcohol* renders nerve-fibres and other animal tissues more opaque, and therefore more evident. *Ether* removes fatty matters, except when they are enveloped in an albuminous covering. *Potassa* and *soda*, in solution, have each of them a solvent effect on certain animal textures. But the reagent perhaps oftenest employed is *acetic acid*, which brings out, in a remarkable manner, the nuclei so commonly possessed by organic cells, by rendering the cell wall transparent.

When a specimen of any kind cannot be at once subjected to microscopical examination, it should be kept in pure water, slightly alcoholized and frequently renewed; in this way its characters will not be changed, as they would be either by the action of strong alcohol or by decomposition.

Let us now inquire in what branches of surgical science the investigation by the microscope of morbid changes, deposits, and processes can be made practically useful. We may, in the first place, exclude prognosis and treatment, which can only be indirectly influenced by this mode of study. Etiology is likewise to be thrown out, for reasons which can be readily illustrated by an instance. Thus, the itch insect cannot be assumed to be the cause of the disease, in cases in which it is found, for we cannot prove that its presence is not a mere epiphenomenon. Pathology and diagnosis are the departments most indebted to the microscope for their advancement. They are of course very closely related to one another, and of great practical importance; and as we are at present especially concerned with them in this combined aspect, we have nothing to say in regard to inflammation, nor to the repair of injuries, however deserving of attention these subjects may be in their appropriate place.

The use of the microscope affords much light in regard to *material* pathology; it shows us the changes in texture, and the adventitious deposits, which accompany or constitute disease. Hence it is at once evident that, great as its value may be, as an auxiliary, it cannot possibly set aside other modes of observation; the results of clinical experience must in every case

be as carefully weighed as if we had nothing else to depend upon ; otherwise we shall not only fall into grave errors, but depreciate the scope and dignity of surgical science. Nor can it be denied that there are some questions which are entirely beyond the range even of the assisted eye ; let any one, for instance, examine under the microscope portions of pus from a chancre, from a urethra affected either with gonorrhœa or with simple inflammation, and from a common boil ; that there exist certain essential peculiarities in each of these no one will deny, but to detect those peculiarities by this means no one need attempt.

The great question in microscopy discussed at present by all pathologists is, whether there is any distinctive and characteristic element in the so-called *malignant* deposits, by which they may be at once recognized. At one time the caudate cell was thought to constitute evidence of malignancy ; at another, the large nucleus ; at another, the double or the vesicular nucleolus ; again, the multiplicity of cell forms ; and finally, the existence of malignant tumors, as a class possessing distinct form-elements, has been practically, if not expressly, denied.

An attempt is even now being made, by certain German pathologists, to show that cancer and tubercle—the latter of which is, in fact, as properly malignant as any other growth—are merely abortive attempts at cells of a healthy character ; tubercle cells being considered as nuclei merely. Any discussion of this view would be out of place here, and mention is made of it simply in order to show that opinions are still at variance in regard to the true theory of morbid growths. It is certain that many tumors recur again and again after removal, which do not present the microscopical appearances of cancer as described by most authors. It is no less certain that some tumors which do present such appearances have been successfully excised ; at least the subjects of them have died without any fresh evidence of malignant disease.

Nevertheless, it is by no means certain that there is not a distinct and specific cancer cell ; but this cell must present different forms in different cases, or even in the same case.

Caudate cells do not signify a malignant character in the growth containing them. All tissues of new formation are apt to have them in greater or less proportion ; some tumors are composed of them entirely. Connective or areolar tissue, and old cicatrices, always contain them.

Nor can any form of nucleus or nucleolus, nor any number of nuclei or nucleoli, be assigned as indicative of malignancy. Pus cells generally possess two or three nuclei ; fibro-plastic or fibre-forming cells often show two or more nucleoli.

On the other hand, there are assuredly circumstances under which the testimony afforded by microscopic examination is by no means unimportant, and is confirmed by subsequent events. For instance, an isolated tumor, apparently composed of areolar tissue, involved the submaxillary gland of a patient ; upon its removal it was examined beneath the microscope, and found to contain cells of various shapes and sizes, some very much elongated, and all with large nucleolated nuclei ; it was pronounced malignant, and reappeared within three weeks. Again, a case occurred in which the diagnosis was somewhat doubtful between cancer and menorrhagia ; the former idea was shown to be correct, by the discovery in the discharge, under the microscope, of cells of extremely various sizes, caudate, elongated, and round, with large single or double nuclei ; some of the cells contained also young cells. Such elements, observed in the discharge from a diseased bladder or rectum, would constitute evidence of malignant deposit in the organ.

There are cases, moreover, in which a knowledge of the microscopic structure of a tumor may enable us to allay the most painful apprehensions on

the part of the patient; thus, a growth occurring in the female breast may be shown to consist simply of a hypertrophied portion of the gland, and therefore to be destitute of any malignant character.

In order to draw any positive inference from microscopic observations, the growths or tissues examined should be carefully scrutinized, and in many instances several different portions of them subjected to separate study. Thus, a hypertrophied lobe of the mammary gland may perhaps contain a deposit of a decidedly malignant character, and this fact may entirely escape notice in a partial or hasty examination; so also bony and cartilaginous deposits are apt, when found in connection with the soft tissues—such, for instance, as the testicle—to be associated with less innocent formations.

Another no less important precaution, for the credit of microscopy, should not be forgotten. We may assert of a particular tumor that it presents no sign of malignancy; but we cannot therefore declare that the individual from whom it has been removed is exempt from cancer. He may be already the subject of a carcinomatous diathesis, which will reveal itself at some future time, perhaps at the very same point rendered more vulnerable by the substitution of cicatricial for normal tissue. Coincidences of this kind have undoubtedly been adduced as proof of the insufficiency of the information afforded by the microscope.

The best guide, in the present state of our knowledge upon this subject, is experience; the beginner will often find himself entirely at a loss, and unable to make up his own mind in regard to particular cases. No argument is necessary to set forth the imprudence of a rash decision under such circumstances; both diagnosis and prognosis should be withheld until further observations can be made.

It is by no means uncommon for the surgeon to be in doubt as to the character of discharges taking place from some of the outlets of the body; and in clearing up these points the microscope may render essential service.

The *saliva* will often be found to contain altered epithelial scales, and various parasitic sporules and filaments, indicating derangement of the mucous membrane of the mouth.

The *sputa* may be examined with benefit in some cases of doubtful pulmonary disease; the presence of the peculiar corpuscles of tubercle, or of fibres from the parenchyma of the lung, indicates phthisis, while that of cancer cells would denote cancer of the lung. Care is necessary in these cases to avoid mistaking the free nuclei of cancer for tubercle corpuscles; an error which may have been committed by those who have asserted the coexistence of the two forms of disease in the same subject. Parasitic plants are sometimes found in the sputa, especially in cases of tuberculous disease; they are probably accidental only. Occasionally an opening is formed in the diaphragm, through which parasitic animal growths find their way from the liver into the air-passages; thus, the hooklets of the *echinococcus* have been expelled by coughing. Fibrinous casts of the smaller bronchial tubes are often met with in pneumonial sputa. All these substances must be distinguished, not only from one another, but also from particles of foreign matter, such as food adhering to the teeth, which may seriously mislead the observer.

Vomited matters present some interest. They consist usually of undigested food, with portions of epithelium, but in some diseases they contain also special ingredients. Blood, pus, cancer cells, and sarcinæ are the chief of these.

The examination of the *urine* microscopically is elsewhere discussed; that of *fecal matter* has some importance in cases of supposed cancerous disease of the rectum, in cholera, melæna, and some other morbid states. This subject has received too little attention, especially when its physiological bearing is taken into account. Here, also, care is requisite, lest particles of undi-

gested food, parasitic growths, or other substances, should give rise to serious errors in theory or in diagnosis.

Uterine and vaginal discharges have been before alluded to; their microscopic study is chiefly important in the diagnosis of cancer, tubercle, and other morbid deposits.

Milk is sometimes to be judged of by its microscopic characters; its colostrous characters—the compound granular bodies and the variability in the size of its oily particles—should disappear by the fifth or sixth day after parturition. In order to compare specimens of milk, it is evident that the drops examined should be of the same bulk, and the thin glass cover made to press equally, in each case.

Blood, examined under the microscope, is sometimes found to contain an abnormally large proportion of white corpuscles; a condition known under the name of leucocythemia. It must be acknowledged that we have as yet by no means appreciated the importance of the changes undergone by the blood in disease.

It is occasionally of great practical moment to determine whether certain fluids or secretions, as mucus, urine, milk, or semen, furnished by an organ laboring under disease, contain *pus*, inasmuch as the presence or absence of this fluid may not only throw great light upon the diagnosis of the case, but lead to important therapeutic indications, perhaps the avoidance of a serious operation, as, for example, the amputation of a limb in the case of granular degeneration of the kidney. The most satisfactory test, undoubtedly, of all is the globular character of the pus, as revealed by the microscope, perfectly healthy mucus having no such bodies. It is only when mucus is derived from an irritated or inflamed surface that it presents corpuscles, which may then consist either of undeveloped epithelial cells, lymph corpuscles, or pus globules. Pus and pus liquor are highly albuminous, and therefore readily coagulable by heat, alcohol, and acids; healthy mucus, on the contrary, contains no pus liquor, and is therefore not coagulable. If the suspected secretion be agitated with a solution of potassa, it will, if purulent, be converted into a dense, gelatinous mass, but not if it consist of mucus. Mucus, treated with acetic acid, coagulates into a thin, membranous pellicle; pus does not. Subjected to the contact of ether, mucus yields no traces of fat, whereas this substance may always be extracted in considerable quantity from pus, especially if at all pure. Finally, mucus floats in water; pus, on the contrary, sinks in it.

Further observations on the distinction between pus and other fluids will appear in the chapter on the urinary organs, so as to render, for the present, any other remarks here unnecessary.

The surgeon is not unfrequently called upon for *medico-legal* information; and here the microscope may be of essential service, as, for instance, in the detection of blood-stains, or of spermatozooids in and about the vagina in cases of alleged rape. Facts of great importance have in this manner been established.

All microscopic examinations should be recorded, and drawings made of any notable appearances observed; in this way alone can permanent additions be made to the fund of knowledge possessed by the individual or by the profession at large.

CHAPTER XIII.

MINOR SURGERY.

MINOR surgery comprises an account of some of the more common instruments used in surgery, of the mode of making incisions, or of performing the elementary operations, the establishment of issues, the introduction of the seton, the application of the actual cautery, bleeding, and the art of bandaging and of dressing. As some of these topics have already been incidentally discussed, especially in the chapter on inflammation, I shall here confine myself to the consideration of those that have not yet been touched upon in previous parts of the work.

SECT. I.—INSTRUMENTS.

Instruments are as necessary to the surgeon in the execution of his operations as they are to the mechanic in the performance of his daily labor. But as the best workman employs the fewest tools, so the best operator employs the fewest instruments; and to the man of science and taste nothing is more disgusting than an ostentatious display of such material. A few articles, well selected, and kept in proper order, ready to do their work at the shortest notice, are all that any surgeon really requires for the successful performance of nearly every operation that he may be called upon to undertake. The simplicity of his armamentary often affords a better idea of his skill and science than the most daring feat upon the operating table.

The elementary and really important instruments are very few in number; they are the scalpel, needle, saw, forceps, probe, and director, which are the parents of nearly all the numerous and diversified surgical contrivances found in the shops of the modern cutler. With a little modification the scalpel is converted into the bistoury, the lancet, and the amputating knife, and may be thus made to answer all the purposes required of a cutting instrument. The same needle with which a suture is made may, with a little difference of size and shape, be readily used for couching and lacerating a cataract, or inserting a seton. The saw may be modified without limit, and the same is true of the forceps, whether intended for dissection, dressing, or the division of bone. The probe, which, from its great usefulness, may almost be regarded as another finger, varies in size and shape, from the little delicate, almost thread-like instrument devised by Anel for examining the lachrymal canal, to the sound employed by the lithotomist for exploring the condition of the bladder. The grooved director, which serves to guide the knife in the division of the soft parts, as in operations for hernia, impermeable stricture, and stone in the bladder, is, in fact, nothing but a modification of the ordinary probe.

The *knives* generally in use among surgeons for the more ordinary daily operations are the scalpel and bistoury, of various sizes and shapes, so as to

adapt them to the exigencies of each particular case. All such instruments should have a tolerably large handle, and I decidedly prefer one that is somewhat rough, as being less likely to slip from the fingers when it becomes wet with blood. The blade should be rather long and slender, gradually tapering to a point, which should be quite sharp, or, at any rate, not at all rounded. In some operations, a double-edged, spear-shaped knife is found serviceable, as in the extirpation of tumors, and the extraction of the cataract. Finally, it is sometimes advantageous to have a knife whose handle terminates in a semi-sharp steel edge. Such an addition is occasionally of great service in the extirpation of tumors. The annexed figures afford a good idea of the more common forms of scalpels.

Fig. 99. Fig. 100. Fig. 101. Fig. 102. Fig. 103. Fig. 104.

The *bistoury* differs from an ordinary scalpel chiefly in being longer and more slender; it may be straight or curved, with a sharp or blunt extremity. It is often made so as to open and shut like a penknife, as in fig. 105; but the best instrument of the kind is one with a fixed handle. The term bis-

Fig. 105.

toury has been supposed to be derived from Pistori, the name of a town where it was at one time extensively manufactured. Particular forms of this instrument, invented for particular operations, will be alluded to in different parts of the work.

The adjoining sketches afford good illustrations of the ordinary forms of

the bistoury; fig. 106 represents the sharp-pointed instrument, and fig. 107 the probe-pointed.

Fig. 106.

Fig. 107.

There are hardly any operations in which it is not necessary for the surgeon to avail himself of the use of *forceps*. The instrument usually employed is the common dissecting-forceps, represented in fig. 108. In some cases, as

Fig. 108.

when the object is to pinch up a delicate structure, as the conjunctiva, or a very thin layer of fascia, a pair of forceps provided with a small side-prong, pointing inwards, as represented in fig. 109, will be found very convenient.

Fig. 109.

Scissors are nothing but two knives united by a screw, and furnished each with a ring-handle; if thin, and properly sharpened, they divide the tissues

Fig. 110.

Fig. 111.

with little or no contusion, and may be employed for a great variety of purposes. They are particularly valuable in many of the more delicate opera-

tions upon the eye. They may be straight or curved on the edge or on the flat, pointed or blunt at the extremity, or one blade may be sharp and the other blunt. The annexed drawings exhibit the two principal forms of scissors used by the surgeon.

For holding the flaps out of the way in performing certain operations, especially such as involve the removal of morbid growths, among the more deep-seated structures, or the exposure of arteries, instruments, called retractors, are often of great service, and should find a place in every well arranged operating case.

For holding and pulling out morbid growths, such as deep-seated tumors of the neck or thigh, and for drawing down the cervix of the uterus in operating for vesico-vaginal fistule, as well as for other purposes, a Museux's forceps, shown in fig. 112, or a common volsella, is often of great use. The teeth

Fig. 112.

being plunged into the morbid mass, the instrument is either held by the surgeon himself, or the requisite traction is exerted by an assistant. Fig. 113

Fig. 113.

represents another contrivance, which may be used for a similar purpose, its prongs being firmly screwed into the substance of the morbid growth.

The forceps shown in fig. 114 is very serviceable in the extirpation of large polyps of the uterus.

Fig. 114.

Fig. 115.

The grooved *director*, sketched in fig. 115, is of great service in laying open sinuses and fistules, in exposing arteries, and in dividing the coverings of herniæ, and of deep-seated tumors. It is generally blunt at the extremity, but in some cases it is found more convenient to have it somewhat sharp, so as to effect more easy penetration of the tissues.

The *trocar*, represented in fig. 116, and so called from the circumstance of having a three-edged extremity, consists of a cylindrical rod, passed through

Fig. 116.

a silver canula. It is employed for drawing off various kinds of fluids, as serum and pus. Its use, at the present day, is chiefly confined to the removal of water from the chest, abdomen, and vaginal tunic of the testicle. There is an instrument of this kind with a flat, spear-shaped extremity, but it is not much employed, its canula being more liable to obstruction than that of the round trocar.

There are few instruments which the surgeon has occasion to use more frequently than *needles*; they may be straight or curved, round or flat, and should be of various sizes, as in Fig. 117. In some instances, as

Fig. 118.

Fig. 117.

when we are obliged to take a deep stitch, sew up a fissure of the palate, penetrate an unusually hard structure, or encircle a deep-seated artery, it is convenient to secure it to a handle, as in fig. 118.

SECT. II.—INCISIONS.

Suture needle; with improved point, *a*. *b*. Needle in fixed handle; useful in tying erectile and other tumors.

It is not my intention to enter into any minute details respecting the manner of holding the knife, in operating upon the living subject, as this is a kind of information which should be acquired in the dissecting-room, in connection with the study of surgical anatomy.

A few rules, concisely and plainly stated, will be quite sufficient for the purpose, and will enable any man of sense to execute, with facility, neatness, and dispatch, any operation he may be called upon to undertake. Anything like a flourish for the sake of display or the hope of attracting the applause of the vulgar, is as repugnant to good taste as it is out of place upon such an occasion.

There are four principal positions in which the knife may be held for operative purposes, and with these every surgeon should make himself familiar. The annexed sketches will serve to convey a better idea of their character than any description however elaborate. They are generally distinguished by the prefix of first, second, third, and fourth.

In the *first position*, fig. 119, the knife is held like a writing-pen, between the thumb and the first two fingers, which grasp the instrument gently yet firmly at the junction of the handle with the blade, the edge being inclined downwards or upwards according to the intentions of the surgeon. This position is a very common one, as it is employed in a great variety of operations, as lithotomy, the extirpation of tumors, herniotomy, and the extraction of the cataract.

In the *second position*, fig. 120, the handle of the instrument lies in the palm, the thumb and middle finger holding it at its anterior extremity, while the index finger is slightly extended along the back of the blade, the ring and little fingers assisting in supporting and steadying the handle. The edge of the blade is inclined downwards or upwards, according to circumstances.

In the *third position*, fig. 121, the knife is held like the bow of a violin; that is, the instrument, turned away from the palm, is lightly balanced in the hand, the four fingers being applied against one side, and the thumb against the other. In the dissection, the blade is usually held somewhat sidewise, and the operation is performed chiefly by alternately flexing and extending the wrist.

In the *fourth position*, fig. 122, the knife is held like an ordinary carving-knife, the handle, which inclines towards the ulnar margin of the wrist, being firmly grasped by, and almost

Fig. 119.

Fig. 120.

Fig. 121.

Fig. 122.

completely concealed in, the hand, the tips of the last three fingers nearly touching the hypothenar eminence. This position is chiefly used in the amputation of the larger limbs, and, occasionally, in the extirpation of huge superficial tumors, when the surgeon wishes to produce a rapid and brilliant effect.

The *incisions* employed in operative surgery may be conveniently reduced to three principal ones, namely, the straight, curvilinear, and angular, which are the parents of all the rest. In executing these incisions certain rules should be observed, of which the most important are the following:—

1st. The knife, whether it be a bistoury or scalpel, should be in as complete a condition as possible, being perfectly sharp and clean, and as light as may be consistent with the necessary strength; its size should also be carefully adapted to the occasion.

2d. Before commencing the incisions, care should be taken to stretch, extend, or tighten the skin, which is done either by the operator alone, or partly by him and partly by his assistants. Attention to this rule is of great importance in numerous operations, as it not only expedites the movements of the knife and imparts precision to the incisions, but, what is often a matter of the greatest consequence, enables us to save integument, as, for instance, in case of amputation.

3d. The incisions, whatever be their shape, should be sufficiently large to answer the purpose for which they are designed, being made so, if possible, before the dissection is begun, as this generally greatly facilitates the removal of the parts, or their separation from each other. The principal exception to this rule is where the operation involves the division of large vessels, which, if they were all wounded at once, might be productive of serious hemorrhage.

4th. The superficial incisions should be of equal depth throughout, the knife being entered perpendicularly at one extremity, and brought out similarly at the other, the object being to avoid the formation of what is called a tail, or a partial division of the integuments at each end, as will inevitably happen when the point of the instrument is introduced obliquely. A gentle but steady sawing motion of the knife should be employed rather than firm pressure.

5th. In dividing the common integuments, the knife should always, if possible, be carried parallel to the axis of the part to be exposed or removed, in order that there may be no interference with any important vessels or nerves, which usually run in that direction. Another great point to be gained, in observing this precaution, is that we prevent the flaps from bagging, and so serving as receptacles for the lodgment of blood and inflammatory deposits.

6th. The incisions should be made as rapidly as possible, seeing that the division of the common integuments is generally the most painful part of an operation. Moreover, while they should be sufficiently extensive for the object in view, care should be taken not to make them larger than is necessary.

7th. All cutaneous incisions should be made with special reference to the prevention of unseemly scars. To do this successfully is not always either easy or even practicable. As a general rule, the object is best attained by carrying the knife in the direction of the muscular fibres of the part, or in the line of its wrinkles. Thus, in operating on the forehead, the surgeon will best attain his wishes if he makes his incision horizontal, not oblique, much less perpendicular. In operating upon the lower jaw, or in extirpating tumors from this region, the incisions should be so directed as to run along the base of the bone which will thus offer the best chance of concealing the resulting cicatrice.

8th. The operator, in the exercise of his functions, must be careful not to wound himself, his assistants, or his patient; an occurrence as awkward as

improper, and one that will seldom happen if everything is properly arranged beforehand.

The straight incision may be made either from without inwards, or from within outwards. The former method is usually adopted in the ordinary operations, as in the extirpation of tumors, in opening abscesses, and in the ligation of arteries. Where great caution, however, is required, as in operating for strangulated hernia, or in the removal of morbid growths in front of the neck, the incision must be made from within outwards. For this purpose a fold of integument, being pinched up, is held by the surgeon and his assistant, while its base is transfixed by the knife, and divided by making the instrument cut its way out. The dissection is afterwards to be conducted upon a grooved director.

Occasionally, as in operating about the neck, especially when the object is the removal of a large tumor at the angle of the jaw, the incision may advantageously be made in a curvilinear direction, either like an Italian *f*, or in the form of a semi-ellipsis, as in fig. 123. The chief reason for this procedure is that, while it affords the operator more room, it leaves a more seemly cicatrice.

Fig. 123.

The elliptical incision consists of two curvilinear cuts, meeting at their extremities, as in fig. 124. It is chiefly employed in the extirpation of tumors, where the object is to remove along with the diseased mass a portion of redundant or unhealthy integument. The incisions are made rapidly, in the usual manner, one after the other, the skin being properly stretched, and care taken not to cut away more than is absolutely necessary, since it will otherwise be difficult, if not impossible, to bring the edges of the wound together, after the operation is over, so as to obtain a good and rapid union. Not a little judgment is frequently required to determine, in a given case, how much integument may conveniently be preserved or removed; the surgeon, remembering how contractile the skin is, will generally be cautious how he sacrifices it. Even if the flap be unseemly immediately after the operation, a few days will generally suffice to reduce it to a proper shape and size.

Fig. 124.

Two semi-elliptical, crescentic, or semi-lunar incisions, as in fig. 125, may sometimes be advantageously made, also with the object of removing a portion of integument, as, for instance, in extirpating a diseased mammary gland.

Fig. 125.

The incisions may be directed vertically, obliquely, or horizontally, as may seem most suitable. The angular incision may be used for various purposes, as in the extirpation of tumors, herniotomy, excision of joints, the exposure of diseased bone, and in the transplantation of flaps for the restoration of lost or mutilated parts. It may be made in different ways, but commonly so as to represent the shape of some letter, as in the subjoined figures, according to the exigencies of the particular case.

Fig. 126.

Fig. 127.

Fig. 128.

Fig. 129.

Fig. 130.

Fig. 131.

In dissecting up the flaps, made by these different incisions, the instrument should, as a general rule, be kept in close contact with the parts to be removed; the knife should be swept along as rapidly as may be consistent with

safety; good use may generally be made of the fingers, which will in most cases be found altogether preferable to the forceps. Special regard should always be had to the prevention of hemorrhage. If well-trained, intelligent assistants be at hand, there will, in general, be no necessity for tying every little artery as soon as it is divided; the instant it springs, a finger is clapped upon it, and thus the operation proceeds to its completion, when, satisfactory clearance being effected, the ligation is at once promptly entered upon, and continued until every bleeding vessel is properly secured.

When the dissection involves the exposure of an important structure, as a large artery, a strangulated hernia, or an encysted tumor, which it is desirable not to pierce, the tissues must be divided layer by layer upon a grooved director gently and cautiously insinuated beneath them; or they may be pinched up with a pair of forceps, although this is both less elegant and less safe than the other method. In performing this part of the operation, the successive divisions must be effected in the line of the external incisions, the best knife for the purpose being a narrow, probe-pointed bistoury.

SECT. III.—AVULSION, ENUCLEATION, LIGATION, AND CRUSHING.

1. *Avulsion*.—Instead of cutting away morbid growths with the knife or bistoury, recourse is sometimes had to avulsion, or to twisting and tearing. It is in this way that the surgeon usually removes polyps from the nose and uterus, the instrument which is employed for the purpose being a suitable pair of forceps, with which the tumor is seized and broken off, by rotating the instrument gently yet firmly upon its axis. All active or sudden and forcible pulling is avoided, as tending to inflict serious mischief upon the parts around by lacerating and injuring them to an undue extent; or, as in the case of the nose, perhaps dragging away the turbinated bone, or, as in that of the uterus, inverting that organ, or pulling it down beyond the vulva. Moreover, by avoiding this procedure there will always, as a general rule, be much less risk of copious hemorrhage, severe pain, and shock to the nervous system.

Avulsion is sometimes advantageously practised in the extirpation of tumors developed in and among the tissues, especially when they are deeply situated, or when they lie in the immediate vicinity of large vessels, which it would be hazardous to approach with the edge or extremity of the knife. Under such circumstances, the finger may occasionally advantageously take the place of the cutting instrument, the connecting structures being forcibly lacerated, and the mass twisted and lifted out of its bed. This mode of procedure is often resorted to in the removal of tumors from the neck and parotid region dipping deeply down behind the base and angle of the jaw, in close proximity with the pharynx and the large cervical vessels and nerves, where a false movement with the scalpel might be instantly fatal. It is astonishing what little bleeding frequently follows operations thus performed, and how well the parts generally heal after such rude manipulations. One reason why there is usually so little hemorrhage is that the vessels are torn instead of being evenly divided, as they are in the ordinary procedure.

2. *Enucleation*.—Enucleation is another species of avulsion, and is often advantageously employed in the extirpation of fatty, fibrous, and fibro-plastic tumors. The integuments having been thoroughly divided over the morbid growth, along with its capsule, if there be any, the diseased structures are rapidly peeled out either with the finger, or with the handle of the scalpel. In certain cystic tumors the bag with its contents may often be peeled off bodily, or, its cavity being laid freely open, and its contents evacuated, the walls of the cyst may be pulled away with the forceps.

3. *Ligation*.—There are certain operations in which the removal of the diseased parts is effected chiefly through the agency of the ligature. Of this mode of procedure familiar examples are afforded in the removal of hemorrhoidal tumors, polypous growths of the nose, vagina, uterus, and anus, and in nervous formations about the face, forehead, and other regions of the body. The ligature may be applied either directly to the part by the fingers, or by means of a needle, and should be drawn with sufficient firmness to strangulate the included structures, as the object is to cut off the supply of blood, and cause an eschar. Occasionally the ligature is used subcutaneously, as in the case of nevous growths, involving often very interesting and complicated operations. Instead of the ligature, a silver wire is sometimes used, either by itself, or by means of a double canula, as in fig. 132.

Fig. 132.

Double canula.

4. *Crushing*.—Parts, again, may occasionally be removed by a process of crushing, as proposed a few years ago by Mons. Chassaignac, of Paris, the instrument which he has devised for that purpose being what he calls the *écraseur*, or crusher; the inventor hoping thus to meet certain contingencies in operative surgery which he, in common with others, had frequently encountered in practice, and which he supposed could not be overcome in any other manner. His chief object was to supply a substitute for the ligature in the removal of certain tumors, as hemorrhoids, and polyps of the vagina and uterus. The idea seems to have been to contrive an instrument that should combine the security of the ligature with the rapidity of the knife, thus preventing hemorrhage and pain, and promptly ridding the part of abnormal structure. The *écraseur*, as might be supposed, was originally rude and clumsy, but, by the ingenuity of surgeons and cutlers, has been rendered very graceful and convenient, if not absolutely perfect. The annexed sketch, fig. 133, affords an

Fig. 133.

Ecraseur.

excellent representation of the shape and construction of the instrument, as manufactured by Gemrig, Kolbe, and others of this city. It will be perceived that it essentially consists of two pieces, a sheath, barrel, or tube, either flattened or cylindrical, and of an articulated chain, attached to a steel rod, lying within the sheath, and moved by a handle. The chain is constructed upon the same principles as in the ordinary chain saw, but the links are stronger, and perfectly obtuse, except when it is desired to combine division with crushing, in which event their edges are somewhat beveled. The instrument is made of various sizes and shapes, so as to adapt it the more readily to the various cases presented in practice. The chain, unless constructed with great care, is very liable to break, especially if used for the removal of dense, indurated structures, the division of which requires a good deal of force.

The application of the *écraseur* has recently been very much extended, and

it is quite impossible to foresee where, in the hands of its admirers, it may ultimately cease. During the last twelve months the journals have been filled with accounts of all kinds of wonderful achievements of this instrument, even including amputation of the arm and thigh by its inventor; while its more moderate and less enthusiastic partisans are content with restricting its use to the removal of various kinds of tumors, especially hemorrhoidal, nervous, and ovarian, and the tongue, penis, prepuce, and neck of the uterus. The advantages claimed for it are, first, the rapidity of the operation, which is greater than that with the ligature, although less than with the knife, the instrument acting more powerfully upon the tissues embraced in its loop; secondly, the prevention of shock, the chain doing its work gradually and almost imperceptibly, so as hardly to afford the system an opportunity of taking cognizance of what is going on; thirdly, the protection of the part against hemorrhage, the vessels being placed in a condition similar to those in a lacerated and contused wound; and, lastly, the making of a smaller and less exposed wound than either the ligature or knife, and, consequently, less inflammation and a more rapid cicatrization.

The principal rules to be observed in the application of the *écraseur* are the following: In the first place, if the tumor has a broad base, it should, if possible, be pediculated, by drawing it away from its points of attachment, and casting a ligature around it, its base having been previously transfixed by one or two stout needles. When the coverings of the morbid growth are unusually hard, or insensibly lost in the surrounding parts, a gutter may be formed in them with the knife, preliminary to the application of the chain. Secondly, the division of the tissues is to be effected slowly and gradually, not rapidly or by fits and starts, and for this purpose the handle of the *écraseur* should be turned only about once every ten, twenty, twenty-five or thirty seconds. The time occupied by the entire operation must of course vary according to circumstances, from five minutes, as the average minimum, to twenty minutes, as the average maximum. The great objection to a rapid operation is the danger of hemorrhage. Thirdly and lastly, the patient, during the whole procedure, should be under the influence of an anæsthetic, otherwise the pain will be extreme, especially in the earlier stages.

The subsequent treatment is very simple. If pain arise when the patient wakes from the effects of the anæsthetic, a full anodyne is given, the part is kept at rest in an elevated position, under the influence of water-dressing, and any constitutional symptoms that may show themselves are met as they occur, just as after any other operation. The wound generally heals in a very short time, with very little appearance of inflammation. I am not aware that the application of the *écraseur* has ever been followed, in cases at all adapted to its use, by pyæmia, or any grave constitutional effects, and this is certainly one of the strongest arguments that can be urged in favor of its employment.

The *écraseur* is one of those novelties whose use is always, at first, followed by great abuses, which time alone can rectify. The indiscriminate employment which characterizes it at the present moment is only calculated to bring it into disgrace, by arraying against it the prejudices of the more calm and enlightened members of the profession. When it shall assume its legitimate rank, which it must do before long, it will cease to be applied to the amputation of the limbs and of the mammary gland, if not also of the penis and testicle, and will be restricted, in great measure, if not entirely, to the removal of the tongue, the neck of the uterus, and hemorrhoidal, erectile, and polypous tumors of the vagina and uterus; but even in these affections it will not always supersede the use of the ligature. In internal piles, for instance, I should certainly myself prefer the ligature, and in polypous growths the most eligible operation will generally be avulsion.

SECT. IV.—ABSTRACTION OF BLOOD.

Abstraction of blood may be effected by scarification, puncture, incision, leeching, and cupping. The fluid is sometimes taken from a vein or an artery; the operation, in the former case, constituting venesection, and, in the latter, arteriotomy.

1. *Scarification*.—Scarification is performed with the lancet, scalpel, or bistoury, passed lightly and rapidly over the inflamed surface, so as to divide the engorged vessels, and afford them an opportunity of freeing themselves of their contents. It is employed chiefly in conjunctivitis, tonsillitis, erysipelas, and irritable ulcers, and may be repeated once a day, or once every other day, according to the exigencies of the case, the bleeding being promoted by the liberal use of warm water. In irritable ulcers of the extremities as well as in other parts of the body, scarification is an exceedingly useful practice, which I have pursued, for many years, with great advantage. The proper mode of proceeding is to immerse the limb, previously constricted just below the knee, in a vessel of warm water, and then to make from four to eight vertical incisions over the sore, extending merely through the superficial portion of the true skin. In this manner I have repeatedly bled my patient to syncope, making thus a most salutary impression both upon the part and system. In granular conjunctivitis, the eyelids, especially the upper, may often be scarified with the happiest effect; and in ophthalmia, attended with chemosis, deep incisions are generally practised to relieve engorgement and prevent strangulation of the vessels of the cornea. In tonsillitis, scarification nearly always greatly mitigates the symptoms, and in erysipelas, especially the phlegmonous variety of that disease, it forms a most important element of the local treatment, nothing else being so well calculated to remove tension and prevent gangrene.

2. *Puncturing*.—Puncturing is performed pretty much with the same intention as scarification. It is particularly valuable in erysipelas, active œdema, boils, carbuncles, hemorrhoids, and affections of the tonsils, uvula, lymphatic glands, scrotum, prepuce, uterus, labia, and nymphae, its beneficial effects depending upon the amount of drainage which follows the operation. The best instrument for performing the operation is a very narrow, sharp-pointed bistoury, thrust rapidly into the inflamed surface, to a depth varying from a line to half an inch, according to the degree of swelling of the affected parts, care being taken to avoid injuring important vessels and nerves. In phlegmonous erysipelas, as many as fifty, seventy-five, or even a hundred punctures may sometimes be made with advantage.

3. *Leeching*.—Leeching is applicable to a great variety of affections, and is perhaps more frequently employed than any other mode of topical bleeding. The operation, however, is not without pain, and, unless properly performed, may even be followed by danger. Thus, in epidemic erysipelas, I have known it to give rise to an attack of this disease, which speedily destroyed the patient. Sometimes, again, leech-bites degenerate into bad sores, and produce a great deal of constitutional irritation. Ill effects will be most likely to arise when the leeches are sickly, and when they are applied to persons of a nervous, irritable temperament. Hence, great caution should always be exercised in their selection, as well as in the manner of using them.

The best leeches are the Swiss, German, French, and Spanish, which generally take hold with great avidity, and draw each from half an ounce to six drachms of blood, including what flows after the animal drops off. The American leech, although much larger than the European, bites reluctantly, and sucks sluggishly, on which account it is now rarely used. Moreover, the

wound made by the foreign leech emits four times as much blood as that made by the native; a fact not to be lost sight of in ordering this kind of bleeding. Whatever species be employed, the rule is to divest the part of hair and dirt, otherwise the animal will either not take hold at all, or only after much coaxing, its tastes and habits being extremely fastidious. If, notwithstanding these precautions, it is not inclined to bite, the best plan will be to smear a little blood upon the surface, drawn from the operator's finger, previously constricted with a tight fillet, or to wet it with a little sweetened milk. Immersion of the leech for a few minutes in small beer will sometimes induce it to take hold when hardly anything else will. When the number to be applied is considerable, they should be put in a tumbler, which is then inverted upon the part from which the blood is to be drawn, by which means they will be prevented from crawling about. It is a good plan, generally speaking, not to group them too closely together, but to let them fasten themselves at some little distance from each other. Another rule is not to pull them off, but to let them detach themselves, as they will be sure to do as soon as they have "taken their fill." Their forcible separation is not only a source of pain, but it sometimes leaves a portion of the jaw in the little triangular wound made by its bite, which is sure to become inflamed and irritable in consequence. As soon as they have all dropped off, the bleeding is encouraged by sponging the surface well with warm water, and then covering it with a thickly-folded flannel cloth, wrung out of hot water, and frequently renewed, for a period varying from thirty minutes to two hours, or even longer, according to the desired effect. The blood having ceased to flow, the part is sprinkled with a little powdered starch, and covered with a dry cloth. If there be any disposition to bleed more, or longer, than is deemed proper, the bites are covered with a piece of dry tinder, which, especially if a little pressure be conjoined with it, generally soon puts a stop to the effusion.

The number of leeches to be applied varies from a single one to several dozens, according to the intensity of the morbid action, and the age and strength of the patient. In the adult a good average number is from fifteen to twenty; in children, under five years of age, from three to six. In infants a single leech has sometimes been followed by fatal depression. The extraordinary delicacy of the skin, and, consequently, the great depth of the animal's bite, are reasons why leeching should be practised with more than common caution at this tender age.

There are certain localities where leeches should not be applied. Thus, in the first place, the face, neck, and other parts habitually exposed are, if possible, avoided, because the bites of these animals are liable to be followed by disfiguring scars, particularly objectionable in the female. Secondly, they must not be applied to the eyelids, scrotum, prepuce, labia and nymphæ, structures abounding in loose cellular tissue, and therefore readily admitting of great infiltration of blood, as well as extensive discoloration. Thirdly, they must not be placed along the course of a superficial artery or large vein, or over any of the nervous trunks; lest, in the first case, they should occasion serious hemorrhage, and, in the second, severe pain. Fourthly, care is taken to avoid the centre or focus of an inflamed surface, as they might seriously aggravate the morbid action, if not induce gangrene. Lastly, surgeons make it a rule not to apply these animals in the vicinity of specific ulcers, as chancres and buboes, for fear of inoculating their bites, and thus propagating the specific disease.

A discharge of blood by leeches for a number of successive hours is sometimes very desirable, as soon as one set drops off another supplying their place. In violent ophthalmia, croup, peritonitis, dysentery, erysipelas, and buboes, there is no mode of depletion so beneficial, or so well adapted to put a prompt and permanent stop to the disease, as this.

In leeching the uterus, vagina, ano-rectal outlet, the nose, and inside of the cheek, the animals must be confined in a glass or wire speculum, the opening in the instrument being held upon the part from which the blood is desired to be taken.

Serious, and indeed, frightful, hemorrhage sometimes follows a leech-bite. The occurrence is especially to be dreaded in children, in whom it occasionally produces fatal exhaustion. The best remedies are dried tinder, bound firmly upon the part, compresses wet with saturated alum water or a solution of the persulphate of iron, and cauterization with the solid nitrate of silver, cut to a delicate point, and inserted into the little wound, previously well cleansed and dried. If these means prove abortive, the edges of the wound are trans-fixed with a cambric needle, and approximated by ligature; a procedure which I have never known to fail.

4. *Cupping*.—Cupping is by no means so eligible a mode of bleeding as leeching, being more painful, less elegant, and not so generally applicable. It is, nevertheless, when properly executed, a valuable operation, particularly in the early and declining stages of inflammation. An incipient pleurisy, pneumonia, or articular inflammation, is often promptly relieved by the application of half a dozen cups; but it is chiefly in the latter stages of acute disease, after the morbid action has been weakened by other remedies, and in chronic affections, that cupping asserts its true rank as an antiphlogistic agent. It is seldom, if ever, permissible in gastritis, peritonitis and enteritis, on account of the great pain produced by the application of the scarificator. The operation, to be really serviceable, should be performed as near to the seat of the disease as practicable, care being taken not to open any large vessel, to prick any nervous trunk, or to wound any tendons. The surface selected for the application of the cups must be free from bony prominences, and, without being very soft, must have a pretty good stratum of subcutaneous cellular substance, otherwise it will be impossible for the cups to maintain their hold, and extract a sufficient amount of blood. If the part be thickly covered with hair, it must be previously shaved.

Fig. 134.

Scarificator.

Fig. 135.

Cupping apparatus.

The scarificator, fig. 134, usually employed for dividing the skin, is provided with eight, twelve, or sixteen little blades, moved by a common spring,

and so arranged as to make a corresponding number of incisions, none of them being deep enough to extend entirely through the cutaneous tissues, lest the fatty matter, projecting into them, should fill up the little orifices, thereby impeding the flow of blood. The cup is capable of holding from one to two ounces; it is bell-shaped, and is composed of glass, having a large mouth, with a stop-cock at the other end, to adapt it to a syringe for exhausting the air, as in fig. 135. When such an apparatus is not at hand, the ordinary cupping-glass may be used, or any still more simple contrivance, the air being rarefied by inverting the vessel over the flame of a lamp, or by means of a little pellet of cotton, wet with alcohol, and set on fire in the glass. In a few moments the skin will rise up and form a red conical swelling,

Fig. 136.

Cupping-glass with
vulcanized India-rub-
ber top.

ing, which is now scarified, the cup being immediately replaced, and allowed to remain until the coagulum which fills its interior prevents the flow of blood, when it is carefully removed, to be again replaced as soon as the incisions have been freed from obstruction. Should the bleeding cease before the requisite supply has been obtained, the surface may now be cross cut, and the operation be proceeded with as previously. As much blood having been drawn as may be considered proper, the glasses are removed, and the parts are covered with a soft cloth moistened with oil. The number of cups to be applied varies from one to a dozen, according to the effect it is designed to produce.

The most elegant and convenient cup, by far, is one recently invented in this country, consisting of the body of the ordinary glass cup, surmounted by a cone of vulcanized India-rubber, as seen in fig. 136. In order to apply it, all that is necessary is to indent the top with the finger, the removal of which permits the part instantly to regain its former position, thus exhausting the air within, which it does with great force and efficiency.

5. *Venesection*.—Venesection is commonly regarded as so trivial, simple, and easy an operation, that it has rarely received the consideration and attention to which its intrinsic importance really entitles it. Everybody, no matter whether he has any knowledge of the anatomy of the parts involved in the operation, or the slightest skill in the use of instruments, is supposed to be capable of performing it, and hence it is often done in the most bungling and disreputable manner, entailing much suffering, if not loss of limb and life, upon the patient, and great discredit, if not ruin, upon the practitioner. When we consider the frequency of the operation, and the character of the men who usually perform it, our only surprise is that these disasters are not more common. During a practice of upwards of a quarter of a century, in which I have often had occasion to open different veins, I have had the good fortune never to do any harm in this way, and it would afford me great pleasure if I could make a similar statement concerning the practice of some of my professional brethren. Candor, however, compels me to assert that I have repeatedly witnessed in their hands the most serious effects from this source. In two cases I have seen the patients perish from phlebitis; in three, I have been called upon to tie the brachial artery at the bend of the arm, on account of injury sustained from the lancet; in several, I have known vast and protracted suffering to succeed the puncture of a nerve; and in three instances I have seen the arm endangered by erysipelatous inflammation, followed by immense abscesses, and great impairment in the function of the elbow-joint, wrist, and fingers. In one of the cases here adverted to, the operator, a young man, was sued for mal-practice, and, after much trouble

and vexation, mulcted in the sum of several hundred dollars, which he was little able to pay. I need hardly add that he never recovered from the effects of his misfortune, which pursued him during the remainder of his life. It is related of Mons. Maréchal, who flourished in the reign of Louis XIV., and who was styled, by one of the poets of his day, the prince of surgeons, that he greatly suffered in his reputation, for several years, on account of a fatal accident which followed the operation of bleeding which he performed upon a foreign nobleman. These circumstances should be sufficient to put practitioners upon their guard, and should induce them to study this operation in all its bearings and relations, so that they may be able to perform it with credit to themselves and advantage to their patients.

A vein may be opened with a spring lancet, a thumb lancet, or a bistoury, according to the whim, fancy, or habit of the operator. I have been so long accustomed to the use of the former of these instruments that I rarely employ any other. My experience has taught me that the operation, when done with the spring lancet, generally answers every purpose, as it respects the size and shape of the orifice, the safety of the parts, and the facility of manipulation, while it is incomparably less painful than when it is performed with the thumb lancet, or bistoury. These are, I think, important desiderata, which no unprejudiced practitioner can overlook. No one who has himself been bled with these different instruments can hesitate about his future choice. I have often heard persons, who had been previously bled only with the thumb lancet, declare, after having been bled with the spring lancet, that nothing could ever induce them again to submit to the use of the former instrument, such was the difference in regard to the pain in the two operations. I know that the thumb lancet is generally considered as a more scientific instrument than the spring lancet; it is certainly more simple, and, perhaps, also more easily kept in order; but these advantages do not, in my judgment, outweigh the disadvantages. Both these instruments are so well known that any description of them here would be superfluous. If a bistoury be used, one of very small size should be selected, somewhat like that used in opening abscesses, described at page 147. It should be quite narrow in the blade, slightly pear-shaped at the extremity, and not more than half an inch long in the cutting part. Such an instrument, confined in a light handle, is more elegant than the ordinary thumb lancet, as well as more easily managed, and is, I think, decidedly more surgical and scientific; a circumstance so much insisted upon by some practitioners.

Whatever instrument be employed, care should be taken that it is perfectly sharp and clean, that is, free from rust and other adventitious matter. It should always be washed and thoroughly wiped both before and after the operation, for it is only by observing these precautions that the instrument can be kept in proper order, and that the surgeon can hope to avoid undue irritation and other mischief in the wounded structures.

In bleeding at the bend of the arm I am always in the habit of selecting the largest and most superficial vein, having previously ascertained that the brachial artery is not in danger of being wounded, as it may be when it lies just behind the vessel, or close along its side. When the artery separates high up, one of its branches generally lies immediately below the skin, and might thus be easily opened by an incautious operator. As it respects the superficial nerves, it is seldom possible altogether to avoid them, whatever vein may be selected; nor is this a matter of much moment, provided they are completely divided, and not merely pricked. The veins of the bend of the arm, with the accompanying nerves, are well seen in fig. 137.

In order to distend the veins, a fillet, a yard long by an inch in width, and consisting of a piece of muslin, is tied firmly round the arm, about two inches and a half above the bend, the ends being secured with a slip knot.

Care is taken not to draw it so tightly as to interrupt the circulation in the brachial artery. The patient, extending his arm at a right angle with the trunk, in a state midway between pronation and supination, grasps a common

Fig. 137.

cane, a yardstick, or any other suitable object, holding the limb in an easy, gentle position. The surgeon then, standing behind the limb, pierces the vein, making the opening obliquely, and of sufficient size to furnish a free stream. The adjoining sketch affords a better idea of the manner of holding the lancet than

Fig. 138.

the most elaborate description could. The surgeon uses whichever hand may be most convenient; the vein is thoroughly steadied with the finger previously to making the incision, and care is taken that the orifices in the skin and vessel do not afterwards lose their parallelism, lest the flow of blood should thereby be seriously embarrassed, or the fluid escape extensively into the subcutaneous cellular tissue. Should the latter accident occur, the fillet must immediately be removed, and the requisite abstraction effected from another vein. Sometimes the blood flows sluggishly, although the opening may be quite capacious and unobstructed. When this is the case, the patient should be requested alternately to flex and extend his fingers, so as to cause energetic contraction of the muscles of the forearm, which often powerfully promotes the bleeding; or, instead of this, or along with it, the operator applies friction to the limb from below upwards with his hand, although such a procedure is seldom attended with much advantage. Sometimes the flow of blood is interrupted by the protrusion of a pellet of fat into the orifice of the vein, or in consequence of the timidity of the patient, or the occurrence of partial syncope.

When the spring lancet is used, the instrument is held between the thumb and the first two fingers, the heel being raised a little from the surface, while the fleam is gently pressed upon the distended vein. The opening is effected in the same oblique manner as in bleeding with the thumb lancet.

The blood should always be received into a large basin held by an assistant, and special pains should be taken not to soil the patient's body or bedclothes. When the object is to make a strong and permanent impression, the blood is taken from a large orifice, the patient being, the while, in the semi-erect posture. If he is very plethoric, and the object is to abstract a very large quantity of blood, without occasioning syncope, the recumbent posture is selected. When the requisite amount of fluid has been discharged, the fillet is untied, and the arm is nicely wiped with a napkin wet at one end; the edges of the orifice are then carefully approximated and covered with a small, thick compress, supported by a narrow roller passed around the elbow in the form of the figure 8. The arm should then be put in a sling and kept at rest for the

next forty-eight hours, as premature motion is calculated to favor the development of suppuration and erysipelas.

When blood cannot be obtained from the arm, it may sometimes, in case of urgency, be drawn from a vein on the back of the hand, from the cephalic vein as it runs along the groove between the deltoid and pectoral muscles, or from the external jugular vein. In the latter case, the requisite distension is produced by pressure with the thumb, applied just above the collar bone, or by means of a thick, narrow compress, firmly secured by a roller carried round the neck and shoulder. The requisite incision is made with a bistoury, carried from below upwards and outwards, in a direction contrary to that of the fibres of the platysma myoid muscle. Before removing the compression, care is taken to close the orifice of the vein, lest air should get into it, and thus occasion serious, if not fatal mischief.

The *accidents* which are liable to attend and follow this operation are, infiltration of blood into the subcutaneous cellular tissue, inflammation of the edges of the wound and of the surrounding parts, phlebitis, angeioleucitis, puncture of the nerves, and wound of the brachial artery.

a. An *extravasation* of blood beneath the skin is one of the most common effects of this operation, and may be caused by various circumstances, as the smallness of the incision, the want of parallelism between the outer and inner openings, the great laxity of the areolar tissue, transfixion of the vein, and the accidental occlusion of the wound by the interposition of adipose substance. The extravasation may be diffused, or circumscribed, forming in the one case an ecchymosis, in the other a thrombus. In the former variety, the blood sometimes extends along the anterior part of the limb, nearly as high up, on the one hand, as the axilla, and, on the other, as far down as the inferior third of the forearm; imparting, at first, a dark, purplish hue, and afterwards, as the fluid becomes absorbed, a mottled, greenish, yellowish, or sallow appearance to the skin. A thrombus is a collection of blood immediately around the wound, from the volume of a marble to that of a pullet's egg, irregularly rounded at the base, and usually somewhat pointed at the top. Both these accidents are most liable to occur in thin, emaciated subjects, in bleeding at the basilic vein, and they should always be promptly remedied by attention to the exciting cause; or, where this is impracticable, the bandage should immediately be removed, and the requisite quantity of blood taken from another vessel. The latter procedure is particularly indicated when the infiltration is dependent upon transfixion of the vein, the presence of a pellet of fat, or unusual laxity of the areolar tissue. Defective parallelism may sometimes be corrected by changing the position of the limb; and a small orifice may be enlarged by the re-introduction of the instrument. Under no circumstances, whatever may be the nature of the difficulty, should the operator attempt to promote the flow of blood by the use of the probe, inasmuch as this would inevitably be followed by mischief.

When the extravasation is slight, it will usually disappear spontaneously in a very few days; when considerable, recourse must be had to refrigerant and sorbefacient applications, particularly a strong solution of the hydrochlorate of ammonia, alcohol and water, and, in the latter stages, camphorated lotions, soap liniment, and stimulating unguents. If matter form, or if the parts become angry and inflamed, leeches, blisters, and cataplasms may be necessary, with incisions to evacuate the effused blood and other fluids.

b. The edges of the little wound, made in this operation, sometimes *inflamm* and suppurate; or, instead of this, a small abscess, conical, circumscribed, and very painful, forms immediately around it. Occasionally, especially in feeble, sickly, and intemperate persons, the morbid action assumes an erysipelatous type. The most common causes of these mishaps are a dull, rusty, or foul lancet, imperfect apposition of the lips of the wound, improper tightness

of the dressings, premature use of the parts, and, above all, the contact of the fingers, after the removal of the fillet, for the purpose of preventing the further escape of blood. The latter circumstance has not received sufficient attention. The fingers of the operator, without his being aware of the fact, are often covered with perspiration and other matter, which, when brought in contact with the edges of the incision, are almost certain to irritate and inflame them. My invariable practice is never to touch the wound for any purpose, but, after the fillet is removed, to approximate its lips with a clean compress, made of old muslin, and confined by an appropriate bandage. If, despite proper precautions, inflammation and suppuration arise, the usual antiphlogistic means must at once be employed.

c. Phlebitis, to a slight extent, is probably of much more frequent occurrence after this operation than is generally imagined, while the severer forms of the disease are comparatively rare. It may be induced by various circumstances, of which the employment of a foul lancet is perhaps the most common. In one instance I knew it to be caused by probing the wound, under the supposition that it contained a piece of the fleam of a spring lancet, broken off in the operation, which was performed by a young and inexperienced practitioner. The patient, a man, about thirty-six years of age, was laboring under bilious fever, from which, but for this unfortunate event, he would probably have recovered; phlebitis, however, set in, and he lost his life in less than a week. In another instance, more recently under my observation, the vein was opened with a thumb lancet, and the disastrous effect seemed to have arisen without any evident cause, the patient, a stout negress, having labored at the time under inflammation of the wrist joint. Death ensued in less than ten days after the operation. In some instances, if, indeed, not frequently, the inflammation takes place without any obvious cause, and that too, perhaps, when the operation has been performed in the most unexceptionable manner.

The symptoms of this form of phlebitis do not require special notice, inasmuch as they do not differ from those of phlebitis in general. The attack is commonly ushered in by pain, stiffness and swelling of the affected part, and by rigors, alternating with flushes of heat, and followed by copious perspiration. The inflamed vein is gradually converted into a hard, rigid cord, and the morbid action steadily pursues its course towards the heart, its progress being indicated by a reddish blush of the skin. In some instances, metastatic abscesses form in different parts of the body, particularly in the subcutaneous cellular tissue round the larger joints, if not also in the joints themselves. Meanwhile, the symptoms assume a typhoid character, the mind wanders, great soreness is felt in the muscles and articulations, the patient complains of excessive prostration, and death generally follows in from six to eight days from the commencement of the invasion.

The treatment consists in the application of leeches, blisters, and iodine along the course of the vein, and the exhibition of calomel and opium, with the twofold object of bringing the system promptly under the influence of mercury, and allaying pain and promoting sleep. Abstraction of blood from the arm is rarely indicated, and is, in general, prejudicial. Active purgation and the free use of antimony must also be avoided. If abscesses form, they must be thoroughly and promptly opened. Should recovery take place, sorbefacients will be required to promote the removal of effused fluids in and around the diseased vein, which, however, despite our treatment, usually remains impervious.

d. Angeioleucitis is usually produced by the same causes as phlebitis, which it also resembles in its nature, progress, and symptoms. The morbid action, still more than in the latter disease, has a tendency to extend up the limb, the course of the affected lymphatics being indicated by reddish lines, very

narrow, and exquisitely tender on pressure. The malady, which is quite infrequent, and which rarely does much harm, requires the same treatment as phlebitis, with which it is occasionally associated.

e. Puncture of a *nerve*, whether a considerable-sized trunk, or a mere thread-like filament, may prove to be a very serious accident. The nature of the injury is always indicated by a peculiar stinging, burning, or pricking pain, and a sense of numbness, creeping, or formication in the distal portion of the limb. When very severe, the local distress may be attended with a certain degree of shock and a tendency to syncope, which, however, generally pass off in a very few minutes. Very unpleasant secondary symptoms sometimes succeed this accident, at a period varying from several weeks to several months. One of the most common and distressing of these is neuralgia, which is often attended with regular paroxysms, precisely as neuralgia is when it occurs from ordinary causes in other situations. The disease is then apt to be exceedingly severe and obstinate, often resisting for months, and even years, the best directed efforts at relief. In the cases which have fallen under my observation, it has usually been accompanied, especially in its earlier stages, with considerable swelling, numbness, and stiffness in the distal portion of the limb, together with exquisite tenderness on pressure along the course of the affected nerve. I have never known tetanus to follow this accident, but such an occurrence I should think quite possible, particularly in a person of a nervous, irritable temperament, laboring, at the time of the injury, under disorder of the digestive organs.

The milder effects of this injury will usually pass off in a very short time without any remedial measures, simply by attention to rest and elevation of the limb. This failing, recourse is had to anodyne and astringent fomentations, the application of iodine and even blisters, purgatives, light diet, and other antiphlogistic means. The bandage will often be of great service, especially when there is considerable swelling. If the pain is of a neuralgic character, quinine, strychnine, and arsenious acid will be indicated, and, if given persistently, and in suitable quantities, will be of immense benefit. Where the suffering is extremely violent and intractable, the best remedy is division of the affected nerve, as near as possible to the seat of the injury, by the subcutaneous method; or, where this is impracticable, by exposing the nerve first, and then severing it. Occasionally it becomes necessary to remove a small portion of the affected nerve, especially if, as now and then happens, it is expanded into a little nodule, or is exquisitely tender and sensitive on pressure.

f. A wound of the *brachial artery* is always a very serious accident, and is probably much more frequent than is generally supposed. The injury may be very slight, amounting to a mere puncture, or it may be several lines, half an inch, or even an inch in extent, as in a case under my observation, some years ago. The direction of the wound may be oblique, longitudinal, or transverse, according to the manner in which the instrument is held at the time of the operation. Occasionally the artery, instead of being pierced or stabbed, as it ordinarily is, is transfixed; a circumstance which always seriously complicates the case.

The immediate effect of this accident, which is always denoted by the impetuous, saltatory nature of the stream, and by its scarlet complexion, is to send the blood into the connecting cellular tissue, forming a soft, dark-colored, and circumscribed tumor, or a diffused swelling, which may involve the greater portion of the anterior surface of the limb from the middle of the forearm to within a short distance of the axilla. Such an occurrence is always formidable in its character, alarming to the patient, embarrassing to the surgeon, and liable to be followed by the worst consequences.

The treatment of this accident is by systematic compression, when the

opening is small, and by ligation of each extremity of the artery, when it is large.

Fig. 139.

Compress applied to the temporal artery, after arteriotomy.

wound, and firmly secured by a bandage, carried round the head in the manner represented in fig. 139.

6. *Arteriotomy*.—This operation is occasionally necessary in urgent affections of the brain and eye, and is usually performed upon the anterior branch of the temporal artery, a vessel which possesses the twofold advantage of being very superficial, and at the same time resting upon a resisting bone. Feeling for the artery, in front of the temple, the surgeon applies firm pressure upon it with the finger, so as to steady it properly, while he makes the requisite incision with a small bistoury, carried obliquely across the vessel, care being taken to cut the parts in such a manner as to admit of a full and rapid stream. A sufficient amount of blood having flowed, the artery is completely divided, in order that its extremities may retract, and thus prevent the formation of an aneurism. A small thick compress is then placed upon the

SEC. V.—TRANSFUSION OF BLOOD.

Transfusion of blood from the veins of one person to those of another is imperatively demanded when a patient is rapidly sinking from hemorrhage, whether the result of disease, accident, or operation. It has hitherto been more particularly employed in profuse and exhausting flooding, and there are about twenty cases upon record where it was thus instrumental in preserving life. In such an event it is the last resource of the obstetrician, and no one should hesitate to perform it, even although the woman should literally be in the act of dying, or when, to borrow the language of an eminent writer, "the vital spirit is fluttering with tremulous delay upon the lip." Instead of blood, saline fluid is sometimes transfused, as in attacks of Asiatic cholera, attended with excessive prostration, consequent upon the copious rice-watery discharges from the bowels effectually draining the vessels of their serous contents.

The operation in question requires great care and skill for its successful execution. The chief danger to be guarded against is the entrance of air into the vein, the smallest quantity of which might prove destructive. As ordinarily performed, it is necessary to have at hand, besides a lancet, a tumbler and a glass syringe, the latter being in complete working order. The person from whom the blood is taken must be in good health, and free from all constitutional taint. The arm being tied up, and the vein opened, the blood is allowed to fall into the tumbler as it stands in a basin of water, at a temperature of about 100°, lest the fluid should coagulate, and thus become unfit for use. As soon as about two ounces have been drawn, it is sucked up into the syringe, the nozzle of which is then inserted into the patient's vein, the median basilic, for example, previously exposed by an incision at least an inch in length, and raised upon a probe. In this manner one portion after another is cautiously thrown in until from twelve to sixteen ounces have been transfused, a quantity which it will seldom be judicious to exceed. Should the pulse flag during the operation, or convulsive tremors arise, the proceeding must immediately be suspended, as it is an evidence that injury instead of benefit is accruing.

A great number of contrivances have been devised for imparting to this operation a more scientific character than when it is performed with the ordinary syringe. The method, however, here described will generally be found to answer any purpose, combining, as it does, simplicity with convenience and safety.

When greater nicety is aimed at, the apparatus represented in fig. 140, and constructed, at my suggestion, by Mr. Gemrig, may be used. It consists, as

Fig. 140.

Author's transfusing apparatus.

will be perceived, of a small cupping glass and syringe, with a gum-elastic tube, about eighteen inches long, having a stop-cock at its distal extremity, which is surmounted with a nozzle cut off obliquely, like the barrel of a pen. The patient's vein having been exposed by an incision and freely opened, the nozzle is inserted into it and securely held by an assistant. A vein is then punctured in a healthy person's arm, but the blood is restrained from flowing by the pressure of the finger applied some distance below, until the cup has been placed over the orifice and exhausted of air by means of the syringe. As soon as this has been done, the stop-cock is turned, so as to permit the fluid to pass readily from one vessel into the other.

SECT. VI.—VACCINATION.

The surgery of vaccination is very simple. It may be performed either with lymph, removed between the sixth and ninth day, or, what answers nearly equally well, with the dried scab rubbed upon a plate of glass, with tepid water, until it is of a thin consistence, and of a very pale milky hue. The matter is taken up with the point of a sharp, narrow lancet, a tenotomy knife, or a common needle, and inserted into the skin on the outer surface of the arm, just below the deltoid muscle, or on the outer and upper part of the leg at a suitable distance from the knee, at two spots, each about the diameter of a three cent piece, and sufficiently apart to prevent them from running together during the height of the resulting inflammation. The impregnation may be effected by a number of little punctures, by three or four superficial incisions, or, simply, by a slight abrasion of the epidermis. Whatever method be adopted, no blood should be drawn, as it might wash away the vaccine matter. When the operation is performed with lymph taken up on bits of ivory, a procedure which some practitioners prefer to any other, the points should be held for a few seconds in the steam of hot water, and then rubbed upon the raw surface.

The progress of a successful vaccination is as follows :—The wound, on the third day after the operation, is found to be slightly inflamed and elevated; and, on the fifth day, a characteristic vesicle appears, of a beautiful pearl-colored

aspect, circular or oval in shape, and occupied by a drop of thin, limpid fluid. On the eighth day the vesicle is in its greatest perfection; it is now somewhat of a yellowish hue, distinctly cellulated in structure, very prominent, slightly umbilicated at the centre, and surrounded by a circular areola, the skin around being inflamed, tense, and painful. Occasionally considerable swelling of the glands of the axilla exists. The constitution is thoroughly implicated, and, as a consequence, the patient is feverish and restless. On the eleventh day, the areola begins to fade, and the vesicle, which usually spontaneously bursts, gradually dries up into a hard, brownish, circular scab, which, dropping off from the eighteenth to the twenty-first day, leaves behind it a small, rounded, pitted and indelible cicatrice, attesting the success of the operation.

Vaccination may be performed as early as the sixth week after birth, and at all periods of life subsequently. If the child is sickly, the general health should previously be amended, particularly so if there be any eruptive disease. Some persons evince the most remarkable insusceptibility to the influence of the vaccine poison. I have seen a number of cases in which the operation was performed upwards of twenty times before it finally succeeded. Healthy children afford the best lymph, and the matter of primary vaccinations is more energetic than that of secondary vaccinations.

The bad effects of the operation are, 1st, too much local action, the inflammation sometimes assuming a real erysipelatous character; 2dly, severe inflammation of the axillary glands; 3dly, ulceration, or even gangrene, at the seat of the vesicle, leaving a sore which is occasionally very tedious in healing; 4thly, a lichenous or roseolar eruption, attended with distressing itching, and often considerable swelling; and 5thly, an appearance of vesicles upon the general surface, resembling those of varicella, or even those of genuine cowpox. It is proper to add that the regular development of vaccinia is sometimes retarded by the pre-occupation of the system by other affections, as measles and scarlatina.

The effects of vaccination are sometimes completely lost, in the proportion, probably, of about forty persons in one thousand. It is for this reason that the operation should occasionally be repeated.

SECT. VII.—COUNTER-IRRITATION.

Counter-irritation may, as stated elsewhere, be established in various ways, as by rubefacients, vesicants, and dry cupping; but when the object is to make a deep and protracted impression, the means usually selected are the permanent blister, the seton, and issue. Sometimes the moxa and acupuncture are employed.

1. *Rubefacients*.—A rubefacient effect, or temporary irritation of the skin, may readily be produced by a great variety of articles, as ammoniated liniments or unguents, spirits of turpentine, hot water, mustard, and the hot iron. The latter, in the form of the objective cautery, as the French term it, consists in passing a piece of iron, heated perfectly white, rapidly over the surface at a distance of from three to five inches. The skin becomes almost instantly red, and if the application be continued for a few minutes vesication will follow.

A very useful and speedy rubefacient action may also be produced by means of Dr. Corrigan's button cautery, fig. 141, heated in the flame of a brass spirit lamp until the forefinger, resting upon the shank of the instrument near the disk, begins to feel uncomfortably hot, the period usually required not exceeding a quarter of a minute. As soon as it is ready, it is applied as quickly as possible, the skin being tipped successively, at intervals of half an

inch, over the whole of the affected part, which soon assumes a bright red appearance, and becomes the seat of a glowing sensation. The disk of the instrument is half an inch in diameter by three lines in thickness, with a flat surface, and a thick iron wire shank, two inches in length, and inserted in a small wooden handle.

2. *Dry Cupping*.—Dry cupping is occasionally employed, especially in chronic affections, in which it is often of great value. The air being exhausted, as in the more common operation, the cup is allowed to remain on the part for a period varying from thirty to forty-five minutes. At the end of this time it will generally be found that there is not only a marked afflux of blood, but likewise more or less vesication of the skin, objects which the practitioner should always endeavor to attain whenever he advises such an operation; for, unless it be performed efficiently, it might as well not be performed at all.

Dry cupping is particularly serviceable in chronic disease of the brain and spinal cord, the thoracic and abdominal viscera, and the larger joints. The number of cups employed, and the repetition of the operation, must of course be regulated by the exigencies of the particular cases.

3. *Permanent Blisters*.—A permanent blister is made by letting the fly remain on the skin an unusual length of time, and then divesting the part of epidermis. It is capable of furnishing a free discharge of pus, which may often be maintained for a long time, either by the occasional re-application of the fly, or by means of some irritating ointment, as the savin or mezereon, or, what I prefer, an ointment composed of an ounce of lard and three to eight drops of nitric acid. Whatever article be used, the surface should be constantly protected with an emollient poultice or the warm water-dressing, otherwise the sore will become excessively irritable, and cease to furnish the desired discharge. Whenever the secretion begins to slacken, a little of any of the unguents here mentioned may be applied to the sore to renew the morbid action. I have occasionally used the dilute fly ointment for this purpose, but having several times produced strangury with it, I have latterly abandoned it.

4. *Seton*.—A seton is a subcutaneous wound, holding a foreign body. It may be made with a bistoury, and a piece of gum-elastic tape, or, in the absence of this, a narrow strip of muslin, conveyed beneath the skin by means of an eyed probe or the seton needle, represented in fig. 142. The integu-

Fig. 141.

Corrigan's button cantery.

Fig. 142.

ments being pinched up, the instrument is pushed on through the cellular tissue, care being taken not to interfere with any muscular fibres, tendon, nerve, or vessel. The ends of the seton are tied long, and held out of the

way by a strip of adhesive plaster. The mode of introducing a seton with the knife and probe is shown in fig. 143.

Fig. 143.

An emollient cataplasm is the most suitable dressing, both immediately after the operation and subsequently, during the sojourn of the foreign body. At the end of the second day, the tape is drawn gently across the wound, a fresh portion taking its place, and this process is afterwards repeated as often as cleanliness and other circumstances may render it necessary. If the discharge becomes deficient, recourse is had to some stimulating ointment; if offensive, to the chlorides. When the tape becomes soiled and unfit for use, it is replaced by a new one. Sometimes fungous granulations spring up at the orifices of the subcutaneous wound, causing much pain and inconvenience. The best remedy is excision, followed by the nitrate of silver. The insertion of a seton is usually attended with little bleeding; but I recollect the case of an elderly gentleman, a patient of a late eminent practitioner, who nearly lost his life from this cause, the operation having been performed upon the nape of the neck. The blood seemed to have proceeded from a small artery among the cervical muscles, the instrument having penetrated too deeply.

A seton is, on the whole, a filthy, painful, and imperfect form of counter-irritation, which it might, perhaps, be well to exclude altogether from practice, as its place may always be easily supplied by the issue.

5. *Issue*.—An issue is an artificial ulcer, intended to furnish a discharge of pus. It is adapted to the same class of cases as the seton, but is more cleanly, less painful, and more convenient. Moreover, such a sore affords a good surface for the local application of morphia and other remedies, which may often be advantageously used, in this way, for relieving pain, as well as for other purposes.

Issues may be made in various ways, as with the knife, the Vienna paste, and the actual cautery. The first of these methods is not sufficiently efficient to justify its general employment; it is better adapted to the scalp than to any other region of the body, and may be advantageously used in diseases of the pericranium, and of the brain and its meninges. An incision being made through the skin and cellular tissue, from half an inch to an inch in length, its cavity is filled with some foreign body, as a pea, grain of corn, small pebble, or piece of orris root, which soon produces a pyogenic action, that may afterwards be increased, if necessary, by the use of some stimulating ointment, in the same manner as in the case of the seton. The substance is confined with a strip of adhesive plaster and a bandage, and is occasionally replaced by a fresh one, cleanliness being maintained in the usual way.

A better plan is to make the issue with the *Vienna paste*, composed of equal parts of quicklime and caustic potassa, thoroughly triturated together, and preserved in a closely corked vial until required for use. The requisite quantity is then put upon a piece of glass, or upon the bottom of a saucer, and converted into a thick paste with alcohol. A layer about two lines in

thickness, and of the desired diameter, is put on the skin, and allowed to remain for eight, ten, or fifteen minutes, according as we wish to make a slight or deep impression. The surface, which will be found to be of a pale drab color, is washed with vinegar and water, to neutralize the alkali, and covered with an emollient cataplasm, to promote the detachment of the slough, which usually happens in from five to eight days. Some pain attends the operation, but this is soon over, and bears no comparison with the horrible distress produced by the application of caustic potassa alone; besides, the Vienna paste does not diffuse itself over the adjacent parts, and thus unnecessarily destroy the skin. The extent of the issue is regulated by the extent of the layer; one of the diameter of a twenty-five cent piece affording, when the sloughing is completed, a sore from three to five times that size. The best permanent dressing is a poultice; the best promoter of discharge, a stimulating ointment, or the occasional use, for a few hours, of a small blister.

The most eligible issue of all, however, is that made with the *actual cautery*; it affords not only an abundant and protracted discharge, far beyond what follows the more ordinary issue, but, what is often a matter of no little consequence, it makes an impression both upon the part and system, which no other mode of counter-irritation is capable of producing. On these accounts, this kind of issue should have a decided preference over every other in all protracted and obstinate cases of disease where the employment of revulsives is indicated, as in caries of the hip-joint, Pott's disease of the spine, and similar affections, in which its powers, as a topical remedy, are unequalled.

The actual cautery, when used for this purpose, is of course attended with pain, and for this reason it will generally be well to administer some anæsthetic, although the suffering is much less than is usually imagined. Formerly, before the discovery of this class of agents, I was constantly in the habit of making this kind of issue, and often had occasion to notice the little pain it produced, even in very young children and nervous persons. The manner of proceeding is to heat the cautery perfectly white in a chafing-dish of charcoal, and then to hold it, with some degree of firmness, upon the proper spot, until the skin is converted into a dark eschar, care being taken not to penetrate beyond the subcutaneous cellular substance. A cloth, wrung out of cold water, is immediately laid upon the part, and frequently renewed, for ten or twelve hours, when it is replaced by a poultice or the warm water-dressing. The slough usually drops off in from five to ten days, leaving a sore, which, while it is easily kept clean, furnishes a free discharge, and may be maintained open, with but little care, for an almost indefinite period. A cautery the size of a half eagle will make an issue, after the separation of the eschar, of the diameter of a silver dollar. The instrument should be fully half an inch thick, otherwise it will not retain its heat sufficiently long.

Fig. 144.

6. *Moxa*.—The moxa is a soft combustible substance held upon the skin, and suffered to burn down slowly, so as to produce a temporary irritant effect. It may be prepared from various articles, as agaric, hemp, cotton, rotten wood, the pith of the common sunflower, and the down of the *artemisia chinensis*; but the one which I usually prefer is soft patent lint, soaked in a strong solution of nitrate of potassa. When thoroughly dried, this is rolled up into tolerably firm cylindrical cones, an inch and a half long by one inch in diameter. In applying them they should be ignited at the top, and held upon the part intended to be cauterized with a pair of dressing-forceps, a long hair-pin, or a porte-moxa, fig. 144; care being taken to protect the surrounding surface with a piece of wet linen perforated at its centre. When it is desired to hasten the combustion a blowpipe may be employed, but in general this is unnecessary. Whatever substance be used, the

Porte-moxa.

heat can be so graduated as to produce any amount of irritation, from the slightest rubefaction to a superficial eschar. When the latter effect is desired, the moxa should remain on until it is wholly consumed; otherwise it may be removed as soon as the pain becomes somewhat severe, or, instead of placing the burning material in contact with the skin, it may be held at a little distance from it. The eschar is of a yellowish, gray, or dark color, and usually drops off in six or eight days. The pain produced by the operation may be promptly relieved by the application of liquid ammonia, cold water, or pounded ice.

The moxa seems to act on the same principle as the objective cauterization, and the ammoniated counter-irritants, already spoken of, and is a valuable agent in many chronic cases, when it is intended to produce a sudden impression upon the nerves of the affected part: it should always be applied as near as possible to the seat of the malady, and the effect should be sustained for weeks, or even months, by the repeated application of the agent. The diseases in which it seems to be most efficacious are amaurosis, neuralgia, nervous deafness, partial paralysis, coxalgia, and spinal irritation.

7. *Acupuncturation*.—Counter-irritation may be effected also by acupuncturation. This consists in the insertion of very slender, well polished, sharp-pointed steel needles, figs. 145, 146, 147, from two to four inches in length,

Figs. 145, 146, 147.

Acupuncturation needles.

furnished with a metallic head, or a head of sealing wax. To prevent them from breaking, they should be rather soft and flexible. They are introduced into the affected part, which is previously stretched, by a gentle rotatory motion, aided by slight pressure, and are suffered to remain from one to six hours, according to the effect they produce, or the object they are intended to fulfil. In some instances a period of ten minutes is sufficient; in others, they may be kept in for one or two days. They may be carried to a depth of several inches, but care must be taken not to transfix any important viscera, vessels or nerves, though this has been often done without ceremony, and without any injurious results. The number of needles to be used varies from one to a dozen, according to the extent of the affected part and the sensibility of the patient. The operation rarely causes much pain, and is scarcely ever followed by any unpleasant symptoms. In most cases a slight blush, which subsides in a few hours, is observed around each puncture. In withdrawing the needles, which is sometimes effected with difficulty, owing to their having become oxidized, a movement of rotation should be given to

them, at the same time that pressure is made upon the adjacent surface with the thumb and forefinger.

Acupuncturation has been employed in a great variety of affections, as neuralgia, rheumatism, gout, sciatica, paralysis, cephalalgia, and epilepsy; recently it has been recommended in the treatment of aneurism, hydrocele, varicocele, and anasarca. Its advantages have been much overrated, and the practice, which has been borrowed from the Chinese and Japanese, has fallen into disrepute.

8. *Electro-puncturation*.—Needles are sometimes introduced into the tissues for the purpose of transmitting to the affected part a current of electricity or galvanism. The operation, denominated, in the one case, electro-puncturation, and, in the other, galvano-puncturation, is performed in the same manner and with the same instruments as in the ordinary process, except that the latter have a small ring at the top for receiving the conducting wires of the

poles of the battery. Only two needles are used at first, but the number is gradually increased as the patient becomes able to endure the action of the current. When it is intended to produce a shock, a Leyden jar may be employed, but for maintaining a steady effect a small horizontal galvanic pile is the most appropriate apparatus. This mode of counter-irritation is almost entirely restricted to the treatment of chronic affections, attended with deep-seated and inveterate pains, as gout, rheumatism, neuralgia, and sciatica.

9. *Galvano-cauterization*.—A very ingenious and useful instrument for applying heat by means of galvanism was invented in 1850, by Mr. Marshall, of London, and is depicted in the annexed sketch, fig. 148. It is called the

Fig. 148.

Marshall's galvanic cautery.

galvanic cautery, and is particularly serviceable as a stimulant in the treatment of old rebellious sinuses and fistules. The apparatus consists of a pair of forceps with projecting iron handles, and long, narrow blades, terminating at an acute curve, and arranged so as to hold a platinum wire. The diseased passages being well cleaned and dried, the wire is introduced cold, and then heated by the galvanic current red hot or otherwise, according to the wished-for effect. When it is designed to destroy the tissues, as in the operation for anal fistule, the wire must be drawn to and fro with a sawing movement to facilitate their division. The battery should have from six to nine cells, filled with a mixture of one part of sulphuric acid to ten of water. The rods are isolated by an intermediate strip of ivory.

SECT. VIII.—ESCHAROTICS.

There is a class of operations which consist in destroying the affected tissues with caustics, consisting of the hot iron and of various escharotic substances. These procedures, however, once so much in vogue among surgeons, have become almost obsolete, although they are perhaps still too much practised in certain quarters, especially in France. At the present day they are restricted, in great measure, to affections of the neck and orifice of the uterus, and of the mammary gland, hemorrhoidal tumors, varicose veins of the extremities, specific ulcers, as chancres and malignant pustules, and the bites of snakes and rabid animals.

When the hot iron is used for the purposes in question, it should be heated to a white heat, and retained in contact with the diseased parts sufficiently long to effect their destruction, their surface being previously thoroughly dried. In performing the operation, the surrounding structures should be carefully protected from injury, and in order to obtain the desired result it is frequently necessary to have two, three, or even four cauteries in readiness, so that, as one becomes cold, another may take its place. The eschar generally drops off at a period varying from four to ten days. The best apparatus for heating the iron is a little furnace, charged with charcoal, the combustion being promoted with a pair of bellows. The annexed sketch,

fig. 149, conveys a good idea of the principal forms of iron in use at the present day. The conical-shaped instrument is well adapted for cauterizing

Fig. 149.

Different forms of cauteries.

narrow and deep-seated cavities; the cylindrical one may also be used for this and similar purposes. The hatchet-shaped iron is well adapted for making a linear eschar, and the large round one for establishing a deep, permanent issue.

Caustic potassa, the Vienna paste, chloride of zinc, bichloride of mercury, arsenic, ammonia, and certain acids, as the nitric, hydrochloric, and sulphuric, are

powerful caustics, producing their peculiar effects more or less promptly, according to the length of time during which they are retained, and the strength in which they are used. As their application is generally attended with severe pain, it is proper that the patient be previously put under the full influence of an anæsthetic. Moreover, as some of the articles here specified have a tendency to diffuse themselves over the surrounding healthy surface, care should be taken to prevent this by placing a wall of simple cerate or collodion around the part to be cauterized.

Caustic potassa is a powerful escharotic, but as it is extremely painful and very tardy in its action, it is now seldom employed. The Vienna paste, composed, as already stated, of equal parts of quicklime and caustic potassa, although also productive of severe suffering, does its work much more rapidly—generally in from ten to fifteen minutes—and is therefore usually preferred.

The *chloride of zinc* is usually mixed with farina, forming thus what is called the phagedenic paste of Canquoin, of which there are three strengths, known as number one, two, and three; the first consisting of one drachm of the metal to double that quantity of farina, the proportions of the second being as one to three, and of the third as one to four, the latter being of course much the weaker. The preparations act with great efficiency, but are productive of excessive pain.

Bichloride of mercury, in the proportion of three parts to one of powdered opium, with the addition of a sufficient quantity of sulphuric acid to convert it into a paste of the consistence of tar, makes a powerful escharotic; but, owing to the excessive pain which it causes, and the risk of its inducing salivation, it is now rarely used. A similar objection is applicable to the caustic mixture, formed of equal parts of white arsenic and sulphur, formerly so much in vogue. A decisive escharotic effect may speedily be produced by the use of equal parts of ammonia and lard.

A very destructive escharotic, admirably adapted for the removal of epithelial growths, may be prepared with fifteen grains of white *arsenic*, seventy-five of cinnabar, and thirty-five of burnt sponge, made into a thick paste with a few drops of water. This constitutes what is called Manec's paste, and is applied in the form of a thin layer to the surface of the affected part, previously well cleansed in order to promote its effects. The great objection to this remedy is the excessive pain it produces and its liability to cause vomiting, depending, doubtless, upon the absorption of some of the arsenic. Generally also its application is followed by deep discoloration and severe swelling. For these various reasons it should be employed with great caution.

The stronger *acids*, as the nitric, hydrochloric, and sulphuric, produce an instantaneous escharotic effect when applied to a denuded surface; hence they are often used for cauterizing inoculated wounds and destroying the edges of ulcers. Of all the acid preparations, however, the best and most reliable is the *acid nitrate of mercury*, of which frequent mention will be made hereafter. The formula which I employ is that usually known in this country as Bennett's. It is prepared by dissolving, with the aid of heat, 100 parts of mercury in 200 parts of nitric acid, and evaporating the solution to 225 parts. The application produces a white eschar, which is detached, piecemeal, in from the third to the tenth day. Whatever article be employed, the utmost care must be taken to prevent its diffusion over the surrounding healthy tissues, otherwise the effects may be most unfortunate. *Chromic acid* also deserves favorable mention; its application, which causes but little pain, is particularly valuable in cases of warty excrescences and of recent chancres.

SECT. IX.—DRESSING.

The art of dressing, humble though it be, must not be despised by the surgeon; since, in many situations, both in private and hospital practice, it must necessarily form a part of his daily routine duties. There is, indeed, great reason to believe that this matter is too much neglected by practitioners, and that it is too frequently delegated to ignorant, careless, and unscrupulous nurses, and to the so-called dressers, who are often not a whit more enlightened, or more conscientious.

The most important appliances used in dressing are forceps, scissors, and syringes, sponges, lint, pledgets, tents, adhesive plaster, bandages, cataplasms, and unguents.

The *dressing forceps*, fig. 150, differ from the ordinary dissecting forceps in having ring handles, and cross blades, terminating each in a rounded, spoon-shaped extremity, supplied internally with serrated edges, to adapt it the better for seizing and holding such substances as may require removal. They are light and slender, and from four and a half to five inches in length. When not at hand, the ordinary dissecting forceps may advantageously be used as a substitute.

Fig. 150.

Dressing forceps.

The best *scissors*, for dressing purposes, are the ordinary straight pocket case instrument, which may be used either for cutting adhesive strips and bandages, or, if necessary, for paring the edges of ulcers, or for removing redundant granulations. Scissors curved on the edge or flat are sometimes very convenient.

The *sponges* used in dressing should be very soft and clean, and the same articles should never be employed upon different persons, especially when they are affected with open ulcers, as the discharges might thus be made the vehicle of propagating disease, as, for instance, in chancre, gonorrhœa, erysipelas, malignant pustule, and hospital gangrene. In all such cases they should be destroyed as soon as the dressing is completed, or thoroughly washed in water, and then soaked in a solution of chlorinated soda.

As a general rule, no sore should be wiped; but the water should be pressed upon it from a sponge held some distance from its surface, which

will generally effectually wash away any secretions that may be in contact with it. Adherent lymph, charpie, or unguent may be picked away with the forceps. The surface around, however, may be gently sponged, if soiled; otherwise it may be wiped with a soft dry cloth. The water may be tepid, cool, or cold, according to circumstances, and arrangements should always be made to receive it into a suitable basin, placed beneath the affected parts. The old dressings should be put into a separate vessel, and promptly removed from the patient's apartment. Fetor is allayed by the free use of the chlorides, sprinkled both upon the body and bedclothes, as well as about the room.

Lint is a soft, fleecy substance, consisting either of prepared cotton, or scraped linen, or, what is preferable, the ravellings of linen, as those of an old napkin, sheet, or pillow-case, each thread being picked out separately. The article generally employed in this country is patent lint, which is kept in rolls in the shops, and makes an excellent dressing, although not equal to linen ravellings, or the charpie of the French surgeons; one surface is glazed, the other smooth. The objection to it is that it is not sufficiently porous to admit of the free escape of the secretions of the parts to which it is applied, and, consequently, also, that it keeps them too warm.

A very excellent, cheap, and convenient article for dressing wounds and ulcers may be prepared by folding a piece of old muslin until it forms a body from a quarter of an inch to half an inch in thickness, and then punching numerous holes into it, giving it thus a sievelike appearance. It is very light and airy, and while it absorbs moisture, it also admits of ready drainage. It forms a good substitute for patent lint, and may be used in cases where the other is not applicable. It may be called the *perforated muslin*. Dr. Levis, who has thoroughly tested its efficacy in the surgical wards of the Philadelphia Hospital, speaks of it in high terms of commendation.

Spongio-piline is now much employed as a dressing. It is a soft, porous fabric, looking very much like a piece of sponge; it is made in sheets from half an inch to an inch in thickness, and being covered with a glazing of India rubber, is well calculated to retain water and prevent evaporation, at the same time that its weight is not so great as to cause oppression.

Sometimes the lint is arranged in the form of a *compress*, pledget, ball, roll, tampon, tent, or pellet, thus adapting it the more conveniently to particular purposes. Thus, a compress consisting of a strip of folded muslin or linen may be employed for pressing together the sides of a deep abscess, or a number of pieces may be piled upon each other, so as to form a graduated compress, which is often advantageously used for compressing a bleeding vessel, as the brachial artery where it runs along the inner edge of the flexor muscle. The *pledget* is a strip of patent lint, usually spread with cerate, for protecting the surface of a granulating ulcer; balls, rolls, and tampons are simply masses of soft substance, as charpie, lint, or cotton, arranged so as to adapt them to particular cavities, as the uterus, the nose, or a deep wound, either with a view of arresting hemorrhage, or for absorbing pus and other fluids. The *tent* consists of a piece of linen, muslin, or patent lint, twisted on its axis, slender, and usually several inches in length, its object being to prevent the reunion of the sides of the incisions made in puncturing abscesses, and in laying open sinuses, as in the operation for anal fistule. Tents are sometimes prepared with wax, in which case they are generally of a conical shape, and employed as dilators. Finally, the *pellet* is a ball, roll, or mass, of soft tissue, inclosed in a strip of soft cloth, firmly tied; it may be used for the same purposes as the tampon, of which, in fact, it is merely a variety. When intended for the nose, uterus, or rectum, a stout thread or piece of twine may be tied to it in order to facilitate its removal.

Within the last two years a good deal has been written respecting the use

of *drainage-tubes*, a means of treatment suggested by Mons. Chassaignac, for favoring the discharge of matter from abscesses and sinuses, especially when large and deep-seated. These tubes, which are from one to two lines in diameter, and perforated by numerous oval foramina, are made of India rubber, and are, consequently, highly elastic and flexible; their shape is cylindrical, and their length varies, on an average, from three to six inches, according to the exigencies of each particular case. The great objection to these tubes is their liability to become clogged, and their tendency to cause undue irritation in the parts into which they are introduced. For these reasons it is questionable whether they will ever come into general use.

Poultices form an important element in a great variety of dressings, but as these have already received sufficient attention, it would be out of place to say anything further respecting them here. I shall only add that, when they are selected for this purpose, they should be used with special reference to the comfort of the parts, care being taken that they do not oppress by their weight, or irritate by their long retention and the stimulating character of their ingredients. The mode of employing water-dressings has also been sufficiently considered in another part of the work to render any further remarks regarding them here unnecessary.

*Unguent*s, ointments, or salves of various kinds are employed as dressings in ulcers and other open surfaces; much has been said and written upon the subject, especially of late years, and attempts have been made to discard these substances altogether from practice. Still, notwithstanding all this, unguents hold a prominent place in the affection of many practitioners, as well as in that of the common people, and it would be difficult, I am sure, always to dispense with their use. I imagine that prejudice has had much to do in proscribing this class of remedies; when such a man as Liston raises his voice against any point of practice, it is usually very hard for the lesser lights of surgery to resist its influence, and the cry therefore at once becomes general, whether there be any just reason for it or not. It cannot be denied that rancid ointments act as irritants; this, however, is not the fault of the article, but simply of him who uses it. Prepared and employed for the occasion, experience teaches me that the application of unguents is often attended with the most salutary effects, admirably protecting granulating surfaces, and rapidly promoting cicatrization. As a general rule, I have found that all the officinal medicated ointments are much too strong, requiring to be diluted from one-half to seven-eighths.

Whatever dressings be employed, they should be carefully confined by means of a bandage, evenly and lightly applied, so as to afford the requisite support, and no more. In most situations, this may be readily done with the common roller; but in certain regions, as in the groin, perineum, anus, and head, particular contrivances may be necessary, as the spica, the T bandage, and the four-tailed bandage. For retaining dressings upon the testicle and mammary gland the suspensory bandage will be found most convenient.

SECT. X.—BANDAGING.

Bandages are substances employed for retaining dressings in cases of wounds, ulcers, abscesses, fractures, dislocations, and other affections, as well as with a view to their direct curative effects, which, as will be shown by and by, are probably much greater than they are generally supposed to be. They vary much in shape and size, and also in regard to the materials of which they are composed, and the object which they are designed to fulfil. A vast number of bandages have been described in certain modern works, especially

those on minor surgery, much ingenuity, and, according to my belief, much time, having been wasted, in trying to adapt them to every part and region of the body, and to every circumstance, however insignificant, to which such contrivances can possibly be applied. By running into these extremes, the art of bandaging has been greatly complicated, and much injury inflicted upon a department of surgery, which, if properly administered, is capable of conferring immense benefit in almost every form of accident and disease affecting the external parts of the body. The ancient surgeons racked their brains to invent names for designating bandages, and the claims of not a few of them to distinction were based almost exclusively upon such absurd and puerile pursuits. If a man was so fortunate as to devise an apparatus for expelling peccant humors, for retaining a cataplasm upon the scalp, or for supporting a diseased breast, the height of his ambition was generally amply gratified. It is to be feared that these employments have had too many imitators in modern times.

The more simple a bandage is the more likely will it be, if judiciously used, to answer the purpose for which it is intended; all complicated contrivances of this kind are objectionable on account of the difficulty of applying them, the ease with which they become deranged, and the trouble and vexation of changing them, the attempts to do so being frequently attended with serious inconvenience and pain to the patient, and perhaps great detriment to the parts affected. In general, the single-headed roller is all that can be required in almost any case; occasionally the strip-bandage, commonly known as the bandage of Scultetus, represented in fig. 151, may advantageously be employed, especially in compound fractures and dislocations. The many-

Fig. 151.

Bandage of Scultetus.

tailed bandage ought, on the contrary, to be discarded from practice, as inconvenient and useless. It consists, as the name indicates, of a number of transverse slips, of the same width but unequal length, stitched to a longitudinal portion, and was formerly much employed in cases of fracture of the leg.

Bandages are composed of various materials; generally of muslin, bleached or unbleached, of calico, or of linen, the only objection to the latter being its expense. Occasionally they are made of flannel, especially when it is desirable to protect the parts from cold, as in œdema of the extremities, and in the swelling attendant upon a gouty or rheumatic state of a joint, in persons of an unhealthy, broken constitution, who are commonly so extremely susceptible of atmospheric vicissitudes. In general, muslin will be found to answer every purpose, being both cheap and easily procured; it should be soft yet firm, smooth, strong, and not too yielding, divested of selvage and seam, and washed before it is applied. Calico is not a good mate-

rial for bandages, as it is usually too light and flimsy; I never employ it. In some cases, particularly in affections of the veins of the leg requiring

steady and equable compression, gum-elastic cloth may advantageously be used.

The length and width of a bandage are of course subject to much diversity, depending upon the shape and size of the part to which it is intended to be applied. Hence, while in one case it need hardly be half an inch in width, and not more than a foot in length, in another it may require a width of two, three, or even six inches, as in injuries of the chest, and a length of many yards. Muslin is usually torn into the requisite sized strip, whereas linen, being much stronger, is best shaped with the scissors. The ravellings being picked away, each piece is rolled into a firm cylinder, and put away for use, so that it may be ready for any emergency that may arise. The winding may be effected either by hand, the cloth being held upon the front of the thigh, or by appropriate machinery, such as is to be found in the office of every practitioner, and of which illustrations may be seen in most of the works on minor surgery. However effected, it should be done with great care, since no one can possibly apply a bandage well that has been wound in a loose and slovenly manner.

When intended to be used upon an extremity, the rule is always to begin at the distal portion of the limb, and to proceed from thence upwards some distance beyond the seat of the disease or injury. The end of the bandage being slightly unfolded is held firmly upon the part with one hand, while the

Fig. 152.

Mode of applying the roller by circular and reversed turns.

Fig. 153.

Appearance of the bandage after it has been applied.

cylinder is carried round the limb with the other, and thus the application is continued by circular and reversed turns, as they are named, until the object has been completed, the fingers being pressed upon each reverse to flatten and equalize it, as in fig. 152. If the bandage were put on spirally, it could not

maintain itself upon the limb for any length of time; but what is worse, the compression would be so unequal as to cause severe suffering, and perhaps even mortification. The application, then, must be made circularly, and care taken that each turn of the roller be reversed, so that the inner surface shall be the outer, and the upper edge the lower, the pressure being uniform throughout, or not greater at one point than at another, as in fig. 153.

The evil effects of unequal compression by the bandage are well illustrated in fig. 154, copied from John Bell's works; it also shows how important

Fig. 154.

Gangrene from strangulation of an injured limb by absurd bandaging

it is always to begin the application of the bandage at the distal extremity of a limb, and not above the wrist or ankle, as happened in the case so graphically described by the celebrated Scotch surgeon. In all cases of severe injury or disease, with a tendency to swelling and to the extension of the morbid action, due allowance must be made for the inflammatory effusions that will necessarily occur. Hence, too much care cannot be taken both in applying the bandage and in watching its effects afterwards. For want of this precaution many a limb has been destroyed, and the reputation of not a few practitioners irretrievably ruined.

Some surgeons are fond of employing the double-headed roller; but I have never had occasion to resort to it, and am satisfied that there are few cases, if any, in which it may not be advantageously replaced by the single-headed, whose application has just been described. The double-headed bandage is considered as being particularly serviceable in the treatment of wounds penetrating deep among the muscles, where it is of paramount importance to effect accurate apposition of the deep as well as of the superficial sides of the solution of continuity; but even here no indication is presented that cannot be readily fulfilled with the compress and single-headed roller. In my own practice I have certainly never been at a loss in this respect.

The bandage of Scultetus, represented in fig. 151, consists of a number of strips, generally from ten to twenty, or of pieces of an ordinary roller, of equal or unequal length and breadth, according to the intentions of the surgeon. They are arranged in such a manner as that, when applied, each succeeding one shall overlap from one-third to one-half of the preceding one, the compression being made in the same gentle, uniform

manner as in the employment of the ordinary roller. This form of bandage is peculiarly useful in the treatment of compound fractures and dislocations, in connection with which it will frequently be mentioned.

Bandages are sometimes applied wet; but in doing this much vigilance must be exercised, lest shrinking too much as they dry, they produce a

greater degree of compression than may be compatible with the comfort and safety of the parts. What is called the starched bandage, an excellent modern device, will receive particular attention in connection with the treatment of fractures of the extremities, to which it is more especially adapted. When it becomes dry, it forms a stiff, firm, immovable case, well calculated to maintain the ends of the broken bone in contact with each other. Amidon, gum-shellac, plaster of Paris, and other kindred articles may be used for the same purpose, the bandage being wet with them, and immediately applied to the affected limb.

The bandage, viewed as a therapeutic agent, has been much neglected by modern practitioners. No one who has properly used it, or who is capable of properly applying it, can, for a moment, doubt its great utility; my experience with it for the last twenty-five years amply attests this fact; still, it is necessary that we should temper our enthusiasm, and that we should not allow ourselves to be betrayed into a species of hobbyism, calculated to mislead the judgment, and to bring surgery into discredit. Employed indiscriminately, it cannot fail, in many cases, to cause serious mischief, and to be followed by chagrin and disappointment. When the hand of a master is not present to direct and guide our practice, the result may frequently be most disastrous both to the patient and the surgeon. The evil effects of bandages, in their aggregate capacity, are hardly less serious than those of mercury, the lancet, and other potent remedies; if they are, it is only because this agent is less frequently employed in practice. Numerous instances have come to my knowledge, where limbs, and even life, have been the forfeit of its injudicious use.

It is not difficult to perceive how the bandage acts in producing its salutary effects. In fractures and dislocations, as well as in large wounds, it powerfully controls muscular contraction, and at the same time prevents tumefaction, by giving tone and support to the capillary and other vessels. Its influence as a sorbefacient is evinced in the rapid abatement of the swelling which so often follows compression by the bandage in erysipelas, œdema, and various kinds of injuries; or, more strikingly still, in orchitis, when, after the subsidence of the more active disease, the testicle is strapped with adhesive plaster, which is but another form of bandage. Here in a short time, ordinarily in less than twenty-four hours, the swelling usually so far disappears as to allow the organ to slip out of its artificial case, or, at all events, to such an extent as to require renewal of the dressing. The general effect of the bandage would thus seem to be somewhat similar to that of mercury, controlling capillary action, and promoting the absorption of effused fluids; but it has the additional advantage, and no trifling one it is, that it supports the muscles and prevents spasm, as is so remarkably evinced in fractures and in the stump after amputation.

Of the extent to which bandaging may be carried, a good idea may be formed from the frequent allusion that will be made to it in different parts of this work; it will suffice here to observe that it is applicable, as a general rule, to the treatment of all classes of wounds, from the most simple to the most severe, to fractures and dislocations, ulcers, abscesses, erysipelas, whitlow, orchitis, chronic inflammation of the superficial veins, and to nearly all affections of the limbs in which there is an effusion of serum, or serum and plastic matter.

CHAPTER XIV.

OPERATIVE SURGERY.

OPERATIVE surgery has too often been regarded as an opprobrium of the healing art. This opinion, as foolish as it is unfounded, is not peculiar to the public, who, in matters of this kind, are generally but poor judges, but has frequently been advanced even by medical men. That this department of surgery is often abused cannot be doubted; but does it thence follow that it is a disgrace to the profession and an injury to the community? Such a view would be absurd, because it would be utterly irreconcilable with the dictates of common sense and the results of daily experience. As long as the human body is liable to accidents, and as long as nature is incapable of arresting, by her own efforts, the various morbid processes which she herself institutes, so long will practitioners be compelled to invoke the aid, and, I may add, the blessings, of operative surgery. Is it a disgrace to amputate a leg for a mortification of the foot, to extirpate a testicle that has been destroyed by cystic disease, to divide the stricture in strangulation of the bowel, to extract a stone from the bladder, to depress a cataract, or to trephine the skull in a punctured fracture? Surely, no one will doubt that in these, and a hundred other instances, our object can be attained only by an operation. Medicine, under such circumstances, however judiciously administered, is not only utterly futile, but is always ready to avail itself of the aid of surgery. Its empire is temporarily suspended, and it only resumes its legitimate functions after the use of the knife. It is true beyond doubt, and it is fortunate that it is so, that, in the hands of judicious and enlightened practitioners, a resort to instruments is much less frequent now than it was even ten years ago; many limbs which would formerly have been subjected to amputation are now easily saved, and many diseases which were once regarded as utterly hopeless now readily yield under the influence of our therapeutic efforts.

Operative surgery is progressive; it has done a vast deal, but a vast deal remains yet to be accomplished. If it has emerged out of chaos into order, and out of darkness into light; if it has laid aside its farrago of instruments, and its fondness for blood; if, in a word, it has assumed the fair and stately proportions of a science, it owes it to itself to perfect itself in the greatest possible degree, as well as in the shortest possible time, in order that it may be still more entitled to the respect and admiration of the profession, and the gratitude of the public. It is only a disgrace when it is practised for base and selfish ends; not when it interposes its resources for the purpose of removing disease and averting death.

Qualifications of a Surgeon.—The performance of operations presupposes the possession of certain qualities on the part of the surgeon. It is not every man that can become an operator, even presuming that he has the requisite knowledge of anatomy and of the use of instruments. Courage, which is so indispensable, is possessed by comparatively few; the sight of blood, and the idea of inflicting pain were so disagreeable to Haller, that, although he taught surgery with great success for seventeen years, he never, it seems,

during all that time, performed a solitary operation upon the living subject. Courage, like poetry, has often been said to be a gift of nature, and nothing is, perhaps, more true; but it is equally certain that a timid man may, by attention to his education, and by constant practice, become, in the end, a good operator. Habit does a vast deal for us in such cases, for it literally becomes a second nature. I recollect a man, who in his youth nearly fainted at the sight of blood as it flowed from a vein of the arm into the basin, which it devolved upon him to hold during the operation of venesection, and yet who, by a course of self-training and a complete knowledge of anatomy, has made himself a thorough master of the knife. Celsus, long ago, happily defined the qualities which constitute a good operator. He should possess, says the illustrious Roman, a firm and steady hand, a keen eye, and the most unflinching courage, which can disregard alike the sight of blood and the cries of the patient.

But the above are not the only qualities, important though they be, which should be possessed by an operator. If he is not honest in his purposes, or scrupulously determined, in every case, to act only with an eye single to the benefit of his patient, and the glory of his profession, he is not worthy of the name which he bears, or fit for the discharge of the solemn duties which he assumes. In a word, such an operator is not to be trusted, for he will be certain, whenever opportunity offers, to employ the knife rather for the temporary eclat which may follow its use, than for the good of the individual whom he unnecessarily tortures. He will not hesitate to amputate a limb, although the patient should die the moment he is removed from the table, or to tie the carotid arteries for a malignant disease of the eye, although he knows full well that such a procedure never has, in any instance, been of the slightest benefit. Such men, of whom there are, even yet, unfortunately, too many in our profession, deserve the name of knivesman and knaves rather than of surgeons and honest men. No operation should ever be undertaken without due deliberation, and without a careful consideration of the various consequences involved in the result. Everything that is done should be done with reference exclusively to the patient; self should not have the slightest weight in the matter. The question, in every case, should be, is an operation necessary to save life, or to place the individual in a condition calculated to promote and insure his recovery? If this can be answered affirmatively, the operation should by all means be proceeded with; but if it be ascertained, clearly and satisfactorily, that it presents no such prospect, both humanity and common sense dictate the propriety of declining it. It is a sad and humiliating spectacle to see a surgeon cut off a limb, or remove a cancerous tumor, merely for the sake of having it said that he performed an operation. I am daily shocked by the reports of cases of the extirpation of malignant growths in the hospital as well as in the private practice of this and other countries. The question may well be asked, when will such silly and unmeaning, or, to use the proper expression, criminal procedures cease to disgrace our profession and to shock our sensibilities?

Every surgeon who wishes to make himself a skilful operator should have a most thorough knowledge of anatomy. His acquaintance with the healthy structures and their relations with each other should be so clear and distinct that he should be able to see them as it were in a mirror, or with his eyes shut. He should carefully study their color and consistence, that, seeing and feeling them, he may readily distinguish them from each other, and not be obliged to ask his assistants whether this is an artery, that a nerve, or this a tendon, a muscle, or a ligament. Nor should he limit himself merely to the study of healthy and relative anatomy. He should also have an intimate and comprehensive knowledge of morbid anatomy, or of the changes which are impressed upon the organs and tissues by disease and accident, and also

of the various growths, formations, and deposits. The information thus derived will be of the greatest aid in facilitating the different steps of the operation, and enabling the surgeon to determine what to remove and what to spare.

No man can become an accomplished operator unless he practises constantly on the dead subject. Dexterity, grace, and elegance are to be acquired only by long and patient exercise. From what I have seen of our students, they are lamentably deficient in the use of the knife. Many of them, indeed, engage in the active duties of their profession without ever having performed a solitary operation on the cadaver, and hence it is not surprising that failure and disgrace should so often attend their early trials on the living subject. There should be, as I publicly declared more than twenty years ago, in every medical school a demonstrator of the operations of surgery, whose duty it should be to perform, in the presence of his pupils, all the operations on the dead body which it is ever necessary to perform on the living. Such exercises could not be too frequently repeated by the teacher, or too often performed by the student. In all operations involving unusual anatomical complexity, a good plan is to make a thorough dissection of the parts immediately beforehand. Langenbeck and Lisfranc always adopted this method, and I have often profited by it in my own practice.

Preparation of the Patient.—No operation, unless it be of the most trivial nature, should ever be attempted without due preparation of the patient's system. The only exception to this rule is in case of emergency, where, in order to save life, we are obliged to act on the instant, without any precaution of this kind, and sometimes even without the necessary assistants. The character and amount of the preliminary treatment must, of course, vary in different cases and under different circumstances, and do not, therefore, admit of precise specification. It may be stated, in general terms, that, if the patient be unusually plethoric and in the vigor of life, he should be bled at the arm, until he begins plainly to feel the effects of the loss, when the flow should be arrested. In opposite states of the system, however, such a procedure will not only be unnecessary, but might even be prejudicial. In all instances it is well to take into the account the probable loss of blood that will take place during the operation. If this is likely to be considerable, all preliminary abstraction must be carefully refrained from, even in healthy, robust subjects; for there can be no doubt whatever that a copious, or even a considerable, loss of blood before, during, or immediately after an operation, has a marked tendency, in many cases, to retard recovery, and to dispose to the occurrence of erysipelas, pyemia, tetanus, and other ill effects. Indeed, so thoroughly am I convinced of the truth of this remark, that I feel as if it could not be urged too frequently, or too forcibly, upon the mind of the practitioner. It was formerly thought that a certain amount of hemorrhage, under such circumstances, would not only do no harm, but that it would positively be beneficial, by rendering the system less liable to inflammation. Modern experience, however, has shown that such an opinion is utterly untenable.

It would be difficult to conceive of any case, about to be subjected to the knife, in which *purgatives* are not indicated, or in which, if they are not positively indicated, their exhibition would not be eminently beneficial. These remedies not only clear out the bowels, but they often exert a most salutary influence in modifying and restoring the secretions of the liver and mucous follicles, and it is just as much of a rule with me to prescribe them before my operations as it is to attend to the patient's diet. The best articles for this purpose are blue mass and colocynth, or calomel and rhubarb, either alone, or in union with a small quantity of ipecacuanha or tartar emetic. The

latter substances are especially valuable when there is much disorder of the secretions, with headache and loss of appetite. Occasionally nothing answers better than, or hardly as well as, a dose of castor oil, Epsom salts, or citrate of magnesia. Independently of their direct cathartic effect, purgatives are often extremely useful in clearing out the bowels, where, as for example in lithotomy and in anal fistule, it is desirable to prevent any action upon them for several days after the operation.

A proper regulation of the *diet* is generally regarded, and very justly so, as of paramount importance. The extent to which this should be carried must, of course, depend upon the circumstances of each particular case; but, as a general rule, it should not, on the one hand, be too rigid or protracted, and, on the other, not too abundant. Much of the success of an operation is often directly traceable to the attention which is bestowed upon this subject. In most instances it will be advisable to enjoin entire abstinence from meat and the coarser kinds of vegetables, coffee and strong tea, hot biscuit, pastry, condiments, and, in short, all articles of an indigestible and heating nature. The quantity of food taken in the twenty-four hours should also be less than ordinary, for nearly, if not quite, as much harm may result from an undue amount of mild and unstimulant food as from the moderate use of the more solid and substantial articles.

Instead of dieting and purging the patient, it may be necessary to feed and stimulate him before it is safe to use the knife. He may be exhausted, deficient in nerve-power, or pale and anemic, requiring a rich, concentrated animal or animo-vegetable diet, milk, brandy, ale or porter, and, perhaps, quinine and iron, especially the tincture of the chloride.

Finally, attention should be paid to the state of the *body* and mind. For some days or even weeks, the most perfect quietude should be observed, especially if the operation is at all likely to be of a serious character. If, for example, the object is to extract a foreign substance from the knee-joint, or to perform an operation for the radical cure of varicose enlargement of the veins of the leg, it is hardly possible to use too much caution in this respect. In such cases the patient should not only refrain from exercise, but he should remain recumbent for several weeks, with the limb in an elevated position. In general, however, the restraint need not be carried to such an extent, a few days' confinement to the house being quite sufficient for the purpose.

The patient's *mind* should always be in as tranquil a state as possible. All business cares should be laid aside, and no outward troubles of any kind should be permitted to obtrude themselves during this probationary period. He should indulge in no unpleasant forebodings concerning the result of the operation, or, if this be inevitable, the surgeon should exert himself to the utmost to assuage and mitigate them by proper explanations. In a word, it is his duty, in all cases, to encourage the timid and console the desponding by every means in his power. A surgeon who neglects his duty in this respect is unfit to be intrusted with the lives of his fellow-beings. Many of our patients are from abroad, away from home and friends, and therefore peculiarly in need of sympathy.

I have never put off an operation on account of the particular *season* of the year. When it is recollected that the gravest accidents, requiring amputation, occur every hour of the day, and every day of the year, such a precaution would seem to be entirely at variance with common sense, if not wholly useless. I should certainly, however, not advise the undertaking of any serious operation in extremely hot weather, if it were possible to postpone it without detriment to my patient. The same objection, however, does not lie against very cold weather, inasmuch as a good fire and a properly regulated temperature of the apartment can generally be obtained, without much trouble, even in midwinter and in the most rigorous climate.

No operation, even of the most trivial nature, should be performed during the prevalence of an *epidemic*. This remark is particularly applicable to erysipelas, which, under such circumstances, is almost sure to ingraft itself upon the wound, much to the detriment both of the part and system. During an epidemic of this kind in Kentucky in 1845, '46, and '47, the slightest abrasion of the skin, a leech-bite, and the application of a blister, were often followed by an obstinate, and sometimes even a fatal, attack of the disease; and the consequence was that I was compelled, for many months, to decline the use of the knife nearly altogether.

Age is, as a general rule, no barrier to an operation. Even infants at the breast have occasionally undergone the operation of lithotomy, and in certain congenital affections, as occlusion of the anus and urethra, the knife is obliged to be used almost immediately after birth. I am, however, as will be stated in its proper place, no advocate for very early interference in harelip; and I should say that it was best, as a general rule, to put off all severe operations in infants as long as possible, for it cannot be denied that they bear the shock and loss of blood, consequent upon such undertakings, much worse than persons of riper years and more developed constitutions. Very old people often bear operations remarkably well, and recover from their effects with surprising facility. Pregnancy should always be considered as a bar to the use of the knife, except in those cases in which it is imperatively demanded to save life. Even the extraction of a tooth is occasionally followed by abortion or miscarriage, from the perturbing influence which it exerts upon the system.

The *habits* of our patients should not be disregarded in considering the question as to the propriety or impropriety of operative interference, for there can be no doubt that they frequently materially influence the result. Intemperance of every description, especially if long continued, always modifies the constitution, and renders it less able, as a general rule, to bear the shock and subsequent effects of the operation than in ordinary cases. In habitual drunkards mania à potu, erysipelas, and unhealthy suppuration are of frequent occurrence after the use of the knife. Huge feeders, or persons who are fond of the pleasures of the table, and who take little exercise in the open air, are scarcely less exempt from these affections. Inordinate sexual indulgence, the habitual loss of blood, and debility from previous suffering, often place the life of the patient in danger after a severe operation. Fat persons, and individuals of a doughy, inelastic constitution, do not bear the knife so well as the fleshy and more robust. The same is true, and in a still greater degree, of strumous people. Nervous, hysterical females are bad subjects for some operations. Hospital patients, especially in the larger cities, do not, as a general rule, possess the same tolerance of the knife as private patients.

Should females be subjected to operations during the *menstrual* period, or just before its occurrence? Of the impropriety of such a course there can, as a general rule, be no doubt, yet there may be exceptions even here. Certainly no sensible surgeon would extract a cataract at such a time, or remove a diseased mamma, or, in short, perform any serious operation, if it could possibly be postponed. But, on the other hand, daily observation teaches us that women who are badly hurt during the menstrual period often make most excellent recoveries. Hence, I should deem it perfectly proper to perform at least any of the minor operations at this time, and, in fact, almost any other where delay might prove prejudicial.

There are certain *diseases*, even some which are not of a malignant character, in which surgical interference is wholly inadmissible, either for the time being, or altogether. I allude to those cases in which the malady demanding operation is complicated with other affections. Thus, in anal

fistule, associated with tubercular phthisis, no surgeon, who has any consideration for his patient, or any respect for the art and science which he professes, would think of using the knife. The anal disease, in such a case, may be regarded as nature's issue, the drying up of which would only be surely followed by an aggravation of the pulmonary symptoms. In stone of the bladder no one operates when there is serious organic disease of the kidneys, or even of the bladder itself. Amputation of a limb is never performed, except in case of accident, when there is an aneurism of the heart; nor is the femoral artery ever tied for popliteal aneurism when a similar affection exists in the arch of the aorta. In all malignant maladies, except the epithelial forms, a resort to the knife is of questionable propriety, even in their earlier stages, and before there is the slightest evidence of the carcinomatous cachexia.

Indiscriminate operations cannot be too much condemned, as they are injurious alike to the patient, the reputation of the surgeon, and the true interests of science. Like a prudent general, the surgeon should know when to retreat as well as when to advance. It is difficult to conceive of anything more laudable than a bold undertaking in a case which must prove fatal without speedy relief. At the same time, it would certainly indicate a degree of weakness, if not of absolute wickedness, to attempt an operation when there is not the slightest prospect of benefit.

There is a class of operations to which the French writers have applied the term *complaisance*, that is, operations of expediency, not of necessity. An individual, for example, has an infirmity, as a distorted foot, or a contracted finger, which is a source rather of annoyance than of suffering or even positive inconvenience; his pride is piqued, and, as a consequence, his mind is incessantly disturbed by it, so much so, perhaps, as to be wholly disqualified for business and social enjoyment. Such persons often importune the surgeon's aid, and it therefore becomes a nice question how he should govern himself in regard to them. Shall he advise an operation, and run the risk of killing his patient, or shall he refrain, and persuade him to bear his cross, for such it actually is? There can, I think, in general, be very little difficulty in arriving at a proper conclusion in such a state of things. For myself, I can see no difference between the physical suffering that is induced by a diseased bone and the mental distress that results from a deformed foot; as far as their effect upon the comfort and happiness of the individual is concerned they are precisely on the same level, and hence, if it be right and lawful to amputate in the one case, why should it not be in the other? If a young man has a varicocoele, even of moderate size, and it completely destroys his happiness and usefulness, not by its physical but by its mental effects, is it not our solemn duty to attempt relief by an operation, although the attempt should jeopard his life? I must confess, I should not hesitate as to the line of conduct to be pursued under the circumstances; at the same time, however, I should not omit to warn my patient of the risk he would be likely to run, and if, after a thorough explanation of the whole matter, he should still persist in his desire to be operated on, I should use every possible precaution, by a course of diet, purgatives, and rest, to put his system in the best possible condition for sustaining the shock of the approaching ordeal. Operations involving the same principle, though not the same risk, are of daily occurrence, and few surgeons hesitate to perform them; I allude to the division of tendons in club-foot and strabismus, the extraction of the crystalline lens in cataract of one eye, when the other eye is sound, and other analogous affections.

Assistants.—There are but few operations which a surgeon can perform alone; in general, he is obliged to have assistants, and the number of these

must necessarily vary in different cases and under different circumstances. Sometimes only one is required; at other times two, three, four, or even half a dozen will hardly suffice. The more simple an operation the less aid will commonly be necessary. In lithotomy an assistant holds the staff, two others support each a leg, one administers chloroform, another takes charge of the patient's hands, and a sixth presents the surgeon his instruments. In depressing a cataract, the operator usually requires only one assistant, to support the head and upper eyelid. Operations on children, especially when we are not permitted to employ anæsthetics, are often peculiarly embarrassing, and demand an unusual amount of aid for their successful execution.

The beauty, elegance, and rapidity, nay, even the success of an operation, are often marred by the awkwardness of the assistants. To act well their part, they should be thoroughly acquainted with the different steps of the operation which is about to be performed, as well as with the nature and relations of the structures involved in it, so as to be able to anticipate every thought and wish of the principal. It is not necessary that they should be compelled, like so many Thespians, to rehearse the part which they are expected to play in the approaching task; but we should see that they are properly instructed in their business, and that they all perfectly understand their duty, which should always be carefully explained and assigned beforehand. Nothing can be more awkward for a surgeon than to stop in the midst of an operation to ask for a knife, sponge, or ligature; once begun, everything should proceed with the utmost regularity, and without the slightest interruption from any cause. Good, well-trained assistants are, unfortunately, not always to be obtained; the older members of the profession are too much occupied, or too jealous of each other, to afford their services, and the younger are too often ignorant of the duties required of them.

Duty of the Surgeon.—When the surgeon has a perfect control of his time, as he almost always has, except in cases of emergency, he generally selects a particular hour for performing the operation. The best period of the day, at least in this country, is from 11 to 2 o'clock, as he will then have a good light, and also be in a better trim for the discharge of his duty. An operation, especially an important one, should never be performed late in the afternoon, or in cloudy weather; for, should hemorrhage arise, he might be sadly puzzled in his attempts to arrest it, on account of the want of a good light, which is so indispensable on such occasions.

At the hour specified for the operation everything should be in its place; the assistants should attend with military punctuality; the table should be properly prepared; the chloroform, ammonia, and brandy, instruments, ligatures, sponges, water, and napkins, should all be at the precise spot where they are required; in short, nothing should be wanting, but everything be at hand, and arranged in the most perfect order. I have heard of a surgeon, engaged in an amputation, make his flaps, and ask for his saw, which had been left in an adjoining room! On one occasion a lithotomist performed the lateral section, and was about to introduce the forceps to extract the stone, when, lo and behold, the instrument had not been put on the tray! Such blunders might create a smile, if they did not sometimes involve serious consequences. It need hardly be added that all these preparations should be made in an adjoining room, away from the patient; it is enough for him to know that he is about to suffer, without seeing the instruments of his torture deliberately spread out, one after another, before his eyes.

Of the precise time, as to the day and hour, of the operation, the patient should usually be kept in ignorance, as the information, if made, could hardly fail to exert a perturbing, and, consequently, a prejudicial influence upon the mind, and, through it, upon the general system. It is only in the milder cases that this intelligence should be communicated. There is, however

much difference in this respect in different individuals, for, while some would shrink from the disclosure, and be, perhaps, seriously affected by it, others will not only be indifferent to, but absolutely court it.

Position of the Patient and Surgeon.—The position of the patient, the surgeon, and the assistants must vary, of course, in different cases, and can be discussed here only in a general manner. When chloroform is to be given, absolute recumbency is required, to guard not only against delay, but also against the occurrence of serious mishaps. But, apart from this consideration, the horizontal posture should always be preferred whenever the operation is likely to be protracted, or attended with much shock and loss of blood. In other cases, again, as in lithotomy, the operation cannot be performed in any other position than in the recumbent. In amputating the thigh and leg, as well, indeed, as the arm and forearm, the patient always lies down, not only on account of apprehended weakness, but because it is always easier, when he is thus placed, to hold the limb and control hemorrhage. In lacerating a cataract, the patient generally sits in a chair, with his head supported upon the breast of an assistant; in operating on hare-lip, the child usually sits upon an assistant's lap, the head being firmly held by another assistant, standing behind or by the side of the first. In lithotomy, the patient lies on his back with the breech reaching over the edge of the table, two assistants support the legs, another holds the staff, a fourth takes charge of the sponges, and a fifth administers chloroform, while the surgeon sits on a low stool in front of the perineum, or, as I usually prefer, rests on one of his knees. Now that anæsthetic agents are so much in vogue, it is seldom that we are obliged to tie our patients, or to roll them up in sheets or aprons, as was the custom prior to the discovery of these most useful remedies.

OPERATION.—Everything being thus prepared—the assistants being at their posts, the instruments arranged upon a tray in the order in which they are likely to be required, the parts divested of hair and dressings, and the patient fully under the influence of chloroform—the operation is proceeded with, slowly, deliberately, and in the most orderly, quiet, and dignified manner. All display, as such, is studiously avoided; ever remembering, in the language of Desault, that the simplicity of an operation is the measure of its perfection. No talking or whispering should be permitted on the part of the assistants, and as to laughter, nothing could be in worse taste, or more deserving of rebuke. Every important operation should be looked upon as a solemn undertaking, which may be followed in an instant by the death of a human being, whose life, on such an occasion, is often literally suspended by a thread, which the most trivial accident may serve to snap asunder.

The time occupied in performing an operation is a matter of some moment, but not as much, perhaps, as is commonly supposed. When a patient is unconscious, whether from cerebral oppression, or from the use of an anæsthetic agent, it is of very little consequence, other things being equal, whether the operation lasts five minutes or ten minutes, provided it is well executed, which it certainly cannot always be when we aim at great speed. Le Cat, it is said, lithotomized half a dozen patients in nearly twice as many minutes, and the result was that he lost nearly every one. Prior to the application of chloroform to the relief of suffering, rapidity was most commendable, inasmuch as it served to prevent shock and pain, though I firmly believe that it was often secured at the expense of much subsequent mischief, if not immediate detriment. The maxim of the schools has always been *cito, tuto et jucunde*; but, as it respects the first of these injunctions, it may be added, in the language of Cato, *sat cito si sat bene*.

Accidents during Operation.—The next topics to be considered are the accidents which are liable to take place during the operation, and the best

methods of avoiding or meeting them. These are, first, hemorrhage, and secondly shock.

The amount of blood lost during an operation may be very small when measured by ounces, but very large in relation to its effects upon the system. Much will depend, in every case, upon the state of the constitution, and the temperament, habits, and health of the patient. A hemorrhage which may affect one individual very slightly, if, indeed, at all, may affect another most seriously and even fatally. A good deal, again, will depend upon mere idiosyncrasy, and upon the presence or absence of epidemic disease, which, as has already been intimated, generally impresses itself, to a greater or less extent, upon every individual in the community in which such disease prevails. Anything like a copious loss of blood is, as before stated, a great evil, and should, therefore, always, if possible, be prevented. I cannot agree with those who think that the loss of twelve, sixteen, or twenty ounces will be likely to be beneficial, even when there is unusual vigor of constitution. If there be any undue vascular repletion, it can always be relieved, if the necessity for it arises, after the operation is over. In all cases, therefore, I deem it to be our duty to guard against hemorrhage as much as possible.

It is not necessary, nor even proper, to tie every vessel as fast as it is divided. A well-trained assistant will generally obviate this necessity by compressing the bleeding orifice the moment the knife has swept beyond it, and by the proper exercise of this dexterity a large tumor may often be removed before a single ligature is applied. Should the bleeding, however, not be controllable by this means, measures must be adopted to arrest it without delay by ligating the principal vessels from which it proceeds.

It is seldom, at the present day, that a patient sustains anything like a serious shock from an operation, even if it be comparatively severe and protracted. The use of anæsthetics, if it do not always effectually prevent, generally restricts it within the limits of tolerance, and thus saves the surgeon a vast amount of trouble and anxiety. It is not, however, to be forgotten that the very means which are employed to prevent pain and shock may themselves induce severe, if not fatal, prostration. Hence, as will be seen by and by, too much caution cannot be used in their administration; the effects of the remedy should be most carefully watched throughout, so that any symptom denotive of danger may be instantly recognized and counteracted. By keeping the patient perfectly recumbent, and providing for the free admission of air into the lungs, all mischief may, in general, be happily avoided. The syncope, caused by the loss of blood, is met by a depressed position of the head, by means of the fan, by dashing cold water upon the face and chest, by holding smelling-bottles *near*, not to the nose, and, in severe and alarming cases, by sinapisms to the extremities, spine, and præcordial region, aided, if necessary, by the use of stimulating injections, as brandy, turpentine, ammonia, or mustard.

Dressings and After-treatment.—The operation being over, the next thing to be done is to adjust the dressings; these should always be as light as possible, and applied in such a manner as to insure the greatest chance for union by the first intention. The question has been much agitated, of late years, whether the dressings should be applied at once, the moment the knife has accomplished its object, or whether the parts should be permitted to remain free for several hours, to afford them an opportunity of contracting and becoming glazed with plastic matter. Much might be said in favor of both methods. The proper rule of practice, I think, is to steer a middle course, adopting neither plan exclusively. In large wounds, as those, for example, left in amputation of the thigh, leg, or arm, and in the extirpation of large tumors, the best plan always is to keep the parts open for three, four, or five hours, or until all oozing has ceased, and the raw surface has become in-

crusted with plastic matter, a light and porous napkin, properly folded and frequently wrung out of cold water, being kept constantly applied to promote these occurrences. If, under such circumstances, approximation be effected immediately after the operation, the surgeon will often be compelled, a short time afterwards, even when he has taken the greatest possible care to secure the vessels, to remove his dressings, in order to arrest the flow of blood; a procedure which is generally not less painful and alarming to the patient than disagreeable and vexatious to the attendant. If, on the other hand, the wound be small, the best plan, I conceive, is to bring the edges together at once, as this saves both time and anxiety.

The dressing being applied, the patient is carried into his bed, previously prepared for his accommodation, and placed in such a position as will best promote his comfort and the reunion of the divided parts. Feathers and heavy quilts are to be carefully avoided; and, in general, it will be well, especially if there is a probability of there being much discharge, whether of blood, secretion, or excretion, to protect the bedding with a piece of thin, soft oil-cloth, spread beneath a folded, movable sheet. The affected parts are placed in an elevated and relaxed position, and maintained, throughout, in a cool, comfortable state. The diet must be light and unirritant, the drink cooling and palatable, and the temperature of the apartment from sixty-five to seventy-five degrees of Fahrenheit. All unnecessary conversation should be avoided; and no persons, except the nurse and the immediate friends of the patient, should be permitted to enter the room during the first twenty-four hours after the operation, or, in cases of great danger and severity, not until a much longer time.

When the operation is at all severe, my invariable rule is to administer a full dose of morphia immediately after it is over, or even sometimes an hour or two before it is commenced. The object is not only to allay pain, which is always a great desideratum, but to induce sleep and tranquillity of the system; in other words, to put the part, body and mind, all in a state of absolute repose for at least the first twenty-four hours after the use of the knife. By a full dose of morphia, I mean not less than one grain; a smaller quantity than this would only serve to fret and worry the patient, instead of composing him. In cases of unusual severity, I do not hesitate to give twice that quantity, never forgetting that excessive suffering always establishes a certain amount of tolerance to the use of anodynes.

Too much attention cannot be bestowed upon the patient's diet. If the operation has been at all severe, or attended with unusual shock and loss of blood, he must be fed, not starved, in order to enable the system to reinstate itself as promptly as possible into its former condition, by the manufacture of blood and nervous fluid, both, perhaps, frightfully expended during the previous contest, and now in danger of being still further exhausted by the traumatic fever and the tumultuous action of the heart. The vessels must be replenished; the brain and spinal cord supported. The most suitable articles for this purpose are milk and stale bread, with the free use of brandy, followed, in a day or two, by animal broths, beef essence, rich soups, and the lighter kinds of meats. Sub-acid fruits will also generally prove both grateful and nourishing. The drinks should consist of ice water, either pure or acidulated, as may be most agreeable to the patient. A cup of tea is often exceedingly soothing and refreshing soon after a severe operation. Starvation after severe shock and loss of blood is often followed by the worst consequences, from the tendency which the system has to run into erysipelas, pyemia, and hectic fever, to say nothing of its incompatibility with the adhesive process.

But patients must not be fed indiscriminately after operations; when the individual is young and robust, perfectly temperate in his habits, and, above

all, when he has not suffered severely from shock or loss of blood, his diet should be restricted and be of the blandest character for a number of days, or, in fact, until the wound left by the knife is in great measure healed. Improper indulgence, under such circumstances, cannot fail to light up a fire which hardly anything afterwards may be able to extinguish.

Attention to the temperature of the patient's apartment is often a matter of great moment; in general, it will be best to regulate it by the thermometer, especially in operations on the respiratory organs, and after the extirpation of ovarian tumors. Everything like a direct draught must be carefully avoided, and in wet weather it will be a good plan to shut the windows.

Some of the above precepts may seem trivial; but I am sure that they are of the greatest importance, and that the want of their observance is often followed by the worst consequences. It is a much easier matter to talk a patient to death, or to retard his recovery, after he has undergone a severe operation, or sustained a violent injury, than most people imagine. Should symptomatic fever arise, or should the parts exhibit evidence of over-action, prompt recourse must be had to the usual antiphlogistic remedies, employed in a decided yet cautious manner, lest they produce harm instead of good.

The after-treatment should always, if possible, be superintended by the surgeon himself; his duty is not over with the operation; it ceases only with the cure or death of his patient. "The practice," remarks an eminent authority, "of performing a serious operation, and leaving the after-treatment to others, has, in my knowledge, repeatedly proved disastrous. The medical treatment, a duty not less responsible than the operative, belongs to the surgeon; and, indeed, to be employed merely as a handicraftsman, conveys an imputation at which the dignity of a scientific mind revolts."

Sources of Danger after Operations.—The great sources of danger, after a severe operation, are, first, excessive depression of the system from shock and loss of blood; secondly, traumatic fever; thirdly, undue inflammation of the parts; fourthly, secondary hemorrhage; fifthly, erysipelas; sixthly, pyemia; seventhly, tetanus; and, lastly, constitutional irritation.

a. The *prostration*, consequent upon an operation, is usually denoted by great pallor of the countenance, feebleness of the pulse and respiration, coldness of the extremities, yawning and sighing, partial blindness, dizziness, noises in the ears, restlessness, thirst, nausea, and even vomiting. To meet these symptoms, all that is necessary, in general, is to place the patient recumbent, to use heat, friction, and sinapisms, to allow a free access of air, and to administer stimulants, as brandy, or brandy and ammonia, by the mouth, if the power of deglutition still remains, or, if not, by the rectum, in the form of enemata. A full anodyne will usually form a most valuable adjunct to these remedies, and should seldom, if ever, be omitted. Great care, however, must be observed in the management of these cases, lest violent reaction follow the depression, and hurry the patient on to a fatal termination. It is only in instances of extreme prostration that stimulants should be given boldly and freely, and without any regard to future consequences in respect to the parts involved in the operation.

b. More or less *fever* must almost necessarily follow every severe operation, offering thus an additional source of suffering and danger to the patient, and of anxiety to the surgeon. To this disease the term traumatic is usually applied; the older writers called it bed or wound fever, and Dr. Simpson has recently given a most excellent account of it under the name of surgical fever.

It generally begins within the first six or eight hours after the operation, and is characterized by a flushed appearance of the face, a frequent, quick and irritable state of the pulse, dryness of the skin, restlessness, and thirst, which is often excessive, especially after profuse losses of blood. In some

cases there is extreme jactitation, with nausea, if not actual vomiting, and a tendency to delirium, or a confused and bewildered condition of the intellect. The breathing is generally somewhat hurried, and slight mucous râles are often present. The appetite is impaired or entirely wanting, the bowels are constipated, and the urine is scanty, high-colored, and often offensive, being surcharged with saline matters and occasionally even slightly albuminous. Now and then the disease is ushered in by distinct rigors. After the fever has continued for some time a tendency to remit appears; the heat, thirst, and restlessness diminish, the pulse descends, the gastric distress vanishes, and the skin becomes covered with a gentle moisture, which often increases to profuse perspiration.

The duration of traumatic fever varies from a few hours to a number of days. In the milder cases, it is generally very evanescent, while in the more severe it is often quite protracted, and is then usually attended with regular vesperal, if not also matinal, exacerbations. Not unfrequently the disease disappears entirely for a few days, and then recurs, with more or less violence, the attack being provoked either by some dietetic or other indiscretion on the part of the patient, or by some change of the system, as the arrest of an important secretion, or the commencement of blood-poisoning.

The causes of surgical fever are sufficiently obvious. Every operation of the slightest severity acts as a disturbing agent, depressing the vital powers, and deranging, as a direct and inevitable consequence, all the secretions. We have familiar illustrations of these occurrences in daily practice, in the lancing of boils, the extraction of teeth, and in the operation of bleeding. The least shock, however induced, is sure to be followed by more or less general disorder, and it is hardly necessary to state that the amount of this disorder is always materially augmented when, in addition to the nervous lesion, there has been considerable loss of blood. Nothing so rapidly, or so powerfully, irritates and frets the vascular and nervous systems as these two circumstances. The heart evinces its suffering first, by the feebleness and irregularity, and, after the occurrence of reaction, by the frequency and rapidity of its contractions. The nausea and vomiting, the excessive prostration, the yawning, and confusion of intellect, not to mention other symptoms, are unmistakable signs of the shock, or loss of power, sustained by the great nervous centres. The use of anæsthetics, doubtless, often contributes to the production of traumatic fever, by the disturbance which it occasions in the general system.

Now, if we take all these circumstances into view, and the fact that thousands of patients are subjected to operations without due preparation of the system, or, indeed, any preparation at all, as in cases of primary amputations, trephining, and the ligation of the larger arteries for the arrest of hemorrhage in gunshot and other wounds, it is certainly not necessary to invoke the agency of blood-poisoning, as is of late so frequently done, to account for the occurrence of traumatic fever. These causes are all sufficient to create the most violent disturbance; or, in other words, to set the whole system in a perfect state of ferment, overturning all its functions, and thus occasioning an amount of reaction capable of destroying life in a few hours, or, at all events, in a few days. While this perturbation is progressing, other and still more serious consequences may ensue, as erysipelas, pyæmia, and effusions into the splanchnic cavities, the result of disordered secretion, and of the retention of hurtful matter, eventuating in a diseased state of the blood, and in a predisposition to local inflammation in parts more or less remote from the seat of the original injury. The constitutional derangement will, of course, be materially increased if, in addition to these disturbing agencies, there is an absorption or ingress of foul pus into the system, constituting toxæmia, or blood-poisoning.

The danger in traumatic fever is often very great, and it is, therefore, impossible to watch the patient too attentively. The risk will be particularly imminent if the disease is very violent, or the system was much prostrated prior to the operation. The danger will then be twofold; first, from constitutional irritation and fatigue of the heart, leading to paralysis of its fibres; and, secondly, from internal congestion and local inflammation.

The proper remedies are cooling drinks, taken in moderation, or ice, if there be nausea, or gastric oppression; sponging the surface with cool or tepid water; mild laxatives; and the neutral mixture, or camphor water, with a minute quantity of antimony and morphia, to promote diaphoresis. If the symptoms are disposed to continue, more active measures may be required, especially purgatives, assisted, perhaps, by a few grains of calomel, particularly when there is marked disorder of the secretions. The lancet is seldom, if ever, to be brought into requisition in any case. Leeching, cupping, and blistering may be necessary when there is congestion, or threatened inflammation of important internal organs. Local remedies must, of course, not be neglected. If the fever be obstinate, quinine will be indicated, combined, if there be profuse sweat with a tendency to hectic, with iron and elixir of vitriol. Great attention is paid to cleanliness and ventilation.

This febrile commotion of the system is sometimes very deceptive, exhibiting an appearance of great violence, when in reality it is most slight, promptly yielding to the most simple remedies, or subsiding of its own accord. It resembles a sudden and violent storm, quite alarming, but altogether transient and harmless.

c. The resulting *inflammation* will rarely exceed the adhesive limits, if proper care has been taken to prepare the patient for the operation, and the parts have not been too roughly handled during its performance. But prevention is not always possible, and hence the wound should be diligently watched, lest it be assailed, and even overwhelmed before the patient and his attendant are aware of the fact; for it should be remembered that the morbid action is not always characterized, under such circumstances, by the usual symptoms; there may even be an entire absence of pain and tension, perhaps even of discharge. Great vigilance, therefore, is often necessary to detect the earliest inroads of the disease, and to counteract its progress. Of course, all officious interference is avoided, and nature is carefully protected in the maintenance of her rights and privileges. The moment over-action is perceived, the dressings are either removed, or, at all events, slackened, and suitable means substituted. Of these the most important consist of leeches, water-dressings, and cataplasms, either simple or medicated, according to the exigencies of the case. If matter form, free vent is afforded, either by a change of position of the parts, or by puncture and incision. Constitutional treatment, of course, receives due attention.

d. *Secondary hemorrhage* may come on within a few hours after the adjustment of the parts, or it may be postponed to a later period, even to a few days or weeks. It may be arterial or venous, slight or profuse, transient or persistent, just as in the primary form of the accident. The most common causes are, imperfect ligation of the vessels, defective dressing, sloughing, and premature detachment of the ligatures. Whatever they may be, they should be carefully sought out, and at once counteracted by appropriate measures. The occurrence is always to be deprecated, because it has a tendency, not only to alarm the patient and his friends, but to impede and even prevent the adhesive process, requiring, as it not unfrequently does, the re-opening of the wound for its successful management. Fortunately, however, it is, in general, easily avoided, especially if proper attention be paid to the dressings and after-treatment.

e. Erysipelas is most apt to occur in persons of intemperate habits, or of a broken-down constitution, and usually makes its appearance within the first three days after the operation, generally at the site of the wound, or in the parts immediately around. Its presence is always denotive of disorder of the digestive apparatus, and hence one of the first things to be done is to administer medicines calculated to clear out the bowels and to restore the secretions of the liver, the mucous follicles, and the salivary glands. For this purpose the best articles are calomel and compound extract of colocynth, or blue mass and rhubarb, followed, if necessary, by the saline and antimonial mixture, with anodynes to allay pain and procure sleep. The local treatment must consist, mainly, of the dilute tincture of iodine, and solutions of the acetate of lead, with punctures and incisions to relieve tension and afford vent to effused fluids.

f. Pyemia may set in almost at any time after an operation, but the most common period is from the third to the eighth day. It is usually ushered in by bold and well-marked symptoms, such as violent rigors alternating with flushes of heat, severe cephalalgia, aching pains in different parts of the body, excessive restlessness, great thirst, a quick and frequent pulse, and inordinate dryness of the cutaneous surface. Delirium and extreme prostration soon ensue, and thus the case progresses from bad to worse, until, frequently in less than a week from the commencement of the attack, the patient expires in a state of utter exhaustion. Little is to be done for a system thus assailed. In nine cases out of ten the disease proves fatal. The proper remedies, at the start, especially if the patient is robust and plethoric, are moderate venesection and leeching, the exhibition of the milder purgatives, as calomel and rhubarb, and mercury with a view to a rapid constitutional impression. When excessive prostration is threatened, brandy, wine, ammonia, and nourishing broths are indicated, and must be administered with a generous hand. Locally, besides leeching, iodine, blisters, and medicated fomentations will be advantageous; if matter form, early and free incisions are made.

g. Still worse than pyemia, because even more fatal, is *tetanus*. This, however, is fortunately a rare occurrence after operations in this country. It is most common in tropical regions. In Europe and North America it is met with chiefly in dissipated persons of a broken-down constitution. It would seem that in India the operation of lithotomy is occasionally followed by this disease, an effect which, so far as I know, has never been witnessed in this country. Excessive loss of blood, severe shock, and exposure to currents of air, undoubtedly predispose to the occurrence of the affection, which usually shows itself within the first five or six days after the operation. The principal remedies are, anodynes, in full and sustained doses, brandy and ammonia, chloroform, and emollient applications to the wounded parts.

h. Life may be assailed by *constitutional irritation* and profuse discharge, and that, too, long after all apparent danger is over. The patient gradually becomes hectic; his appetite and sleep fail; the bowels are irregular, at one time constipated and at another relaxed; and the parts, exhibiting an unhealthy aspect, refuse to heal. Such a state of things, which, in general, but too surely foreshadows an unfavorable result, is to be combated upon the same principles as hectic produced by ordinary causes.

i. Patients sometimes *die* suddenly and unexpectedly after operations without any ascertainable cause, and where, at the time, everything seemed to be in a promising condition as to their ultimate recovery. A more sad and distressing occurrence can hardly be thought of, and yet it is one which cannot always, there is reason to believe, be avoided, no matter what precautions may be observed. Mere loss of blood, or shock, is not always sufficient to account for this unfortunate event, although it, doubtless, in many instances, materially contributes to its production; for death not unfrequently happens where no

such effects were witnessed. Nor can it be due to the introduction of air into the veins, as, for example, when operations are performed about the neck, inasmuch as, in this case, the patient either perishes instantaneously, or, at any rate, exhibits unmistakable evidence of the accident. Besides, this occurrence is not peculiar to operations upon the cervical region, but has been witnessed in operations upon all parts of the body, even in some of the more insignificant amputations and the removal of small tumors. When there has been much loss of blood, or severe shock, the event is probably due, at least for the most part, to syncope, or actual paralysis of the heart, preventing this organ from transmitting a sufficiency of blood to the brain for the due performance of its functions; and such an effect is most likely to take place when the patient, through neglect, wilfulness, or mismanagement, sits up in bed, or stands on the floor, thus suddenly depressing the heart's action. In this way life is sometimes instantaneously destroyed in lying-in females, especially in those who have suffered seriously from hemorrhage; and similar results are occasionally witnessed after surgical operations and accidents. In another class of cases, death is probably caused by embolism, that is, by the formation of heart-clots, and of fibrinous concretions in the vessels, impeding the passage of blood, and so arresting, suddenly and unexpectedly, the functions of an important organ. It is well known that copious hemorrhage, or severe shock, invariably renders the blood more coagulable, and hence such a state of the system must be regarded as powerfully predisposing to the occurrence of embolism.

It is sufficient, for all practical purposes, to know that such an event may occur after operations, without any formal attempt at its solution, which the present state of the science hardly enables us to do. Whatever the cause may be, no efforts should be spared to prevent it. For this purpose, the utmost care should be taken, after all serious operations, not to prop the patient up in bed, or to let him get upon his feet; nay, further, he should not, if he is very weak or exhausted, be permitted to move about in bed, or, in short, to do anything calculated to induce syncope, or promote the occurrence of embolism. The diet should be of a suitable kind, and such medicine should be given as shall have a tendency to give tone and strength to the system. Free use, in particular, should be made of brandy and milk. If syncope occur, the head must immediately be placed low, and recourse be had to sinapisms and stimulating injections, to reassure the heart, although this will probably be in vain, especially if the cause of the failure of its action be the presence of a clot, either in its own cavities or in some vessel. As it is impossible to foretell, in any given case, when the patient may be exempt from sudden death, after severe shock, or great loss of blood, the precautions here enjoined should be rigidly observed until there is reason to believe that all danger from this cause is passed.

j. The *mortality* of surgical operations is subject to numerous contingencies, some of which have an intimate relation with the patient himself, some with the nature of the injury, or accident necessitating the interference, and some with the surgeon, either directly or indirectly. It may be assumed, as a general rule, that all the capital operations, as they are termed, are attended with a certain degree of risk to life, while not a few of the minor or more insignificant ones have, from causes which it is not always easy to determine, a fatal issue. It has been asserted by an eminent authority, Professor Simpson, that a patient who is about to undergo a severe operation incurs as much danger as a soldier engaged in the most fierce and bloody battle. This is a strong declaration, but I believe it to be fully borne out by facts; nevertheless, it must be received with some degree of reserve. If a man serves as a forlorn hope, he will stand a fair chance of being killed; and so precisely with a patient who submits to the knife on account of some terrible accident or dis-

ease. But such cases constitute the exception, not the rule; under ordinary circumstances, if the system is properly prepared, and the operation well performed, the surgeon looks with great confidence for a good recovery. If he could always select his cases, the general result would be very different. He would then not employ the knife against his judgment, as a dernier resort, with the certainty that there was hardly one chance out of a hundred for a favorable issue; he would let all the bad, desperate, or unpromising cases alone, to get well or perish, as a kind Providence might direct. But so long as a surgeon has any feelings of humanity he cannot do this; he must take the good, bad and indifferent cases as they present themselves, and do the best he can with them. It is only when he is guilty of neglect, or of serious mismanagement, that he should be considered culpable. He does not expect to save all; he knows that many must necessarily perish, not so much as an effect of the operation as of the injury or disease for which the operation is performed, and in attempting to estimate the probable result of his interference, he does not forget to take into the account the risk which his patient is obliged to incur from hemorrhage, erysipelas, pyemia, tetanus and other intercurrent but often unavoidable affections. He is assured that there is no case, however desperate, that may not recover, or one, however insignificant, that may not perish.

The following tables will serve to show what has hitherto been the mortality after some of the so-called capital operations:—

Operations.	Cases.	Recoveries.	Deaths.	Proportion.
Lithotomy	7,874	6,792	1,082	1 in $7\frac{5}{8}$
Ligation of arteries . .	401	287	123	1 in $3\frac{1}{4}$
Herniotomy	622	323	296	1 in $2\frac{1}{6}$
Amputation of the thigh .	1,642	907	735	1 in $2\frac{1}{4}$

But these results, so humiliating to surgery, refer chiefly to hospital practice, and can, therefore, hardly be considered as affording a fair average of the experience of the profession in general. The great majority of the most desperate cases, both of injury and disease, in all large towns and cities, find their way into public institutions, where they rapidly sink under the joint influence of vitiated air, erysipelas, pyemia, and want of proper attendance. It is a notorious fact that many more patients recover after bad injuries and severe operations in the country than in the city; and, to go no further, it may confidently be asserted that an experienced operator will lose fewer cases than one who is just commencing his career.

CHAPTER XV.

PLASTIC SURGERY.

PLASTIC SURGERY is that branch of the subject which treats of the restoration of lost parts by the transplantation of healthy integument from some neighboring region. Originally restricted to the repair of the nose, it has, during the present century, busied itself, in different ways, with the emendation of various other organs, and has thus greatly enriched the domain of general surgery; having, in fact, created a new department of operative medicine, as fertile in its resources as it has already been brilliant in its results. The perfection which plastic surgery has attained within the last twenty years is truly wonderful, and affords a striking evidence of the ingenuity, talent, and enterprise of the medical profession in different parts of the world. It has literally been a field of conquests, upon which have been achieved some of the proudest triumphs of the human mind in modern times. Among the many names that are honorably associated with this department of surgery, on account of their persevering efforts to advance its interests, those of Carpue, Dieffenbach, Blandin, Zeis, Jobert, Serre, Liston, and Von Ammon, of Europe, and Pancoast, J. M. Warren, and Mütter, of this country, hold deservedly a high rank. Several of these surgeons have composed able treatises on plastic surgery, and have thus indelibly identified their names with its history.

Various names have been devised to designate this branch of surgery. Thus, Blandin denominates it autoplasty, from a Greek compound literally signifying self-creation. Another French authority, Mons. Velpeau, prefers the word anaplasty, the true meaning of which is reconstruction. By others the term plastic, from the Greek verb to mould, model, or adjust, is used, and this is perhaps less objectionable than any other; at all events, it possesses the advantage of being easily understood.

It is exceedingly probable that one branch of plastic surgery has been practised in India from time immemorial. In that country the barbarous custom has existed for ages of punishing certain classes of criminals by cutting off their noses, and there can be no doubt that sympathy for these poor wretches gradually induced persons to turn their attention to the means of affording them relief. Hence arose rhinoplasty, or the operation of making new noses, pursued chiefly by a low order of native priests, whose ignorance of the healing art was too profound to justify the idea that their efforts were often crowned with success. According to Galen, the ancient Egyptians were well acquainted with rhinoplasty, but self-interest and pride prevented them from communicating a knowledge of it to other nations. Whether the operation was ever performed in Greece and Rome history does not inform us, although it can hardly be supposed that, if it had been, it would have been silent on the subject. In Europe attention was first prominently drawn to the restoration of lost parts by Gaspar Taliacotius, Professor of Anatomy and Surgery in the University of Bologna. In a work on the subject, remarkable for its erudition, and the simplicity of its diction, published at Venice, in 1597, he has described with great minuteness the art of repairing

mutilated noses, lips, and ears, illustrated by numerous engravings. It bears the title of "*De Curtorum Chirurgia per insitionem*," and is curious as furnishing a record of the observation and experience of a truly great surgeon soon after the revival of learning. His practice must have been very great as a rhinoplastic surgeon, for it is distinctly stated that patients visited him from all parts of Europe. The pupils of Taliacotius, settling in different parts of the continent, took great pains to disseminate a knowledge of the operation among the profession, although it does not seem to have been often applied in practice, doubtless from fear of failure. The operation, moreover, was doomed to encounter many obstacles from ridicule, which always exerts a powerful influence upon the weak and prejudiced in every country, and not unfrequently has the effect of throwing a new and useful invention completely into the shade.

The method of Taliacotius consists in borrowing the required material from the arm; the operation is very tedious and complex, and has been almost entirely superseded by the Indian method, in which the flap is taken from the forehead. These two processes will be described in their proper place. Meanwhile, it may be observed that the Oriental operation was first successfully performed in Europe in 1814, by Mr. Carpue, of London, who, in 1816, published an account of this and of another case, equally fortunate. To Dieffenbach, however, more than to any one else, is due the merit of having first generalized the operation, by pointing out the sphere of its application.

The nomenclature of these plastic operations has assumed quite an imposing character, from the numerous structures to which they are applicable. It is formed by adding the word *plasty* to the anatomical name of the part concerned, as *rhinoplasty*, *genoplasty*, and *urethroplasty*. Before I proceed to speak of these operations separately, it will be necessary to offer some remarks of a general nature respecting the causes which necessitate them, the preparation of the system, the proper mode of conducting them, and the character of the after-treatment.

The causes necessitating these operations are various kinds of accidents and diseases. Thus, in India, as already stated, *rhinoplasty* is generally required on account of wilful mutilation of the nose as a punishment for crime; in Germany, on the contrary, it is often called for on account of injury sustained by the small sword in duelling. The vicious cicatrices left by burns and scalds frequently led to the necessity of their performance; in fact, a large field for plastic surgery has been opened in this class of lesions, in which good service was rendered by the late Dr. Mütter, since attention was first directed to it. Of the various diseases which may create a necessity for this kind of interference, carcinoma, struma, and syphilis occupy the first rank, these affections not unfrequently destroying the greater portion of the nose and lip, and thus causing the most disgusting deformity. *Genoplasty* is generally required on account of ulceration of the cheek from the effects of mercury; and *urethroplasty*, in consequence of urinary fistule, the result generally of stricture and abscess.

Whatever may be the causes leading to the necessity of these operations, none should ever be undertaken without thorough preparation of the system, extending through a number of days, if not several weeks. Upon this subject it is impossible to insist too strongly. I have seen enough of these cases to satisfy me that too little attention is paid to preliminary treatment, and that most of the failures which attend the procedure are due to the neglect of this precaution, for which there is the less excuse, seeing that there is never any need of immediate interference. There is no necessity, unless the patient is very plethoric, for the use of the lancet; light diet, rest, and an occasional purgative will generally suffice to bring down the system to a proper point of tolerance for the approaching ordeal. If the patient is from

abroad, he must not be molested until he has recovered from his fatigue, and become accustomed, in some degree, to his apartment and to those who are to attend to his wants. Above all, let it be seen to that his room is spacious, cheerful, and well-ventilated. If the weather be cold, the temperature must be regulated by the thermometer, uniformity in this respect being of paramount importance to the success of the enterprise. No operation of this kind should be undertaken in the heat of summer.

It is hardly necessary to state that no plastic operation should ever be attempted so long as the disease necessitating it is not completely eradicated from the part and system. It would be the height of folly, for example, to undertake the restoration of a nose lost in consequence of constitutional syphilis if there were any traces of this affection, in any portion of the body, however remote, or however distantly connected with the disfigured organ; for there could be no possible guarantee here that the disease might not attack the new nose or the adjoining parts of the old, and so frustrate the design of the surgeon. Besides, even supposing that such an untoward occurrence did not take place, still, it would be improper to operate, because the subjects of this disease are not only very prone to erysipelas but wounds in them generally unite with more difficulty than in healthy persons. The same remarks apply to struma, although I have great doubts whether this disease, by itself, ever destroyed any nose, ear, or lip. The mischief that is so often ascribed to it is nearly always done by syphilis, or by a combination of these affections from the transmission of the two poisons from the parent to the offspring. It is different with carcinoma. Here the plastic operation may, in general, be performed immediately after the excision of the specific disease.

The manner of performing the operation relates to the position of the patient, the surgeon, and the assistants; the administration of chloroform; the mode of selecting, making, and fastening the flaps; and several other circumstances which it is not necessary to specify.

If the operation be very simple, and likely to be soon over, the patient may sit up; otherwise he should lie down, his head and shoulders being properly supported by pillows. The surgeon and the assistants should dispose themselves in such a manner as may seem most useful for the prompt and successful execution of the operation. An anæsthetic is proper in almost every case, since the operation is frequently not only very tedious, but it is always desirable that the patient should be as passive as possible while it is in progress.

There are, as has already been stated, two points from which the integument may be transplanted for filling up the chasm in the mutilated organ; either from the immediate vicinity of the part, or from a distance. Thus, in making a new nose, or mending an old one, the flap may be taken from the forehead, according to the Indian method; or, if the gap be very small, even from the cheek, at a still shorter distance from the nose. Or the surgeon, adopting the plan of Taliacotius, now known as the Italian operation, may borrow the necessary material from the arm, although this method, owing to its tedious and complicated character, has become almost obsolete. In some cases the flap is obtained by a kind of migratory process, being successively transferred from one region to another until it reaches its final destination. Roux, in this manner, attempted to close an opening in the cheek, by inserting a piece of the lower lip into the upper, and, after a time, when the parts had contracted thorough adhesions and become accustomed to each other, transferring it to the place which it was intended permanently to occupy. Such a procedure would seem, at first sight, to be puerile, but upon reflection it will readily be seen that cases might arise where it would not only be justifiable but very proper.

However obtained, it is important that the integument should, if possible, be perfectly sound; free, not only from disease, but from scars. The importance of attention to this rule is too obvious to require comment. A cicatrice, having only a low vitality, is extremely apt to slough when transplanted. A sickly graft cannot take root on a sound bough, nor will a diseased bough permit the growth of a sound graft. To unite and maintain their future relations, both must be healthy. Another point of consequence is that the flap should be as destitute as possible of hair; for, although it might be divested of this after it has grown fast in its new position, yet it is always best not to incur any risk of unseemliness from this source.

The size of the flap must, as a general rule, be at least one-third larger than the opening which it is intended to cover, to allow for the necessary shrinkage. If the integument be very thick the contraction will be less than under opposite circumstances, but even here it is well for the surgeon to be on his guard, lest, when the cure is completed, the result should disappoint him. The shrinkage is always gradual, and generally continues for many months after the operation, the part gaining in thickness and density what it loses in circumference.

The shape of the flap must accurately correspond with that of the gap which it is destined to close. Hence the best plan is always to define its outline before the operation by means of a pattern, placed upon the surface whence the integument is to be taken, and marked off with ink, nitrate of silver, or, what is better than either, tincture of iodine.

The composition of the flap is a matter of importance. It should consist merely of skin and areolar tissue, with a small quantity of adipose substance; muscular fibre, nerves, and veins being carefully excluded. The presence of a thin layer of fat is always conducive to the preservation of the flap, as it tends to protect the subcutaneous vessels, and facilitate adhesion. A large pedicle must always be left, otherwise the part may die from inadequate supply of blood and nervous fluid. No large artery should be embraced in it, as this would convey more blood into it than would be required for its nutrition, or than the veins could return.

These preliminaries being disposed of, the surgeon is ready to begin the operation. With a sharp scalpel he now pares the edges of the part to be repaired, vivifying them with great accuracy, and removing all redundant and callous matter; or he may first dissect up the flap, and do the paring afterwards, as fancy or convenience may dictate. In executing this step of the operation, great care must be taken not to press or pinch, either with the finger or forceps, any portion of the flap or old skin, but to leave everything in as natural a condition as possible, since nothing will so readily promote reunion. The edges may be bevelled off or cut straight, according to circumstances, as will be more particularly described hereafter. The dissection is frequently attended with smart hemorrhage, but the rule is never to apply any ligature to the flap, lest it should interfere with the adhesive process, although any vessel that may spirt on the wound should at once be secured, and the wound itself promptly closed by suture. More or less gaping will of course remain, but it is astonishing how small a cicatrice is usually left even in the most extensive lesions of this description.

All bleeding having ceased, the flap is gently sponged, and accurately stitched to the edges of the chasm which it is designed to close. The most eligible suture will be found to be the interrupted, with an interval of from two to three lines between the threads, the ends being tied with a slip-knot over a narrow roll of adhesive plaster. The advantage of this procedure is that the suture may be loosened at any time if it be found to be too tight. Much harm is often done by placing the stitches too closely, the effect being to cut off the circulation. The twisted suture is objectionable for the reason,

first, that the needles are, in many places, difficult of introduction, and, secondly, that they are liable to cause too great a degree of tension. The grooved suture, so happily used in plastic surgery by Professor Pancoast, will be described in connection with rhinoplasty, to which it is more particularly applicable.

The dressing is completed by covering the edges of the newly related parts with lint, spread with simple cerate, or wet with olive oil, in order to prevent them from becoming dry and shrivelled, an effect which is very liable to happen when this precaution is not duly attended to. The surface of the flap may be protected with dry lint, or, what is generally preferable, be exposed to the air. If it is very large, it will be necessary to confine it lightly in its place with adhesive plaster and a bandage, but anything like firm pressure must be carefully avoided. The wound from which the flap has been borrowed is dressed with cold water, and a similar application may be made to the amended organ if appearances indicate that there is a likelihood of over-action. The operation being completed, the part is kept at rest in a relaxed and elevated position; a light, cooling diet is enjoined; and the air of the apartment is carefully regulated by the thermometer, an equable temperature being of the greatest consequence to the welfare both of the part and system. A full anodyne is given the moment the patient is put to bed; but, if things go on well, the bowels must not be disturbed under forty-eight hours, when they may be opened by a cooling laxative.

The sutures may be removed, on an average, from the third to the fifth day; but so long as they are doing well they should not be disturbed, and there are few cases in which it is proper to take them all away at once. Great attention to cleanliness must be observed, and the best mode of effecting this is to irrigate the parts occasionally with the syringe.

If undue swelling and discoloration arise, the patient must be promptly bled and purged, and such local means employed as shall be best calculated to meet the emergency of the case. Leeches may be applied to the neighborhood of the flap, but not to the flap itself for fear of exciting erysipelas. Occasionally, a considerable flow of blood may be obtained by slightly lifting the flap at one or more points, the bleeding being encouraged with a sponge and warm water.

The great danger after an operation of this kind is erysipelas, which may be so considerable as to destroy not only the flap but also the patient. Such an occurrence should be promptly met by the topical use of dilute tincture of iodine, and by appropriate internal remedies, especially quinine and iron; aided, if there be any tendency to a typhoid state of the system, by stimulating drinks and a generous diet. Now and then a patient is lost by pyemia, but such an event is fortunately very uncommon. Gangrene of the flap, either from inadequate nutrition, over-action, or undue constriction, occasionally occurs, and destroys the success of the operation.

For a time the flap remains pale and cold, but these symptoms soon subside, and are succeeded by a bluish appearance and an increase of temperature. The circulation is evidently temporarily embarrassed, the arteries conveying blood faster to the part than the veins can remove it. Hence a certain degree of stagnation ensues, followed by a bluish, threatening condition of the part, which, however, soon disappears spontaneously. Natural sensation does not return for a long time; it begins first along the edges of the flap, and thence gradually extends over the rest of its surface. For the first few months the transplanted skin may appear unnaturally large and unseemly; gradually, however, it becomes smaller and smaller, and eventually may shrink so much as to answer but imperfectly the objects of the operation.

CHAPTER XVI.

SUBCUTANEOUS SURGERY.

SUBCUTANEOUS SURGERY is one of the creations of modern times, due chiefly to the genius and intrepidity of one man, Dr. Louis Stromeyer, of Hanover, who was the first to practise, upon a rational and philosophical plan, a subcutaneous operation, the undertaking consisting in the division of the tendo Achillis for the cure of club-foot. The operation was performed in February, 1831, and eventuated in the complete restoration of the use of the limb. Prior to this period several attempts had been made, by different surgeons, as Lorenz, Thilenius, Michaelis, Sartorius, and Delpech, to relieve this complaint, but they had all signally failed, simply because they had not been based upon correct scientific principles. The results of Dr. Stromeyer's observations and experiments were given to the profession in 1838, in a volume replete with interest, entitled *Contributions to Operative Orthopædic Surgery*, in which he has described, with circumstantial minuteness, the proper method of dividing the different tendons concerned in the production of the various distortions of the foot, with an account of the after-treatment.

Since the publication of Stromeyer, the domain of subcutaneous surgery has been greatly enlarged, by the application of its principles to other parts of the body, for the relief of which it has already performed the most valuable services. Dieffenbach, in 1839, gave it a new impulse by devising the operation for strabismus, which, although not practised by him subcutaneously, did much to inspire new confidence in the procedure, and to awaken a new interest in its application. Soon afterwards, however, the section of the muscles of the eye was performed without external wound, and the operation, originally suggested by Guérin, seems to be growing more and more in favor with the profession. The latter surgeon has extended the subcutaneous practice to the treatment of lateral curvature of the spine, by the division of the muscles of the back; and, at a more recent period still, it has been applied to the relief of numerous other affections, which would hardly admit of cure in any other manner. Among the more important operations which have grown out of this branch of surgery are the removal of cartilaginous bodies from the joints, the radical cure of hernia, the reduction of chronic dislocations, the evacuation of abscesses, the cure of ankylosis, and the obliteration of serous cavities. Too short a time has elapsed since the discovery of subcutaneous surgery to enable us to form a just estimate of its limits, or the extent to which it may with propriety be carried in practice; but it is not difficult to perceive that in a field affording such unbounded opportunities for the exhibition of display and selfishness, much abuse must creep in, which time alone will be able to rectify.

The practice of subcutaneous surgery is founded upon the great law that all wounds and injuries occurring without an opening in the integument unite with very little, or, according to some, with no inflammation, and with no suppuration, differing thus essentially from similar lesions accompanied with a solution of continuity of the skin, which are always followed by considerable inflammation, and also very frequently, if not generally, by a discharge of pus. This law, which is now universally recognized by surgeons, was clearly

enunciated by Mr. John Hunter, in his writings, near the close of the last century, but did not attract the serious attention of his countrymen until within a very recent period; not, indeed, until the facts of the subcutaneous section had been placed upon a firm and immutable basis by the practitioners of the continent of Europe. The idea of the illustrious Englishman lay in his writings, like a pebble upon the sea shore, often seen but never observed, until accident directed attention to it years after the establishment, by others, of the great principles which he had so clearly enunciated. One reason, perhaps the chief one, of this was that he himself had never performed a subcutaneous operation: if he had, there is certainly no evidence of the fact in any of his writings. The only passage in his works which has any relevancy to the present subject is the following: "The injuries done to sound parts, I shall divide into two sorts, according to the effects of the accident. The first kind consists of those in which the injured parts do not communicate externally, as concussions of the whole body or of particular parts, strains, bruises, and simple fractures, either of bone or tendon, which form a large division. The second consists of those which have an external communication, comprehending wounds of all kinds, and compound fractures. Bruises which have destroyed the life of the part may be considered as a third division, partaking, at the beginning, of the nature of the first, but finally terminating like the second. The injuries of the first division, in which the parts do not communicate externally, seldom inflame, while those of the second commonly both inflame and suppurate." It is evident, from the tenor of this passage, that Mr. Hunter had carefully studied the influence of the air upon the effects of wounds, but it is not very clear, from aught that appears in it, that he had any conceptions whatever of the nature of subcutaneous surgery, properly so called.

Several of what are now dignified as subcutaneous operations have been performed for a long time. The mode of evacuating chronic abscesses by a valvular incision, first practised by Mr. Abernethy, early in the present century, legitimately belongs to this division of surgery, its object, as clearly enunciated by the originator, being the exclusion of the air, it being well known that the contact of this fluid with the pus in the interior of the sac was the cause of the excessive local and constitutional disturbance which so often followed the old mode of opening these collections. Of the value of this procedure there can be no doubt, although the class of cases which it is intended to relieve is, from their very nature, unfortunately too often fatal. The operation of dividing the stricture in strangulated hernia, external to the sac, originated with J. L. Petit upwards of a century ago, but has only of late years received the attention it merits. Some of the English practitioners, commencing with Mr. Aston Key, have recently bestowed much attention upon the subject, and have adduced a body of testimony in its favor highly flattering to this mode of treatment. The object of the operation, whose advantages and disadvantages will be considered in their appropriate place, is, by relieving the bowel subcutaneously, to guard against the occurrence of the severe inflammation which so frequently attends the ordinary procedure, even in the hands of the best surgeons. The injection of hydrocele with irritating fluids, as suggested by Sir James Earle, early in the present century, is another instance of a subcutaneous operation, which has long been familiar to the profession, and been practised by every enlightened surgeon in Europe and America. Some recent writers have gone so far as to class the use of the seton in the treatment of ununited fracture among the expedients of subcutaneous surgery; such an application is certainly carrying this department altogether beyond its legitimate limits, and is therefore calculated to do the subject much harm by giving to it a wrong direction. The wound made by a seton is, to all intents and purposes, an open wound, followed not only by high inflammation but by profuse suppuration; occur-

rences which it is the peculiar province of subcutaneous surgery to guard against. A better example of a subcutaneous operation, performed for the relief of ununited fracture, is the division without wound, by means of a long, slender knife, of the soft tissues which form around the ends of the broken bone, the raw surfaces being afterwards approximated and maintained by appropriate apparatus.

On the whole, regarding subcutaneous surgery in its legitimate application, it appears to me that the cases to which it is adapted are susceptible of being arranged under the following heads: 1. Cases involving the division of tendons, muscles, and aponeuroses for the relief of various distortions, as club-foot, club-hand, spinal curvature, and strabismus; the reduction of dislocations, especially those of the foot; and the cure of ankylosis of the joints, depending upon contraction of the soft parts. 2. Operations for the radical cure of hernia, whether by puncture or injection; and division of the stricture in strangulated hernia external to the sac. 3. The evacuation of chronic abscesses and of purulent, serous, and sanguineous collections of the chest and other cavities, by a valve-like opening of the skin. 4. The withdrawal of cartilaginous concretions from the joints, as originally suggested by Goyrand and Syme. 5. Operations for obliterating serous cavities, when, in consequence of inflammation, they become occupied by serous fluid; as the vaginal tunic of the testicle, certain synovial bursae, especially those about the hand and wrist, and various adventitious cysts, particularly those which are so liable to form in the neck in connection with the thyroid gland. 6. The comminution, by the knife, of diseased lymphatic ganglions, the incision of inflamed periosteum, and the division of morbid adhesions, as those existing in chronic luxations, in depressions of the nose, and similar affections. 7. Forced extension of ankylosed joints, rendered so by the formation of fibro-ligamentous bands. 8. The subcutaneous obliteration of nevi or vascular tumors, by ligature or injection. 9. The operation for the radical cure of varicocele.

The mode of operating for subcutaneous purposes must vary of course according to the particular indication which it is designed to fulfil. Whatever, however, the object may be, the rule is to make as small an external wound as possible, consisting, in fact, rather of a puncture than an incision, for it is ever to be borne in mind that one of the cardinal aims of every procedure of the kind is the exclusion of the air. The knife with which the operation is performed must therefore always be very narrow, sharp-pointed, and rather short, a length of edge from half an inch to an inch being a good average. The annexed sketch, fig. 155, represents the knife which I have long been in the habit of using in all my subcutaneous operations. Such an instrument is generally much more manageable than a longer one, while one of greater width would make too large an opening.

If the object be to evacuate an abscess, a medium-sized trocar may be used, the skin having been previously divided with a bistoury. The instrument is then passed for a variable distance—usually from an inch to an inch and a half—through the subcutaneous cellular tissue, when its point is plunged into the pyogenic pouch, its entrance being denoted by the want of resistance and the escape perhaps of a few drops of thin pus. In extracting cartilaginous concretions from the joints, a delicate knife is carried along under the integument through the capsular ligament and synovial membrane, which are then divided to a sufficient extent to admit of the displacement of the morbid growth, previously fixed by the thumb and fingers, into the cellular substance external to the articulation, from which, after the wound is healed, it is removed by a

Fig. 155.

Tenotome.

secondary operation. The operation for the radical cure of hernia, requiring instruments of particular construction and use, will be described in its proper place, and so in regard to several other procedures which cannot be noticed here.

All operations of this kind should be performed with great gentleness and care; and whenever this is done there will be no risk either of severe inflammation, or of the division of any important vessels, nerves, or other structures not concerned in the particular affection for the relief of which the procedure is undertaken. I do not agree with those who maintain that tendons and other textures may be cut without the operation being followed by inflammation; on the contrary, I believe that a certain degree of incited action is present in every instance, and if this view of the case be correct it proves how important it is that it should be kept within proper limits. This subject, however, will again be adverted to in speaking of tenotomy. In general, the little puncture made in the operation unites in a few hours, while the gap which intervenes between the retracted ends of the divided structures is gradually filled up by plastic matter, which is eventually converted into analogous tissue.

Most subcutaneous operations are nearly bloodless, and this circumstance constitutes one of their great peculiarities. While open wounds always bleed to a greater or less extent, those made beneath the skin by a narrow, sharp-pointed knife, used with proper care, are almost free from hemorrhage. In dividing the tendo Achillis for club-foot, frequently not more than a few drops of blood are lost. As to shock, or serious depression of the nervous system, consequent upon such an operation, such an occurrence is never witnessed. The proceeding, however, is not always free from pain, especially during the efforts which are sometimes required to straighten the affected part after the division of the faulty structures; and hence it is often useful to administer an anæsthetic, the more so, because this not only prevents suffering, but, by rendering the patient passive, gives the surgeon a more complete control over his own movements.

Active preparatory treatment is rarely required in these operations. I have frequently performed the most extensive tenotomy at my clinic upon children whom I had seen for the first time only an hour before, and yet in no instance, so far as I have been able to learn, have any bad effects followed. The operations, however, for the radical cure of hernia, for breaking up adhesions in ankylosis, for the removal of cartilaginous bodies from the joints, and for the relief of some other affections, always demand more or less attention of this kind.

The after-treatment, for the first few days, is generally very simple. As soon as the operation is over, the little wound is covered with adhesive strips, to exclude the air, and the part, surrounded by a bandage, is maintained in a perfectly easy, quiet position. If active inflammation arise, which, however, will seldom be the case, the usual antiphlogistics must be employed. After nearly all of these operations suppuration must be prevented at all hazard.

When the operation has been practised for the relief of some deformity, as club-foot or spinal curvature, the cutting constitutes only a trivial part of the proceeding. The great care and trouble of the case come afterwards, in the fitting and wearing of the necessary apparatus. It is usually recommended that no apparatus should be used until after the lapse of several days, and this, as a general rule, will be found to be the best practice. I have, however, in many cases, so far deviated from this rule as to confine the affected limb at once, and usually without any disadvantage. Indeed, I have latterly thought that this ought to be the rule, and the delay the exception. As this subject, however, will have to be considered in connection with the various operations to which it relates, any further remarks upon it here would be out of place.

CHAPTER XVII.

AMPUTATIONS IN GENERAL.

SECT. I.—INTRODUCTORY CONSIDERATIONS.

THE word amputation was formerly employed, and is occasionally even yet, to signify the removal of various kinds of tumors; thus, many of the older writers speak of amputation of the breast, amputation of the jaw, and amputation of the scrotum. At the present day, however, the term excision is generally used as more appropriate in connection with these procedures, while that of amputation is applied exclusively to operations for the removal of the limbs whether in their continuity or at their articulations.

I cannot agree with those who have denounced amputations as a disgrace to surgery; it is only when they are performed unnecessarily that they ought to be stigmatized by the profession and the public as an evil. Every pursuit is liable to abuse, to sins of omission and commission, and it would be strange if limbs were not occasionally cut off that might, under judicious management, have been saved. To denounce amputations, and to declare that they afford evidence only of the impotency and imperfection of our art, is to take a very narrow and erroneous view of the subject. It is not intended, as far as our own feeble powers of reflection enable us to comprehend the matter, that man should be able to cure every disease to which "flesh is heir." There are many maladies, as well as accidents, which are of necessity mortal; lesions which no human agency can repair or remedy. Who can save a limb that has been mangled and cut to pieces by the passage of a railway car, by the explosion of a steamboat boiler, by the fierce contact of a cannon ball, or by a fall from the top of a house down upon a heap of stones? Where is the surgeon that can prevent mortification from a burn that has charred the flesh, from a cold that has completely frozen the toes and feet, or from a malignant pustule that has inoculated all the tissues of an extremity? Is surgery to be held responsible because it cannot cure cancer of the bones, scrofula of the joints, and aneurism of the thigh and leg? So far from imputing blame to it in these and similar cases, we should be grateful for the assistance which it is capable of affording us as a means of relieving suffering and prolonging life. It is under such circumstances, in particular, that we can best appreciate its great and inestimable value. If it were not for the merciful interposition here of the knife, such cases would inevitably be doomed to a rapid and miserable death. Mortification would speedily do its work, the cancerous tumor would steadily spread and finally ulcerate, forming a frightful, disgusting, and painful mass of disease, and the scrofulous joint would soon wear out the system by hectic irritation. It is a sad thing to lose a limb, but it is also a sad thing to die; and what rational being, if he could have his choice, would not rather part with an extremity than with his life? No humane, enlightened, and conscientious surgeon will ever resort to amputation without being satisfied of its entire and perfect necessity; if he is young and inexperienced, he will be sure to avail himself of the best counsel within his reach, while, if he is thrown upon his own resources, he will not fail to

give the case all the consideration and reflection that his own knowledge, wisdom, and judgment, may enable him to bring to his aid for the relief of the poor sufferer whom he is obliged to mutilate in order that he may rescue his life from the dangers which threaten him. I know of no operation which I approach with so much reluctance as the amputation of a limb, or one which gives me more real pain. To cut off an arm at the shoulder on account of an incipient cancerous affection of the head of the humerus, when the elbow, forearm, hand, and fingers are all perfectly natural and glowing with health, unconscious, so to speak, of the fate which awaits them, is enough to sicken the stoutest heart, and to discourage the boldest operator. If there be a more disagreeable task than this, I am ignorant of it; and yet I would not shrink from its performance even when there is but a faint prospect of prolonging life, if only for a few months. But the case is different, widely different, when the surgeon is called upon to amputate a limb crushed and lacerated by machinery; here there is no choice, no question concerning a cure by mere therapeutic measures; the knife is the only remedy, and the sooner it does its work the greater, as a general rule, will be the patient's chance of recovery. The body, it is true, is mutilated, perhaps sadly disfigured, but life is safe, and surgery, science, and humanity have achieved a real triumph. So long as there are accidents and diseases incurable by medical treatment, so long will there be a necessity for amputation, and happy is he who shall know when and how to perform it to the best advantage for his patient and the greatest credit to the art and science of surgery.

SECT. II.—CIRCUMSTANCES DEMANDING AMPUTATION.

The circumstances for which amputation may be required are not only numerous but extremely diversified in their character, and therefore deserving of the most careful consideration. They may be comprised under the following heads. 1. Mortification, however induced. 2. External injury, as wounds, fractures, and dislocations. 3. Morbid growths. 4. Aneurisms. 5. Diseases of the bones and joints. 6. Intractable ulcers. 7. Malformations and deformities. 8. Tetanus. The topics here enumerated comprise almost every kind of morbid action that can arise in the animal economy, and it will be perceived that they afford a wide and complicated field for the exercise of the talents and judgment of the surgeon. Space will not permit me to enter as fully into their details as might, perhaps, be desired; but I shall endeavor to advert briefly to the more important facts included under each head, having already called attention to some of them in the chapters on gangrene and wounds.

1. *Mortification*.—Mortification, in whatever manner induced, necessarily imperils limb and life, and therefore often becomes the subject of amputation. Hence the question arises, under what circumstances is a resort to the operation advisable and proper? This question can only be answered satisfactorily by a consideration of the nature of the mortification. In the chapter on mortification is an account of the several varieties of this affection, the causes under whose influence they take place, their symptoms, and the means required for their relief. By a reference to that portion of the work, it will be found that, as it respects the operation under notice, the great rule, recognized by nearly all surgeons at the present day, in acute gangrene, is, to wait for the formation of a line of demarcation between the dead and living parts, on the ground that it is not generally safe to interfere sooner, lest the disease should reappear upon the stump, and thus destroy the patient, or necessitate a repetition of the amputation. Of the propriety of this rule there can be no question, for there is no surgeon of experience who has not

witnessed its beneficial effects in his own practice, as well as in that of his friends, and yet it is equally true that it may occasionally be violated with great advantage. But I would apply to these cases the term "exceptional," comprising under this head those attacks of mortification which are so apt to supervene upon inflammation caused by external injury, as wounds, fractures, and dislocations, which often spread with immense rapidity, hopelessly overwhelming, if they be not promptly arrested, both the part and system in a few hours. It will not do for the surgeon, in such a case, to fold his arms and become an idle spectator; he must have his eyes and wits about him, or his patient is irretrievably lost; whatever is done must be done quickly. The wished-for line of demarcation will be looked for in vain; the gangrene will rapidly extend to the trunk, and death will soon close the scene. But in spontaneous mortification, or in mortification from erysipelas, carbuncle, and analogous affections, the judicious surgeon waits for the arrest of the morbid action, his chief care being to bring about this event as speedily as possible by appropriate local and constitutional measures. His rule of action is the same in hospital gangrene; in both cases means are employed for supporting the system, or, what is equivalent to the same thing, for improving the condition of the fluids and solids, and the knife is used only when the wished-for line of circumvallation is fully established, not a minute before.

In senile, chronic, or dry gangrene, the result usually of ossification of the arteries and of their occlusion by fibrinous concretions, thus depriving the tissues of their due supply of blood, the rule has heretofore been to wait for the cessation of the mortification, experience having shown that, when this precaution is neglected, the disease will be certain to reappear in the stump. It is in view of this liability in mortification to recur that some surgeons, of great eminence and experience, have given it as their judgment that the case should always be left entirely to nature's efforts; in other words, that we should wait for spontaneous amputation, shaping the stump after the dead parts have been nearly completely detached from the living, when, it is alleged, the part and system will be better prepared to withstand the shock of the interference. The propriety of such advice is sufficiently obvious when it is considered that this disease occurs nearly always in very old and infirm subjects, and that it is essentially dependent upon obstruction of the arteries leading to the affected parts. Such individuals, as I know from personal observation, are usually very feeble, and have consequently very little power of resisting the effect of shock caused by the use of the knife, and the loss even of a small quantity of blood. Hence it often happens that they sink soon after the operation, even when there has been a distinct line of demarcation, or that the disease speedily breaks out upon the stump, and soon destroys life secondarily. Seeing how common these events are, would it not be wise in the surgeon, the moment he is brought in contact with these cases, to amputate at a great distance from the disease, ere yet the vital powers have been seriously assailed by the morbid action; to remove, for instance, the thigh at its middle, for senile or chronic gangrene of the toes and foot? The only objection to such a procedure, it seems to me, would be where occlusion of the main artery of the limb reaches above the knee, a circumstance which would readily be determined by a careful previous examination. Where no such disease exists, and the general health has not yet materially suffered, I should not hesitate to resort to the expedient, under the conviction that, however severe, it was perfectly justifiable in a class of cases so unpromising as this confessedly is.

2. *Injuries.*—There are no lesions for which amputation is so frequently required as for wounds, fractures, and dislocations. Although they differ widely from each other in regard to the nature of the structures involved, these injuries may all be very properly classed under the same head, the more

especially as they often coexist, thus rendering it difficult to determine which of them is the most serious.

Of wounds, properly so called, the only ones which require to be considered in connection with the present subject, are the lacerated, contused, gunshot, and railway. Wounds inflicted by rabid animals occasionally, it is true, demand amputation, particularly when they extend deeply among the bones, as, for example, when they occur in the hands and feet; but even in such instances complete riddance can generally be easily effected by a careful excision of the bitten parts, and the cauterization of the raw surface after the cessation of the hemorrhage. I should certainly hesitate to cut off an arm or leg under such circumstances; with the knife and saw I should expect to accomplish all that was necessary, in any case, for the safety of the patient.

Lacerated wounds, as well as contused and gunshot wounds, of a most frightful, and, at first sight, apparently of the most desperate character, are sometimes recovered from in an extraordinarily short time, and with hardly any unpleasant symptoms. On the other hand, experience shows that the most insignificant injuries of this kind occasionally prove fatal in a manner and under circumstances which render it extremely difficult to account for the result. It would be a fortunate matter, both for the public and for the interests of science, if the surgeon could always form, if not a positive, at least an approximative estimate of the danger involved in each particular case of these wounds, for then it would be comparatively easy for him to adopt a suitable treatment for the relief of his patient; but, as it is, much must be left, in every instance, to the experience and judgment of the practitioner. In general, however, it may be observed that all such wounds are fraught with danger, both to limb and life, when they are attended with extensive laceration of the soft parts; when the muscles have been horribly bruised and pulpified, important nerves cut across, the principal arteries, or arteries and veins, torn open, large joints penetrated, and the bones broken in pieces. Under such circumstances there is not even a "forlorn hope," no matter what may have been the previous health and habits of the sufferer; the knife is required, and the sooner it is employed the better. Such cases are absolutely desperate, and no one who has any knowledge of consequences can hesitate as to the course to be pursued. Upon this point there is no discrepancy of opinion whatever among surgeons. But the injury may be of a less severe character, involving, perhaps, merely a considerable contusion of the soft structures with a compound fracture; or several muscles may be badly lacerated and the principal artery of a limb cut across; or a large nerve, the main trunk, it may be, be divided, and the interior of a large joint exposed. The case now assumes a more trying aspect; the responsibility falls upon the surgeon with tenfold force; for the question naturally, and at once arises, What shall be done? Shall such a limb be immediately amputated, or shall an attempt be made to preserve it? This is a question which will probably be asked by the patient himself, or by his friends for him, and which it is often extremely embarrassing and difficult to answer; in fact, it can only be answered upon general principles in one sense, and upon special principles in another. Looking at such injuries in a general manner, we might be inclined to give a favorable prognosis, because it is undoubtedly true that recovery from such lesions is by no means uncommon; but when we come to examine into the particulars of the case, we might not regard it in so auspicious a light. Thus, for example, the patient's antecedents may all have been bad, perhaps of the worst possible description; intemperance and dissipation of various kinds may have undermined his constitution, and thus rendered it unfit to bear up under an injury which he would formerly have supported without difficulty; or, instead of this, there may be serious structural disease of some vital organ, as the heart, stomach,

or lungs, disqualifying him for enduring the accidental and now heavy burden. All these circumstances must have their weight with the practitioner when he is called upon to sit in judgment respecting the propriety or impropriety of an amputation. Conservative surgery may, and does do much, but it cannot do everything; it has its limits, beyond which it cannot safely go, and there are many points which require to be considered in order that it may do itself justice. A very severe injury, occurring in a stout youth, of healthy constitution and temperate habits, is often promptly recovered from, while less than one-third of its amount in a sickly, anemic, or dissipated person, will frequently destroy life in a few days, or, at all events, so far endanger it as to cause great anxiety for the result.

Gunshot, railroad, and steamboat accidents, and injuries occasioned by the caving in of stone quarries, are extremely liable, if an attempt be made to save the limb, to be followed by the worst results; and, what is particularly embarrassing in these cases, is the difficulty which the practitioner often encounters in ascertaining the precise amount of the lesion. The limb, perhaps, is entirely free from contusion and wound, or if there be any injury of this kind, it may be so slight as to be regarded as of no consequence. The mischief is deep-seated, and, upon careful examination, it will probably be found to involve nearly every important structure; muscle, tendon, aponeurosis, vessel, nerve, bone, and joint. Such cases obviously require the closest scrutiny with a view to the speedy detection of their true nature and their proper mode of management. Generally the limb is hopelessly injured, and will require removal.

Compound fractures and dislocations, and gunshot wounds of the joints, often require amputation, and yet it is remarkable how the parts and system sometimes bear up under such injuries, especially in young and healthy subjects. Under the improved methods of management of modern surgery recoveries occasionally occur, which, in former times, when their treatment was less perfectly understood than it is now, would have astonished the practitioner. In this country the treatment of compound fractures and dislocations by collodion, thereby converting these lesions into simple accidents, and of the former by extending and counter-extending bands of adhesive plaster, has greatly contributed to this result. The danger of these injuries is much greater, other things being equal, when they occur in the inferior extremity than when they occur in the arm and forearm, and in all cases the risk is much increased when they are accompanied by an open state of an important articulation, as that of the hip, knee, ankle, shoulder, elbow, or wrist. Compound fractures in the continuity of a limb, unless complicated with serious lesion of the soft structures, do not generally require amputation; if judiciously managed, they will usually get well without much trouble. Gunshot wounds, occurring in civil practice, are commonly less dangerous than injuries of this kind happening on the field of battle or on shipboard. I have seen enough of the former of these accidents to satisfy me that the patient will often recover with a very good limb, even when there has been extensive loss of substance and great comminution of the bones. In military practice, on the contrary, there will often be much difficulty in preserving the parts, simply because it is frequently impossible to treat the case properly on account of the want of suitable accommodations and a salubrious atmosphere. It is for these reasons that amputation is so often resorted to, during and after engagements, in cases which, if they took place under ordinary circumstances, would be successfully managed by milder means.

When amputation is determined upon, in these and similar accidents, the next question that arises is, when should the operation be executed? Shall it be performed immediately, or shall we wait until some time has elapsed, until the system has had an opportunity of recovering from the shock of the

injury? To use the knife while the patient is in an exhausted, pallid, and perhaps almost pulseless condition, would only serve the more certainly and effectually to seal his fate; the additional shock to the constitution resulting from the loss of blood and nervous fluid could hardly fail to prove most disastrous. Hence the rule is always to postpone a resort to the knife until there is satisfactory evidence of reaction; until, in short, warmth and color return to the surface, the pulse beats vigorously at the wrist, and the sufferer regains, in some degree, his consciousness and courage. Now the use of chloroform is well borne, and the limb is removed with comparative impunity. On the other hand, care is taken not to defer the operation until the part and system are assailed by inflammation, which, as experience teaches, often extends with frightful rapidity under such circumstances, placing the case, perhaps, literally beyond the resources of surgery in the course of a few hours. There is, therefore, a time when interference must be avoided, not less than a time when it must be courted. The limits of these two periods are not always well defined, and hence much must be left, in each individual case, to the judgment of the attendant.

When amputation is performed immediately after reaction has taken place, it is usually designated by the prefix "primary," while the term "secondary" is used to denote the operation when it is executed after the limb has passed through the different stages of inflammation, an attempt having been made, perhaps well grounded, so far as the interpretation of the symptoms is concerned, to save the parts. Such a contingency must necessarily happen rather frequently, especially in civil practice; indeed, it is often altogether unavoidable on account of the obstacles interposed by the patient and his friends, not to say anything of the wavering and indecision of the professional attendant. But, although often unavoidable, such an occurrence is always much to be regretted; for if the chances of saving limb and life were bad in the first instance, they are now generally much worse; the system has been impaired by fever and perhaps hectic irritation, the secretions are seriously deranged, the patient has little appetite and sleep, the blood is thin and watery, and the whole body is much emaciated. Life may possibly still be preserved, but the probability is that the operation will be attended with much risk, and that ultimate recovery is far off. Moreover, a much larger amount of limb may now have to be sacrificed; originally a foot might have sufficed, whereas now, in consequence of the ravages of the inflammation, the whole leg may perhaps require removal. There is, then, obviously an advantage in a primary over a secondary amputation, provided it is performed at the proper time, that is, after the establishment of reaction and before the occurrence of inflammation; and this circumstance is often eagerly embraced by the military surgeon, whose will is always law with his patients.

3. *Morbid Growths.*—Amputation is sometimes required on account of morbid growths, or tumors, both benign and malignant. The removal of the forearm is perfectly proper for the cure of carcinoma of the hand, and of the arm at the shoulder for a similar affection of the humerus. No such operation is of course admissible if there is marked constitutional involvement, enlargement of the neighboring lymphatic ganglions, or decided tendency to ulceration; the propitious period has gone by, and interference would only hasten the fatal event. It is not so, however, as long as the general health remains good, and there is no evidence of general or local contamination; under such circumstances the probability is strong that removal of the limb, although it may not prevent a recurrence of the disease, will yet considerably prolong the patient's life.

A tumor, wholly divested of malignancy, may, in consequence of acting obstructingly, cause so much functional and other disturbance as to demand removal of the limb upon which it is situated. The procedure will be par-

ticularly called for when the morbid growth is intimately connected with a bone, or deeply and inseparably involved in the soft parts, or prolonged into an important joint, compelling free exposure of its surfaces during the operation. A valuable rule in tumors is to excise the benign, and to get rid of the malignant by amputation.

4. *Aneurism.*—Neglected aneurisms, seated in the extremities, and unamenable to ordinary treatment, occasionally call for the removal of the limb; in former times, such operations were sufficiently frequent when the disease occupied the popliteal region, though at present they are seldom, if ever, required, except when mortification sets in after ligation of the femoral artery, or in consequence of the injurious compression exerted by the tumor upon the leg.

5. *Affections of Bones and Joints.*—Various affections of the bones and joints, as caries, necrosis, morbid growths, aneurism, and ankylosis, may impose the necessity of amputation; and there is, according to my experience, no class of diseases in which the operation has been more frequently abused, or misapplied. There can be no question that many a limb, merely temporarily crippled by remediable disease, has been ruthlessly sacrificed to ignorance and a desire for eclat; carious joints, now that excision has been revived, can seldom demand so harsh a procedure, and as to necrosis, pure and uncomplicated, it is difficult to conceive of a case justifying the use of the knife. It is only, or mainly, in white swelling, or scrofulous disease of the knee, ankle, and elbow, attended with hectic irritation, excessive pain, and exhausting diarrhœa, that the removal of the limb can be proper, and even then it should not be thought of if it be possible to exsect the affected structures without imperilling life by shock and loss of blood. In whatever manner the offending parts are gotten rid of, it is surprising to witness the great improvement which usually follows the operation; the profuse sweats and alvine discharges rapidly disappear, the appetite improves, the sleep becomes refreshing, and the patient soon regains his flesh and strength. Unfortunately, the operation is generally put off to an unreasonable period, so that when it is at length performed, the sufferer too frequently sinks under its effects.

Of malignant growths of the bones almost the only one demanding amputation of the limbs is encephaloid; scirrhus, melanosis, and colloid are extremely infrequent in the osseous tissue, but whenever they occur, and their diagnosis can be determined, the same treatment must be applied to them as to medullary cancer; that is, early and thorough removal by the sacrifice of the suffering extremity, mere incision being always inadequate by reason of the involvement of the soft parts. Temporary relief only is aimed at; sooner or later the disease recurs, either at the cicatrice, or in some neighboring organ, and carries off the patient.

Fibrous, fibro-plastic, cartilaginous, and osseous growths, involving the bones, sometimes constitute a legitimate ground for amputation. An exostosis, of enormous size, and grotesque form, may render an extremity not only perfectly useless, but a source of the greatest inconvenience and even suffering. The so-called osteo-sarcomatous tumors are, perhaps, of all the morbid growths of the skeleton, the most common causes of amputation of the limbs. Aneurismal formations of the osseous tissue, met with chiefly in the head of the tibia, always demand the same remedy.

Finally, amputation may be required on account of ankylosis of a joint, interfering with the comfort and usefulness of the extremity. Thus, in ankylosis of the knee, the leg may stand off at a right angle with the thigh, so as to interfere materially with the occupation of the individual, and induce a wish for an artificial limb, which, if well constructed, is generally worn with great satisfaction. Stiff and crooked fingers and toes are often the subjects of amputation.

6. *Ulcers*.—Amputation is sometimes performed on account of old and inveterate ulcers of the extremities; the operation, however, is less frequently resorted to now than formerly, and might, with proper management, be almost entirely dispensed with. Unless the sore is of a cancerous character, or caused by burns, scalds, and frost-bites, or complicated with serious lesion of the bones, excessive enlargement of the veins, or great hypertrophy of the integuments, there are few cases, it seems to me, that will not gradually yield under judicious treatment. Of the numerous ulcers of the extremities that have fallen under my observation, embracing, of course, many of the worst description, I have a distinct recollection of only three that required this harsh measure. Whether other practitioners have been equally fortunate I am not able to state; but, judging from the reports of cases in our periodicals, it is highly probable that the operation is still not unfrequently performed on this account.

7. *Malformations*.—There are certain malformations and deformities for the relief of which amputation may be demanded. An irremediable club-foot, especially if complicated with a painful bunion, and intractable ulcer, or excessive atrophy of the leg, would form a proper subject for such an operation, for there are few men who would not rather run the risk attending its performance than to be incessantly fretted and worried by such a disagreeable and useless companion. Supernumerary thumbs and fingers are disposed of in the same manner; the operation is usually done within a few months after birth, and I have never known it to be followed by any bad consequences. Amputation is occasionally necessary on account of deformity caused by burns and scalds, or badly treated fractures and luxations.

8. *Tetanus*.—The propriety of amputating in tetanus has been so long doubted by many of the highest authorities in surgery that the question hardly merits serious consideration in a work of this kind. I have certainly not seen anything in my own practice tending to contradict an opinion now almost universally entertained by the profession in this and other countries. If such a measure is ever justifiable, it must be at the very commencement of the disease, before the supervention of the characteristic symptoms. I have seen a very considerable number of instances of acute traumatic tetanus, and, with one solitary exception, they have all proved fatal. This case occurred in a stout, well-fed countryman, aged fifty years, the fore and middle fingers of whose right hand had been badly mashed by the passage of the wheel of a wagon; symptoms of tetanus came on five weeks after the accident, and, although the disease had existed for five days when I amputated at the metacarpophalangeal articulation, yet complete recovery followed, not, however, without a slight continuance of the spasms for a short time after. I presume a practitioner would hesitate to cut off a large limb after the development of tetanus in any case; for, whatever notions we may entertain respecting the pathology of this affection, there can be no doubt that, once fully established, it must be looked upon as a constitutional disorder in the widest sense of that term.

SECT. III.—METHODS OF AMPUTATION.

Two principal methods are in vogue for performing amputation of the limbs, whether in their continuity or at the joints. These are the circular and the flap, both of which, but especially the former, are of ancient date, and therefore well grounded in the esteem of the profession. To these was added, early in the present century, the oval operation, which, although excellent in its way, has hitherto received but little attention; certainly less than it deserves. Very recently, an operation, termed the rectangular, has

been proposed. It is not my object to enter into the history of these different methods, for to do so would carry me back into the regions of doubt and speculation; but it will be expected that I should offer some remarks concerning their respective advantages and disadvantages, and this I shall endeavor to do in as concise and impartial a manner as may be consistent with the great interest and importance of the subject.

1. *Circular Method.*—The circular operation, the most ancient of all, was originally performed in the most simple manner, the integuments, muscles, and bones being all divided upon the same level. The consequence of this procedure was that the bones, being inadequately covered by the soft parts, or, rather, not covered at all, invariably perished to the distance of several inches, thus sadly protracting the cure, besides subjecting the patient to much suffering and not a little risk in the interval. As surgeons became more enlightened, they endeavored to provide against this contingency by forcibly pulling back the muscles, by means of a peculiar contrivance called a retractor, before using the saw, which was then applied close to the surface of the tissues. At a later period still, and as a decided improvement upon the preceding methods, arose the plan of double incision, devised by Cheselden, better known for his success as a lithotomist than for his exploits as a general operator. It consisted, as, indeed, the name sufficiently indicates, of two stages, in the first of which the integuments were cut and drawn back, while in the second the muscles were divided higher up, the object being to afford more thorough protection to the bone. The operation of the English surgeon has undergone various modifications, some of which, having only served to render it more complex, have been justly discarded from practice. To this category belong the division of the muscles by two circular incisions, one higher up than the other, and the plan of scooping out the parts as the knife was being swept obliquely around them by cutting from below upwards and from without inwards towards the bone, which thus formed the apex of the hollow cone.

The circular operation, as now generally practised, consists, first, in dividing the common integuments, dissecting them from the parts beneath, to a variable extent, and then drawing them back, or even turning them up like the cuff of a coat; secondly, in cutting through the muscles on a level with the retracted skin, and after detaching them for some distance from the bone, to hold them also forcibly back; and, thirdly, in sawing off the bone as high up as possible without doing violence to the soft structures. In executing these several stages of the proceeding the long amputating knife, poised lightly between the thumb and fingers, is carried rapidly round the limb, the point being inserted into its anterior surface, external to the median line, and thence drawn towards the operator in such a manner that the heel of the instrument shall finish the incision. The wound thus made extends simply down to the aponeurosis, and care should be taken that it occupies the same level throughout, unless there be special reasons for carrying it higher or lower at one point than at another, rendered necessary, it may be, by the presence of a vicious cicatrice, ulceration, gangrene, or some morbid growth. The flap is then rapidly dissected up either with the same instrument, or a large scalpel, and held out of the way, its length being

Fig. 156.

Circular amputations shown in the leg, the integuments being turned back, and the muscles divided down to the bones.

regulated by the thickness of the limb, about two inches being a good average. The amputating knife being now resumed, and held as before, is applied closely to the edge of the retracted integuments, and then drawn round the member so as to divide all the muscles down to the bone, as represented in fig. 156. This part of the operation is usually the work of a few seconds. The next step is to separate the muscles carefully from their connection to the bone, to the distance of at least an inch and a half, if not more, when, being pressed forcibly back by means of a retractor, the bone is sawed off close to their surface. The adjoining cuts, figs. 157 and 158, afford a good illustration of the appearances of the limb, both below and above the stump, after this operation.

Fig. 157.

Appearance of the limb below the seat of the amputation, in the circular operation.

Fig. 158.

Appearance of the stump in the circular amputation.

In sawing the bone, whether in this or in the flap operation, it is an object of primary importance to inflict as little injury as possible upon the periosteum; for the less the integrity of this membrane is disturbed the less likelihood will there be of necrosis and other bad consequences. When the periosteum is very thick, as in the thigh-bone, it would be well, in view of this circumstance, to make a circular track in it for the saw, in order that there may be no risk of laceration. The manner of dividing the bone is a matter of some moment. In most of the amputations that I have witnessed the instrument was applied against the front of the bone, instead of being held perpendicularly so as to divide the bone from side to side, as it generally should be to avoid fracture, which is so liable to happen if proper care be not taken to support the limb in this stage of the procedure. Particular rules are usually laid down by authors for working the saw. Thus, it is generally stated that the heel alone of the instrument should be used until a track is made for it to move in; but I consider all such directions to be unnecessary, if not frivolous. If the saw is properly set it is of little consequence, according to my experience, what part is applied first or last, or whether it be moved rapidly or slowly, although, as a matter of choice, I should prefer to finish the operation as quickly as possible. When there are two bones of equal size to be cut, as in amputations of the forearm, they should be divided simultaneously; but if one is thicker than the other, as in the leg, the weaker must always be separated first, lest, if it should remain until the other is sawed through, it

should be broken or splintered, and so impose the necessity of employing the nippers to smooth off its extremity.

When a limb is removed at a joint, the best plan, as a general rule, is to dispense with the use of the saw and pliers altogether, experience having shown that the preservation of the articular cartilages greatly favors the adhesive process, and thereby expedites the cure. Sawing off the ends of the bones exposes the parts to suppuration, erysipelas, caries, necrosis, and even to the danger of pyemia.

2. *Flap Method.*—Although the flap operation was described, and no doubt practised, by some of the earlier surgeons, yet it does not seem to have received any particular attention until towards the close of the seventeenth century, when Lowdham, of Oxford, England, published a short tract upon it, setting forth its advantages over the circular method. After this period, it was occasionally performed in different parts of Europe, especially in France and England, but it never fully acquired the confidence of the profession until the time of Mr. Liston, whose teachings and writings brought it into general notice.

There are several methods of forming the flaps, the choice of which must be regulated by the particular circumstances of each individual case. Thus, the operation may be performed by transfixion of the limb, and cutting from within outwards, by commencing at the surface, and carrying the knife inwards towards the bone, or, lastly, by making one of the flaps after the former fashion, and the other after the latter. In amputations of the thigh and arm, it is customary to make both flaps by transfixion, as the operation is thus greatly simplified and rendered more expeditious; but in the forearm, hand, fingers, leg, foot, and toes, they are formed either by cutting inwards, or one by cutting inwards and the other by cutting outwards. The number of flaps varies; in general there are two, but occasionally there is only one, and, on the other hand, there may be as many as three; accident, or the situation and structure of the limb, rendering one of these modes preferable to the other. Thus, in one instance, I amputated the thigh at its middle by a solitary flap, and succeeded in effecting an excellent cure. The military surgeon is often compelled to form his flaps as best he can, owing to the manner in which the soft parts are injured, and in civil practice the same difficulty sometimes occurs in consequence of the effects of disease. Whatever may be the nature of the case, the rule is never to include any unsound tissues or any portion of bone that is fractured or divested of periosteum. In amputating the thigh and arm at their middle, the flaps are generally cut of the same length; but in most other situations one is usually made considerably longer than the other, depending upon the greater amount of muscular substance. Their relative length must be regulated by the thickness of the limb, and the quantity, laxity, and contractility of the soft parts. It is better, in every case, to have too much substance than too little, but the judicious surgeon will always endeavor so to cut his flaps as to have just enough, and no more, to form a well-shaped and useful stump, redundancy being always unseemly, if not actually in the way of comfort and convenience. As a general rule, their length should equal about three-fourths of the diameter of the limb, being invariably greater than in a similar operation upon the dead subject, to allow for contraction and shrinkage. The form of the body of the flaps is commonly somewhat convex, while the extremity is more or less oblique, care being taken that they do not terminate in thin, narrow ends, and that there is always an abundance of integument after they are adjusted over the bone. When the muscular tissue is unusually abundant, as often happens in amputating through the calf of the leg, I have found it advisable to retrench it with the knife, in order to give the stump a more seemly shape, as well as to place it in a better condition for bearing the pressure of an artificial limb.

In performing the operation the same general rules are to be observed as in the circular method; hemorrhage is restrained by the same means, and the skin is drawn back by the hands of an assistant, who also retracts the flaps as one after the other is made, and thus holds them out of the way of the knife and saw. Any important vessels that may be bleeding are instantly compressed by the fingers until they can be tied. Before applying the saw the knife is pressed closely around the bone so as to divide every muscular fibre, and also, if possible, the periosteum. The most suitable instrument for removing the larger limbs is a long amputating knife; for the smaller ones, an ordinary scalpel, bistoury, or catlin will answer best. Separation of the member having been effected, and the vessels carefully secured, the next thing to be done is to cut off the principal nervous trunks a little above the level of the surface of the stump, and, as the operation is one of excessive pain, it should always be performed before the patient has fully recovered from the influence of chloroform. I need not dwell upon the importance of thus dealing with the nerves involved in the flaps; the necessity of the procedure must be obvious upon the slightest reflection. When it is considered that they always become more or less enlarged and bulbous after all operations of this kind, it is easy to perceive what would be the consequence if they were brought in contact, as some of them almost inevitably would be, with the extremity of the bone, before it has had time to become rounded off. I regard no amputation by the flap method as being finished unless provision has been made against such a contingency. The adjoining cuts, figs. 159 and 160, represent the appearances of the stump and of the limb after its removal.

Fig. 159.

Fig. 159. The flap operation illustrated in the thigh. The sloping wounds, whence the flaps have been taken, shown in the amputated part.

Fig. 160.

Fig. 160 The corresponding stump; intended to exhibit the comparatively small extent of wound that remains.

3. *Oval Method*.—In the oval method, as it is termed by Scoutetten, by whom it has been generalized, or the oblique process, as it has been called by others, the wound has somewhat of the shape of an ovoid, the small extremity of which corresponds to the bone or joint which is the seat of the amputation. The operation holds a kind of intermediate position between the other two, resembling the circular process in the mode of incising the soft parts, and the flap in the form of the wound. It is more especially

adapted to amputations of the joints, particularly the smaller, as, for example, the metacarpo-phalangeal, but has also been applied to the joints of the hip and shoulder, especially by Guthrie, Larrey, and Scoutetten, who have devised plans which severally bear their names.

In the oval operation the flaps are formed by cutting from without inwards, or one is formed in this way and the other by cutting in the opposite direction, or from within outwards. It is commenced by making two incisions in the shape of the letter V reversed, the angle of union falling a little above the place where it is intended to saw the bone or effect disarticulation. These incisions are, of course, extended as far as the periosteum, when the knife, drawn closely round behind the bone, is carried downwards on a level with the termination of the two cuts already made, thus connecting them by one thrust, as the instrument sweeps through the intervening tissues. By adopting this plan of procedure the surgeon will have it in his power to leave the principal vessels and nerves until the operation is nearly completed, a circumstance which thus affords him a much better control over the hemorrhage.

The oval operation usually makes an excellent stump, there being always an abundance of material for covering the bone; it is generally a little more tedious than the flap amputation, but this should not be urged as an objection to it, as in all other respects the result is most satisfactory.

4. *Rectangular Flap*.—Mr. Teale, of Leeds, has recently modified the double flap operation by substituting a long and a short rectangular flap.

The long flap should be made from the portion of the limb which does not contain important bloodvessels and nerves, these being included in the short one. Before proceeding to the operation, the lines of the incision should be traced with ink, in order to insure the proper dimensions of the large flap, which should be equal, in its length and breadth, to one-half the circumference of the limb at the point amputated. The short flap, which should be made last, should be one-fourth the length of the long one. The lines of incision and the length of the flaps will be more easily understood from the annexed cut, fig. 161, representing an amputation of the thigh. The parts having been dissected off, in close contact with the periosteum, the long flap will be found to be perfectly square, and to contain a sufficient amount of movable soft parts to form a complete cushion for the end of the bone, which must be sawn off perfectly straight, and must be free from spicules, in order to prevent ulceration of the soft structures. The arteries having been taken up, the long flap is brought down over the end of the bone, and attached to the short one by several points of the interrupted suture. The short flap is also attached to the long flap laterally, as

Fig. 161.

Teale's amputation, shown in the thigh, the lines indicating the size and form of the flaps.

Fig. 162.

Teale's operation, the flaps being drawn together.

is also the reflected portion of the long flap to its unreflected portion. The appearances of the parts, when brought together, are shown in fig. 162.

Beside the sutures no other dressings are employed. The stump is placed on a pillow covered with a sheet of gutta-percha, and is protected by a wire cage from the pressure of the bedclothes. Should the wound gape during the process of union, a few adhesive strips may be applied, to give the flaps proper support. Absolute rest is enjoined; and the stump should not be disturbed, the discharges being removed from the parts and the gutta-percha cloth by a soft sponge.

Mr. Teale publishes a summary of fifty-six cases treated by his method during the last three years. Of these, the whole number of deaths was seven, or in the proportion of one to eight. Eighteen operations were performed on the thigh, twenty-eight on the leg, six on the arm, and four on the forearm. Of this whole number, only six cases were of traumatic origin, and of these but one resulted in death. This shows a great contrast with seventeen traumatic operations at the Leeds General Infirmary, by the same surgeons, of which ten died, seven from the effects of purulent infection. Amputation of the thigh for disease by this method exhibits a mortality of nearly one case in six, whilst in the London hospitals it is as one in four and a half, and in the provincial hospitals, as one in four.

The rate of mortality in amputations of the leg for disease is one in twenty-seven. In the London hospitals it is one in three and two-thirds, and in the provincial hospitals one in four. Mr. Teale, after carefully analyzing 640 amputations of the thigh and leg, for disease or injury, performed by the ordinary methods in the London and provincial hospitals, found the mortality to be nearly one in three. In forty-six amputations of the thigh and leg by the rectangular flap, for injury or disease, the fatality is one in fourteen, showing a most striking contrast with the above facts.

SECT. IV.—OPERATION AND AFTER-TREATMENT.

The position of the patient and the surgeon, the number and duties of the assistants, and the character of the instruments, must necessarily vary in different cases and under different circumstances, and can therefore be pointed out here only in a general manner.

Whenever it is practicable, the patient should be placed recumbent, as he will thus be much less liable to become faint, and at the same time bear the effects of chloroform much better than when he sits up. He may, however, put himself in the latter position without any inconvenience during the amputation of a finger or toe, or even of the arm or leg, if he is courageous, and willing to dispense with chloroform, or to take ether in its stead. The limb is generally held horizontally, away from the table, one assistant retracting the integuments, and another supporting the portion to be removed. A third assistant takes charge of the tourniquet, but before applying it care is taken to empty the superficial veins by raising the limb and pressing it from above downwards: or, instead of this, the extremity is tightly bandaged just before the operation. Such a precaution, however, is only of material moment when the patient is very feeble, and therefore ill able to bear the loss of blood. Chloroform having been administered, the instrument is firmly secured round the limb, the frame resting upon a thick, narrow compress, lying directly over the main artery, and, when all pulsation is arrested, the operation is proceeded with in as rapid, orderly, and careful a manner as possible. When the amputation is performed high up near the trunk, the tourniquet may advantageously be replaced by the compression of the hands of an assistant, who trusts either to his thumbs alone, or else makes the requisite pressure by

means of the handle of a stout key, wrapped round with a piece of muslin. The same plan for restraining hemorrhage is adopted in amputating at the hip and shoulder-joints. In separating a large limb, not less than five assistants are generally necessary; one for administering chloroform, a second to take charge of the tourniquet, a third to hold up the flaps, one to support the distal portion of the member, and a fifth to hand the instruments and sponges, and aid in securing the arteries. A small number will of course suffice when we remove a finger or other insignificant part.

The different methods of amputation are described in the preceding section. The one which I prefer is that by flap, though it cannot be denied that a most excellent stump may be made by the circular operation. The rectangular method I have never performed, but it seems to me to be a procedure well worthy of attention, as the arrangement of the long flap not only thoroughly protects the bone, but, what is a matter of great consequence, admits of ready drainage. The oval operation is admirably adapted to amputations at the joints and to resections of the bones.

My reasons for preferring the flap to the circular operation, are, first, because it is more simple and easy of execution; secondly, because it makes, as a general rule, a much better covering for the bone, and, lastly, because the patient experiences much greater comfort in wearing an artificial limb. Mr. Palmer, who has for many years been engaged in the manufacture of artificial legs, assures me that stumps made by the circular operation seldom answer well for the adaptation of an artificial substitute.

The principal instruments required for the operation are, for the larger limbs, a tourniquet, an amputating knife, a catlin, saw, and pliers, which are properly arranged upon a tray in the order in which they will be needed. For removing the fingers, hand, toes, and foot, an ordinary scalpel will commonly suffice. The tourniquet in general use is that of Petit, the construction and arrangement of which may be readily learned from the annexed sketch, fig. 163, a circumstance which, besides the fact that it is found in every cutler's shop, will render any formal description of it unnecessary.

The tourniquet of Petit was recently modified by Mr. Tiemann, of New York, in such a manner as to concentrate a much greater amount of pressure upon the artery, at the same time that it does not embarrass the venous circulation. The pad is placed either horizontally or crosswise upon the vessel, and the strap, carried round the limb, is passed through the two side

Fig. 163.

Petit's tourniquet.

Fig. 164.

Tiemann's improved tourniquet.

apertures in the metallic plate, after which the ends are drawn very tight, and fastened on the protruding hooks. The arrangement of the different pieces of the instrument is seen in fig. 164.

Fig. 165 represents an arterial *compressor* which I devised several years ago, as a convenient substitute for the ordinary tourniquet, over which, I conceive, it possesses several decided advantages; first, in the facility of its

Fig. 165.

Author's artery compressor.

application; secondly, in the amount of pressure which it is capable of exerting; thirdly, in its ready adaptation to limbs of different dimensions; fourthly, in the circumstance that it makes pressure only at two points, that is, over the artery, and at the spot immediately opposite to the artery; and, lastly, the facility with which it may be slackened or removed at any stage of the operation. With a little modification, the instrument may readily be adapted to the femoral artery as it emerges from beneath Poupart's ligament, or even to the external iliac just above this ligament, in amputation at the hip-joint, and also to the axillary artery, in disarticulation of the shoulder-joint.

By a reference to the cut, it will be seen that the instrument is composed of two blades, differing in the degree of their curvatures, united by a screw, and regulated by a ratchet. Each short blade is provided with a pad, capable of being worked by a screw, and designed to rest upon the artery which it is intended to compress. By this arrangement two tourniquets are produced: a large one for the thigh, and a small one for the arm, or the thigh of a small subject.

The ordinary amputating knife, seen in fig. 166, is from nine to twelve inches in length, by about five lines in width, with a moderately thick back, spear-pointed, and furnished with a stout, rough, ebony handle to prevent

Amputating knife.

it from dropping out of the hand if it should become smeared with blood. The principal edge should extend the whole length of the blade, and be in the best possible condition for executing its important office, well tempered, and perfectly sharp. The edge upon the back should not be longer than an inch and a half. With such an instrument properly managed, nearly all the amputations in the body may be performed with great neatness and despatch.

The catlin, shown in fig. 167, is a double-edged knife, used principally in removing the forearm and leg, and for dividing the interosseous muscles and ligaments; I cannot see, however, that it possesses any special advantage, even in these cases, over the larger knife just described.

Fig. 167.

Catlin, or double-edged knife.

Every amputating case contains a large saw, resembling the common dove-tail saw of the cabinet-maker. The adjoining sketch, fig. 168, repre-

Fig. 168.

Amputating saw.

sents the form of the instrument which I am myself in the habit of using. The blade, which is very firm, is ten inches and a half in length at the cutting edge, by two inches and one eighth in breadth, exclusive of the back, which is very thick and convex, in order to afford the proper degree of strength which such an implement should always possess. The handle is rough, and sufficiently large to receive two fingers, while the thumb and forefinger are applied to its surfaces, parallel with the upper border, to keep it steady while engaged in the discharge of its duty. The teeth are rather large but sharp, set crossways on the edge, that the instrument may not hang or hitch as it works its way through the bone. The manner of using the saw has already been described.

A small saw, such as is represented in fig. 169, will be of great service in amputations of the hand and foot.

Fig. 169.

Small amputating saw.

Cutting-pliers, seen in fig. 170, of various sizes and forms, must be at hand; they should be short but rather slender in the blades, and very long

Fig. 170.

Bone nippers.

and strong in the handle. Although I never use these instruments when it is possible to employ the saw, on account of their tendency to bruise the

osseous tissue, yet they are of great convenience for removing sharp spicula, and cutting off certain pieces of the skeleton, as the phalanges of the toes and fingers, the ribs, and jaws.

As it respects the permanent *dressings* after amputation, they should be of the lightest and most simple character. In the larger operations they should not, as a general rule, be applied before the lapse of four or five hours, by which time the surfaces of the wound will usually be glazed with lymph, and all danger of hemorrhage be past. I can conceive of nothing more awkward for the surgeon or disagreeable to the patient, than the necessity of undoing the dressings, some hours after the removal of a limb, for the purpose of searching for bleeding vessels. Such a procedure is sure to cause alarm and suffering; and, although it is always desirable to complete the dressings as early as possible in ordinary cases, yet after a large amputation, involving vast and numerous muscles liable to conceal arteries of considerable size, I regard it as a matter of great consequence not to hazard the necessity of their removal. During the period that intervenes between the operation and the permanent dressings, the limb should be placed in an easy and elevated position, and the flaps should either be loosely approximated with a few adhesive strips, or, what is better, left apart, and covered with light compresses wet with cold water, and frequently irrigated; not changed, unless soaked with blood, as this would only lead to exposure and irritation of the parts.

All bleeding and danger of bleeding having ceased, the flaps are carefully stitched in place, the ligatures are brought out at the nearest points, and the intervals between the sutures are covered with long and rather narrow strips of plaster, to admit of sufficient drainage. This should be still further favored, when the breach is very large and deep, by the insertion of a slender tent in the lower angle of the wound, and strict attention to the position of the stump. To a want of these precautions are unquestionably to be ascribed some of the bad effects of these operations, as pyemia, profuse suppuration, and the death of the extremity of the bone. The wound being firmly closed at all points, the matter, of which there is nearly always more or less after all large amputations, accumulates in the depths of the stump, around the bone, and among the muscles, thus causing necrosis of the former, and affording the veins and lymphatics of the latter an opportunity of conveying the fluid into the system, and thereby inducing secondary abscesses. Now, all this risk may be effectually prevented by adopting the plan here suggested of keeping a long, slender, and well-oiled tent in the lower part of the wound for the first thirty-six or forty-eight hours; at the end of this time it may be carefully removed, and any pus that may be present gently pressed out. A gum-elastic tube may now, if necessary, take the place of the tent, with a view to a more ready and steady drainage; or, if the suppurative crisis is passed, the foreign body may be dispensed with, and the case managed in the ordinary way.

The adhesive strips must, if possible, extend four or five inches beyond the upper extremity of each flap, especially in the larger amputations, so as to prevent the retraction of the integuments; and for the purpose also of quieting the muscles and bringing them well forward over the bone. I have been in the habit for many years of beginning the application of the roller at the part of the limb nearest the trunk, carrying it firmly and equably downward to the very verge of the stump, which is then enveloped by a few crucial turns of the bandage, to give it greater support. No other dressing is necessary. The limb is now placed in an easy and slightly elevated position, over a sheet of gutta-percha, and kept constantly wet with cold water, applied by means of a light porous napkin, substitution being employed only in the event of the cloth becoming bloody or offensive. If suppuration be threat-

ened, or the cold is disagreeable and chilling in its effects, the most eligible remedy will be an emollient cataplasm or the warm water-dressing. Provision is of course made to protect the stump from the contact of the bedclothes. As soon as the operation is over, a full anodyne is ordered, for the twofold purpose of relieving pain and preventing spasm; and the dose is afterwards repeated from time to time as circumstances may seem to demand its exhibition. The diet should be light but rather nourishing than otherwise; and, with the exception of a mild aperient on the second day, no medicine whatever should be given unless it is absolutely necessary on account of the violence of the traumatic fever, or the danger of exhaustion from shock and hemorrhage. When the system is much depressed at the time of the operation, it will be well, as a general rule, to put the patient at once upon a generous diet, and perhaps even upon the use of milk punch. I am satisfied, from what I have seen of these cases, that the worst possible plan that can be pursued is starvation; this not only weakens the system still farther but tends powerfully to the production of pyemia and typhoid fever.

The dressings may require removal within forty-eight hours after the operation, or not under three or four days, according to the condition of the parts. When the adhesive action is progressing favorably, the less interference there is the better; any discharge that may collect upon the surface of the stump may be easily soaked up with a soft sponge. If considerable swelling and pain take place, or profuse suppuration set in, the change cannot be effected too soon; and it need hardly be added, that, while it is being made, the stump should be well supported by an assistant, and that all pressure and unnecessary manipulation should be avoided. Any tendency to bagging that may show itself is to be counteracted by the judicious application of the adhesive strips and bandage. The sutures should not be cut out too soon; as long as they are affording support they should be permitted to remain.

After the wound has healed, the stump should be protected for some time with a piece of soft flannel, to prevent the ill effects that might otherwise arise from atmospheric vicissitudes; and all pressure upon its surface should be carefully avoided until the parts have regained their natural sensibility.

SYNCHRONOUS AMPUTATION.

In cases of accident, as well as in certain diseases, but especially in the former, it occasionally becomes necessary to amputate two limbs simultaneously, or in immediate succession, the circumstances which call for the removal of the one demanding the separation of the other. This constitutes what is termed the synchronous double operation. It is founded upon the assumption that the recovery is more rapid when two limbs are cut off simultaneously than at two separate and distinct periods; that the loss of blood will be comparatively little more from two amputations thus performed than from one alone; that there will be, in the aggregate, much less pain, shock, and inconvenience; and, lastly, that the patient will thus escape the harassing anxiety of mind growing out of the knowledge that he will be obliged to submit to another operation. Synchronous double amputation has occasionally been performed in various parts of this country and Europe; but so far as my information extends it was first adopted, as a rule of practice, by the surgeons of the Hôtel-Dieu, at Quebec, the first case having occurred, many years ago, in the hands of Dr. Morris, of that city. Within the last ten years the operation has also been performed several times by Dr. Carnochan, of New York. But the most remarkable instance of the kind of which I have any knowledge, occurred in 1847, at Schuylkill Haven, Pennsylvania, in the hands of Dr. John G. Koehler, who removed simultaneously, on account of a railroad injury, both legs and one arm from a lad, aged thirteen years,
