PREFACE.

In a Dictionary whose object is to elucidate the Physical Sciences, there are various points of great importance, which must be studiously kept in view, if the Editor's task is to be worthily performed, and the book is to take, and to hold its place, as a standard work of reference on the subjects that it includes. The field of the Physical Sciences is so vast—the inventions of the present age are so numerous and startling—processes and methods become so quickly obsolete, as they are replaced by new and more effective means towards the desired ends—that continual vigilance and industry are requisite in the preparation of such a book, lest essential matters should be omitted, and the work should thus fall short of completeness, as a repertory of useful knowledge, which may be at all times consulted, with complete confidence in its fulness and accuracy.

In this Dictionary, accordingly, most anxious care has been bestowed in bringing the information up to the present time, adding such novelties as may have accumulated in the various departments, and rendering complete the articles treating of subjects that have undergone the greatest change within the last few years. Scientific knowledge teaching and processes have in these latter times made gigantic strides, and new theories, methods and operations have taken the place of the time-honoured and old. Scientific principles that were formerly merely matter of conjecture, have been carried into practical adaptation, and increase the comforts and conveniences of every-day life. The electric light, for instance, is an outcome of the scientific advance of the last few years, and has already changed from an ingenious toy to a practical and widely used method of illumination. In these days, the aspect of the world has been changed, partly by the results of travel undertaken by the pioneers of discovery and civilisation, partly by the political changes that have altered the boundaries of existing states, and created new governments and principalities; and in no small measure also, by the healthy spirit of enterprise and adventure, the colonising and empire-spreading instinct of the Anglo-Saxon race, that has caused thriving communities to spring up, where a few years since there were wide uninhabited plains or regions sparsely occupied by insignificant villages or habitations widely distant from each other. All this activity could not fail to have a most important influence on the advance of knowledge, and the processes of experimental and practical science.

These changes necessitate the introduction of a large number of new articles in a Dictionary of the Physical Sciences, and the very careful preparation of the whole. Science and its applications, naturally make large demands upon the care of the editor, in a work of this kind. Electricity, Telegraphic and Telephonic communications, Railways, Steam Navigation, and the various kindred subjects will be found treated in this book, in a manner which, while thoroughly intelligible to the attentive though unscientific reader, gives complete and unduly condensed information with due consideration of technical detail.

Throughout the whole work, in the writing and preparation, and the apportioning of space to the various articles, the object kept steadily in view has been to give the greatest possible amount of accurate information that could be compressed into the space, and to make it in every respect a valuable and trustworthy book of reference. Some pardonable pride may be allowed in recording that the opinions of the press and the suffrage of many thousands of readers have already been given in favour of various works of universal utility in various departments of knowledge, that comprise the series of Beeton's practical reference books; and it is hoped that the present work, prepared as it is with anxious care for accuracy and completeness, will be found not unworthy of taking rank with its predecessors, and will make good its claim to the favour of the people of the British Empire, throughout the world.

BEETON'S

DICTIONARY OF SCIENCE AND NATURAL HISTORY.

AARD-WOLF, *ard'-woolf* (Du., earth-wolf), a genus of digitigrade carnivorous mammals forming the link which connects the civets with the dogs and hyænas. It is a rare and singular animal, having externally the appearance and bone-structure of the hyæna united to the head and feet of the fox, with the intestines of the civet. Its size is about that of a full-grown fox; its habits are nocturnal, and it constructs a subterraneous abode.

AARD-VARK, *ard'-vark* (Du., earth-pig), in Zool., a genus of animals which belongs to the class *Mammalia*, order *Edentata*, genus *Orycteropus* (of which it is the only known species). It feeds upon insects and roots, and burrows in the ground. It is about three feet long, with very short legs, nocturnal in its habits, and passes the greater portion of its time in eating and sleeping. It lives entirely upon ants. The name was given by the Dutch at the Cape of Good Hope. The flesh of the aard-vark is eaten, and even considered, when preserved, a delicacy.

ABAX, *a'-bax*, in entomology, a genus of coleopterous insects.

ABDOMEN, *ab-do'men* (Lat., *abdo*, I hide), in Anat., the belly, or lower part of the trunk, separated from the chest or upper part by the diaphragm. It contains the stomach, intestines, liver, spleen, pancreas, kidneys, &c., and is lined within by a membrane called the peritoneum. For convenience of description, the abdomen is divided horizontally into three regions—the upper or epigastric; the middle, or umbilical; and the lower, or hypogastric. It may also be divided longitudinally by two lines, when the above terms are confined to the central portion, the epigastric having on each side the right and left hypochondriac; the umbilical, the right and left lumbar; and the hypogastric, the right and left iliac.

In Ent., the whole lower portion of the body of an insect consisting of a number of rings or segments, frequently nine, more or less distinct from each other.

ABDOMINALES, or ABDOMINAL FISHES, *ab-dom-i-nai'lees*, the fourth class of animals in the Linnæan system. *Charac.* Ventral fins (those of the belly) placed behind the pectoral, (those of the breast) in the abdomen, and the branchiæ or gills ossiculated. The arrangement of Linnæus is now, however, generally discarded, the term abdominales denoting a subdivision of the *Malacopterygii*, or soft rayed osseous fishes. Carp, salmon, trout, herring, and pike, are familiar specimens.

ABDUCTOR MUSCLES, *ab-duk'-tor*, a term given in Anatomy to those muscles which draw one part of the body from another; as *adductor* muscles are those which draw one part of the body to another.

ABELE-TREE, *ab-ee'-le*, in Bot. called the *Populus alba*, a species of the poplar, having very large leaves.

ABELIA, *a-be'-li-a*, in Bot. a genus of pretty flowering plants belonging to the order *Caprifoliaceæ*, and named from Dr. Abel, a botanist attached to the embassy at China.

ABELMESAK, *a-bel-me'-sak*, the musk-seed, which grows in the West Indies and in Egypt, and is used as a perfume.

ABELMOSCHUS, *a-bel-mos'-kus*. (See Hibiscus.)

ABERDEVINE, *ab'-er-de-vine*, (*Fringilla Spinus*), a song-bird, sometimes called the Siskin, included in the genus *Carduelis*. It resembles the goldfinch, but is rather smaller and less elongated. The crown of the head and the throat are black, and the prevailing colour of the body is dusky green. It is often paired with the canary, to produce what are called mule birds. In its habits it is migratory, breeding in the north of Europe, and visiting Germany, France, and Britain only in the autumn and winter.

ABERRATION, *ab-er-ai'-shun* (Lat., *ab*, from, and *erro*, I wander), a term applied to three highly-important optical phenomena:—

Aberration of Light (or aberration of celestial bodies) designates a small apparent displacement of the fixed stars. It arises from these combined causes—the progressive movement of light (travelling at the rate of 195,000 miles per second), and the movement of the earth in her orbit, by which the eye of the observer is being carried onwards during the time that light takes to travel from the star to the earth. Its effect is to give the fixed stars an apparent movement in space around their true place. The discovery of this remarkable fact was made in 1727, by Dr. Bradley; and it is one that affords an incontrovertible proof of the motion of the earth around the sun.

Aberration of Sphericity designates that deviation of the rays of light which takes place after they have passed through a curved lens, whereby the rays, instead of being collected into a single point, are extended over a small space; thus giving a rather confused image of the object. This deviation is due to the spherical form of the lens itself.

Aberration of Refrangibility is the term applied to that dispersion of the rays of light which happens after they have passed through a lenticular glass, and in consequence of which a variegated ring of colour is seen encircling the image, and thereby rendering it a confused one. This defect has, however, been remedied by the invention of achromatic lenses. (*See* ACHROMATIC.)

ABIES, *ai'-bi-ees* (Lat., *abies*, the fir-tree), in Bot., a genus of plants included in the natural order *Coniferæ*, or cone-bearing family. (*See* CONIFERÆ). They are generally divided into four classes, with the following distinct characters:— 1. Leaves growing singly round the branches, and all turned towards one side (*silvers*); 2. Leaves growing singly round the branches, and all growing equally (*spruces*); 3. Leaves growing in clusters, deciduous (*larches*); 4. Leaves growing in clusters, evergreen (*cedars*). Several species of this genus are valuable timber-trees; as *Abies excelsa*, the spruce fir; *A. alba*, the white spruce; and *A. canadensis*, the hemlock spruce. The resins and gum-resins which these trees exude are extensively used in the arts. The spruce fir produces common frankincense, from which Burgundy pitch is prepared; the balm of Gilead fir (*A. balsamea*) yields Canada balsam; the silver fir (*A. picea*), Strasburg turpentine; and the common larch (*A larix*), Venice turpentine. Essence of spruce, used in the preparation of spruce beer, is formed by boiling the shoots of *A. nigra*, and some other species, in water, and afterwards concentrating the decoction.

ABIETINE, *ai-bi'-e-tine* (Lat., *abietarius*, connected with firs), the neutral resin obtained from Strasburg turpentine and Canada balsam. It is insoluble in water, but soluble in alcohol.

ABIETINEÆ. (*See* CONIFERÆ.)

ABILGAARDIA, *ab'-il-ga-ar'-di-a*, a genus of plants belonging to the order *Cyperaceæ*, and named after Professor Abilgaard, of Copenhagen.

ABIOGENESIS, *ab'-i-o-gen'-e-sis*, a term used by modern biologists, to indicate the production of living from inanimate matter. It was first used by Professor Huxley, to replace the older, but less definite phrase, "spontaneous generation." It is the opposite of Biogenesis, or "derived from life." (*See* BIOLOGY.)

ABLANIA, *ab-la'-ni-a*, a genus of arboreous plants, belonging to the order Tiliaceæ; natives of Guiana.

ABLEPSY, *ab'-lep-se* (from a Greek word signifying blindness), in pathology, defect of sight, blindness.

ABLUENT MEDICINE, *ab-loo'-ent* (Lat., *abluo*, I wash away), a term formerly applied to those medicines which are used for purifying the blood.

ABNORMAL, *ab-nor'-mal* (Lat. *ab*, from, and *norma*, a rule), in Bot., a term applied to aërial roots, like those of the mangrove, which help to support the stem.

ABOMA, *a-bo'-ma*, a species of large serpent inhabiting the morasses of South America. (*See* BOA.)

ABOMASUM, *ab-om-a'-sum*, the fourth stomach of ruminating animals, in which the food is converted into chyme, after being macerated and ground down in the first three stomachs. (*See* DIGESTION.)

ABORTIVE, *a-bor'-tiv*. In Bot., the essential part of the stamen is the anther, and when this is absent the stamen is said to be abortive. The general term abortion is applied to the suppression or new development of any organ.

ABOU-HANNES, *a-boo-'han'-nes*, an African bird (*Ibis religiosa*, Cuvier), identical with the ancient ibis. Although solitary in its habits, it is sometimes seen in small bands of from six to ten, and is capable of a lofty and powerful flight. It has some resemblance to the curlew found in Britain, but has not been observed to run. In Egypt it is called by the inhabitants *Abou-Menzel*, which literally signifies "Father Sickle-bill," from the curved resemblance which it bears to that implement. The Ethiopic name, however, is *Abou-Hannes*, which means "Father John," and which, according to M. Dumont, is applied to it because it arrives in Ethiopia about the day of St. John.

ABRAMIS, *a-brai'-mis* (Gr. *abramis*) a sub-genus of the *Malacopterygii*, including the bream. (*See* ABDOMINALES.)

ABRANCHIANS, *ab-ran'-ke-ans* (Gr., *a*, without, and *branchia*, gills), an order of Anellidians, so called because they possess no organs of respiration. (*See* ANELLIDIANS.)

ABRAXAS, a genus of nocturnal *Lepidoptera*, in which is included the common magpie-moth. Its colour is a yellowish white clotted with black, and a band of pale orange marks the wings. It deposits its eggs on the leaves of the currant and gooseberry in July or August, and the caterpillars are hatched in September. Its chrysalis is black.

ABRAZITE, *ab'-ra-zite*, from a Greek word signifying "without bubbles," a mineral which does not effervesce when liquefied before the blow-pipe.

ABROMA, *ab-ro'-ma*, in Bot., a genus of tropical plants in the *Byttneriaceæ*, or Chocolate order.

ABRUPT, *ab-rupt'* (Lat., *abrumpo*, I break off), in Bot., a term applied to any main root which ends abruptly, as though the point had been bitten off.

ABRUS, *ai'-brus* (Gr., *abros*, elegant), in Bot., a genus of leguminous plants, sub-order *Papilionaceæ*. The seeds of the *Abrus precatorius*, common in tropical regions, are used as beads: they are about the size of a pea, of a bright scarlet colour, with a black mark on one side. The roots possess properties exactly similar to those of the common liquorice.

ABSCESS, *ab'sess* (Lat., *abscedo*, I separate), the name given in Surg. to an accumulation of pus, or matter, in some tissue or organ of the human body. The pus is formed from the blood during the process of inflammation, and the production of it is termed suppuration. When an opening is formed in an abscess, and matter still continues to be discharged from it, it is styled an ulcer. There are few tissues or organs of the body in which abscesses may not form. Abscesses in some organs are comparatively unimportant; in others they are highly dangerous. In the early stage, abscesses are treated by the application of warm bandages or poultices.

ABSCISS, OR ABSCISSA, *ab-siss'-a* (Lat., *abscindo*, I cut off), in Geom., a term signifying a segment cut off from a right line by an ordinate to a curve.

ABSINTHINE, *ab-sin'-thene*, a crystalline principle obtained from the *Artemisia Absinthium*, or wormwood. (*See* ARTEMISIA.)

ABSORBENTS, *ab-sorb'-ents* (Lat., *absorbeo*, I suck up), a name given in Anat. to certain small delicate vessels which imbibe fluids that come in contact with them, and carry them into the blood. (*See* LACTEALS and LYMPHATICS.)

In Med., substances used to absorb or neutralize the acids sometimes formed in the stomach: chalk and magnesia are examples. In Surg., spongy substances used in dressing wounds, such as lint and AMADOU (German tinder).

ABSORPTION, *ab-sorp'-shun*, is the interpenetration of certain bodies by other bodies or influences, which by this means disappear or become lost. There are several important examples of this in Physics.

In Bot., the chief function of the root by which food is taken up in a state of solution for the uses of the plant. (*See* ENDOSMOSE.) The leaves of plants absorb carbonic acid gas and fluids.

In Chem., the disappearance of a gaseous fluid on entering into combination with a liquid or solid; thus, when the gas, ammonia, is passed into water, absorption takes place, and the result is the liquid commonly called spirits of hartshorn.

In Physiol., a term employed to designate that natural function of the body which is exercised by the absorbent vessels; as the absorption of the chyle by the lacteal vessels.

Of Heat, is where the heat-rays seem to disappear within the substances of bodies subjected to their influence, the effects differing greatly according to surface and colour. As this subject is closely connected with the phenomena of radiation and reflection, it will be considered at greater length under the article HEAT. (*See* HEAT.)

Of Light, will be best explained by considering the causes of transparency, opacity, and colour. Transparency in a body is caused by one part of the light striking on it being transmitted through its substance, another being reflected from its surface, and a third being absorbed or lost in its interior. When a body reflects nearly the whole of the light, absorbing only a very small portion, it is said to be opaque. Colour is produced in transparent media by part of the colour contained in white light being absorbed. (*See* COLOUR and LIGHT.)

ABSTRACT SCIENCES (Lat., *abstraho*, I withdraw), those sciences, as pure mathematics, which deal with knowledge independent of its practical application (*See* ABSTRACTION.)

Abstract Mathematics, or Pure Mathematics, signifies that branch of the science which deals with magnitude, figure, and quantity in general, and without reference to any particular magnitude, figure, or quantity. Abstract Mathematics is opposed to Mixed Mathematics, which deals with the application of mathematics to navigation, astronomy, optics, &c.

Abstract Numbers, in Arith., a term which signifies numbers considered in themselves, and without being applied to any individual thing—as 4, 8, 12, &c.—in distinction from numbers applied, or in the concrete—as 4 men, 8 feet, 12 ships, &c.

ABSTRINGENT, from a Latin word meaning "unbinding," in pathology, a term applied to any medicine used for removing concretions or obstructions.

ABUNDANT NUMBERS, *a-bun'-dant*, in Arith., are those numbers the aliquot parts of which, added together, make more than the number itself: thus, the aliquot parts of 20 (1, 2, 4, 5, 10), on being added together, make 22. (*See* ALIQUOT PARTS.)

ABUTILON, *a-bu'-te-lon*, a genus of plants, belonging to the natural order *Malvaceæ*. The most interesting species is the *Abutilon esculentum*, commonly called Bençao de Deos, the flowers of which are boiled and eaten as vegetables in Brazil.

ACACIA, *a-kai'-she-a*, in Bot., a genus of plants, belonging to the natural order *Leguminosæ*, sub-order *Mimosæ*. Many kinds furnish good timber and valuable gums. Various species, natives of Africa and the south of Arabia, yield gum arabic; and the inner wood of the *A. Catechu*, an Indian shrub, affords a kind of catechu, or cutch, rich in tannin, which is used for tanning, and in medicine as an astringent. The pods of some of the Indian varieties are saponaceous and used in washing. The flowers of many species are fragrant.

ACÆNA, *a-see'-na*, from the Greek for a thorn, a genus of herbaceous plants, of the *Tetrandria-Monogynia* class. (*See* SANGUISORBACEÆ.)

ACÆNITUS, *a-see'-ni-tus*, a genus of insects of the tribe of ICHNEUMONIDES.

ACALEPHÆ, *a-ka-le'-fe* (Gr., *akalephe*, a nettle), a class of marine invertebrate animals, comprehended in the sub-kingdom *Radiata*, and otherwise called Sea-nettles. It embraces an extensive number of animals, of which the genus *Medusa* of Linnæus may be taken as the type. This genus has a nervous system and senses; a muscular system; a reproductive system and development; the power of stinging when touched; and is phosphorescent. *Acalephæ* have been separated into four families—the *Pulmograda*, the *Ciliograda*, the *Cirrhigrada*, and the *Physograda*. These families exhibit a great variety of genera of peculiar structure and form. Some of them are extremely beautiful. (*See* JELLY-FISH and MEDUSA.)

ACANTHACEÆ, *a-kan-thai'-se-e*, in Bot., the *Acanthus* order. Herbs or shrubs found in most parts of the world, and abounding in the tropics. There are nearly 1,400 known species, some having very beautiful flowers. The elegant lobed and sinuated leaves of the acanthus, which may be taken as the type of the order, are stated to have suggested the capital of the Corinthian pillar. (*See* ABACUS.)

ACANTHION, *a-kan'-the-on*, in Zool., a genus of *Rodentia*, known, at present, only by their osteology. The genus was established by Cuvier.

ACANTHOCEPHALA, *a-can'-tho-cef'-a-la* (from two Greek words meaning "spine-headed"), intestinal worms which attach themselves by means of curved spines. (*See* ENTOZOA.)

ACANTHODERMA, *a-kan-tho-der'-ma*, a fossil genus of fishes, from Glaris.

ACANTHODES, *a-kan-tho'-dees* (Gr., *akantha*, a point; *odous*, a tooth), a genus of fossil Ganoid fishes, found in carboniferous strata, near Edinburgh, Scotland.

ACANTHOPHIS, *a-kan'-tho-fis*, in Zool., a genus of venomous serpents, allied to the vipers. From these, however, they are distinguished by their having a single series of plates beneath the tail, except towards the very end of it, where, in some instances, they are separated into two small rows. They are viviparous, and conceal themselves among the roots of trees, depending for their prey on the effects of the poison with which they are imbued.

ACANTHOPHTERYGII, *a-kan-thof-te-ry'-ge-i*, one of the two primary divisions of osseous fishes, divided by Cuvier into fifteen families. They have spinous rays in the first portion of the dorsal fin, or in the first dorsal, if there are two. The bass, perch, gurnard, mackerel, and tunny belong to this division.

ACANTHURUS, *a-kan'-thu-rus*, a genus of fishes, of the order *Thoracici*, natives of the Indian and Arabian seas. The genus contains a large number of species, many of which are extremely beautiful in form and colour.

ACARUS, *ak'-a-rus* (Gr., *akari*, a mite), the tick or mite, the common mite found in dry provisions. There are many species, and it was an acarus which some years since M. Crosse supposed was produced by electricity. (*See* SPONTANEOUS GENERATION.)

ACAULESCENT, *a-kawl-es'-sent* (Gr., *a*, without, and *kaulos*, a stem), in Bot., a term applied to plants having very short or inconspicuous stems.

ACCELERATION, *ak-sel-le-rai'-shun* (Lat., *acceleratio*, hastening), is when the velocity of a moving body is continually increased. With whatever velocity a falling body moves in the first second, it will, at the end of two seconds, move with twice that velocity, and so on; the force of gravity increasing as the body approaches the earth. This is, however, practically modified, as a little time is lost through the increased density and consequent resistance of the air at each moment.

Of the Moon, is the apparent increase of the moon's velocity in her revolution round the earth. It is exceedingly slight, not more than ten seconds in a century, and is supposed to have been going on for about 141,000 years. It is due to the varying eccentricity of the earth's orbit.

Of the Stars, the time by which the fixed stars, in their transits over a meridian, anticipate the diurnal motion of the earth.

Of the Tides, are certain irregularities in the difference between the time of high water, which difference would be constant supposing the tides occurred at regular intervals. (*See* TIDES.)

ACCIPENSER, *ak-se-pen'-ser* (Lat., *acipenser*, a sturgeon), a genus of fishes, of the order of *Amphibia nantes*. It has a single linear nostril; the mouth is in the under part of the head, and without teeth; the filaments are below the snout, and before the mouth. There are three species of this genus—1. *Accipenser Huso*, the largest, is a native of Russia. The skin is so strong that it is used for traces in drawing vehicles. The isinglass of the shops is made from its sounds and scales.—2. *Accipenser Ruthenus* is also a native of Russia.—3. *Accipenser Sturio*, or the sturgeon, is frequent in our rivers. Isinglass is also made of the sounds of this fish. The sturgeon is sometimes found of the length of 18 feet, and weighing 700 lbs. It is oviparous, and spawns in water. (*See* ISINGLASS and STURIONIDÆ.)

ACCIPITRES, *ak-sip'-e-trees* (Lat., *accipiter*, a hawk), the Linnean name of an order of birds having eagles' crooked beaks and powerful talons. In this order are classed vultures, falcons, hawks, and owls. Later ornithologists prefer for the name of the order, RAPACES.

ACCLIMATIZE, *ak-kli'-ma-tize* (Lat., *ad*, to, and *clima*, a climate), to accustom an animal or plant to a climate not natural to it. A change of climate induces a certain change in the constitution of the individual, greater or less, according to the amount of difference between the two climates. In cases where the difference is extreme, diseases and even death may be the result. The change produced by acclimation may be either an improvement or a deterioration. Some plants or animals possess the power of bearing changes of climate to a much greater extent than others; and, frequently, a change which cannot be effected in one individual, may be brought about more gradually in the course of a few generations. The power of bearing changes of climate is remarkable in the human species, particularly in the Anglo-Saxon race. The Jewish race exhibits a remarkable facility for acclimatization. Next to man, the dog is the animal best adapted to change of climate.

ACCRESCENT, *ak-res'-sent*, in Bot., a term applied to a persistent calyx, that continues to grow after the flowering, so as to form a sort of bladder round the fruit.

ACCUMULATION, *ak-ku-mu-lai'-shun*, (Lat., *cumulus*, a heap), is that kind of motion existing in some kind of machines at the end of intervals of time during which the velocity of the moving body has been constantly accelerated.

ACCUMULATOR, an electrical machine which generates or accumulates, by means of friction, electric currents of high tension. It is an adaptation of the ordinary cylindrical frictional machine, and the exciting body consists of a large disc or circular plate of vulcanite, or "ebonite" as it is generally named by electricians.

ACEPHALA, *a-sef'-a-la*, from a Greek word for "headless." (*See* MOLLUSCA.) Also an order of insects. (*See* ENTOMOLOGY.)

ACEPHALOCYST, *a-sef'-a-los-ist* (Greek, "a headless bladder"), an intestinal parasite which has the appearance of a simple bladder without any visible organs. (*See* ENTOZOA.)

ACER, *ai'-ser* (Lat., sharp), in Bot., an important genus of the natural order *Aceraceæ*. Many useful and ornamental trees are included in this genus.—*Acer saccharinum*, the sugar-maple, yields a great portion of the sugar used in America. (*See* MAPLE.) *A. campestre* and *A. pseudo-platanus* are common timber-trees in Britain; the latter is commonly known as the sycamore.

ACERACEÆ, *ai-ser-ai'-se-e*, in Bot., the maple order. The plants of this order are handsome trees, which furnish light and beautiful wood, much used in the arts. They are also remarkable for their saccharine sap. They grow in the temperate regions of Europe, Asia, and North America. (*See* ACER.)

ACERANS, ACERA, *a-ser'-rans* (Gr., *a*, without, and *keras*, a horn), in Ent., a family of wingless insects.

ACERIC ACID, *a-ser'-ick* (Lat., *acer*, the maple), an acid obtained from the sap of the maple-tree.

ACETABULUM, *a-se-tab'-u-lum* (Lat., a small cup or dish), signifies, in Zool., the suckers of the arms of the cuttle-fish, as well as other dibranchiate cephalopods, which have on this account been termed acetabulifera.

In Anatomy, that deep cup-like cavity which receives the head of the femur, or thigh bone, thus forming the hip-joint.

In Entomology, the cavity in the trunk in which the leg is fitted.

ACETAL, *as'-e-tal*, in chemistry, a thin colourless fluid, boiling at 221° F., its specific gravity being ·821. It is one of the products of the slow oxidation of alcohol vapour under the influence of finely-divided platinum.

ACETARIOUS PLANTS, *a-se-tair'-e-us*, (Lat., *acetaria*, a salad), plants such as endive, mustard-and-cress, lettuce, &c., used for salads.

ACETATE, *a'-se-tait*, in Chem., a compound formed by the union of a base with acetic acid. Many of the acetates are of great importance in the arts. The most important is acetate or sugar of lead. All the acetates are soluble in water.

ACETIC ACID, *a-set'-ik*, in Chem., is produced by the oxidation or destructive distillation of organic bodies containing its elements—carbon, hydrogen, and oxygen. When pure, it is a colourless liquid of specific gravity 1·064, which crystallizes at a temperature below 60° F. It has a pungent smell, and is highly corrosive. Vinegar and pyroligneous acid are impure varieties of acetic acid. (*See* VINEGAR.) The crude acetic acid, known as pyroligneous acid, is one of the liquid products of the destructive distillation of wood. Oak and beech are the woods most commonly used in the manufacture, and the distillation is generally conducted in large iron cylinders. By a beautiful but tedious process, the acetic acid contained in the impure product is made to unite with soda, so as to form pure acetate of soda. This salt, when distilled with concentrated sulphuric acid, yields a colourless liquid, which is acetic acid. A portion of this crystallizes at a temperature of from 40° to 50° F., constituting what is called *glacial acetic acid*. The chemical composition of acetic acid is represented by the symbol $C_4H_4O_4$. Its uses are numerous and important. In the Arts, it is employed for the preparation of the various acetates, especially those of iron and alumina, which are the chief mordants of the calico-printer, for dissolving gums in making varnishes, and for photographic purposes. In Medicine, it is used externally as a local irritant, and internally as a febrifuge.

ACETONE, *a-se-tone'*, in Chem., a colourless volatile fluid, having the composition $C_6H_6O_2$, obtained by the distillation of the acetates of the alkaline earths. It has a peculiar odour, and is very inflammable. It is sometimes called *pyroacetic spirit*. As a remedy for asthma, it is occasionally used in medicine. In a pure state, it is a colourless mobile fluid which boils at 133° F.

ACETYL, *a'-se-til*, in Chem., a term applied to the supposed basis of vinegar and other acids. It is known also as Acetoxyl and Othyl.

ACETYLENE, *a'-set-e-leen*, a luminous hydrocarbon gas, resembling coal-gas, discovered by Berthelot, the eminent French chemist.

ACHENIUM, *a-ke'-ne-um*, in Bot., a one-seeded fruit, having a dry shell, or pericarp, which is closely applied to the seed, though separable from it. This pericarp is indehiscent, that is to say, it remains closed, and the seed can only become free by its decay. The little hard bodies scattered over the surface of the strawberry, and those we find clustered together in the centre of the buttercup, are achænia.

ACHATMA, *a-kat'-ma*, in Zool., a genus of terrestrial gastropods.

ACHERONTIA, *a-ke-ron'-she-a*, a genus of Lepidopterous insects, fam. *Sphingidæ*, which embraces some of the largest European Lepidoptera, the most remarkable of which is the *Acherontia atropos*, or Death's-head Hawk-moth (which *see*).

ACHILLEA, *a-kil'-le-a*, in Bot., a genus of plants belonging to the natural order *Compositæ*. The *Achillea Millefolium*, commonly called the Yarrow, or Milfoil, is the most important British species. Its white or rose-coloured flowers adorn many of our meadows, particularly those with silicious soils, from June to September. From these flowers an essential oil is obtained, and an infusion of the leaves and flowering heads is said to be a valuable stomachic. The leaves are in repute with some country people for healing wounds. The pretty garden plant known as white bachelor's buttons is a cultivated variety of a species of achillea. The familiar sneezewort and the aromatic genipp of the Alpine districts are other varieties. The generic name is derived from Achilles, who, in the Homeric legend, is said to have discovered the medicinal properties of the milfoil while studying botany under Chiron.

ACHILLES' TENDON, *a-kil'-lees ten'-don* (Lat., *tendo Achillis*), in Anat., a tendon which connects the muscles of the calf of the leg with the bone of the heel. It takes its name from the fable of the mother of Achilles dipping him in the river Styx to render him invulnerable. During this operation she held him by the heel, which was consequently untouched by the water, and there he subsequently received his death-wound.

ACHILLEUM, *a-kil'-le-um*, a genus of fossil *Spongiadæ*, of which there are two species found in the cretaceous strata of England. (*See* SPONGIADÆ.)

ACHLAMYDEOUS, *a-kla-mi'-de-us* (Gr., *a*, without, and *chlamus*, a cloak), in Bot., a term applied to flowers which have only stamens and pistils, the floral envelopes being wanting. The naked flower of the common ash is an example. This consists merely of the essential organs of reproduction, and has neither calyx nor corolla.

ACHRAS, *ak'-ras*, in Bot., a genus of plants belonging to the order *Sapotaceæ*, or *Sappodilla* family. They are natives of the tropical parts of India, Africa, and America. Several species yield luscious fruits; thus, the *A. sapota* produces the sapodilla plum, and the *A. mammosa* the marmalade. The barks of certain species are used medicinally in the treatment of fevers, and the milky juices of others yield substances resembling gutta-percha. (*See* SAPOTACEÆ.)

ACICULAR, *a-sik'-u-lar*, in Bot., a term signifying needle-shaped, applied to narrow leaves, like those of the fir. The term *linear* is more commonly used, and is to be preferred.

ACIDASPIS, *as-sid-as'-pis*, a genus of fossil *Crustacea*, of the group *Trilobites*, found in the Wenlock limestone.

ACIDIFIABLE BASES, *a-sid'-e-fi-a-bl*, in Chem., substances which are capable of being converted into acids; also termed *radicals*.

ACIDS, *as'-sid* (Lat., *acidus*, sour), a numerous and important class of chemical bodies, which are distinguished by the property of combining with alkaline bases to form salts, which have neither acid nor alkaline characters. (*See* BASE and SALTS.) Acids are generally sour to the taste; in most instances they have a great affinity for water, and are soluble in it; they redden nearly all the vegetable blues; they unite with metals or their oxides, alkalies, and earths. It was long held that oxygen was contained in all the acids. This element does indeed enter into the composition of the greatest number; but every true acid must contain hydrogen, and an acid is now commonly defined as a salt whose base is water. The acids furnished by the mineral kingdom are termed *mineral acids*. *Metallic acids* are formed by the combination of oxygen and a metal; and *organic acids* are those which contain carbon, or are formed with organic substances. (*See* CHEMICAL NOMENCLATURE.) The organic acids, which are very much more numerous than the mineral acids, and which all contain carbon and hydrogen, a large proportion oxygen, and some nitrogen, have no regular nomenclature. The most important of these chemical bodies are—among the mineral acids, sulphuric, sulphurous, hydrosulphuric, nitric, phosphoric, arsenious, arsenic, chromic, hydrofluoric, hydrochloric, chloric, iodic, carbonic, boracic, and silicic; among the organic acids, formic, hydrocyanic, oxalic, acetic, malic, tartaric, succinic, benzoic, citric, &c. (*See* these words.) Acids are extensively employed in medicine, principally in cases of inflammation, fever, palpitation of the heart, and irritation of the skin.

ACINACIFORM, *a-se-na'-se-form* (Lat., *acinaces*, a scimitar, and *forma*, form), in Bot., a term signifying scimitar-shaped; applied to certain succulent leaves.

ACINUS, *as'-e-nus*, in Bot., one of the divisions of the fruit of the raspberry.

ACONITE, *ak'-on-ite*, OR ACONITUM, *a-kon-i'-tum* (Greek, *akoniton*), in Bot., a genus of plants belonging to the natural order *Ranunculaceæ*, the Crowfoot or Buttercup family. Nearly all the species are poisonous; but when the extracts prepared from them are used in proper doses, their narcotic and diaphoretic effects prove highly beneficial. The flowers of many species are remarkable for their beauty, and resemble little helmets. The root of the *Aconitum ferox* is the principal source of the celebrated Indian poison, *bikh* or *bish*. The monkshood, *Aconitum Napellus*, is a native of Europe, and is cultivated as a garden plant for the sake of its handsome purple flowers. Preparations from this species are used in the treatment of neuralgia, acute rheumatism, and diseases of the heart. Its active principle is aconitine. The root of the *A. heterophyllum* is said to possess no poisonous properties, and to have a high reputation in India as a febrifuge and antiperiodic medicine.

Aconitine, or Aconitia, a powerful vegetable alkaloid, prepared from the root of the *Aconitum Napellus*. An ointment containing aconitine is often used in cases of neuralgia.

ACONTIA, *a-kon'-she-a* (Gr., *akon*, a dart), a genus of serpents established by Cuvier, and forming a link between the true serpents and the common snakes. Without bones; the usual lizard or serpent head; body covered with small scales only, but without the horny plates which guard its under surface in the common serpents; without poison-fangs, and with gentle habits; in general, of a small size, and it feeds on worms and insects. It is found in almost every part of the old world.

ACORN, *ai'-korn* (Sax., *aac*, an oak, and *cern*, grain), in Bot., the fruit of the oak-tree. (*See* QUERCUS.)

ACORN SHELL. (*See* BALANUS.)

ACORUS, *ai'-ko-rus* (Gr., *a*, without, and *kore*, pupil of the eye), in Bot., the sweet flag, a member of the natural order *Orontiaceæ*. This plant grows in watery places, and abounds in the rivers of Norfolk, whence the London market was formerly supplied. It blossoms during the months of May and June, and is the only truly aromatic plant growing wild in this country. The thick creeping stem or rhizome, commonly called the Calamus root, is the valuable part of the plant; it is somewhat spongy and powerfully aromatic, and has a bitterish taste. It is used by rectifiers to improve the flavour of gin, and is also employed to give a peculiar taste and fragrance to certain kinds of beer. Perfumers make use of it in the manufacture of hair-powder, and tanners in the preparation of peculiar sorts of leather. From the fresh rhizome a volatile oil is obtained by distillation, used in making aromatic vinegar, and for scenting snuff. In many parts of the continent, the root, cut into slices and prepared with sugar, is eaten as a sweetmeat. In Med., the sweet flag is sometimes used as an aromatic stimulant and a tonic, and many physicians speak highly of its beneficial effects in cases of ague. It grows in most parts of Europe, in Asia, and in the United States; and in Catholic countries it is used for strewing the churches at great festivals. It is supposed to be the *calamus* of the Song of Solomon: hence its botanical name, *Acorus Calamus*.

ACOTYLEDONS, ACOTYLEDONES, *ai'-ko-ti-lee'-dons* (Gr., *a*, without, *cotuledon*, seed-lobe), in Bot., are those plants which are propagated by spores, or cells, and not by true seeds. Cotyledons are the rudiments of the first leafy organs which make their appearance in the development of plants springing from seeds properly so called. These rudimentary organs do not exist in spores, which are accordingly said to be acotyledonous. Cryptogamous, or flowerless plants, are included in this great class, horsetails, pepperworts, club-mosses, mosses, liverworts, charas, lichens, fungi, and algæ.

ACOUCHI, *a-koo'-she*, is a small rodent animal very much resembling the agouti, but less in size. It is an inhabitant of the woods of Guiana, has only the rudiments of a tail, and subsists upon almonds, nuts, and other forms of vegetable food. (*See* AGOUTI.)

ACOUSTIC DUCT, *a-koo'-stik* (Greek, *akoúo*, to hear), in Anat., a term applied to the *meatus auditorius externus*, or external passage of the ear.

ACOUSTICS is the science which treats of the nature of sound, the laws regulating the production and the propagation of atmospheric or other vibrations in substances, solid or fluid. Sound is really a vibrating movement caused by putting the parts of an elastic body in rapid motion. When this is sufficiently rapid to strike the ear—that is, when the regular vibrations amount to about forty in a second—we hear what we term a harmonious sound, or musical note. Noise is a single blow inflicted on the ear, or an irregular motion of air particles. But, before the ear can have a perception of sound, it is necessary that some medium capable of vibration should exist, so as to transmit the vibrations to the brain. This "sounding body" is known to us as the "drum" of the ear, and the air is the conductor.

Take away the air, or alter its usual component parts, and the sounds previously audible will become indistinct. Newton showed that sound propagation depends upon the elasticity of the medium. Subsequent observations proved that when a force disturbs the particles in the atmosphere, or other body, they are moved to and fro, somewhat after the manner of a pendulum; these first moving particles strike other particles, causing them to vibrate also, so the "wave of sound" is created and travels on. This can be shown by the tuning fork. The prongs beat the air in opposite directions at the same time, and, as one prong strikes the air, it is driven away and condensed; the condensation then travels outwards, the prong recedes, beats back the air, and rarefies it on the first side. The rarefication and the condensation travel one behind the other at the same rate, and maintain the same relative positions. As the fork vibrates, each wave travels on with equal rapidity. Thus, if the fork makes one hundred vibrations in a second, at the end of that time the first sound-wave would have travelled, say, eleven hundred feet, and between the fork and the limit there would exist one hundred sound-waves, each eleven feet long. And so on, the quicker the vibrations, the less the wave length. Eleven hundred vibrations per second would produce eleven hundred waves, each a foot long; for, as we said above, sound-waves of all lengths travel at the same pace. When the vibrations of the air-particles take place at right angles to the direction in which the disturbance moves, the vibrations are said to be *transversal*. If moving in the same direction they are called *longitudinal*; but, of course, the vibrations may take place in any direction. The loudness usually diminishes as the distance increases between the hearer and the place where the sound originated, in consequence of the diminution in the density of the air; but Poisson states—and balloonists have verified the statement—that when *different* densities of air interpose between the ear and the sound source, the loudness of the sound heard depends upon the density of the air *at the source*. So, people in a balloon may and do hear sounds proceeding from the earth quite as distinctly as we upon the earth, at equal distances, hear the same sounds, while a faint sound from the balloon would be no louder, but not less loudly heard, on the ground, as when equi-distant in the air on a level with the balloon. Although air, from its being the medium most commonly in contact with the *membrana tympani* of the ear, is the most general conductor of sound, yet, other agents are capable of transmitting it. A bell rung under the waters of Lake Geneva was heard across the whole extent of the water, a distance of nine miles. With respect to its production in the air, Sir John Herschel has shown that, in round numbers, sounds of every intensity travel, at the temperature of 62° Fahr., at the rate of 1,125 feet per second, equal to $12\frac{3}{4}$ miles per minute, or 765 miles an hour. The velocity with which sound travels through different bodies varies greatly. The velocity of sound in air differs with temperature, and the rate of transmission, though different, varies considerably, being much slower through carbonic acid than through atmospheric air, and increasing in a fourfold proportion when passing through hydrogen. We need not here touch upon musical harmony farther than to mention the different qualities of sounds, which are *loudness*, *pitch*, and *timbre*. The first depends upon the *extent*, the latter, the *pitch*, on the rapidity of vibration. "Loudness is the violence with which the vibrating portions of the ear are excited." The *pitch* of a note is higher in proportion to the number of vibrations of the air in a given time—a second. *Timbre* is the different impression produced by similar sounds on different instruments—as the same note on a trumpet and on a flute. The intensity of sound is much augmented if the vibrations be confined in tubes and cavities of any kind. By means of a speaking-pipe, sounds, however slight, may be transmitted from one part of a building to another; whilst the stethescope conveys to the ear the slight sounds generated in the chest. The invention of the telephone and microphone have made a remarkable revolution in our sound-carrying instruments. Biot ascertained that the slightest sound can be heard through an iron pipe 3,120 feet in length. Sound is reflected like light, reflected sound being termed an echo. Some sounds are different only in intensity or loudness, as the reports of a musket and of a cannon; other sounds differ in musical pitch, as two notes from the same instrument; while others, again, are different in character of tone—what the French call *timbre*. We have seen that sound is produced by a certain vibratory force being transmitted through air, producing what is termed a wave of sound. The ear is designed to take cognisance, within certain limits, of these pulses of force, waves, or tremors. The nature of things prevents a single wave of sound from ever coming alone; the more nearly alone a wave comes, the more sharp and sudden the sound. When several nearly equal waves come at irregular intervals, the sound is called a noise. When the waves are equal and at equal distances, the sound is called a musical note. The middle C, between the bass and treble clef, is produced by waves about 8ft. 10 in. apart; waves at half that distance apart produce a tone one octave higher. If the distance apart of the waves of one note bears a simple ratio ($\frac{1}{2}$, $\frac{1}{3}$, $\frac{2}{3}$, $\frac{1}{4}$, $\frac{3}{4}$, $\frac{2}{5}$, $\frac{3}{5}$, $\frac{4}{5}$, $\frac{3}{7}$, or $\frac{4}{7}$) to the distance apart of the waves of another note, the two notes harmonize; otherwise, they are discordant. The gravest musical sound is produced by about 16, and the sharpest by about 12,000 vibrations in a second. The sonorous vibrations of bodies are exceedingly curious, and the more difficult to be understood from our habits of measuring changes or motions by the sight; but these motions affect very sensibly another organ. The ear at once perceives the difference between a grave and an acute sound; but it is only from attentive observation by the eye that we discover the different rapidity of succession in the vibrations which produce them. The vibrations of a great many bodies, as strings, bells, and membranes, when emitting sounds, may, however, be distinctly seen, and even felt; but they may often be rendered more visible to the eye by a little artifice, such as sprinkling the vibrating body with sand, or some light granular substance. It was reserved for Ernest Chladni, a German of the last century, to contrive an apparatus for rendering sonorous vibrations visible, and his discoveries have proved of the greatest importance to the science of Acoustics. The idea was suggested to him of employing a violin bow to examine the vibrations of different sonorous bodies. When he applied the bow to a round plate of glass, fixed at its middle, it gave different sounds, which, compared with each other, were (as regards the number of their vibrations) equal to the squares of 2, 3, 4, 5, &c. The experiments on the electric figures formed on a plate of rosin, discovered by Lichtenberg, led him to presume that the different vibratory motions of a sonorous plate might also present different appearances if a little sand or some similar substance, were spread on the surface. These effects may be clearly shown by squares of plate glass. These plates may be held by a small wooden vice, or secured by a clamp in the centre. The edges of the plate must be smoothed by emery, and sand strewed upon them. On drawing the fiddle-bow across the edge of the plate, near one of its corners, the sand forms a figure in consequence of the vibration. This is the gravest tone, and the tone next to it in graveness is produced by applying the bow to the middle of one of the sides, upon which the sand is loosed away from certain parts of the surface and assumes another figure. By varying the points when the bow is applied, many beautiful figures may be produced. Dr. Tyndall, in one of his lectures upon sound at the Royal Institution, demonstrated that sound was really the consequence of waves in the air, or, in other words, that without air sound could not be propagated, by the following experiment. The professor placed a bell in the glass receiver of an air-pump; he then exhausted it of its atmospheric air. The bell was agitated, but gave out no sound. He allowed hydrogen gas, which is fourteen times lighter than air, to enter the receiver: the bell was scarcely heard to sound. On exhausting the receiver of the hydrogen gas, an almost perfect vacuum was obtained; the hammer was made to strike the bell violently, but, though a spectator placed his ear close to the glass vessel, not the faintest tinkle could be heard. The bell, in this instance, was suspended by strings; had it been placed upon the plate of the air-pump the vibrations would have been communicated to the air outside the receiver. When the atmospheric air was allowed to re-enter the vessel, a slight sound was at once heard, which, as the air became more dense, grew louder and and louder until the full sound of the bell was heard. The vibrations of a membrane may be well exhibited by stretching a piece of bladder over the mouth of a funnel and passing a horse-hair, retained by a knot, through its centre. By drawing the hair through the fingers, previously rubbed over with rosin, the membrane will be made to vibrate; and if sand or lycopodium be scattered on its surface, a symmetrical arrangement of the heavy particles at the nodal lines, as well as the accumulation of the light particles at the centres of vibration, may be observed. If a thin membrane be stretched on a triangular, square, or circular wooden frame, and strewed with sand, its vibrations will be readily excited by holding a tuning-fork, bell, or other vibrating body, near it, and they will be indicated by the motions of the particles of sand. French tracing-paper, or still better, thin parchment-paper (prepared by immersion in strong sulphuric acid), damped a little and attached by paste to the edges of the frame, will answer very well for these experiments.

ACRASY, *ak'-ra-se*, OR ACRATIA, *a-kra'-she-a*, (Greek "wanting strength"), in pathology the undue prevalence of one particular quality in the human constitution more than another; constitutional weakness of the body.

ACRIDIANS, ACRIDIA, *a-krid'-e-ans* (Gr., *akris*, a locust), a family of orthopterous insects.

ACRITES, ACRITA, *a-kri'-tees* (Gr., *akritos*, indiscernible), the simplest and lowest division of the animal kingdom, which embraces the *Infusoria*, *Rhizopoda*, and Sponges. (*See* these words.)

ACROCHORDUS, *ak-ro-kor'-dus*, a genus of serpents discovered in Java. The special characteristics are—head flat, and with the body covered with small scales; without poison-fangs, but possessing a double row of sharp-pointed teeth; throat capable of great extension; tongue thick and short; length from 8 to 10 feet. This serpent is supposed to eat fruit.

ACROGENÆ, *ak-ro'-je-ne* (Gr., *akros*, summit, *gennao*, I produce), in Bot., those acotyledonous or cryptogamous plants with visible stems and leaves. The stems of such plants are always acrogenous; that is to say, they grow only at their summits. (*See* STEM.) The tree ferns are examples. Various names have been given by botanists to plants of this class. This term is itself, however, only applicable literally to those plants which, destitute of flowers, possess a stem growing in a manner distinctive from those called Exogens and Endogens.

ACROLEIN, *ak'-ro-leen* (Lat., *acer*, sour; *oleum*, oil), in Chem., a highly volatile liquid produced by the action of heat on fat. Its vapour attacks the eye and the mucous membranæ of the nose most distressingly. It is composed of the elements carbon, hydrogen, and oxygen.

ACRONYCHAL, *ak-ron'-e-kal* (Gr., *akron*, and *nuktos*, of night), in Astron., applied to a star when it is opposite to the sun, or passes the meridian at midnight. A star is said to rise acronychally when it rises at sunset, and to set acronychally when it sets as the sun rises. Opposed to cosmical, which means rising or setting with the sun.

ACROPATHY, *a-krop'-a-the*, diseased action and pain at the extremities of the body.

ACROSALENIA, *a-kros-a-le'-ne-a*, a genus of fossil *Echinadermata*, occurring in the Isle of Sheppey.

ACROSPIRE, *ak-ros-pire'* (Gr., *akros*, *speira*, a spiral), in Bot., the sprout at the end of a seed which has commenced to germinate—the *plumule* of modern botanists. Maltsters use this term to express the growing of the barley.

ACROSTICHUM, *a-kros'-te-kum*, in Bot., a genus of ferns, of the *Polypody* sub-order. The species *Huacsaro* is used medicinally in Peru, and is much esteemed for its suderific, diuretic, and febrifugal properties.

ACROTEMNUS, *a-kro-tem'-nus*, a genus of fossil Ganoid fishes. One species is found in the chalk of Sussex.

ACROTERIA, *a-kro-te'-rea* (Gr., *akroterion*, the extremity of anything), in Architecture, a statue or ornament of any kind placed on the apex of a pediment.

ACTÆÆ, *ak tee'-e*, in Bot., a tribe of plants belonging to the Buttercup order, or *Ranunculaceæ*. They have elegant flowers and succulent fruits. The most important species is the *Podophyllum pelatum*, the May-apple or wild lemon of North America, which is employed in medicine, and has a very powerful cathartic effect. The active principle has lately been isolated, and is termed *Podophyllin*.

ACTINIA, *ac-tin'-i-a.* (Gr., *aktin*, a ray), in Zool., a genus of Polypes. (*See* CŒLENTERATA.) There are many British species, which are commonly known as *sea anemones*, from their resemblance to flowers. They are found on all rocky coasts, and they form the chief attraction of the marine aquarium. The body is conical or cylindrical, adhering to the rock by a broad disc-like base. The mouth, which is a simple opening into the internal cavity serving as a stomach, is surrounded by numerous tentacles which are often beautifully marked. These organs are retractile, and, when not covered by water, the actinia appears as a smooth hemispherical lump of elastic matter, sometimes of a brilliant colour. The reproductive power of these plant-like animals is very great, for when one is cut across, new tentacles form in a few weeks on the lower half, and each piece becomes a perfect creature. They are very sensitive to light. In many parts of the world they are eaten and considered a delicacy.

ACTINISM, *ak'-tin-ism*, the chemical principle of light. Three distinct principles emanate from the sun—light, heat, and actinism. It is actinism which fades colours, bleaches linen, rots fabrics, tans the human skin, puts out the fire, and performs the operations of photography. It acts principally by abstracting oxygen from the bodies which it affects. Fire is extinguished by sunlight through the diminution of the amount of oxygen necessary for combustion; and photographic operations are mostly affected by the reduction of oxide of silver to the metallic state, by the abstraction of its oxygen. We may have actinism without light, or *vice versâ*. Yellow glass transmits the latter, but stops the former. Hence, the photographer works in a yellow light. Dark blue glass, which transmits but little light, is quite pervious to actinism. Blue objects reflect great quantities of it, while red or yellow ones reflect but little or none. For this reason, in photographs, red or yellow materials are always too dark, while blue ones are too light. The electric and lime lights give out great quantities of actinism, from their blue tinge; and gas and candles but very little, from their yellow colour. The amount of actinism received from the sun differs considerably, according to the time of year, being at its maximum about the end of March, and gradually diminishing until the end of December, when it arrives at its minimum. Actinism in large quantities is necessary to the proper condition of the human system. It has been noticed that when dark rooms have been coloured with yellow paint or paper, the inhabitants of them have been sickly and delicate; as soon, however, as the colour was changed to blue, a marked difference in their state of health took place. The germination of seed is greatly retarded by actinism; hence, the malster puts his grain into the dark, to malt or semi-germinate. For the same reason, seed is buried in the ground. As soon, however, as the young plant makes its appearance, a supply of actinism is necessary, and, by a wonderful provision of nature, this influence is at its height when young plants are beginning to show their heads above the earth. White, red, brown, and green sea-plants owe their colour to the different amounts of actinism they receive: the green, being near the surface, receive most; while the white, being at great depths, receive nearly none. (*See* LIGHT and SPECTRUM.)

ACTINOCRINITES, *ak-tin-o-crin-i'-tees*, a genus of *Crinoidea*, comprehending a great many species. It is found in carboniferous and Silurian strata. (*See* CRINOIDEA.)

ACTINOLITE, *ak-tin'-o-lite*, a crystallized mineral, found in masses in primary stratified rocks, and, occasionally, in trap rocks. It is of a green colour, and is a variety of hornblende.

ACULEI, *a-ku'-le-i* (Lat., *aculeus*, a prickle), in Bot. (*See* PRICKLES.)

ACUMINA, *a-ku'-me-na* (Lat., *acumen*, a point), omens taken by the ancients from the points of spears or swords.

ACUMINATE, *a-ku'-me-nait* (Lat., *acumen*, the point of anything), in Bot., a term applied to the apex of a leaf when it is long and tapering. The leaf of the white willow has an acuminate apex.

ADAMANT, *ad'-a-mant* (Gr., *a*, not, *damao*, I break), a supposed impenetrable stone; a term applied to the diamond and other bodies of extreme hardness. (*See* DIAMOND.)

ADAMANTINE SPAR, *ad-am-an'-tine.* (*See* CORUNDUM.)

ADAMIA, *a-dai'-mi-a*, a genus of plants of the order *Hydrangeaceæ;* natives of Nepaul, and named after John Adam, a celebrated promoter of natural history in India.

ADANSONIA, *ad-an-so'-ne-a*, in Botany, a genus of plants, named after Michel Adanson, a celebrated French naturalist, and belonging to the tribe *Bombaceæ*, of the Silk-cotton order, or *Sterculiaceæ*. *Adansonia digitata*, the baobab-tree is the typical species. This is remarkable for its enormous size, and for its extraordinary longevity. One specimen has been found to have a trunk nearly 100 feet in circumference; and the age of this gigantic vegetable is probably many thousand years. The leaf of the baobab is digitate, branched into finger-like leaflets; hence its specific name. The fruit commonly known as monkey-bread, or Ethiopian sour-gourd, is a large oval capsule, containing a starchy pulp, having a slightly acid flavour, which forms a wholesome and agreeable article of food. Mixed with water, it makes an acid drink, which is highly esteemed as a specific in putrid and pestilential fevers, and is also employed by the Egyptian doctors in dysentery. The leaves have astringent properties; and, when dried and powdered, they form the condiment called *lalo*, which the Africans mix with their daily food as a preventive of excessive perspiration. The bark is said to be febrifugal, and its fibres are used by the African tribes living in the districts where the Baobab flourishes for the manufacture of cordage and various articles of dress. Adanson first described this remarkable plant.

ADAPIS, *a'-dap-is*, in Zool., the name of a genus of fossil pachydermatous (thick-skinned) mammals, first described by M. Cuvier, who deduced its existence and anatomical conformation from three fragments of the head, which had been discovered in the gypsum-quarries of Montmartre.

ADAPTATION, in Biology, the process by which an organism or species becomes modified to suit the conditions of its life. As employed by evolutionists, the term generally implies such modification as arise in an individual, when some change of function and structure is produced by a change of external conditions. *Indirect adaptations* are those which are directly generated in an organism, but only become apparent in its offspring. (*See* EVOLUTION.)

ADDA, *ad'-da*, the Arabic name for a small species of lizard found in Arabia, Egypt, and Nubia, wherever the smallest degree of moisture exists.

ADDAX, *ad'-dax*, a large white antelope, *Addax* (or *Oryx*), *nasomaculátus*, found in Northern and Central Africa.

ADDER, *ad'-der*, the common viper. The death or black adder (*Acanthopis tortor*) of Australia, and the puff adder (*Clothio arietans*) of South Africa, are both highly poisonous. In the Bible "adder" means poisonous serpents generally. (*See* VIPER.)

ADDER'S-TONGUE, in Bot., the familiar name for a tribe of ferns. (*See* OPHIOGLOSSEÆ.)

ADDISON'S DISEASE, so named from its discoverer, Dr. Addison; a super-renal melasma, a mysterious disease connected with the kidneys, for which no cure is known.

ADDUCTOR MUSCLES, *ad-duk'-tor* (Lat., *adduco*, I draw towards), in Anat., are those muscles which draw the parts to which they are attached together. They are opposed to the abductor muscles. (*See* ABDUCTOR MUSCLES.)

ADELPHOUS, *a-del'-phus* (Gr., *adelphos*, a brother), in Bot., a word used to denote the union of the filaments of the stamens in certain flowers. The number of bundles formed by the union of the filaments is indicated by a Greek numeral prefixed to the word. Thus, when all the filaments join together in a single bundle, as in the mallow, the stamens are *monadelphous*. When the filaments unite so as to form two bundles, the stamens are *diadelphous*. The formation of three bundles is expressed by the term *triadelphous;* and of any greater number, by *polyadelphous*.

ADENITIS, *a-den-i'-tes*, in Surgery, inflammation of the lymphatic glands, with which is ordinarily associated inflammation of the lymphatic vessels (*angeioleucitis*.) It generally originates in a puncture, cut, or other open wound being infected by some morbid matter, or the putrid secretion of a sore, or by some irritating or poisonous matter from without. In severe cases the symptoms are rigour, nausea, vomiting, thirst, sleeplessness, and the characteristics of fever. It is a good precaution to smear the hands with oil or grease before touching noxious fluids.

ADENOCELE, *a-dene'-o-se-le*, from a Greek word signifying a gland and a tumour, a mammary or glandular tumour on the breast of a woman. Excision is generally necessary.

ADHERENT, *ad-he'-rent*, in Bot., a term applied to a calyx or perianth, the tube of which adheres more or less to the ovary, as in the flowers of the iris, gooseberry, and myrtle.

ADHESION, *ad-he'-shun* (Lat., *adhærere*, to stick to), in Phy., a term applied to the property possessed by certain fluids and solids of becoming attached to each other when brought into contact. Adhesion is frequently confounded with cohesion, which is generally taken to mean the force which keeps the particles of the same body in close union. The examples and uses of adhesion are too familiar and numerous to need mention in detail. It will be sufficient to notice those cases where it is likely to be confounded with cohesion, atmospheric pressure, or chemical affinity. If metals are dipped into mercury, an adhesion of the particles of mercury, differing in force in different metals, takes place. This is evidently the result of chemical affinity, as those metals which most readily form amalgams exercise the greatest attraction for the mercury, gold being at the top of the scale, and iron and cobalt at the bottom. If two pieces of lead are scraped clean and pressed together, they adhere with considerable force. When two flat polished glass plates are pressed together they can scarcely be separated. Friction is the result of the adhesive force existing between bodies, and is generally greatest between those of similar constitution. In machinery, grease, oil, plumbago, or French chalk is used to lessen the grinding action of moving bodies, on account of the small amount of cohesion existing between their molecules. When parts of machinery rub against each other, they are always made of different metals, for the reason above mentioned. Iron, working in gun-metal, is generally found to produce the least amount of friction. (*See* COHESION, FRICTION.)

In Surgery, the process by which parts, naturally separate, or separated by artificial means, become united. It is caused by the effusion of a lymph, or sticky fluid, produced by inflammation; and hence, it is sometimes necessary to produce inflammation, by scraping or paring, in surfaces which it is desirable to unite. This tendency of inflamed surfaces to adhere when in contact is sometimes troublesome, as in inflammations of serous membranes.

ADIANTUM, *ai-di-an'-tum* (Gr., *adianton*), in Bot., the Maiden-hair genus of ferns, including some sixty species, mostly tropical. Two are found in temperate regions, namely, *Adiantum capillus Veneris*, the true maiden-hair; and *A. pedatum*, the Canadian maiden-hair. The former, which has obtained its name on account of the colour and extreme fineness of its stem and nerves, is found in Scotland and Wales, growing on damp rocks; and its elegant fronds make it a great favourite with collectors. Syrup of capillaire is properly prepared by adding sugar and orange-flower-water to an infusion of maiden-hair.

ADIPOCERE, *ad'-i-po-seer* (Lat., *adeps*, fat, *cera*, wax), a term applied by the French *savans* of the last century to a product of the decomposition of animal substances in moist earth or under water. It is principally margarate of ammonia, and is a fatty body, somewhat resembling spermaceti. A similar substance found in peat is known in Ireland as bog-butter.

ADIPOSE TISSUE, *ad'-i-pose* (Lat., *adeps*, fat), in Physiol., comprises an aggregation of minute cells filled with fat, which they appropriate from the blood. This tissue serves several important purposes in the animal body; filling up interstices, forming a pad or cushion for the support of the moveable parts, and assisting in the retention of heat.

ADJUTANT, a gigantic crane belonging to the *Ardeidæ* or Heron family, inhabiting the warmer parts of India. Its scientific name is *Leptoptilos argala* the extended wings measure about fourteen feet from tip to tip. It stands five feet high; the neck and head are almost bare; the beak very large, long, and of extraordinary strength. Beneath the beak hangs a downy pouch like a dewlap, which the bird has the power of inflating. The upper part of the adjutant is of an ash-grey colour, the under part white. Its voracity is wonderful: it can swallow a fowl, a rabbit, or a leg of mutton at a mouthful; and it is extremely useful in devouring all sorts of carrion. In Calcutta it is called the Scavenger, and any person wantonly killing one is fined. In their wild state, these birds live in companies. (*See* MARABOU).

ADMIRAL, in Conch., a beautiful shell of the Volute species, and comprising four kinds:—the Grand-admiral, the Vice-admiral the Orange-admiral, and the Extra-admiral. The first is of a fine white enamel, with bands of yellow finely turned about the head, and the clavicle excited. It is principally characterized by a denticulated line along the centre of the large yellow band: this distinguishes it from the Vice-admiral. The Orange-admiral has more yellow; and the bands of the Extra-admiral run into each other.

ADNATE, *ad'-nait* (Lat., *ad*, to, and *natus*, a growing), in Bot., a term applied to certain portions of a plant when they adhere to other portions: thus, when the stipules are united to the petiole, as in the leaf of the rose, they are called *adnate stipules:* when the anther is closely attached to the filament, as in the flower of the buttercup, it is said to be an *adnate anther.* The term *adherent* has the same signification.

ADONIS, *a-do'-nis*, in Bot., a genus of plants belonging to the Buttercup order, or *Ranunculaceæ.* The common adonis, *A. autumnalis*, or pheasant's-eye, is a favourite annual in English gardens. Its flower is of a bright scarlet, with a black spot or eye in the centre. The colour of the petals has been poetically ascribed to their being stained with the blood of Adonis.

ADOXA, *a-dox'-a* (Gr., *a*, without, and *doxa*, glory), in Bot., the Moschatel, a genus of plants belonging to the Ivy order, or *Araliceæ.* The typical species, *A. moschatellina*, is a curious inconspicuous little plant, having a tuft of pale green flowers.

ADRAGANT. (*See* TRAGACANTH.)

ADULARIA, *ad'-u-lai'-ri-a*, in Min., a kind of felspar, resembling clear transparent glass. It is found in volcanic districts, and is named from Mount Adula, in Switzerland.

ADVANCEMENT OF SCIENCE. (*See* BRITISH ASSOCIATION.)

ADVENTITIOUS ROOTS, in Bot., roots which are not produced by the direct elongation of the radicle of the embryo. They generally spring from the true roots, from suckers, runners, bulbs, and other subterranean modifications of the stem.

ÆCIDIUM, *e-sid'-i-um*, in Bot., a genus of microscopic parasitic fungi. There are numerous species, some of which infest useful garden plants, such as the mint and the gooseberry.

ÆGAGRUS, *e-gai'-grus*, the Paseng of the Persians, a wild species of Ibex. (*See* GOAT.)

ÆGICERACEÆ, *e-ji-se-rai'-se-e*, in Bot., the Ægiceras order of dicotyledonous plants. This includes but one genus, of which there are five species. These plants grow near the sea in tropical regions, throwing out adventitious roots into the mud, like mangroves.

ÆGILOPS, *e'-ji-lops*, in Bot., a genus of *Glumaceæ*, the Grass order. The species *Ægilops ovata* was formerly supposed to be the origin of all the varieties of cultivated wheat; and it is undoubtedly true that a kind of wheat may be produced by the union of this plant with a species of *Triticum.* The hybrid, after about twelve years' cultivation, becomes a wheat-bearing grass.

ÆGLE, *e'-gle*, in Bot., a genus of *Aurantiaceæ*, the Orange order. The bark of the *Ægle marmelos*, or Indian bael, has been introduced into this country as a remedy for diarrhœa. The rind of its ripe fruit yields an agreeable perfume.

ÆQUILATERUS. (*See* EQUILATERAL.)

AERIAL BULBS, *ai-eer'-i-al*, in Bot., small conical or rounded bodies of the nature of bulbs, which grow in the axils of the leaves of certain plants, as the bulbiferous lily and in the pilewort.

AERIAL IMAGES. (*See* MIRAGE and FATA MORGANA.)

AERIAL LEAVES, in Bot., leaves which grow in the air, as distinguished from those which flourish under water.

AERIAL POISONS. (*See* MIASMA.)

AERIAL ROOTS, those adventitious roots which are produced in the air. The little threads which spring from the stem of the ivy, the descending columns of the banyan-tree, and the green fibres thrown out by the curious air-plants, are examples.

AERO-DYNAMICS, *ai'-e-ro-di-nam'-iks* (Gr., *aer*, air, and *dynamis*, power), is the science which treats of properties of aëriform fluids in a state of motion. Currents are created in innumerable ways; amongst others, by the local change of temperature; by the permanent difference of temperature between the polar and equatorial regions; and by the rotation of the earth on its axis. It is also effected by the evaporation of the sea and rivers. Aqueous vapour being much lighter than the air, causes motion in its passage to the cloud region. The laws which govern projectiles are properly part of this science. (*See* PROJECTILES; *see also* RIFLE, GUNNERY, ANEMOMETER, ACOUSTICS.)

AEROGRAPHY, *ai-e-rog'-ra-fe*, the description of the nature, properties, and phenomena of the atmosphere. (*See* ATMOSPHERE.)

AEROLITE, *ai'-e-ro-lite* (Gr., *aer*, air, *lithos*, a stone), a stone fallen from the atmosphere, meteoric stones, fireballs and shooting-stars are now known to be varieties of aërolites. The source of these bodies has greatly puzzled philosophers; and until the commencement of the present century they were regarded as instances of ancient superstition. Since the report of M. Biot, however, in 1803, concerning an extraordinary shower of stones which fell near L'Aigle in Normandy, the existence of meteoric stones has never been questioned, and the researches of La Place, Chladni, and others have now placed the fact beyond dispute. They are mostly of uniform composition, consisting principally of silica, magnesia, and iron, with small quantities of nickel, sulphur, and chromium. Some of them are very large, weighing many pounds. The largest known is one which fell in Brazil, estimated to weigh 14,000 lbs. Sometimes they fall singly, and occasionally in showers, but they all present the same characteristic when they reach the earth of having a thin black covering like varnish, which is supposed to indicate the rapid action of heat. Shooting stars are now known to be meteoric stones which are consumed by the heat generated in their passage to the earth. The most recent researches seem to point to the fact that every form of matter exists in the inter-planetary spaces, and that there are detached masses of minerals and also rings or belts of smaller stones all circling round the sun. The former give rise to the *sporadic* or single meteors or aërolites, and the latter to the showers of stones or shooting stars. Thus astronomers are able to predict with some degree of certainty as to the date of the more brilliant swarms. November, 1799, 1833, and 1866, have been the dates of the most brilliant manifestations, and as each appeared after a lapse of 34 years it is predicted that November, 1900 will be the occasion of the next brilliant display.

AEROPHYTES, *ai'-e-ro-fites* (Gr., *phyton*, a plant), in Bot., plants having only aërial roots. (*See* AIR-PLANTS.)

AEROSTATICS, *a-e'-ro-sta'-tics*, the science of the equilibrium and pressure of air and other gases and the method of measuring it; also the phenomena of the compression of gases. The mean pressure of the atmosphere, nearly 15 lbs. on every square inch is generally taken as the unit of measure of expansive or elastic force. A rise of temperature of 1° Fahr. causes any gas to expand about 1-480th of its own bulk.

ÆSCHYNOMENE, *ees'-ki-nom'-i-ne*, in Bot., a genus of leguminous plants, mostly natives of India. The stems of the *Æschynomene paludosa* furnish the shola, or Indian rice-paper, and, on account of their extreme lightness, are used for making floats and buoys. *Æ. cannabina* yields the fibre known as Duchai hemp.

ÆSCULUS, *ees'-ku-lus*. (*See* CHESTNUT.)

ÆSTIVATION, *ees-ti-vai'-shun*, in Bot., a term literally meaning the summer state, is applied to the general arrangement of the different parts of a flower, but previous to its opening into full bloom. When the parts are placed in a circle, and in nearly the same plane, the æstivation is said to be *circular*, and when they are placed at slightly different levels, so as to overlap each other, it is said to be *spiral*. If the edges are turned in, the æstivation is spoken of as *induplicate*, and if they are turned out, it is *reduplicate*. In poppies, the petals are crumpled together. The term *præfloration* is used by some botanists instead of æstivation.

ÆSTUARY. (*See* ESTUARY.)

ÆTHER. (*See* ETHER.)

ÆTHUSA, *e-thu'-sa*, in Bot., a genus of umbelliferous plants. *Æthusa Cynapium*, fool's parsley, is a common indigenous plant, highly poisonous, which has been frequently mistaken for parsley.

ÆTOBATES, *e-to-bai'-tees*, a genus of fossil fishes allied to the Rays, the species of which are found at Sheppey, in the London clay.

AFFINITY, OR CHEMICAL ATTRACTION, is the force which causes the particles of dissimilar kinds of matter to unite together, so as to form new matter. It differs from *cohesion*, (which is a modification of molecular attraction, and produces merely a mechanical mixture) by bringing about the union of heterogeneous particles, and causing them to lose their individual properties. The result is a new compound differing entirely from the substances which combined to produce it. For example, the inflammable metal *sodium* unites with the suffocating gas *chlorine*, and the compound thus produced is *chloride of sodium*, or common salt, a substance which does not bear the slightest resemblance to either of its components. Chemical combinations do not take place indifferently, but in accordance with certain strict rules or laws. One substance will unite with another in preference to a third, or in some cases in preference to any other. This preference is denoted by the term *elective affinity*. By means of this discriminating action of affinity, some combinations may be *decomposed*. Affinity is generally much stronger between bodies which are very unlike each other, than between bodies which are closely allied. Thus, potassium and sodium tend strongly to unite with chlorine and iodine, but the bodies of each pair do not attract one another with sufficient force to enter into combination. The discoveries of Faraday and others have established the fact, that whenever two substances unite to form a compound, they are in opposite electrical conditions; one being electro-negative, and the other electro-positive. This and other facts go to prove that chemical affinity is a particular modification of electrical attraction. (*See* ELECTROLYSIS.) The word "affinity" appears to have been employed for the first time by Barkhausen, a German chemist, in his "Elements of Chemistry," published at Leyden in 1703. (*See* CHEMISTRY.)

AGALMATOLITE, *a-gal'-ma-to-lite* (Gr., *agalma*, statue, *lithos*, stone), a white, translucid, waxy-looking mineral, commonly known as *figure-stone*, brought from China, carved into little grotesque figures. It is usually delicately tinted with pink, grey, yellow, or green, and can be easily cut and modelled with a sharp instrument. It consists solely of silica and alumina, with a little carbonate of lime and potash.

AGAMI, OR GOLD-BREASTED TRUMPETER, *a-ga'-me*, *Psophia crepitans*. A bird about the size of a pheasant or large fowl, with long neck and legs, but a short tail. It is found in numerous flocks in South America; can run swiftly, and, when pursued, trusts less to its wings than to its legs. It is easily domesticated.

AGAMA, OR AGAMIDÆ, *a-ga'-ma*, a family of Saurian reptiles. They have short, broad, flat heads, and thick depressed bodies, enveloped in a loose skin, which is capable of being distended with air at the will of the animal. Different species of Agamidæ are found in Asia, Africa, Australia, and America. Some species can change the colours of their skin, which causes the natives of South America to call them chameleons. They are of diminutive size, and generally lurk among rocks, heaps of stones, and mouldering ruins. Some of the more active kinds, however, climb trees, play among the branches, and feed upon insects and other small animals. One tribe, found in India, is said to be herbivorous. The *Frilled Agama*, a native of Australia, is a very extraordinary looking animal. Around its neck, and covering its shoulders, it carries a frill, which, on the approach of danger, is elevated.

AGAMÆ, *ag'-a-me* (from a Greek word meaning "without sex"), in Botany, a term applied to cryptogamic and other plants, which have the organs of reproduction, but are flowerless and without seed-lobes.

AGAMOGENESIS, *ag'-a-mo-jen'-e-sis*, a name given by M. Quatrefages, the French naturalist, to reproduction without influence of sex, which has been observed both in animal and vegetable nature. The aphides, or "blight-insects," and the daphniæ, or "water-fleas," and several kinds of butterflies, possess the power of producing living offspring when perfectly developed; although, in the case of aphides, the ordinary mode of reproduction by eggs is also common. The pistil-bearing, or female plant of the cælobygne, an Australian plant, kept in the country with no male, or stamen-bearing plant near it, annually bears fruit and fertile seed.

AGAMOUS, *ag'-a-mous* (Gr.), is a term used by some writers instead of cryptogamic. It is principally confined to confervæ, lichens, fungi, and similar groups. They are said to have no functions analogous to those of sex.

AGAPANTHUS, *ag-a-pan'-thus* (Gr., *agape*, love, *anthos*, flower), in Botany, plants belonging to a genus of the natural order *Liliaceæ*. The typical species is *Agapanthus umbellatus*, the African blue lily, a native of the Cape of Good Hope, whence it was brought to Holland, and, in 1692, it was cultivated at Hampton Court. It is now a favourite garden plant. It grows nearly a yard high, and, in July, bears a handsome bunch of blue flowers, which have no scent.

AGAR-AGAR, *ag'-ar*, a name sometimes given to the alga commonly known as Ceylon moss, used for making jellies. (*See* GRACILARIA.)

AGARICUS, *a-gar'-i-kus* (Gr., *agarikon*, a fungus), the mushroom, a genus of fungi, characterised by the pileus, or cap, being distinct from the stalk, and having, on the under side, numerous flakes or gills radiating from the centre. The genus comprehends an immense number of species, many of which are edible. (*See* MUSHROOM.)

AGATE, *ag'-at* (Gr., *achates*), a semi-pellucid, variegated, and uncrystallized variety of quartz, named after Achates, a river in Sicily, whence the Greeks are said to have first procured it. Chemically, it consists almost entirely of silica, coloured by metallic oxides. The colours of agate are generally arranged in parallel or concentric bands, but sometimes form spots, clouds, and moss-like stains. These colours can be artificially heightened by boiling the stone in oil, and afterwards in sulphuric acid, and by other ingenious processes. Agates occur in nature as rounded pebbles, and are brought into this country from Oberstein, in Saxony, from Arabia, and India; some varieties, however, are found in Perthshire and other parts of Scotland. The Scotch pebble, or fortification agate, so called from its zig-zag pattern, is one of these varieties. Agates take a high polish, and their beautiful colours adapt them for many ornamental purposes. They are cut into brooches, seals, bracelets, and similar objects, and are largely employed for mosaic work. Veined calcedony, or agate, is, when properly prepared, used for the production of cameos and intaglios in imitation of ancient gems sculptured on onyx. In the useful arts, agates are employed as burnishers, and, when sufficiently large, they are made into mortars for chemical purposes. The moss agate, or Mocha-stone, is curiously marked with figures resembling growing tufts of moss. These markings were, until quite recently, supposed to be produced by vegetable structures imbedded in the stone; but Professor Göppert has proved that they are merely deposits of oxide of iron. Some of the remarkable figures resembling men or animals are usually artificially produced.

AGATHOPHYLLUM, *ag'-a-tho-fil-lum*, a genus of plants in the natural order *Lauraceæ*. The species *A. aromaticum* yields the Ravensara nut, or clove nutmeg of Madagascar.

AGAVE, *a-gaiv'* (Gr., *agauos*, admirable), a genus of monocotyledonous plants of the Amaryllis order, or *Amaryllidaceæ*. The typical species is *Agave Americana*, the American aloe or maguey. This agave was brought to Europe in 1561, and has been naturalized in Southern Europe and Northern Africa. The plant is of slow growth; but when fully developed, its leaves, which spring directly from the ground, attain a height of from five to eight feet. From the midst of the great cluster of leaves a flower-stem arises, and from this numerous flower-bearing branches spring, so that the whole plant has somewhat the appearance of a candelabrum. It was formerly erroneously supposed that the agave lived a hundred years before flowering; hence, it was frequently called the hundred years plant. It really flowers only once in about ten years, and the planter has to wait patiently for the flowering season to obtain a supply of pulque, as this liquor is formed from the juice contained in the young flower-stalk. As soon as this organ makes its appearance, the planter makes a deep cut in it, and scoops out the whole heart or middle part, leaving nothing but the outside rind. A natural basin, about two feet in depth, is thus formed, and into this basin, the sap which was intended to feed the shoot flows so rapidly, that it is necessary to remove it twice, and sometimes three times a day. To make this more easy, the leaves on one side of the basin are cut away. This sap before it is fermented, has a very sweet taste, and is called *aguamiel*, or honey-water. It ferments spontaneously, and forms the pulque, which is a refreshing, slightly-intoxicating drink, with a pleasant acid taste, but a very disagreeable odour. From pulque an ardent spirit is distilled, which is known by the name of *mexical*, or, less commonly, *aguardiente de maguey*. From the leaves of this and other species of the agave genus, the useful fibre called aloe-fibre, *pita*, or *pité* hemp, is obtained.

AGE, *aij*. During the progress of life from infancy to manhood, and from manhood to old age, the body undergoes certain marked changes, which distinguish the different periods or stages of life. The first age commences at birth, and extends to the end of the second year, by which time the first dentition is generally completed; the second extends to the end of the seventh or eight year, when the second dentition is commonly over; the third extends to the age of puberty, which varies in different countries, but with us is from twelve to fourteen in the female, and from fourteen to sixteen in the male; the fourth extends to about the twentieth year in the female, and the twenty-fourth in the male; the fifth period extends in the female to about the forty-fifth or fiftieth year, when the power of procreation usually ceases, and in the male to about the fiftieth year; the sixth period extends to the sixty-third year, when the seventh and last period of life commences. These divisions are of course not very precise in the latter stages; but mark with sufficient accuracy the successive periods of life. Shakspeare's description of the seven ages, in *As You Like It*, is known to everybody.

Of Animals.—It has been stated that the duration of an animal's life is generally seven or eight times longer than the period it takes to arrive at its full growth, a rule that applies moderately well to domestic animals, such as dogs, horses, sheep, oxen, and even elephants and camels, but is not applicable to man, or to the majority of quadrupeds, fishes, birds, or reptiles. The age of the horse may be calculated by an examination of the incisive teeth or nippers; but at ten years old these marks are lost, and no accurate calculation can be arrived at. Deer shed their horns every year, and, in the males of some species, each year adds a branch to the horns, until a certain size is attained. In sheep, oxen, antelopes, and goats, a ring is annually added to the base of the horn up to a certain age. There are no certain indications by which the duration of life of birds, fishes, and reptiles can be ascertained. The Indians assert that the elephant lives 300 years. Dogs live from 12 to 14 years, sheep 8 or 9, oxen about 20, horses, if well treated, from 25 to 30, camels from 40 to 50. Eagles have lived more than a century, and many instances are recorded of ravens having exceeded that period. Swans, also, have been known to live 100 years, parrots 60 and 80; pheasants and domestic poultry seldom reach more than 12 or 15 years. Among fish, the carp has been known to live 200 years. River trout have been confined in a well for 30 and 50 years. A pike has been known to exist in a pond 90 years. A story is related of one caught in a lake near Hailerun, in Suabia, which had attained the age of 267 years. Of reptiles, the tortoise is said to be the longest lived; but this may be doubtful, as nothing is known of the duration of life of the various tribes of serpents. Of the ages of insects, but little is known. The life of the caterpillar or grub, in its first period, extends to several months; but after the attainment of their perfect form, they live but a few days or weeks. As a general law of nature, early maturity indicates shortness of life.

Age of Trees.—This has been computed in a twofold manner—first by comparing them with other old trees whose rate of growth had been ascertained, and secondly by removing a portion of the trunk from the circumference to the centre, and counting the number of concentric rings, each of which, in exogenous trees, marks a year's growth. The following is a list of the ages to which certain trees have been known to attain:—Palm, 200—300 years; Elm, 355; Cypress, 388; Ivy, 448; Maple, 516; Larch, 263—576; Chestnut, 360—626; Oranges, Lemons, &c., 400, 509, 640; Plane, 720; Cedar, 200—800; Walnut, 900; Lime, 364, 530, 800, 825, 1,076; Spruce, 1,200; Oak, 600, 800, 860, 1,000, 1,600; Olive, 700, 1,000, 2,000; Yew, 1,214, 1,466, 2,588, 2,880; Baobab, 4,000; Dragon-tree, 6,000.

Age of the Moon, a term signifying the number of days elapsed since the last new moon.

AGGREGATE FRUITS, *ag'-gre-gait*, fruits formed by the combination of several flowers, as the pineapple and the mulberry. The term *anthocarpous* is more generally used. Some botanists apply the term aggregate to a compound fruit, consisting of numerous achænia, borne by a single flower; as the fruit of the ranunculus or the raspberry.

AGGREGATION, STATES OF. The three states in which matter occurs, solid, liquid, and gaseous. In the solid state, the molecules adhere so firmly that their relative positions cannot be changed without the application of force; in the liquid state, they more freely and readily act on each other; in the gaseous state, they have a tendency to separate and diffuse through a vacant space.

AGLAIA, *ag-lai'-a*, one of the group of small planets revolving between Jupiter and Mars. (*See* ASTEROIDS.)

AGLAIA, *ag-lai'-a*, a genus of dicotyledonous plants, order *Meliaceæ*. The flowers of *Aglaia odorata* are used for perfuming certain varieties of tea.

AGONIC LINES, *ag-on'-ic* (Gr., *gonia*, an angle), the imaginary lines on the earth's surface where the magnetic needle indicates a declination or deviation from the terrestrial meridian—that is, points to the true north and south. (*See* MAGNETISM, TERRESTRIAL.)

AGOUTI, *a-goo'-te*, the *Chloromys* of Cuvier, the *Dasyprocta* of Illiger, a genus of animals belonging to the class *Mammalia*, order, *Rodentia*, and family, *Hystricidæ*. They are about the size of a hare, have toes armed with long and very strong claws, and completely separate from each other; hind legs very much longer than the fore; head large, forehead and face convex; eyes full and black; ears short, round, and almost entirely denuded of hair; hair for the most part coarse and bristly, but in some species nearly as fine as the fur of the rabbit; twenty teeth. At the first settling of the West India islands they were very numerous, and were an article of consumption by the Indians; but the planters, finding them too destructive to the sugar-canes, have destroyed them in great numbers. Whilst eating, these animals sit upon their hind quarters, and hold their food between their fore paws. They are exceedingly voracious, live under decayed trees and fallen timber, are very prolific, and produce young more than once a year. Their flesh is good eating. There are seven perfectly ascertained species—viz., the common agouti (*Dasyprocta Aguti*), known also by the name of the long-nosed, or yellow-rumped cavy; the black or crested agouti (*Dasyprocta cristata*), sometimes termed the black-crested agouti; the acouchy, or olive agouti (*Dasyprocta Acuchi*); the white-toothed agouti (*Dasyprocta croconata*; the *Dasyprocta prymnolopha;* the sooty agouti (*Dasyprocta fuliginosa*); Azara's agouti. They are found in the hotter parts of South America, the West India islands, and Guiana.

AGRIMONIA, *ag-ri-mo'-ni-a* (Lat.), the Agrimony, a genus of dicotyledonous plants, belonging to the Rose order, or *Rosaceæ*. The species *A. Eupatoria* is one of our common roadside plants, and is found in flower about June. The leaves are large and deeply cut at the edge, and divided even down to the main stalk; the flowers are yellow, arranged on a long simple spike, with a little leaf at the base of each, and the fruit is beset with bristles. This plant has been used in medicine as a vermifuge and an astringent.

AGROSTEMMA, *ag'-ros-tem'-ma*(Gr., *agros*, a field, *stemma*, a crown), a genus of dicotyledonous plants of the Pink order, or *Caryophyllaceæ*. The species *A. githago* is the common corn-cockle, a well-known ornamental plant in our corn fields.

AGROSTIS, *ag-ros'-tis*, a genus of Grasses, including numerous species, all furnishing excellent forage.

AGUE, OR INTERMITTENT FEVER, *ai'-gu* (Fr., *aigue*, sharp), a disease generally occasioned by exhalations arising from marshy grounds, stagnant water, or decaying vegetable substance. It is characterized by a series of separate attacks, occurring at regular intervals of one or more days, according to which it is termed quotidian, tertian, or quartan. Each attack is divided into three stages—cold, hot, and sweaty, which follow each other in regular succession. During the cold stage, warm baths, diaphoretic drinks, and such like means, are to be adopted; in the hot stage, saline draughts and diaphoretics should be administered; and, in the last stage, the patient is to be kept cool, and, if very weak, may receive a little wine or brandy-and-water. The general treatment in ague is to strengthen the system by means of tonics, such as quinine or Peruvian bark. A temperature above 60° Fahr., combined with moisture, appears to be necessary to produce this disease.

AHRIAN, *air'-i-an*, a term applied by geologists to the middle group of the series of Devonian rocks belonging to Belgium and the Rhine. This group includes bluish-grey grits, sandstones, and shales.

AIGLET, *ai'-glet*, a young eagle. (*See* EAGLE.)

AIGRETTE, OR EGRETTE, *ai'-gret*, a term formerly applied to a little feathery crown or tuft attached to the seed-case or fruit of the dandelion, the scabious, and many other plants, and by means of which the seed is transported through the air to a distance. This peculiar appendage is now called a *pappus*. (*See* PAPPUS.) The term is also applied to the feathery tuft on the head of several birds, as the heron; and to long upright feathers when worn in a lady's headdress, or even to a bunch of flowers arranged in plume fashion and fastened with diamonds. The Shah of Persia wears in his headdress a magnificent arrangement of precious stones in the shape of a fan, described as an aigrette.

AILANTO, *ai-lan'-to*, a tall and beautiful tree, the *A. glandulosa*, of the natural order Xanthoxyton. The leaves are large and pinnate, with an odd leaflet. The tree is a native of China, but has been introduced into Europe, and is used as a shade for public walks. It grows well in chalky soil, and the timber is fine grained.

AIR, *aar* (Gr., *aer*, air).—This term is generally taken to mean the atmosphere with which our globe is surrounded; but in the chemical works of the last century it is often applied to bodies known at the present day as gases. (*See* ATMOSPHERE.)

In Music, a term which, when applied to vocal music, signifies a composition for a single voice. It is synonymous with melody.

AIR-BLADDER, OR SWIMMING-BLADDER, an organ which, in fishes, generally adapts the specific gravity of their bodies to the weight of the water in which they are at different depths. This purpose is served by the increase or diminution of its volume, according to the degree of pressure exerted upon it by the water. The air-bladder is placed in the abdomen, under the spine, and it varies considerably in size and shape in different kinds of fishes. The finest kind of isinglass is made from it. (*See* ISINGLASS.)

AIR-CELLS OR SACS, are cells, or cavities, in the lungs of animals of the class Mammalia, into which the air is conveyed by minute ramifications of the windpipe. In birds, the air-cells are distributed along the inside of the whole cavity of the chest and abdomen, and in birds of rapid flight are often prolonged into the bones. They are connected with the respiratory system. In insects, air-tubes connected with the cells ramify throughout the whole body. In some of the lower organizations, air-cells may be said to form the whole respiratory apparatus.

In Botany, cavities containing air in the stems or leaves of plants. They are large and numerous in aquatic plants, for the purpose of buoying them up in the water.

AIR-PLANTS, are those members of the vegetable kingdom which derive nourishment entirely from the air by means of slender aërial roots. (*See* EPIPHYTES.)

AJUGA, *a-joo'-ga*, the Bugle, a genus of plants belonging to the Labiate order. *A. reptans* is a common plant in moist pastures. The stem is creeping, but the flowering part erect. This part has many leaves or bracts of a purplish hue, proceeding from each whorl of labiate flowers: the latter are generally blue, sometimes white or flesh-coloured.

AKEE FRUIT, *a-ke'*, the produce of a species of soapwort growing in the West Indies. (*See* CUPANIA.)

AKI, *ai'-ki*, the native appellation for the *Lignum vitæ* of New Zealand. This and other species of the genus *Metrosideros* (and the *Myrtaceæ*, or Myrtle order) afford valuable timber, used by civilized races in many of the peaceful arts, and by the South-Sea Islanders to form their terrible clubs.

ALABAMA BEDS, *al-a-ba'-ma*, a group of rocks in North America, placed by Sir Charles Lyell among the productions of the middle Eocene period.

ALABASTER, *al-a-bas'-ter*, a white substance used for ornamental purposes. Its name is derived from Alabastron, in Upper Egypt, whence the ancients obtained a supply of the stone, and where it was manufactured into vases and other small vessels. The ancients made use of these vessels to hold a certain kind of perfume, with which, according to Horace, it was the custom to anoint the heads of the guests at a feast. Mary, the sister of Lazarus, poured a "very precious ointment" from an alabaster box upon the head of our Saviour whilst seated at supper. In the British Museum there are several of these ancient alabaster vessels. There are two varieties of alabaster; one a carbonate of lime (known as Oriental alabaster, and deposited from water in the form of stalagmite, &c.), and the other gypsum, or sulphate of lime. The latter is that which is generally known as alabaster. It is a soft stone, may be scratched with the nail, and is beautifully white and semi-transparent. Being easy to work, large quantities of vases, lamps, and toys are made from it. The finest sort of alabaster is obtained from Volterra, in Tuscany, and it is also found in Derbyshire and Staffordshire.

ALANGIACEÆ, *al'-an-ge-ai'-se-e*, the *Alangium* order of monocotyledonous plants, including four genera and eight species, which are trees or shrubs, natives of various parts of the East Indies, and North America. The fruits of most of these plants are edible; that of the *Nyssa capitata* is used as a substitute for lime-fruit, and is sometimes called the *Ogechee* lime.

ALARIA, *a-lair'-i-a*, a genus of fucoideous sea-weeds. One British species is known, *A. esculenta*, a common sea-weed, having a large flat and narrow leaf-like frond, with a thick midrib, or prolongation of the stalk by which it is attached to the rocks. It grows from four to twelve feet long, and is sometimes employed for food. Its common names are Bladderlocks, Hen-ware, and Honey-ware.

ALAUDA. (*See* LARK.)

ALBATA. (*See* NICKEL.)

ALBATROSS, *al'-ba-tross* (*Diomedia*), a gen. of web-footed birds, of which there are three species—the common albatross, *D. exulans;* the albatross, *D. fuliginosa* (chiefly found in the Antarctic circle, and known to sailors as the Quaker Bird, on account of the prevailing brown colour of its plumage); and the yellow-and-black-beaked albatross, *D. chlororynchos.* A long hard beak, curved at the extremity, the upper mandible composed of several articulated pieces, the lower mandible smooth and short; the nostrils lateral, and placed like small rolls in the furrow of the mandible; feet short, with the three toes long and completely webbed; wings long and narrow. The common albatross, which is often met with in the seas of Southern Africa, is the largest sea-bird known, its weight varying from 12 to 28 lbs. A specimen in the Leverian Museum measured 13 feet between the extremity of the extended wings. One remarkably large bird, shot off the Cape of Good Hope, measured from wing to wing 17½ feet. The top of the head is a ruddy grey, the rest of the plumage, with the exception of several transverse black bands on the back, and a few of the wing-feathers, is white; the bill is of a pale yellow, and the feet and membrane of a deep flesh-colour. Towards the end of June, these birds hover in immense flocks about Behring's Straits and Kamtschatka, attracted thither by the shoals of fish, whose migrations the albatross perseveringly follows. So great is its voracity, that it will swallow a salmon of 5 lbs. weight; it does not, however, limit its diet to fish, but will prey on any sea animal. Its strength of wing is very great, and it will accompany a ship for many days without appearing to require rest. Sailors regard its presence as a good omen, and Coleridge's ballad, "The Ancient Mariner," relates the doom of the man who wilfully shot an albatross.

ALBINO, *al'-bee-no* (from Lat., *albus*, white), a person of a preternatural whiteness of the skin and hair, and peculiar redness of the pupil of the eye, which, in some cases, is so weak as not to be able to bear the light of day. The Portuguese first applied the term to the white negroes whom they found on the coast of Africa, but it is now used to designate persons who exhibit similar characteristics, of whatever race. Albinism, or Leucopathia, is the name applied by scientific writers to the peculiarity. Albinism does not imply a diseased condition of body, or a want of physical or mental vigour; and it is to some extent hereditary. The appearance arises from the absence of the colouring matter of the epidermis, or outer skin. It is common in many species of animals.

ALBUMEN, *al-bu'-men* (Lat., *albus*, white), in Chem., a whitish viscous matter slightly salt to the taste, and an important element in vegetable and animal organic substances. It is distinguished by its peculiar property of becoming coagulated or insoluble at a high temperature. White of egg and serum of blood consist almost entirely of albumen. The hair and nails contain large quantities of it in its coagulated state. Pure albumen is insoluble in water. White of egg and serum contain a certain amount of free alkali, in which it is dissolved; hence its precipitation when acids are added. It is also precipitated when salts of mercury, copper, silver, lead, &c., are added to its solution, forming with them definite insoluble compounds. This property renders it valuable as an antidote to metallic poisons. Tannin, gallic acid, and extractive matter behave with it in a similar manner; for which reason it is used much in the arts as a clarifying agent. It is very important as an element of diet. (*See* FOOD.) It is greatly used in photography, for giving depth and intensity to photographic prints. Its chemistry is very complex, and requires investigation. Its average composition is given below, the presence of sulphur being rendered familiar to all by the effects of cooked eggs upon silver spoons.

Carbon, ...	53·5
Hydrogen, ...	7·0
Nitrogen, ...	15·5
Oxygen, ...	22·0
Phosphorus, ...	0·4
Sulphur, ...	1·6

In Botany, the cellular structure which surrounds the embryo of a seed. It is not present in every case; for sometimes the embryo alone forms the nucleus of the seed, as in the pea, the bean, and the wallflower. When it is present, the amount of space it occupies is in inverse proportion to that occupied by the embryo; in other words, the larger the embryo the smaller the albumen. A seed entirely devoid of this structure is said to be *exalbuminous*, and one which includes it, *albuminous*. The cells of the albumen contain nutriment for the germinating embryo in the form of starch, of oil, or of cellulose. Sometimes the cells are thickened by secondary deposits, and the whole structure becomes horny; thus, vegetable ivory is nothing more than the albumen of the seed of a species of palm. The stone of the date, and the nut of the areca palm, are further examples of hardened albumen. In the seed of the coffee-plant, the albumen is the horny portion which is so familiar to us as the "coffee-berry." Some botanists use the term *perisperm* for this structure, as the word *albumen* has a totally different signification in chemistry.

ALBUMINURIA, *al-bu-mi-nu'-ri-a*, or BRIGHT'S DISEASE, a disease characterized by the presence of albumen in the urine, a more or less general dropsy both of the cellular tissue and the internal cavities, and an organic change in the substance of the kidneys. The disease was first described by Dr. Bright.

ALBURNUM, *al-bur'-num* (Lat., sap-wood), the white and comparatively soft part of an exogenous stem, between the inner bark and the *duramen*, or heart-wood. The difference between these two kinds of wood is often very striking. Thus, in the ebony-tree the duramen is black and the alburnum pale. All the vital functions are performed by the sap-wood, as is proved by the vigorous growth of many a hollow tree.

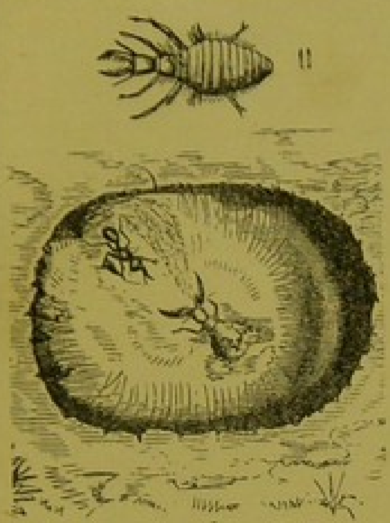
ALCA AND ALCADÆ, *al'-ka, al'-ka-dæ.* (*See* AUK.)

ALCEDO. (*See* KINGFISHER.)

ALCES, *al'-sees*, the Elk. (*See* DEER.)

ALCHEMILLA, *al-ke-mil'-la*, in Bot., the Lady's mantle, a genus of plants in the natural order *Rosaceæ*, sub-order *Sanguisorbeæ.* Three British species are known—*A. alpina, A. vulgaris*, and *A. arvensis*—the mountain, common, and field lady's-mantles. They have small green flowers arranged in bunches. The latter species is thought to be diuretic.

ALCOHOL, *al'-ko-hol* (Arab., *al*, the, *koohl*,



ANT-LION.

ARAUCARIA.

any volatile substance), the characteristic ingredient of fermented liquors is produced by the fermentation of sugar or other saccharine matter, the produce of the vegetable world. Pure alcohol cannot be obtained by distillation alone, the strongest product containing about 10 per cent. of water; but, if chloride of calcium, quicklime, or carbonate of potash be added, the water is absorbed, and pure alcohol can be obtained. Pure alcohol is colourless and limpid, pungent to the taste and smell. Its specific gravity at 60° is ·7938. It boils at 173°, and has been rendered gelatinous by cold, but has never been frozen. It is very inflammable, and burns without smoke. It mixes with water in all proportions, and has a great attraction for it. Its solvent powers are great, especially with respect to resins and resinous gums. The strength of alcohol is in exact proportion to its density, which is estimated by means of a hydrometer. Excise proof spirit has a specific gravity of ·9186, and contains 49¼ per cent. of absolute alcohol. Spirits of wine, the strongest form of alcohol which can be produced by distillation alone, is from 54 to 58 over proof; and, when mixed with 10 per cent. of wood spirits, is known in commerce as methylated spirit. The chemical formula of alcohol is C_2H_6O; and it is thus composed—

Carbon	52·67 per cent.
Hydrogen	12·90 „
Oxygen	34·43 „
	100·00

Alcohol, when acted on by other chemical substances, produces a great variety of new compounds. One, the well-known anæsthetic chloral, is produced by the treatment of alcohol with chlorine. Another, bromal, is obtained by the employment of bromine. Chloroform is produced by the treatment of alcohol with a solution of chloride of lime. As alcohol does not freeze, it is employed to fill thermometers for registering low temperatures, in place of mercury; it is very valuable as a solvent, and is used in the manufacture of varnishes and as fuel for spirit-lamps. In medicine it is applied both internally and externally; in the former case as a stimulant and restorative, and externally as an anti-septic to stop hemorrhage and to harden the skin. The physiological action of alcohol on the human body has given rise to much acrimonious debate. The intoxication arising from excess has induced many well-meaning persons to regard it with horror—the epithet "fiend alcohol" being freely applied by extreme temperance advocates; and some physicians repudiate its use even in medicine, the majority, however, regarding it as a valuable aid. Total abstainers declare that, as analysis fails to discover any element of nutriment in it, alcohol cannot be of use as an article of food; but they forget that, by its stimulating properties, it may, temperately taken, assist the stomach to properly digest the food taken. In truth, like many other things, it should be made available under the control of the reasoning and moral faculties, and its value must vary according to different constitutions. Some persons can do very well without it, and they had better do so; others find a rational use of it beneficial, and there is no reason why the benefit should not be received. Extreme advocates of total abstinence may, perhaps, be perplexed to know, on the authority of an eminent modern chemist, M. Müntz, that it is almost impossible to avoid alcohol. By the employment of very delicate tests, he has been able to detect the presence of one-millionth of alcohol when added to water. Alcohol, he asserts, is present in spring, river, sea, and rain water, excepting the very purest sea-water. There is reason to suppose that it exists in the state of vapour in the air. The diffusion of the substance in nature he explains by the destruction of organic matter by various agents of fermentation. The earth contains it, especially when rich in organic matters, and it can be extracted and its essential properties verified. A Brahmin, who conscientiously objected to the destruction of animal life for the purposes of food, was horrified when, by means of a powerful microscope, he was shown a multitude of living organisms in the water he drank; and total abstainers may be equally surprised when they are told that they breathe alcohol, drink alcohol at the bubbling spring, and that when they die they will be buried in alcoholic earth.

ALCYONIDÆ, *al-se-on'-i-de*, a genus of animals belonging to the fresh-water polyzoa, or ascidian zoophytes. (*See* ANTHOZOA, CORALS, POLYPES, SPONGES.)

ALDEBARAN, *al-de-ba'-ran*, a name given by the Arabs to a bright star of the first magnitude, situate in the southern eye of the constellation Taurus. It is the largest and most brilliant of a cluster of five stars, named by the Greeks the Hyades.

ALDEHYDE, *al'-de-hide.*—When alcohol is submitted to any process by which hydrogen is extracted from it (deoxidation, for instance), it becomes an aldehyde, every alcohol having its corresponding aldehyde. Ethylic, or vinous aldehyde, is limpid and colourless, with a peculiar and characteristic odour. Its density is ·790; it boils at 72°, and is neutral to test-paper. On exposure to the air, it absorbs oxygen, and resolves into acetic acid.

ALDER. (*See* ALNUS.)

ALEMBROTH, *a-lem'-brawth*, a compound of the bichloride of mercury and sal-ammoniac, from which is prepared the whole precipitate of mercury; the salt of wisdom of the alchemists.

ALEURITIS, *al-u'-ri-tees*, a genus of dicotyledonous plants, belonging to the order *Euphorbiaceæ*. The most interesting species is *A. triloba*, the candle-nut tree, the seeds of which contain the oil called *kukiu*, or *kekune*, which is used in some parts of the world for illuminating purposes, and which has been recommended as a substitute for castor-oil in medicine.

ALEXANDERS, a biennial plant of the natural order *Umbelliferæ*. The stem is about three feet high, the leaves are of a bright yellowish, green colour, and the flowers of the same colour. It was formerly cultivated as an edible vegetable, and the fruit has carminate properties.

ALGÆ, *al'-jee* (Lat., seaweeds), this great class of plants, belonging to the class *Cryptogamia* of Linnæus, as the Acotyledones of the natural cycles, comprehends the sea-weeds and the multifarious green vegetable forms of simple cellular structure met with in fresh water and in permanently damp situations. The humblest members of the vegetable kingdom belong to this class. Algæ are flowerless, and consequently seedless. They are propagated in various ways by reproductive particles, called spores or sporules. The class comprehends a vast variety of plants, exhibiting a wonderful multiplicity of forms, colours, sizes, and degrees of complexity in structure. These plants have, however, been arranged into three groups or orders, which have certain striking distinctive characters. These three orders are named *Rhodosporeæ*, or *Florideæ; Melanosporeæ*, or *Fucoideæ; Chlorosporeæ*, or *Confervoideæ*. *Rhodosporeæ*, or red-spored algæ, grow in salt water, and are generally rose-red or purple, rarely brown-red or greenish-red. *Melanosporeæ*, or dark-spored algæ, are marine plants of an olive-green or brown colour. *Chlorosporeæ*, or green-spored algæ, are generally green, rarely red or livid purple, found sometimes in sea-water, but more frequently in fresh-water ponds, streams, and ditches, and on damp surfaces. Professor Bentley roughly estimates the number of species of algæ at 2,500. Many are used for food in different parts of the world, their nutritious properties being due to the presence of starch, mannite, mucilage, albumen, and gelose. The ashes of several kinds of sea-weeds form *kelp*, formerly extensively used for the preparation of carbonate of soda. Iodine is obtained from sea-weeds. None of the plants in this great class are known to be poisonous.

ALGAROTH, POWDER OF, *al'-ga-roth*, a mixture of the terchloride and teroxide of antimony, invented by Victor Algarotti, a Venetian chemist, and formerly much used in medicine.

ALGEBRA, *al'-je-bra* (Arab., *al-gebr*), the science of computing abstract quantities by means of signs or symbols instead of arithmetical figures, a species of calculation which takes the quantity sought, whether it be a number or a line, or any other quantity, as if it were granted, and, by means of one or more quantities given, proceeds by consequence, till the quantity at first only supposed to be known, or at least some power thereof, is found to be equal to some quantity or quantities which are known, and consequently its own value, or quantity, or number is determined. Algebra was originally a kind of higher arithmetic, in which the numbers are replaced by symbols; but by later applications the symbols are used as well for geometrical quantities in space, or in mechanism for velocities, distances, and times, so that at present algebra occupies itself with quantities in general, whatever be their nature.

Letters and Signs.—In algebra, numbers are represented by letters. It is a method of performing calculations of all sorts of quantities by means of general signs or characters. Known quantities are generally represented by the first letters of the alphabet, as a, b, c, &c. Unknown, by the last; as x, y, z. The sign $+$ (*plus* or more) is the mark of addition. Thus, $a+b$ means that the quantities represented by a and b are to be added together. When no sign is prefixed, $+$ is understood. The sign $-$ (*minus* or less) denotes subtraction: as, $a-b$, that is, the number represented by b is to be subtracted from that represented by a. In algebraical operations the word *therefore*, or *consequently*, often occurs. To express this word, the symbol $\therefore$ is commonly used; thus, the sentence, "therefore, $a+b$ is equal to $c+d$," is expressed by $\therefore a+b=c+d$.

Algebraic Quantities.—Quantities with the sign $+$ prefixed are called positive or affirmative; and those with the sign $-$ negative quantities. The sign $\times$ (or multiplied *by*) denotes multiplication; as, 5×4 means that 5 is to be multiplied by 4. $\div$ is the mark of division; thus, $a\div b$ means that a is to be divided by b. A number prefixed to a letter is called a numeral co-efficient. When no number is expressed, 1 is understood: *i.e.*, 1 is the numeral co-efficient of such letter. A simple quantity consists of one part or term, as $+a$, $-abc$; a compound quantity of more than one, connected by the signs $+$ or $-$; as, $a+b$, $a-b+c$, are compound quantities. If there are two terms, it is called a *binominal*, if three, a *trinominal*, &c. Like quantities consist of the same letters repeated; thus, $+ab$, $-5ab$, are like quantities; but $+ab$, and $+a^2b$ are unlike quantities.

Powers of Quantities.—The powers of algebraic quantities are expressed by placing a *small figure* (equivalent to the number of factors, and called the index or exponent of the power) at the right-hand side of the letter. Thus $a\times a$, or the square of a, is expressed by a^2; $b\times b\times b$, or the cube of b, is expressed by b^3; $x\times x\times x\times x$, or the fourth power of x, is expressed by x^4; $\overline{a+b}\times\overline{a+b}\times\overline{a+b}$ or the cube of $a+b$, is expressed by $\overline{a+b}^3$, and so on.

Roots of Quantities.—The *roots* of quantities are expressed by the sign $\surd$, with the proper index annexed: thus, ${}^2\sqrt{a}$, or $\sqrt{a}$ expresses the square root of a; ${}^3\sqrt{b}$, the cube root of b; ${}^4\sqrt{a+x}$, expresses the biquadrate root of $a+x$, &c.

Equality of Quantity.—The sign $=$ placed between two or more quantities, expresses the *equality* of such quantities; thus, $a+b=c+d$, means that $a+b$ is equal to $c+d$; and $ax+by=cx+dy=2x+fy$, means that the quantities $ax+by$, $cx+dy$, and $ex+fy$, are all equal to each other. The symbol $\urcorner$ placed between two unequal quantities signifies that the first is greater than the last; thus, $a \urcorner b$, intimates that a is greater than b; but when the character is inverted, it signifies that the first quantity it less than the second; thus, $a \angle b$, intimates that a is less than b.

Operations of Algebra.—The operations of algebra are the same as those of arithmetic—addition, subtraction, multiplication, division, extraction of roots, &c. In its application to the resolution of problems, the problem must first be translated out of common into algebraic language, by expressing all the conditions and quantities, both known and unknown, by their proper characters, arranged in an equation (*see* EQUATIONS), or several equations, if necessary, and treating the unknown quantity as if it were a known one: this forms the composition. Then the resolution, or analytic part, is the disentangling the unknown quantity from the several others with which it is connected, so as to retain it on one side of the equation, while all the known quantities are collected on the other side. This process is called analysis or resolution; and hence algebra is a species of analytic art.

History.—The origin of algebra cannot be determined with exactitude. In the middle of the 4th century, when the mathematical sciences were declining, Diophantus wrote a treatise on arithmetic, in thirteen books, of which seven only remain to us. Hypatia, the daughter of Theon, who fell a victim to the fury of a mob, in the early part of the 5th century, wrote a commentary on the work of Diophantus: this, however, is also lost. In the 16th century, the works of Diophantus were discovered in the Vatican library at Rome. They were written in the Greek language, and were translated into Latin by Xylander, in 1575. A more complete translation, by Bachet de Mezeriac, appeared in 1621. In 1670, the French mathematician Fermot published notes of his own on the writings of Diophantus. The important invention of algebra, as well as numeral characters and decimal arithmetic, was first made known in Europe by the Arabians, who had collected the works of the Greek mathematicians, and translated them. By means of the Arabic tongue, Euclid was first introduced into Western Europe. The Arabians award the invention of algebra to their famous mathematician Mahommed-Ben-Musa, or Moses, who was also called Mahommed of Buziana, in the 9th century, a copy of whose treatise on the subject is preserved in the Bodleian library at Oxford. The science of algebra was originally introduced into Italy by Leonardo, a merchant of Pisa, who had spent his youth in Barbary, and there became acquainted with the Indian method of computing by nine numeral characters. He composed a treatise on arithmetic in 1202, which he afterwards revised in 1228, two centuries before the invention of printing. The manuscript was discovered in the middle of last century, in the Magliabecchian library at Florence. The first book on algebra that ever was printed was written by Lucas Paciolus, or Lucas de Borgo, a Minorite friar. It appeared in 1494 and again in 1523. It is called "Summa de Arithmetica, Geometria, Proportione, et Proportionalita." Not only are we indebted to Italy for the first European knowledge of algebra, but it was there that it received its earliest improvements at the hands of Scipio Ferreus, Florido, Tartalea of Brescia, Cardan, Lewis Ferrari, and Bombelli. Stifelius and Scheubelius, two German mathematicians, were contemporary with Cardan and Tartalea. Stifelius introduced the characters which denote addition and subtraction, and the symbol for the square root. The first treatise on algebra in English, was from the pen of Robert Recorde, a mathematician and physician of Cambridge. Vieta was the first who introduced general symbols, applicable to all problems of the same kind, without the labour of repeating the same process of analysis for each; thus happily applying algebra to geometry. The early Italian teachers described algebra as the *Arte Maggiore*, as having to do with the higher kind of calculations, or *Regola de la Cosa*, because the unknown quantity was denominated *Cosa*, the "thing," and that gave rise to the term Cossicke Art given by early English writers. Sir Isaac Newton designated it "universal arithmetic;" Sir William Hamilton "the science of pure time;" and Mr. de Morgan "the calculus of succession."

Algebraic Equation.—An equation of which the terms contain only algebraic quantities.

Algebraic Geometry is a name given to the application of algebra to geometrical problems.

Algebraic Curve is a figure the intercepted diameters of which always bear the same proportion to their respective ordinates, or the lines which, drawn perpendicular to the axis of the curve, meet the curve in a number of points.

ALGORITHM, *al'-go-rithm*, derived from the Arabic, the root being a word which means or refers to calculation or reckoning. Among many authors, and especially the Spanish, the word is naturalised, as meaning the science of numbers, or system of notation: thus, there is an algorithm of the differential calculus, an algorithm of function, &c. Though sometimes used by English writers, our language does not need it, the word *notation* being an exact equivalent.

ALHAGI, *al-hai'-gi*, Camel's-thorn, a genus of leguminous plants in the sub-order *Papilionaceæ*. The species *A. maurorum*, a native of South-Western Asia and some parts of Africa, yeilds a kind of manna, which is used as food for cattle, which is obtained by shaking the branches of the tree, and is believed by Arabian writers to be a supernatural production.

ALIMENTARY CANAL, or DUCT, *al-i-men'-ta-re* (Lat., *alimentum*, nourishment, food), is the name given to that great canal or conduit in animal bodies through which the food passes from the mouth to the anus. It distinguishes animal from vegetable life, plants having no common receptacle for their food nor canal for carrying off the excrements. In the human subject, it comprises the pharynx, œsophagus or gullet, stomach, and large and small intestines, being, in a full-grown individual, nearly forty feet in length. (*See* ANATOMY.)

ALIMENTS, *al'-i-ments* (Lat., *alimentum*, from *alo*, I nourish), a term applied to those substances which, upon being taken into the stomach, are capable of affording nourishment to the body. Every aliment must be derived from either the animal or vegetable kingdom, as the capacity of affording nourishment to the animal system would appear to belong exclusively to organized matter, or that which has possessed life. Nevertheless, certain substances appertaining to the inorganic kingdom, although incapable of themselves to form an aliment, have yet the power, when taken in conjunction with aliments, of assisting in the process of nutrition. These inorganic substances are principally water, salt, lime, &c. The first, or *Farinaceous*, class, includes barley, wheat, oats, rice, maize, potatoes, haricots, lentils, peas, &c. The second, or *Mucilaginous* class, comprehends melons, cabbages, turnips, beet-root, carrots, asparagus, &c. The third, or *Sweet* class of aliments, includes dates, apricots, dried grapes, figs, the various sorts of sugars, &c. In the fourth, or *Acidulous* class, there are grapes, strawberries, raspberries, mulberries, pears, prunes, apples, cherries, oranges, gooseberries, &c. In the fifth or *Fatty* class, there are animal fats, oils, butter, cocoa, nuts, walnuts, olives, sweet almonds, &c. The sixth, or *Caseous* class, includes the various sorts of milk, cheese, &c. In the seventh, or *Gelatinous* class, there are several kinds of fish, the flesh of young animals, calve's-feet, &c. In the eight or *Albuminous* class, there are included brain, eggs, &c. The ninth, or *Fibrinous* class, comprehends the flesh and the blood of various animals. To these nine divisions a tenth may be added, comprehending the *Condiments*, as pepper, salt, mustard, vinegar, horse radish, &c. Certain liquids, or *Drinks*, should also be reckoned among the aliments, as water of various kinds (spring-water, well-water, river-water), the infusions of tea and coffee; the various kinds of fermented liquors, as cider, perry, beer, wine, &c.; the alcoholic liquors, as gin, whisky, brandy, &c.

ALIQUANT PART, *al'-i-kwant* (Lat., *aliquantus*, a great part), a number which cannot measure any other without some remainder. Thus, 5 is an aliquant part of 12; for twice 5 wants 2 of 12, and three times 5 exceeds 12 by 3. The exact reverse of aliquot.

ALIQUOT, *al'-i-kwot* (Lat., *aliquoties*, how many times), a number or fraction which divides another number or fraction, without leaving a remainder. Thus, 6, 4, 3, 2, $1\frac{1}{2}$, $\frac{3}{7}$, and $\frac{1}{8}$, are aliquot parts of 12, being contained in it 2, 3, 4, 6, 8, 28, and 96 times. Aliquot parts are chiefly used in the rule of *Practice*.

ALISMACEÆ, *al-is-mai'-se-e*, an order of monocotyledonous plants, in the sub-class *Petaloideæ*. Swamp or floating plants, with parallel-veined leaves. Their flowers are perfect, or very rarely unisexual. The perianth is inferior, that is to say, it does not adhere to the ovary, and is arranged in two whorls, each consisting of three parts; the outer whorl being green, the inner coloured. The stamens vary in number, and there are several ovaries. Plants belonging to this order are principally found in the northern parts of the world. The typical genus is *Alisma*, the water-plantain, some species of which are well adapted for aquaria.

ALIZARINE, *a-liz'-a-reen*, a crystalline body, the pure colouring matter of madder. Purpurin and garancine are also found in this dye-stuff.

ALKALI, *al'-ka-li* (Arab., *kali*, the name of a plant from the ashes of which an alkaline substance was first procured). This term is applied, in Chemistry, to a class of substances characterised by the energy with which they combine with acids (*see* ACIDS) by their acidity and caustic property, and by their action on vegetable colours. The use of the term is now generally limited to such members of the group as are soluble in water. The alkalies proper are potash, soda, lithia, and ammonia. Potash is known as the vegetable alkali, being largely present in the ashes of plants; soda is designated the mineral alkali; and ammonia, being of gaseous form, is known as the volatile alkali. The pure form of these alkalies is called the caustic state, from the burning properties possessed by them all when not combined with any acid. When they are in combination with carbonic acid, which is a very weak acid, they are said to be in their mild form, and still preserve, in a minor degree, many of their characteristics as alkalies. Many vegetable colouring matters are changed in tint by alkaline solution, a matter of some importance in chemical analysis—vegetable blues turn green, and vegetable yellows reddish-brown. Combined with carbonic acid, alkalies are used to correct acidity in the stomach.

Alkaline Earths—Lime, magnesia, baryta, and strontia—are distinguished from alkalies proper by their carbonates not being soluble in water.

Alkaline Spectra. (*See* SPECTRUM.)

ALKALIMETER, *al-ka-lim'-e-ter* (Arab., *al-kali* and Gr., *metron*, a measure), a graduated glass tube used to determine the proportion of pure carbonate of potash or soda contained in commercial samples. (*See* ALKALIMETRY.)

ALKALIMETRY, *al-ka-lim'-e-tre*, the art of determining the proportion of caustic alkali, or alkaline carbonate, contained in commercial potash or soda, upon the amount of which depends their value for manufacturing purposes. The method by which this is effected is by adding to a certain amount of the potash or soda dissolved in water, enough dilute sulphuric acid of definite strength to exactly neutralize the alkali, and noting this quantity. For instance, if it is found that one dram of the test acid will neutralize seven grains of pure alkali, it is evident that, if six drams are required to neutralize fifty grains of impure potash, there are only forty-two grains, or 84 per cent., of pure alkali in the sample, the other 16 per cent. being combined with another acid, or replaced by some neutral compound.

ALKALOIDS, VEGETABLE, *al'-ka-loids* (Arab., *al-kali*, Gr., *eidos*, likeness).—The discovery of these substances is one of the most remarkable of modern chemistry. They are salifiable bases, found in various vegetable and animal substances, and are similar in their actions to the mineral alkalies mentioned above, uniting with acids to form salts. They are all violent poisons, highly nitrogenous, sparingly soluble in water, but more so in alcohol and dilute acids. The following is a list of the principal vegetable alkaloids. They are of great value in medicine, the exhibition of the fraction of a grain being attended with the most marked curative results. The principal vegeto-alkalies are:—morphia, from opium; quinia and cinchonia, from Peruvian bark; strychnia, from nux vomica; veratria, from hellebore; atropia and hyocyamia, from belladonna; nicotine, from tobacco; aconita, from aconite; caffeine or theime, in coffee and tea.

ALKANET-ROOT, *al'-ka-net*, a dye-stuff, giving a red colour, used for staining woods and for colouring oils and spirits used in perfumery. It is the root of the plant named by botanists *Anchusa tinctoria*. (*See* ANCHUSA.) It is used for colouring spurious port wine, and in furniture polish.

ALKANNA, *al-kan'-na* (Arabic, *al-henna*). (*See* HENNA.)

ALLAMANDA, *al-la-man'-da*, a genus of plants of the natural order *Apocynaceæ*, native of the tropical parts of America. The *A. cathartica*, indigenous to the West Indies, has strong emetic and purgative properties, and is of considerable value in medicine. The name was given in honour of Dr. Allamand, of Leyden.

ALLANITE, *al'-lan-ite*, an opaque mineral found in Greenland, consisting of oxides of iron, silica, and other substances. Named from its discoverer, Mr. Allan, of Edinburgh. (*See* ORTHITE.)

ALLIGATION, *al-li-gai'-shun* (Lat. *ad*, and *ligare*, to bind together, or unite), a rule of arithmetic by which the price of a mixture is found when the cost of the ingredients is known. This rule is divided into two cases—*alligation medial* and *alligation alternate*. The following question would belong to alligation medial. Suppose 8 gallons of brandy, at 24s. per gallon, to be mixed with 12 gallons at 34s. per gallon, what would be the price of a gallon of the mixture? But if the question were reversed, and it were required how many gallons of brandy, at 34s. per gallon, must be mixed with 8 gallons at 24s. per gallon, to make the cost of the mixture 30s. per gallon, it would belong to alligation alternate.

Rules.—To find the answer to a question in *alligation medial*, multiply each quantity by its price, and divide the sum of the products by the sum of the quantities. The solution of a problem in *alligation alternate* is obtained by arranging the given prices in one column with the proposed average prices on the left; linking each less than the average with one greater, and placing against each term the difference between that with which it is linked and the average; the respective differences will be the quantities required.

ALLIGATOR, (*See* CROCODILE FAMILY.)

ALLLIGATOR TORTOISE, (*See* TORTOISE.)

ALLIUM, *al'-li-um* (Lat., garlic), a genus of plants belonging to the natural order *Liliaceæ*, the Lily tribe. Many species are very familiar plants, being largely cultivated for the sake of their nutritious and piquant bulbs; such are *Allium Cepa*, the onion; *A. sativum*, the garlic; *A. Porrum*, the leek; and *A. ascalonicum*, the shalot. All the species are characterized by a strong, and, to some people, an extremely disagreeable odour. *Allium ursinum*, the common ramsons of our meadows, diffuses its peculiar odour through the air, and imparts its unpleasant flavour to the milk of the cows that feed upon it. The substance which gives the garlic and onion their pungent smell and flavour is a compound oil, called by chemists *sulphide of allyle*. The different species of Allium, when cultivated in warm climates, loose much of their pungency; hence the mild flavour of the Spanish onion.

ALLOCHROITE, *al-lok'-ro-ite*, a variety of garnet. (*See* GARNET.)

ALLOPHANE, *al'-lo-fain* (Gr., *allos*, other, *phaino*, I appear), the name given to a clayey mineral of a pale blue or greenish colour. Chemically, it is a hydrated silicate of alumina. It loses its colour before the blowpipe: hence its name.

ALLOTROPY, *al-lot'-ro-pe* (Gr., *allotropos*, capable of being turned from one thing into another), a term applied to a modification in the properties of a body, not resulting from chemical combination, but from the arrangement of its molecules; or, in other words, the existence of the same element in various forms, each of which, though containing no extraneous substances, possesses different properties from the other. Phosphorus, in its usual state, is a waxy, semi-transparent body, of a pale lemon-colour, which is so inflammable that the heat of the hand is sometimes sufficient to kindle it; but, by a simple though dangerous process, this substance can be procured in an allotropic state, when it is an infusible substance of a dark-red colour, which will not take fire until heated to 500° F., when it is reconverted into ordinary phosphorus. Again, iodide of mercury, when freshly sublimed, is of a lemon-yellow colour, but it becomes scarlet if pressed or agitated. Sulphur can be made to take several allotropic forms. The diamond, graphite or plumbago, and soot, are allotropic forms of the element carbon. Silica is soluble in water in one allotropic state, and insoluble in another. Oxygen and ozone afford another striking illustration of the principle. In all these cases, the change of properties is not due to the addition or subtraction of anything, but to some inexplicable molecular action. (*See* ISOMERISM.)

ALLSPICE, *awl'-spice*, the dried unripe fruit of *Eugenia Pimenta*, a plant of the Myrtle order. It is much used as a spice, and is thought to combine the flavours of cinnamon, cloves, and nutmegs; hence its common name. It is sometimes called Jamaica pepper, from the island in which it is chiefly cultivated, and sometimes pimenta.

ALLUVIUM, *al-lu'-vi-um* (Lat., *alluere*, to wash upon), in Geology, a name formerly given to those accumulations of sand, earth, and loose stones or gravel brought down by rivers, which, when spread out, form what are called alluvial plains and deltas. The term is seldom employed by modern geologists. (*See* FLUVIATILE DEPOSITS, DELTA.)

ALMANDINE, *al-man'-deen*, a gem found in Greenland, Ceylon, and the Brazils. It is an iron garnet, and consists of silica 36·3, alumina 20·56, protoxide of iron 43·2.

ALMOND, *ah'-mond*, in Botany. (*See* AMYGDALUS.)

Fixed Oil of.—An oil exuding from almonds when subjected to pressure. It is used in medicine as a mild laxative, and is sometimes administered to newly-born infants, and has a value as an ingredient in cough medicine.

Volatile, or Essential Oil of.—When the fixed oil has been expressed, the cake remaining is placed in a retort, and the volatile oil rises in vapour. When condensed, the crude oil is poisonous, but redistillation gets rid of the prussic acid. It has a use in medicine, and is employed to flavour custards and confectionery, and for scenting toilet soaps.

ALNUS, *al'-nus*, the Alder, a genus of plants belonging to the Birch order *Betulaceæ*. The species *A. glutinosa* is a well-known tree. Its timber resists the destructive action of water for a long time, and on this account is much used for the piles of bridges. Its bark is astringent, and has been employed in medicine and for tanning; it is also used as a dye-stuff, giving a red colour when alone, and black when added to a solution of copperas. It is a low tree with a rugged bark, and grows in moist situations. The leaves are roundish, waved, serrated, and somewhat sticky, being downy underneath about the veins. The flowers grow in long hanging catkins. The species *A. incana* is found in Kamtschatka, where its bark is used for making a kind of bread.

ALOE, *al'-o* (Lat.), a genus of monocotyledonous plants belonging to the natural order *Liliaceæ*, the Lily tribe. There are several species, all natives of warm climates, but capable of being cultivated in colder regions as ornamental garden plants. The leaves are succulent, and edged with spines; they yield the juice which, when inspissated, constitutes the bitter drug called aloes (*see* this word). The flowers are usually red, growing in a bunch at the top of the stem. Some of the larger kind of aloes are of great importance to the inhabitants of countries in which they grow. In the arts, a particularly beautiful violet colour is obtained from the leaves of the Socotrine aloe (*A. Socotrina*). Mohammedan pilgrims suspend an aloe over their doors on their return from Mecca, to signify that they have performed the pilgrimage. The perfume of aloes is mentioned in the Old Testament and in the Gospel of St. John.

Aloe, the American.—(*See* AGAVE.)

Aloes, a drug used medicinally in small doses as a tonic, and in larger doses as a purgative and cathartic. It is the inspissated juice of the leaves of various species of *Aloe*.

Aloes Wood.—The inner part of the trunk of trees of the natural order *Aquilariaceæ*, natives of the tropical part of Asia, and supposed to be the lign (*lignum*) aloes of the Old Testament. It contains a fragrant resinous substance used in the East as a medicine. By the ancients it was esteemed to be as valuable as gold, and fragments worn about the person were supposed to ensure beneficial results; and it was also used as a setting for precious gems.

ALOYSIA, OR LIPPIA, *a-loi'-si-a*, a genus of plants belonging to the natural order *Verbenaceæ*. *Aloysia*, or *Lippia citriodora*, is the sweet verbena or lemon-plant of our gardens.

ALPACA, *al-pak'-a*, a species of the genus Lama, with which it is so closely allied, that by some it is set down as being only a variety of it. The alpaca (used by the ancient Peruvians as a beast of burthen) inhabits the mountainous parts of Peru, and obtains its aliment from the coarse and scanty herbage growing on the sterile soil of those elevated regions. Its general form bears a close resemblance to that of the sheep, but its head and neck more nearly resemble those of the camel. The upper part and sides of this animal's body are covered with light chestnut-brown wool, which hangs down in slightly curled meshes almost a foot in length. This wool is extremely soft and elastic, and is nearly as fine as that of the Cashmere goat. The face, up to the posterior margin of the jaws, has short smooth hair; but, from the forehead, a stiff silky hair falls over the eyes. The shearing of the wool takes place annually, from 10 to 12 lbs. of wool being obtained from a single animal. Efforts, only partially successful, however, have been made to acclimatize the alpaca in Europe. The first alpaca brought to this country was placed in the menagerie of the Earl of Derby, in 1836.

ALPINE PLANTS (by some botanists designated Alpestris), plants which are found at elevations approaching the limits of perpetual snow in alpine regions. The snow line varies considerably in different parts of the world. (*See* PHYSICAL GEOGRAPHY.) Rhododendrons, gentians, saxifrages, ferns, and mosses, and beautiful cryptogamous plants are familiar forms of alpine vegetation.

ALPINIA, *al-pin'-i-a* (from Prosper Alpin, a celebrated botanist), a genus of aromatic herbaceous plants, in the natural order *Zingiberaceæ*, the Ginger tribe. The roots of the species *A. galanga* and *A. chinensis* constitute respectively the Java and Chinese, or greater and lesser galangals. These roots have similar properties to ginger, and are used for the same purposes. The ovoid China cardamum, used in veterinary medicine, is the fruit of *A. alba*. The seeds of this plant are commonly employed as a condiment by the Chinese.

ALSINEÆ, *al-sin'-e-e*, the Chickweed sub-order of *Caryophyllaceæ*. There are numerous genera; *Alsine*, *Cerastium*, *Arenaria*, and *Stellaria*, being examples. (*See* CARYOPHYLLACEÆ.)

ALSODEÆ, *al-so'-de-e*, in Bot., one of the two sub-orders into which the natural order *Violaceæ* has been divided. The species have regular flowers, with anthers not furnished with appendages. (*See* VIOLACEÆ, VIOLEÆ.)

ALSTONIA, *al-sto'-ne-a*, a genus of dicotyledonous plants, belonging to the natural order *Apocynaceæ*, the Dog-bane tribe. The species *A. scholaris* has a bitter tonic astringent wood, and is a native of South America.

ALSTRŒMERIA, *al-stre-meer'-i-a*, a genus of plants belonging to the Amaryllis order, or *Amaryllidaceæ*. The species are all South American. Their leaves are twisted, so that what should be the upper surface becomes the lower; the tuberous roots are eaten; and in Chili a kind of arrow-root is prepared from them.

ALTERNATION, *al-ter-nai'-shun*, in Mathematics, a term applied to the changes of orders in any number, called also Permutation. It is found by a continual multiplication of all the numbers; thus, to know how many changes can be rung on six bells, multiply the numbers 1, 2, 3, 4, 5, 6 continually into one another, and the last product is the answer.

Alternation of Generations. (*See* GENERATIONS, Alternation of.)

ALTERN BASE, *awl'-tern*, in Mathematics, a term used in contradistinction to the true base. Thus, in oblique triangles, the true base is either the sum of the sides (the difference of the sides then forming the true base), or the true base is the difference; in which case the sum is the altern base.

ALTHÆA, *al-the'-a* (Gr., *altheo*, I heal), the marsh-mallow, a genus of plants belonging to the natural order *Malvaceæ*. (*See* MARSH-MALLOW.)

ALTITUDE, *al'-ti-tude* (Lat., *altitudo*, height), is the height of a celestial body above the horizon. It is measured by the angle which a line from the eye to the star or planet makes with the horizontal line. An altitude may be *true* or *apparent*. If it be taken from the real horizon, the altitude is true; if from the apparent or sensible horizon, the altitude is apparent; or rather, the apparent altitude is that which appears to our observation, and the true is that from which the refraction is subtracted. The true altitudes of the heavenly bodies differ but little from their apparent altitudes, on account of their distance from the earth's centre, and the smallness of the earth's semi-diameter compared thereto. In observatories, altitudes are taken by means of telescopes attached to graduated circles, and at sea, by instruments called sextants.

Altitude, in Geometry, one of the dimensions of a body, being the same with what is commonly called height. The altitude of a figure is the distance of its vertex from its base; in other words, it is the length of a perpendicular line let fall from the vertex to the base. The altitude of a cone is measured by a line perpendicular to the plane of the base, drawn between the vertex and base of the cone.

ALUM, *al'-um* (Lat., *alumen*), a salt consisting of sulphate of alumina in combination with sulphate of potash, soda, or ammonia. Potash and ammonia alum are used in dyeing, in calico-printing, in paper-making, in the manufacture of colours, and in medicine. Alum is obtained by submitting alum-shale, or alum-slab, which consists of alumina, iron pyrites, and coaly matter, to the action of fire in enormous heaps for one or two years. During the combustion, the sulphur of the iron pyrites (sulphide of iron) combines with the oxygen and alumina, forming sulphate of alumina, which is dissolved out of the cooled mass by water. This solution is then converted into alum by the addition of either sulphate of potash or sulphate of ammonia, the latter being most generally used on account of its cheapness. Ammonia alum is more valuable than potash alum, from containg 11·90 per cent. of alumina, which is the active ingredient, while potash alum contains but 10·82 per cent. Soda alum is not used in the arts. The great use of alum in dyeing and printing is on account of the property possessed by alumina of uniting with and precipitating certain vegetable substances in an insoluble form. Alum is also used in the preparation of leather; and in medicine is a powerful astringent. Alum rarely occurs in nature, except in a few springs and some extinct volcanoes, where it appears to have been formed by the action of the vapours of sulphuric acid. Muslin dipped in a solution of alum is rendered incombustible.

Alum-Root, a name given to the root of the *Geranium maculatum*, which contains much tannin. It is used in North America as an astringent.

Alumstone or **Alunite.**—A mineral found near Civita Vecchia, in Georgia, at Pic-de-Lancy, in France, and in the Grecian archipelago. It consists of alumina 37·13, sulphuric acid 38·53, potash 11·34, and water 13. It is one of the principal sources of alum.

ALUMINA, *a-lu'-mi-na*, the sesqui-oxide of the earth-metal aluminium, the principal constituent of clays. It occurs in nature in combination with silica and other bases. Felspar is a silicate of alumina and potash. (*See* FELSPAR and GRANITE.) The hydrate is obtained in the form of a gelatinous precipitate, by adding ammonia, or carbonate of ammonia, to a solution of alum. By drying and igniting, it is changed into the anhydorus sesqui-oxide, insoluble in water, but soluble in acids and alkalies. Mr Walter Crum has discovered a modification or allotropic condition of alumina, produced by igniting bi-acetate of alumina, which is soluble in water, and forms a translucent coagulum with dye-woods. By the addition of a small quantity of acid, alkali, or even neutral salt precipitation of alumina, a third allotropic condition takes place; this form being insoluble in acids, but soluble in alkalies. By the use of the oxy-hydrogen blow-pipe, aluminum is fusible. It occurs in nature in a crystallized form, the coarser specimens forming emery powder. The transparent crystals when of a blue colour, owing to a haze of metallic oxide, constitute the sapphire, and when red, the ruby.

Acetate of.—The acetate of alumina is much used in the arts on account of the easiness with which it parts with its alumina. It is formed by adding acetate of lead to sulphate of alumina, and filtering off the insoluble sulphate of lead.

Silicate of.—The chief ingredient in common clay.

ALUMINIUM, *al-u-min'-i-um*, a white, malleable ductile metal, dicovered by Wöhler in 1827. It is now regularly prepared as a commercial product in the following manner:—Anhydrous alumina is mixed with charcoal and oil, and ignited in a covered crucible. When cold the mass is broken to pieces, and exposed at a red heat to the action of chlorine gas. Chloride of aluminium is formed, and, when cold, is mixed with half its weight of chloride of sodium and fluor spar. This mixture is placed in a crucible with one-eighth of metallic sodium, and heated to the melting-point of the materials employed. The sodium seizes on the chlorine, leaving the aluminium in a refined state. Aluminium thus prepared is a bluish-white metal, similar to silica. It becomes as hard as iron on being hammered and rolled. Its extraordinary lightness, 2·5 (the specific gravity of glass) has led to its employment in jewellery. It forms a hard gold-coloured alloy with copper, called aluminium bronze. Added to iron in the proportion of 25 per cent., it prevents the oxidation of that metal by moist air.

ALVEOLA, *al'-ve-ol-a* (Lat., *alveolus*, a small hollow vessel), a term applied by botanists to any little pit or socket, but particularly to a cavity in the receptacle where the seed is placed.

ALYXIA, *a-lix'-i-a*, a genus of dicotyledonous plants, belonging to the Dog-bane order *Apocynaceæ*. The species *A. stellata* has an aromatic bark, resembling in properties that of canella.

AMADOU, *am'-a-doo* (Lat., *ad manum dulce*, soft to the touch), a spongy substance, generally known as German tinder, which can be ignited by a spark from a flint and steel. It is prepared by soaking thin slices of the fungi *Polyporus fomentarius* (which grows on old trees, especially the oak, ash, fir, and cherry), in a solution of nitrate of potash (saltpetre), after they have been softened by beating with a mallet. Similar slices not treated with the salt are sometimes used in surgery to give support to affected parts, and also to restrain hemorrhage. The fungi *Pigniarius*, a hard amadou, is known as touchwood. When impregnated with gunpowder, the prepared fungus forms black amadou. (*See* POLYPORUS.)

AMANITA, *am-a-ni'-ta*, a genus of fungi, named from Mount Amanus, in Cilicia, where they were very abundant. The species have a close resemblance to some edible fungi, and are not unlike the common English mushroom. *Amanita muscaria* is a very poisonous kind, though the natives of Kamtschatka are in the habit of eating it for the sake of its narcotic effects. It is sometimes called Fly Agavic, and it is steeped in milk and employed to kill insects.

AMARANTHACEÆ, *am-a-ran-thai'-se-e*, the Amaranth order of dicotyledonous plants. There are 46 genera and 486 species, herbs or shrubs, nearly all natives of tropical regions.

AMARANTHUS, *am-a-ran'-thus*, the typical gen. of the nat. ord. *Amaranthaceæ*. Some of the species have bright-coloured persistent flowers, and have been introduced into this country as ornamental garden plants. The best-known are *A. caudatus* (Love lies bleeding), *A. hypochondriacus* (Prince's feathers). In poetry the name is applied to plants which, from not soon fading, typified immortality; and for that perhaps the Globe Amaranth, the purple flowers of which retain their beauty for several years, is much used in Roman Catholic countries for the decoration of churches.

AMARYLLIDACEÆ, *am-a-ril-li-dai'-se-e*, the Amaryllis order of monocotyledonous plants. There are 68 genera and 400 species, natives of many parts of the world, but most abundant at the Cape of Good Hope. Several of these plants have poisonous properties, and some yield excellent fibres. The different species of NARCISSUS belong to this order.

AMARYLLIS, *am-a-ril'-lis*, the typical genus of the natural order *Amaryllidaceæ*. Several beautiful garden and greenhouse plants are included in this genus. They are remarkable for their brilliant and symmetrical flowers, which exhale a sweet perfume. The Guernsey lily (so named from its successful cultivation in that island, but supposed to be a native of Japan), belongs to this species.

AMAUROSIS, *am-aw-ro'-sis* (Gr., *amaurosis*, obscurity), is a blindness or obscurity of vision, proceeding from a diseased state of the optic nerve, or of that part of the brain in connection with it. It generally comes on gradually, with dimness or confusion of sight, variations of colour, or the presence of floating objects called *spectra*. It is commonly occasioned by long-continued over-excitement of the organs of vision, or by a sudden exposure to a bright light, or it may proceed from a disordered state of the stomach. The use of tobacco is one of the predisposing causes. It is also sometimes hereditary. It may be permanent, or only temporary. In a full habit, it is to be treated by depletion; in the weak, by tonics and alteratives. Counter-irritants are also to be used.

AMBER, *am'-ber* (Fr., *ambre*, Gr., *elektron*), a resinous mineral solid, of a fine yellow colour, which, on being rubbed, becomes strongly electric. It has given its name to the science of electricity, being the first substance which was found to possess such properties. It is much used for jewellery and pipe mouthpieces. Dissolved in chloroform, it forms one of the best photographic varnishes. It is found abundantly on the shores of the Baltic, and, occasionally, in Greenland, England, Italy, Spain, Sicily, Siberia, China, and America. It is supposed to be a fossil gum or resin, from its constituents and properties, and from containing the bodies of insects, and sometimes leaves, inclosed in its mass. There are amber mines on the Baltic coast of Prussia, worked to the depth of 100 feet. Pieces of amber weighing as much as 12 lbs. have been found. Greek legends describe amber as the tears of the sisters of Phaethon who were killed by the lightnings of Jove for his presumption in attempting to drive the chariot of the sun-god, one of whose names was Electron. Medicinal virtues were formerly ascribed to amber, and it was believed to be a charm against witchcraft.

AMBER, ACID OF. *See* SUCCINIC ACID.

AMBERGRIS, *am'-ber-gris* (Fr., *ambre*, amber; *gris*, grey), is a morbid secretion of the sperm whale, much used in perfumery, found floating on the sea, or deposited on the coast. It imparts a delicate odour to perfumes. In the East it is used as a flavouring material in cookery.

AMELANCHIER, *am-e-lan'-she-er*, a genus of plants belonging to the sub-order *Sanguisorbeæ*, of the natural order *Rosaceæ*. The species *A. canadensis* is a native of the arctic regions, and its fruit, called the shad-berry, or service-berry, is used for mixing with pemican.

AMENTACEOUS, *a-men-tai'-se-us*, a term applied to those plants which bear catkins (*see* AMENTUM), as the oak, willow, poplar birch, and walnut.

AMENTUM, *a'-men-tum*. (*See* CATKIN.)

AMETHYST, *am'-e-thist* (Lat., *amethystus*), a variety of crystallized quartz, having a violet tint, due to a small quantity of paroxide of iron or of manganese. The most beautiful specimens are obtained from Ceylon, India, and Brazil. It is also found near Cork, in some parts of Scotland, in Saxony, and in Transylvania. The Oriental amethyst is a purple variety of the sapphire, and consists of alumina, with a small portion of oxide of iron.

AMIANTHUS, *am-i-an'-thus*, a fine variety of asbestos. (*See* ASBESTOS.)

AMIDINE, *am'-i-dine*, the soluble portion of starches.

AMIDOGEN, *a-mid'-o-jen*, a chemical base containing three equivalents of hydrogen to one of nitrogen. It is produced by the action of the metal potassium on dry gaseous ammonia.

AMMONIACUM, *am'-mo-ni'-a-kum*, a gum-resin used in medicine. It exudes from the stem of an umbelliferous plant known to botanists as *Dorema ammoniacum*, which grows in Persia and the adjacent parts of Asia. It is occasionally prescribed as an expectorant, and is applied externally to promote the absorption of tumours and chronic swellings of the joints.

African Ammoniacum is a very different substance, the product of a plant growing in North Africa. It is a dark-coloured gum resin, and is used, especially in Egypt, for purposes of fumigation.

AMMONITE, *am'-mo-nite*, a genus of fossil shells allied to the living genus Nautilus. In shape they resemble a ram's horn—whence their name, from their supposed likeness to the horns upon the statue of Jupiter Ammon. Having, also, very much the appearance of a coiled snake, they were, before the science of geology was known, commonly described as petrified snakes. More than 200 species are known. They are found plentifully in the cretaceous oolite formations, and in the entire series of fossiliferous rocks, and are so abundant in some parts of Burgundy, that the roads are paved with them. They vary in size from two or three inches to three or four feet in diameter. The animal that inhabited this shell was provided with air-sacs, by means of which it could rise or sink in the water; and its shelly covering, necessarily delicate in order to float, was made strong enough to bear the pressure of great depths by its tubular form and internal ribs or supports.

AMMONIUM.—The existence of a hypothetic compound metal called ammonium, and having the constitution NH_4, has been assumed as the only method of explaining the perfect analogy that exists between the salts of ammonia and those of the various metals. An equivalent of ammonia united to an equivalent of water is supposed to form the oxide of this metal, $NH_3+HO=(NH_4)O$, corresponding to potassa, the oxide of potassium KO. The theory of the existence of a compound metal is borne out not only by analogy, but by actual experiment. If a few globules of mercury are immersed in a solution of chloride of potassium, and an electric current be passed through them, the mercury gradually swells up into a pasty mass, which experiment has proved to be an amalgam of mercury and potassium. If chloride of ammonium be substituted, the same effect takes place, the only difference being that the bulk of the mercury is much more increased, and at last floats on the solution, from its lightness. The formation of this amalgam seems not only to demonstrate the existence of ammonium, but also to show that it is a metal, non-metallic amalgams being unknown. When thrown into water, these amalgams form solutions of potash and ammonia respectively, with the evolution of hydrogen.

AMMOPHILA, *am-mof'-e-la*, a genus of grasses closely allied to the reeds. *A. arundinacea*, commonly known as sea-reed, sand-reed, or mat-grass, grown on the sandy shores of Britain and the continent of Europe. In Ireland it is used to make mats. In English and Scotch law it is described as Marum, or Marrum, and its destruction was prohibited under severe penalties, because of its great utility in fixing the shifting sand.

AMOMUM, *a-mo'-mum*, a genus of plants belonging to the natural order *Zingiberaceæ*, the Ginger family. Several species have aromatic seeds, which are used medicinally and as spices in many parts of the world. *A. meleguela* is a native of Western Africa, and yields the so-called grains of Paradise, or Guinea pepper, used in this country in veterinary medicine, and for giving pungency to beer, wine, spirits, and vinegar. Most of the fruits called cardamoms, so largely employed in medicine as stimulants, are produced by plants included in this genus. So also is the species known as the grains of Paradise.

AMORPHA, *a-mor'-fa*, the bastard indigo, a genus of plants belonging to the natural order *Leguminoseæ*. The typical species, *A. fruticosa*, is a native of South Carolina, and is cultivated in English gardens. Its flower is purple or violet, and very irregular, the corolla wanting both wings and keel; its leaf is very dark green. The root, when peeled, is sometimes chewed as a remedy for toothache. A blue dye-stuff resembling indigo, but much inferior, may be obtained from this plant; hence the common name for the genus.

AMORPHOUS, *a-mor'-fus* (Gr., *a*, without, *morphe*, form), in chemistry and mineralogy, substances are said to be *amorphous* when they do not assume any crystalline form or regular structure. Glass, resin, coal, and albuminous substances are amorphous, exhibiting uniformity of properties in every direction.

AMPELIDEÆ, *am-pe-li'-de-e* (Gr., *ampelos*, vine), in Bot., a name given by some botanists to the Vine order. (*See* VITACEÆ.)

AMPELOPSIS, *am-pe-lop'-sis*, in Bot., a genus of plants belonging to the natural order

Vitaceæ, the Vine family. The species constitute the climbing shrubs called Virginian creepers.

AMPHIBIA, *am-fib'-i-a* (Gr., *amphi*, both, and *bios*, life), an order of the class of Reptiles. In ordinary language, the term amphibious has been applied to animals such as frogs, which at one period of their existence are aquatic, breathing by means of gills, and which at another period of their life respire air, and are frequently on land; to animals such as seals, which, although breathing by means of lungs, are yet capable of remaining under water for some time; to various terrestrial animals, such as the hippopotamus, which frequent an aquatic medium. In the system of Linnæus the amphibia comprehended the whole of the animals now known as reptiles; such as serpents, frogs, tortoises, and lizards, and even the cartilaginous fishes; but according to later naturalists, the term amphibia has been restricted to that order of reptiles called Batrachians; for this reason, that these animals breathe by means of gills in their earliest or tadpole condition, and afterwards acquire lungs, and respire air on assuming their perfect form as reptiles. (*See* BATRACHIANS, FROG, SALAMANDER, SIREN, PROTEUS.)

AMPHIBRYA, *am-fi-bri'-a* (Gr., *amphi*, around, *bryo*, I grow), the name given by Endlicher to a section of the vegetable kingdom, corresponding with the *Monocotyledones*, or the divisions *Rhizogens*, *Endogens*, and *Dictyogens*.

AMPHIOXUS, *am'-fi-ox'-us*, a remarkable species of fish. (*See* LANCELET.)

AMPHISARCA, *am'-fi-sar'-ka*, a many-celled fruit like that of the Baobab.

AMPHISBŒNA, *am'-fis-be'-na* (Gr., *amphi*, and *baino*, to go), a genus of animals belonging to the order of lizards, found only in South America and the West Indies, but having the general appearance of snakes or worms. They are about 20 inches long, burrow in the soft earth, and appear to move with equal facility in either direction. Their food consists of ants and other small animals.

AMPLEXICAUL, *am'-plex'-i-kawl* (Lat., *amplecti*, to embrace, *caulis*, a stem), a term applied to a leaf which is enlarged at its base, so as to clasp the stem from which it springs, as in fool's parsley.

AMPLITUDE, in Astronomy, is the distance of a heavenly body, at the time of its rising or setting, from the east or the west point of the horizon.

AMYGDALEÆ, OR DRUPACEÆ, *am'-ig-da'i-le-e* (Lat., *amygdala*, an almond), a sub-order of the natural order *Rosaceæ*. It includes most of our stone-fruit trees, as the almond, the plum, and the cherry. The seeds, flowers, leaves, and young shoots of many of the *Amygdaleæ*, when moistened with water, yield hydrocyanic, or, as it is commonly termed, prussic acid. Their barks have generally astringent and febrifugal properties, and yield a kind of gum.

AMYGDALIN, *am-ig'-da-lin*, a white crystalline solid, found in bitter almonds, peach-kernels, and laurel-leaves. By the action of the alkalies amygdalic acid may be formed. Sweet almonds contain no amygdalin.

AMYGDALOID, *a-mig'-da-loid*, a rock consisting of a basis of some kind of trap rock, commonly of greenstone, forming numerous small almond-shaped cells, filled with nodules of calcareous spar or zeolotic minerals. These nodules are evidently the result of imperfect crystallization.

AMYRIDACEÆ, *am-i-ri-dai'-se-e*, the Myrrh and Frankincense order, consisting of trees and shrubs remarkable for the abundance of their fragrant balsamic or resinous juice. There are about 50 species known, all natives of tropical regions. The most important are described under the heads of the genera to which they belong.

AMYRIS, *am'-i-ris*, a genus of tropical plants belonging to the natural order *Amyridaceæ*. Many species yield fragrant resins, and *A. balsamifera* is said to furnish, besides, a kind of rosewood.

ANABASIDÆ, *an-a-bas'-i-de*, or Labrinthibranchidæ, a family of fresh-water fishes, natives of the south-east of Asia, and of South Africa. They are characterized by a remarkable structure of the upper membrane of the pharynx, which contain cellular reservoirs, by means of which sufficient water is retained to keep the gills moist for a considerable time, and so enable the fish to subsist out of water and travel some distance on dry ground. The climbing perch of India (*Anabass-candens*) is a well-known member of this family.

ANABLEPS, *an'-ab-leps* (Gr., to look up), a genus of fishes of the order *Malacopterygii Abdominales*, characterized by a very peculiar structure of the eyes, each eye having two pupils. The best known species inhabit the rivers of Guiana and Surinam.

ANACARDIACEÆ, *an-a-kar'-di-ai'-se-e*, the Cashew-nut, or Sumach order of plants. There are 49 genera and about 100 species, nearly all of which are natives of tropical regions. They yield, by exudition, resins and gums, or acrid and occasionally poisonous juices. The fruits and seeds of some species are edible.

ANACARDIUM. (*See* CASHEW-NUT.)

ANACONDA, *an-a-kon'-da*, an enormous snake, sometimes measuring 30 feet in length, frequenting the swampy districts of South America, and feeding on water animals. It is not venomous, but its great size makes it an object of terror. The colour of the body is rich brown, with bright orange rings on each side, and two rows of large black spots along the back. An oil, prized by the natives, is obtained from the carcase.

ANACYCLUS, *an-a-si'-klus* (Gr., *ana*, in the form of, and *kyklos*, a circle), a genus of plants belonging to the natural order *Compositæ*. The root of *A. pyrethrum*, pellitory of Spain, is employed in medicine as an energetic local irritant and sialogogue, its properties depending on the presence of a volatile oil.

ANÆMIA, *a-ne'-mi-a* (Gr., *a*, not, and *aima*, blood), a term used to denote a deficiency of the red globules or colouring matter of the blood. It is characterized by a pale waxy complexion, and a pallor in those parts, as the lips, which are generally suffused. It is to be treated with pure air, nourishing diet, and tonics, such as iron.

ANAGYRIS, *an-aj-i-ris* (Gr.), a genus of leguminous plants. The seeds of *A. fœtida* are very poisonous.

ANAL GLANDS, glands differing in character, found in many animals, and generally characterized by the disagreeable odour of their secretia, they are of frequent occurrence among carnivora and rodents. The secretion peculiar to polecats, skunks, and badgers, which they use as an instrument of defence, shielding themselves from their adversaries by an overpowering and intolerable odour, comes from a pouch situated beneath the tail, and the civet cat has four glands of this character. Anal sacs are possessed by the crocodile and some serpents.

ANALCIME, *a-nal'-seem*, a silicate of soda and alumina, remarkable for peculiar optical properties possessed by it. (*See* POLARIZATION OF LIGHT).

ANALOGUE, *an'-a-log*. In comparative anatomy, glans are analogous to each other, or analogue, when they perform similar functions, although different in structure, as the wings of a bird and the wings of an insect. (*See* HOMOLOGUE.)

ANALYSIS, *a-nal'-i-sis* (Gr., *analyo*, I loosen or untie), is a method of reasoning by which we resolve or separate a whole into its constituent parts, and is opposed to SYNTHESIS, in which the parts are collected into a whole.

In Mathematics, the method of analysis practised by the ancient writers consisted in its application to the solution of geometrical questions. Modern mathematicians, in applying the analytical process, treat all quantities as unknown numbers, and represent them for this purpose by symbols, the relations subsisting between them being thus stated and subjected to further investigation.

ANAMIRTA, *an-a-mir'-ta*, a genus of plants, belonging to the natural order *Menispermaceæ*. The species *Anamirta paniculata*, or *cocculus*, is a beautiful climbing plant, which is a native of the Malabar coast and the Indian archipelago. Its fruit is poisonous. (*See* COCCULUS INDICUS.)

ANANASSA, *an-a-nas'-sa*, a genus of plants belonging to the natural order *Bromeliaceæ*. The species *A. sativa* furnishes the delicious fruit known as the pine-apple. (*See* PINE-APPLE.)

ANAS, *a'-nas*, a genus of birds included in the order *Palmipedes*, web-footed birds. (*See* DUCK, EIDER, GOOSE, SWAN, &c.)

ANASTATICA, *an-a-stat'-i-ka* (Gr., *anistemi*, I rise again), a genus of cruciferous plants. The principal species is *A. hierochuntina*, the rose of Jericho, which is found in the deserts of Egypt and Syria. This plant is remarkable for its hygrometric properties; thus, when full grown, and its branches have become dry and withered, it contracts so as to assume the form of a ball, in which state it is blown hither and thither by the winds; but, if it then meets with any moisture, it uncoils and for a time seems to regain life.

ANASTOMOSIS, *an'-as-to-mo'-sis* (Gr., *ana*, through, and *stoma*, a mouth), a term used in Anatomy to denote the communication of the blood-vessels with each other. The necessity of a constant supply of blood to every part of the human body has led to a wise provision, by which, though even one of the larger arteries become obstructed, there are numerous smaller ones communicating with the same part, which, by the increased pressure upon them, become enlarged, and supply its place.

ANATOMY, *a-nat'-o-me*, is a term derived from the Greek verb *anatemno*, I cut up, and literally signifies the separation of a thing into parts by cutting. In the more usual acceptation of the word it denotes the science which determines the construction, the form, and the structure of organized bodies. All material substances either are or have been, or are not and have not been, possessed or endowed with life. The former have an organized structure, in which, in the living state, changes take place, and processes are carried on necessary to their existence. The latter are composed of homogeneous particles, and are subject only to mechanical or chemical changes. In the former are comprehended all plants and animals, in the latter all mineral or inorganic substances. It is to the former of these two great divisions that the term anatomy is applied. It is the art of dissecting organized bodies for the purpose of ascertaining their internal structure; it is also the science which deals with the knowledge thus acquired, and deduces general principles from it. As organized bodies naturally form themselves into two distinct classes—plants and animals; so we have *vegetable anatomy*, or the anatomy of plants, and *animal anatomy*, or the anatomy of animals. Animal anatony, again, is subdivided into *comparative anatomy*, which treats of the structure of all animals except man, and *special anatomy*, which deals with the structure of one animal only. Human anatomy treats of the several parts and organs of the human body, in respect to their form, structure, and relation to each other. It is usually divided into *general*, *descriptive* or *physiological*, and *pathological*. General anatomy treats of the nature and general properties of the separate substances of which the body is composed, not as these exist combined in special organs, but as they form distinct and peculiar substances. Descriptive anatomy comprehends a description of the several parts and organs of the body, with an account of their situation, connections, and relations, as existing in the natural and healthy state. Pathological, or morbid anatomy, traces and describes the changes produced by disease upon healthy structures, whether existing in individual organs, or in the primitive or common substances of which these organs are composed. As an account of the various parts and organs of the human body, as well as of the diseases to which they are subject, will be found under their several names, in other parts of this work, it is unnecessary to do more here than give a short summary of the subject, referring to these articles for more special information.

General Anatomy.—The human body consists of solid and fluid substances, the fluid bearing to the solid parts a general ratio of from 7 to 1 to 9 to 1. The fluids of the body are various, but may be divided into three classes:—the circulating nutritious fluid called the blood; the fluids which are incessantly poured into it for its renewal, viz., the chyle and lymph; and the fluids which are separated from it by secretion, as saliva, bile, gastric juice, &c. The blood is that well-known red fluid which, by means of the heart, arteries, and veins, circulates through all parts of the system, and supplies the waste that is constantly going on. The chyle is a milky fluid, separated from the chyme or digested food after it has passed from the stomach into the small intestines, and become mixed with the bile and pancreatic juice. It is absorbed by the lacteals, and conveyed by ducts or canals to the *receptaculum chyli*, where it is taken up by the thoracic duct, and poured into the blood. The lymph is a colourless fluid, like water, taken up by the lymphatic vessels, which pervade almost every part of the body. It seems to differ little from chyle, except that the latter contains a greater preponderance of fatty matter.

The greater portion of the lymph is poured into the receptaculum chyli, where it becomes mixed with the chyle, and is carried with it into the blood; that, however, collected from the right side of the head and chest, and right upper limb, is conducted into the right subclavian vein, by the right lymphatic or right thoracic duct. The secretions are those fluids secreted or separated from the blood. The term is sometimes used to include the excretions which are thrown off from the body as useless or noxious, as urine from the bladder, or perspiration from the skin; but it is properly applied only to such products as are secreted from the blood, but still retained in the system for the performance of certain subordinate actions. These are—1, saliva, secreted by the salival glands of the mouth; 2, gastric juice, by the stomach; 3, pancreatic juice, by the pancreas; 4, bile, by the liver; 5, tears, by the lachrymal gland: 6, milk, by the mammary glands; 7, semen, by the testes; 8, oil, by the vessels of the adipose tissue; 9, synovia, by the synovial glands of the joints; and 10, mucus, by the mucous glands.

The organized solids of the human body are usually divided into the following seventeen elementary tissues:—1. Bone, or osseous tissue, which forms the framework of the body, to which the other structures are attached, or in which they are contained. 2. Muscular tissue, consisting of fine fibres, which are for the most part collected into distinct organs called muscles, by means of which the active movements of the body are performed. 3. Adipose tissue, which constitutes the fat of the body as well as the marrow of the bones. 4. Areolar, cellular, or connective tissue, a soft filamentous substance of considerable tenacity and elasticity, which is extensively distributed over the body, and forms the connecting medium of all the other tissues. 5. Fibrous tissue, formed of a number of minute fibres running chiefly parallel to each other, and sparingly supplied with blood-vessels or nerves, and used for connecting, enveloping, or binding together, various parts of the human body, as tendons, ligaments, fasciæ, periosteum, perichondrium, dura mater. 6. Elastic, or yellow tissue, characterized by possessing a high degree of elasticity, and employed wherever that quality is required, as in forming the spinal ligamenta-subflava. 7. Cartilage, an opaque substance, usually of a pearly or bluish-white colour but sometimes yellow, covering the articular extremities of the bones, connecting the surfaces or margins of immovable bones, or lining the walls of certain cavities, also found in the ear, nose, larynx, &c. Fibro-cartilage is, as its name indicates, a structure intermediate between fibrous tissue and cartilage, partaking, in some measure, of the firmness of the one with the elasticity of the other. 8. Nervous tissue, which goes to form the nervous system. 9. Blood-vessels, comprising the arteries by which the blood is conducted from the heart to all parts of the body: the veins, by which it is brought back again to the heart: and the capillaries, minute vessels by which it is carried from the extremities of the one to those of the other. 10. Absorbent vessels and glands, comprising the lacteals and lymphatics, together with the glands in connection with them. 11. Serous and synovial membranes, which resemble each other in general form and structure, but are distinguished by the nature of their secretions; the former lining the cavities of the body which have no outlet, as the peritoneum in the abdomen, the pleuræ and pericardium in the chest, and secreting a transparent and nearly colourless fluid, which moistens the surface; the latter lining the cavities of the joints, and secreting a viscid fluid which lubricates their surface. 12. Mucous membrane, which lines those internal passages of the body exposed directly or indirectly to contact with the atmosphere, and secretes a fluid of a more consistent and tenacious character than the serous membranes. 13. Secreting glands, a class of organs widely differing from each other in their nature and form, but all devoted to the function of secretion. 14. Vascular or ductless glands, so called from their general resemblance to secreting glands, but differing from them in having no duct for the conveyance of their secretions, which are reabsorbed or filtered through the tissues, or find an outlet by bursting. 15. Skin—cutis vera, derma, or corium, the innermost of the three structures that go to make up what is commonly termed the skin, and which covers the whole body. 16. Pigment, a black or dark-coloured substance occurring in various parts of the body, and giving colour to the skin of the negro and other dark races. 17. Epithelium, a thin transparent structure covering the whole surface of the body, as well as the walls of the different cavities, and named differently, according to the parts which it covers; as, epidermis, covering the skin; the epithelium of mucous membranes, &c.

Descriptive or Special Anatomy is commonly divided into several branches, according as it regards the bones (*Osteology*); the articulations; the muscles (*Myology*); the blood-vessels and absorbents (*Angiology*); the nervous system (*Neurology*); the organs of sensation, respiration, digestion, &c. (*Splanchnology*).

Osteology.—The number of bones in the human body is variable; but in the adult they are estimated at about 244. They are usually divided into long, flat, and irregular—long, as in the thigh and leg; flat, as in the skull and pelvis; irregular, as in the hands and feet. Bones are covered with a peculiar membrane called the periosteum, which serves to conduct the blood-vessels and nerves. The osseous skeleton is divided into head, trunk, upper and lower extremities. The head comprises the bones of the cranium and those of the face, including three common to both. The bones of the cranium are eight in number—the frontal, in the fore part of the skull; the two parietal, forming a portion of its sides and all its superior part; the occipital, forming its lower and back part; the two temporal, forming the lower part of the sides and part of the base; the sphenoid, in the middle of the base; and the ethmoid, in the middle of the fore part of the base. The bones of the face are fourteen in number—the ossa nasi, which form the arch of the nose; the ossa lacrymalia, at the fore part of the inner edge of the ocular orbits; the malar bones, forming the prominences of the cheeks; the upper maxillary bones, forming the upper jaw, and containing the upper teeth; the ossa palati, situated at the posterior part of the palate, the nose, and the orbits; the vomer, a flat bone forming part of the septum of the nose; the ossa turbinata inferiora; and the lower maxillary bones, forming the lower jaw, and containing the under teeth. There are thirty-two teeth—sixteen in each jaw, viz., four incisors or front teeth, two cuspidati or canine, four bicuspidati, and six molares. The last molar on each side is called the *dens sapientiæ*, or wisdom-tooth, from not appearing till about the age of twenty-one. The os hyoides, or hyoid bone, is placed in the anterior and upper part of the neck, and has no osseous connection with any other bone. The trunk is divided into the spine, thorax, and pelvis. The spine is a pyramidal column, extending from the head to the pelvis, and is composed of twenty-four bones, termed vertebræ. Each vertebra consists of a body of seven processes, and has a foramen, or ring, through which the spinal cord passes. They are divided into three classes—the cervical, including the first seven; the dorsal, consisting of twelve, which are larger than the cerebral, and are distinguished by having their sides and transverse processes depressed for connection with the ribs; and the lumbar, consisting of five, which are larger than any other. The first two cervical vertebræ differ from the others, and are known as the atlas and the axis, or vertebra dentata. There are likewise five so-called false vertebræ, on account of their being separate in early life, but afterwards uniting to form the os sacrum, which constitutes the posterior part of the pelvis. The thorax, which contains the principal organs of circulation and respiration, is the largest of the three great cavities connected with the spine, and is formed by the sternum and costal cartilages in front, the twelve ribs on each side, and the dorsal vertebræ behind. The sternum is a flat narrow bone, situated in the anterior part of the thorax, and connected with the ribs by means of the costal cartilages. The ribs are twenty-four in number, twelve on each side, of which the first seven are termed vertebro-sternal, or true ribs, and are attached to the sternum; three are attached to the costal cartilages, and are called vertebro-costal; and two are termed vertebral or floating ribs, from their anterior extremities being free. The pelvis, or lower cavity of the trunk, consists of four bones—the os sacrum and os coccygis behind, and the two ossa innominata on either side. The os coccygis, which forms the terminal bone of the spine, is sometimes regarded, like the os sacrum, as composed of four false vertebræ, which are at first distinct, but afterwards become united. The ossa innominata are two irregularly-shaped bones, situated one on each side of the pelvis, and consisting of three parts, the ilium, ischium, and pubis, firmly united in the adult, but distinct in the young subject. Each of the two upper extremities is composed of the bones of the arm, the forearm, and the hand, and is united to the trunk by means of the scapula and clavicle, which form the shoulder. The scapula is a flat triangularly-shaped bone, placed upon the upper and back part of the thorax, The clavicle, or collar-bone, is a long bone, something in the form of the italic letter *f*, and situate between the top of the sternum and the acromion process of the scapula. The arm has only one bone, the os humeri, which extends from the scapula to the bones of the forearm. The forearm consists of two bones, the radius and ulna, which are parallel, and play upon each other; thus admitting of freer motion in that part. The radius, so called from its resemblance to the spoke of a wheel, is situate on the outer side of the forearm. Its upper end is small, and forms only a small part of the elbow-joint, while its lower extremity is large, and forms the chief part of the wrist-joint. The ulna is placed at the inner-side of the forearm, and differs from the radius in being larger at the upper than at the lower extremity. The bones of the hand are divided into the carpus, the metacarpus, and phalanges. The bones of the carpus, or wrist, are eight small bones, arranged in two rows, the upper row comprising the scaphoid, semi-lunar, cuneiform, and pisiform—the lower, the trapezium, trapezoid, os magnum, and unciform. The metacarpal bones, or bones of the palm, are five in number, and correspond to the fingers. The phalanges, or bones of the fingers, are fourteen in number, each finger, with the exception of the thumb (which has only two), having three of them. The upper and lower extremities bear a great resemblance to each other in the nature and form of their bones. Like the upper, each of the lower extremities consists of three distinct parts—the thigh, leg, and foot. The thigh is composed of a single bone, the os femur, which is the longest and largest in the body. The upper part forms a round head, which is inserted into a deep cup-like cavity of the os innominatum, called the acetabulum: the lower terminates in two protuberances, known as the inner and outer condyles, separated posteriorly by a deep fossa, called the inter-condyloid. The leg consists of three bones—the patella, tibia, and fibula. The patella, or knee-pan, is a small, flat, triangular bone, of a spongy texture, situated at the anterior part of the knee-joint, between the femur and the tibia. The tibia and fibula in the leg resemble the radius and ulna in the forearm; the tibia is, after the femur, the largest bone of the body; it is situated at the anterior and inner side of the leg, articulating with the femur above and the astragalus below. The fibula is considerably smaller than the tibia. Its upper extremity is small, and placed below the level of the knee-joint, but the lower extremity projects below the tibia, and forms the outer ankle. The foot, like the hand, is composed of three classes of bones—the tarsus, the metatarsus, and the phalanges. The tarsus is composed of seven bones—the os calcis, astralagus, cuboid, scaphoid, and three cuneiform. The metatarsal bones are long small bones, five in number, connected at the one extremity with the tarsal, at the other with the phalangeal bones: these last go to form the toes, each of which has three, except the great toe, which has only two.

Articulations.—The different bones of the skeleton are connected together in various ways, and such connections are termed articulations. They are of various kinds, but are usually divided into immovable, movable, and mixed. Immovable articulations exist where flat and broad bones are united to inclose important organs, as in the cranium and pelvis. In some parts the edges indent or interlock each other; in others they are brought into close contact, or are united together by a thin layer of cartilage. The movable articulations are of various kinds, according to the kind of motion required. In such cases, the bony surfaces brought into contact are covered with cartilage, bound together by ligaments, and lined by synovial membrane. Mixed articulation prevails where only a slight degree of motion is required, combined with great strength, as in the vertebræ.

Myology.—The following are the principal muscles of the human body: The *occipito-frontalis* is spread over the whole of one side of the vertex of the skull, from the occiput to the eyebrow. It is composed of a broad musculo-fibrous layer, and consists of two slips of muscle. Its action is to raise the eyebrows and the skin over the root of the nose. The *levitor labii superioris* acts as the elevator of the upper lip. The *orbicularis oris* is a muscle of elliptic form, composed of concentric fibres, and situated round the opening of the mouth. In action it is antagonistic to all those muscles which converge to the lips from the various portions of the face. The *deltoid* has been so named from its resemblance to the Greek letter Δ reversed. It is a triangular thick muscle, which surrounds the shoulder-joint. Its action is to raise the arm from the side, bringing it at right angles with the body. The *pectoralis major* is a thick triangular muscle springing from the anterior surface of the clavical. In its action it will singly draw the arm across the front of the chest, and, when assisted by the *teres major* and the *latissimus dorsi*, will depress the arm, previously raised by the *deltoid*, to the side of the chest. The *linea alba* is a cord extending along the middle line of the abdomen. It runs between the inner borders of the *recti* muscles, and has many appertures for the passage of nerves and vessels. In common with the other abdominal muscles, the *linea alba* acts as a compressor of the viscera in the cavity of the abdomen. The *pyramidalis* acts like the other abdominal muscles. The longest muscle in the human body is the *sartorius*, or tailor's muscle, a flat and narrow band arising from the anterior superior spinous process of the ilium, passing obliquely across the upper part of the front of the thigh, and ending in a tendon, which afterwards expands into a wide aponeurosis inserted in the shaft of the tibia near the crest. "The relations of this muscle to the femoral artery should be carefully examined, as its inner border forms the chief guide in tying the artery. In the upper third of the thigh it forms, with the abductor longus, the side of a triangular space—Scarpa's triangle—the base of which turned upwards is formed by Poupard's ligament; the femoral artery passes perpendicularly through the centre of this space, from its base to its apex. In the middle third of the thigh the femoral artery lies first along the inner border, and then beneath the *sartorius*."—(Gray's *Anatomy, Descriptive and Surgical*.) The *rectus femoris* is a muscle of fusiform shape, arising by two round tendons from the inferior spinous process of the ilium, as well as from the upper lip of the acetabulum, and is inserted in the upper border of the knee-cap. It's action is to assist the *iliacus* and *psoas* muscles in supporting the trunk and pelvis upon the thigh-bone. The *anterior annular ligament* of the ankle serves to bind down the extensor tendons which descend upon the posterior portion of the fibula and tibia. The *latissimus dorsi* is a broad muscle which covers the lumbar and lower half of the dorsal regions. It arises from the lumbral, sacral, and inferior gorsal vertebræ, and is inserted into the humerus. The *gluteus maximus*, the outermost muscle of this region of the body, is a broad fleshy mass of quadrilateral form, which contributes greatly to the characteristic power of the human being to support the body in a constantly erect posture. The *biceps* of the thigh is a very long muscle, the action of which is to rotate the leg slightly outwards when the knee is semi-fixed. The *gastrocnemius* muscle is the most superficial of the posterior tibio-fibular region. It arises from the upper portion of the two condyles of the femur, and by means of the *tendon Achillis* is inserted into the lower portion of the tuberosity of the *os calcis*.

Angiology.—The aorto is the large vessel which arises from the left ventricle of the heart, and thence conveys the artenal blood by numerous branches to the various parts of the body. It is an elastic tube about three inches in circumference at first, but afterwards becomes considerably narrower. In the first part of its course, it is nearly vertical; it then forms an arch, and, curving from right to left, and from before backwards, it descends through the diaphragm out the abdominal cavity. The aorta gives off numerous branches, which may be divided into two sets—those which supply the viscera, and those which are distributed to the walls of the abdomen; the former comprising the cœliac artery (which shortly divides into the gastric, epatic and splenic arteries), the superior mesenteric, the inferior mesenteric, the capsular, the renal and the spermatic arteries; the latter, the phrenic, lumbar, and middle sacral arteries. The veins which return the blood from the capillaries to the heart are of two kinds—the pulmonary, conveying arterial blood from the lungs to the left auricle of the heart, and the systemic, carrying venous blood from all parts of the system back to the right auricle of the heart. The pulmonary veins are four in number, two for each lung, and differ from other veins in being destitute of valves. The systemic veins are usually arranged into three groups, according to their mode of termination in the heart:—1, Those of the head, neck, thorax, and upper extremities, which terminate in the superior vena cava; 2, those of the abdomen, pelvis, and lower extremities which terminate in the inferior vena cava; and 3, the cardiac veins, returning the blood from the substance of the heart, and opening directly into the right auricle. The veins, in their general form and distribution, correspond to the arteries. The vena cava superior is a short trunk formed by the junction of the two venæ innominatæ, and terminating in the upper parts of the right auricle. The vena cava inferior is formed by the junction of the two common iliac veins between the fourth and fifth lumbar, vertebræ and terminates in the lower and back part of the right auricle. The capillaries (from *cappilus*, a hair) are minute vessels pervading every part of the body, and uniting the extreme points of the arteries with those of the veins. Their diameter varies in different parts, but is usually about $\frac{1}{3000}$th part of an inch. (*See* CIRCULATION OF THE BLOOD, LACTEALS and LYMPHATICS.)

Neurology.—The Nervous System consists of two parts, known as the cerebro-spinal and the sympathetic or ganglionic systems. The former includes the brain and spinal cord, with the nerves proceeding from them, and is regarded as the nervous system of animal life; the latter consists of a double chain of ganglia, running along the spinal column, whose functions seem to be less directly connected with the mind, and chiefly bearing upon the animal life. The cerebro-spinal system is divided into the encephalon, or portion contained within the cranium, and the spinal cord, inclosed within the vertebral canal. The encephalon comprises the cerebrum, the cerebellum, the pons Varolii, and the medulla oblongata, and is covered with three membranes, called the dura mater (or outermost), the arachnoid membrane, and the pia mater. The substance of the encephalon is of two kinds—a cineritious or greyish substance, called also corticle, from forming the outer part of the cerebrum and cerebellum; and a white or medullary matter, forming the inner substance of the cerebrum and cerebellum, but the outer of the medulla oblongata and pons Varolii. The cerebrum, or brain proper, forms by far the largest portion of the encephalic mass. Its upper surface is divided into a right and left hemisphere, by a longitudinal fissure lodging the falx cerebri. The under surface of each hemisphere is marked off into three lobes, called the anterior, middle, and posterior. The entire surface of each hemisphere presents a number of convoluted eminences, separated from each other by depressions of various depths. The cerebellum, or little brain, is situate beneath the hinder part of the cerebrum, from which it is separated by the tentorium cerebelli. It is likewise divided into two lateral hemispheres; but its surface is not convoluted, but laminated. It is connected with the rest of the encephalic masses by means of connecting-bands, called crura or peduncles, two of which ascend to the cerebrum, two descend to the medulla oblongata, and two unite in front to form the pons Varolii. This last occupies a central position on the under surface of the encephalon, and constitutes the bond of union between the other parts, being connected above by crura from the cerebrum, at each side by crura from the cerebellum, and being in contact below with the medulla oblongata. This last extends from the lower border of the pons Varolii to the upper part of the spinal cord. It is pyramidal in form, with its broad extremity directed upwards, and measures about an inch and a quarter in length. By means of two fissures, it is divided into two lateral and symmetrical halves. The spinal cord is situate within the vertebral canal, and extends from the foramen magnum of the occipital bone to the first or second lumbar vertebræ, where it terminates in the cauda equina, an aggregation of nervous cords occupying the remainder of the canal. The spinal cord, like the encephalon, is inclosed by the three membranes—the dura mater, arachnoid, and pia mater. It it composed of white and grey matter; the former external, the latter internal. The grey substance is found, on making a section, to be arranged in a crescental shape in each hemisphere of the cord, the posterior corners being much longer than the anterior. From the spinal cord spring thirty-one pairs of spinal nerves, corresponding to the number of true and false vertebræ, between which they issue, except that there are eight pairs of cervical nerves and one coccygeal. Each spinal nerve arises by two roots, —an anterior, or motor, and a posterior, or sensitive. These approach one another, and, with few exceptions, unite in the corresponding inter-vertebral foramen into a single cord, which almost immediately divides into two branches, one of which proceeds to the muscles, &c., of the back, the other to the anterior parts of the body. Besides the spinal nerves, there are nine pairs of nerves that issue from the encephalon to different parts of the head and face. They are connected with the organs of seeing, hearing, taste, smell, &c.; and are hence named optic, audatory, olfactory, &c. They are also distinguished numerically, as first, second, third, &c., according to the part of the brain from which they spring. The sympathetic, or ganglionic nervous system, is composed of a series of ganglia, or nervous centres, extending along the spinal column from the base of the skull to the coccyx, connected with each other by filaments, and also communicating in various parts with the cerebro-spinal system. They are regarded as the nerves of organic life, and principally supply the various viscera and blood vessels.

Splanchnology.—Regarding the anatomy of the various organs of SENSATION, RESPIRATION, DIGESTION, &c., we must refer to the accouuts given under their proper names, in other parts of this work.

History.—Some knowledge of the internal structure of the human body was doubtless obtained at a very early period. The ancient Egyptians are said to have acquired great anatomical skill from their practice of embalming, and Homer displays a considerable amount of knowledge of the human body in his description of wounds, in the "Iliad." Hippocrates, who flourished about 400 years B.C., is regarded as the first author who treated anatomy as a science. Erasistratus, and Herophilus of Alexandria, are considered as the first that dissected and described the human body, nearly 300 years B.C. Galen, however (B. 131 A.D.), is the author of antiquity that displays the most intimate knowledge of the human body; and even he evidently obtained a great part of his knowledge from dissections of apes and other animals, there being a law in Rome which forbade the use of dead bodies. During the dark ages, anatomy, like the other sciences, made little progress. The interest in anatomy began to revive about the 13th century, and, in the beginning of the 14th, Mundinus dissected and demonstrated the different parts of the human body, at the University of Bologna, and published a work which formed the text-book in Italy for nearly 200 years. During the next 200 years, the interest in anatomy continued to increase, and, within that period, there are several respectable names in connection with it; as Gabriel de Zerbio, Achillini, Berenger, and Massa. The errors of Galen, however, still prevailed till the time of Vesalius, who flourished about the middle of the 16th century, and boldly, by dissections of the human body, pointed out the errors into which he had fallen. He is regarded as the father of modern anatomy. His great work, *De Corporis Humani Fabrica*, was published before he was twenty-eight years of age. He gave a great impulse to human dissection; and, among his contemporaries, or immediate successors, were Fallopius, Eustachius, Varoli, and Fabricius. In the 17th century the progress of anatomy was rapid. In 1619 Harvey's great discovery of the circulation of the blood was announced. Asellius, in 1627, gave out his discovery of the lacteals; and in 1651 Rudbeck discovered the lymphatics. Among the other distinguished anatomists of this century were Bartholin, Pecquet, Jolyffe, Wharton, Swammerdam, Willis, Malpighi, and Ruysch. In the 18th century we have many eminent names. In Italy, which still retained a first place, were Valsalva, Santorini, and Morgagni; in France, Winslow, Vicq d'Azyr, and Bichat (the founder of General Anatomy); in Germany, Haller, Meckel, Zinn, and Soemmerring; in Holland, Boerhaave, Albinus, Camper, and Bonn; and in England, Cheselden, the two Hunters, Charles Bell, and the Monroes of Edinburgh. The present century has been specially characterised by the great advance made in minute or microscopic anatomy.

Comparative Anatomy.—The differences in the structure of various animals was first treated systematically as a distinct science by Cuvier. Other great names connected with this subject are Blumenbach, Tiedemann, Geoffrey, St. Helaire, Carus, Oken, Owen, Huxley, and Darwin.

Practical Anatomy includes dissection and the making of preparations by dividing parts or organs so that their respective forms and positions may be clearly shown. The bones are cleared of all adhesions, bleached, and connected by wires in natural order. Vessels are injected with a mixture of linseed oil and turpentine and certain metallic compounds in due proportion. Anatomical preparations are either dried and varnished or preserved in spirits.

ANCHOVY, *an-tcho've*, or *an'-cho-ve* (Fr., *anchois*), a genus of abdominal malacopterygious fishes of the herring family. With the exception of the common anchovy, they all inhabit the tropical seas of America and India. The common anchovy (*Engraulis Enchrasicholus*, so named from the bitter taste of its head), is found in the Atlantic, along the shores of France and Portugal. It is sometimes taken off the coasts of Holland and England; but is abundant in the Mediterranean, where, off the island of Gorgona, to the west of Leghorn, it is very plentiful. The months of May, June, and July are the periods when they quit the deep seas and visit the shores of the Mediterranean, which they enter in immense shoals by the Straits of Gibraltar. The Romans compounded from them a favourite sauce, which they termed *garum*. In Modern times, the anchovy is also regarded as an appetizing morsel in the form of pastes, &c. Colour, the bluish-brown on the back, and silvery white on the belly; the anal fin short, and the dorsal placed immediately above the ventral. The length of the anchovy is about three inches. The well-known Indian condiment, "red-fish," is made from a variety of the anchovy, *E. Brownii*, found at the mouth of the Ganges, and in the Straits of Malacca.

ANCHOVY PEAR. (*See* GRIAS.)

ANCHUSA, *an-choo'-sa*, a genus of plants belonging to the natural order *Boraginaceæ*. The calyx is divided into five segments; the corolla is funnel-shaped, the mouth of the tube being closed with five scales; the stamens are five in number; the stigma is obtuse; and the achænia, which are ovate, are surounded by a thick ring. The species are herbaceous plants growing in temperate climates, and are all characterized by short stiff hairs on the leaves and stems. Two are inhabitants of Great Britain; namely, *A. officinalis* (the common alkanet or bugloss) and *A. sempervivens*. The roots of the former, when boiled, yield a demulcent drink, which was once much used as a medicine. Both plants have spikes of blue flowers, very similar to those of the forget-me-not. The most important species is *A. tinctoria*, a native of the Levant and of the southern parts of Europe. It is cultivated for its root, which contains a resinous red colouring matter, and is much used in the arts. (*See* ALKANET ROOT.) *A. paniculata* and some other species are grown as ornamental garden plants.

ANCILLA, OR ANCILLARIA, *an-sil-lai'-ri-a*, a term given by Lamarck to a genus of mollusca. They are somewhat numerous, principally found in tropical climates. Some of them are furnished with a small tooth, which is placed at the end of a groove crossing the front of the shell. The most common species is the ivory-shell; this and some others are distinguished from the genus in general, by having the front of its axis deeply pierced. The shells are usually very smooth, as if polished.

ANCONEUS, *an-ko'-ne-us* (Gr., *agkon*, the elbow), a small triangular muscle, situated immediately beneath and behind the elbow-joint. It is connected with the humerus above, and the ulna below, and assists in extending the fore-arm.

ANCYLUS, *an-si'-lus* a mollusc, commonly known as the fresh-water limpet. It is common in stagnant water and rivulets in Europe, America, and the West Indies, adhering to stones and plants. It is closely allied to the pond-snail, differing principally in the conical form of the body and shell. A cavity in the middle of the back serves for the purposes of respiration, and an aperture closed by a valve opens in the middle of left side.

ANDA, *an'-da*, a genus of plants belonging to the natural order *Euphorbiaceæ*. The species *A brasiliensis* is a tree which grows in Brazil, having large yellow flowers, and producing fruit about the size of an orange, but of an angular form. Each fruit contains two roundish seeds, resembling small chestnuts. These seeds, called *Purga dos Paulistas*, yield a very purgative oil, used medicinally in Brazil, the ordinary dose being twenty drops. These seeds are also used for the same purpose as the oil. The bark, when thrown into ponds, is said to stupify fish; and this part of the tree, roasted, forms a favourite remedy for diarrhœa brought on by cold.

ANDIRA, *an-di'-ra*, a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Papilionaceæ*, characterized by a one-celled one-seeded pod, almost orbicular. The species *A. inermis* is a native of the West Indies, and is commonly known as the Cabbage-bark tree. It is a tall tree, bearing reddish-lilac flowers. The bark, called either cabbage-bark or worm-bark in commerce, was formerly much used medicinally, but has recently been discarded from the Pharmacopœia of Great Britain. It possesses cathartic, emetic, and narcotic properties; but in large doses it is poisonous. The species *A. retusa*, a native of Surinam, yields a bark with similar properties, which is commonly known as Surinam bark.

ANDRÆACEÆ, *an-dre-ai'-se-e*, Split mosses, a family of terminal-fruited mosses, characterized especially by the peculiar mode of splitting of the fruit, or, more correctly speaking, the *sporangium*. This urn-shaped capsule divides perpendicularly, when ripe, into four or eight valves, which remain attached together at their upper and lower points. The few British species which constitute the genus *Andræa* are natives of rocky and usually mountainous districts.

ANDRENIDÆ. (*See* BEES.)

ANDRŒCIUM, *an-dre'-shi-um* (Gr., *aner*, a male, *oikion*, habitation), a term applied to the stamens or male organs of a flowering plant, taken collectively.

ANDROGYNOUS, *an-droj'-i-nus*, a term signifying male-female, sometimes applied to that kind of inflorescence which exhibits distinct male (staminal) and female (pistillate) flowers. In zoology, the term applied to animals which possess a distinct male and female generative system in the same individual. (*See* HERMAPHRODITE and REPRODUCTION.)

ANDROMEDA, *an-drom'-e-da*, in Astronomy, a constellation named by the Greeks after the mythical daughter of Cepheus and Cassiopeia. This constellation is composed of fifty-nine stars. A line drawn through the brightest star of the five forming the constellation Cassiopeia and the Pole-star passes through a star of the first magnitude, named Alpherat, in the head of Andromeda. This constellation is represented in the celestial planisphere by the figure of a chained woman.

ANDROPHORE, *an'-dro-for* (Gr., *aner*, male, *phoros*, brought into), a name given to a tube or column formed by the union of the stamens by their filaments, as in the flower of the mallow.

ANDROPOGON, *an'-dro-po-gon*, (Gr., *aner*, man, *pogon*, beard), a genus of grasses, or natural order *Graminaceæ*. A tufted root thought to resemble a man's beard is one of the characters of the genus; hence its botanical name. Many species are remarkable for their fragrance, which is due to the presence of volatile oils, some of which are used in perfumery and medicine. *A. Iwarancusa* is supposed by some to have furnished the precious spikenard oil of Scripture; and *A. calamus aromaticus* has been pointed to as being probably the plant termed the sweet calamus and sweet cane. The oil is known in India as *roshé* or *rosé* oil, and, in England, as Turkish essence, or oil of geranium, and oil of ginger-grass, is reputed to be the produce of the latter species; but, in all probability, it is derived from several Indian andropogons. This oil is employed by the Turks to adulterate otto of roses, and is considered by some to be identical with the grass-oil of Nemaur. The species *A. citratum*, Indian lemon-grass, is much employed in perfumery, under the name of oil of verbena, from its odour resembling that of the sweet verbena, or lemon-plant. The leaves of the Indian lemon-grass have been used as a substitute for tea, and the centre of the stem is employed for flavouring curries. *A. muricatus*, vittievayr or cuscus, also yields a fragrant oil, which is much used medicinally in India, and there known as kuskus oil. Its root, which is imported into this country for scenting baskets and other articles, has been employed medicinally as a gentle stimulant and antispasmodic.

ANDROSÆMUM, *an-dro-se'-mum*, a genus of plants belonging to the natural order *Hypericaceæ*. The species *A. officinale* has tonic and astringent properties, which render it useful in medicine.

ANDROUS, *an'-drous*, a term signifying a stamen, which is affixed to the Greek numerals, in order to form names used in describing flowers, when it it desirable to indicate the actual number of stamens they contain. Thus, the presence of only one stamen makes a *monandrous* flower, as in the Hippuris; if two male organs are present, the flower is *diandrous*; *triandrous*, means three stamens; *tetrandrous*, four; *pentandrous*, five; *hexandrous*, six; *heptandrous*, seven; *octandrous*, eight; *enneandrous*, nine; *decandrous*, ten; *dodecandrous*, twelve; *icosandrous*, twenty; *polyandrous*, numerous stamens. In the old Linnæan system of classification, many of the classes were determined by the number of stamens in the flower, and these terms were in constant use. The natural system has, however, quite superseded that arrangement; but the terms have been retained in descriptive botany, on account of their expressiveness.

ANELECTRIC, *an-e-lek'-trik*, a term sometimes applied to a body in which, under ordinary circumstances, electricity cannot be excited by friction. It is synonymous with the more familiar word *non-electric*. Anelectrics have the power of transmitting or conducting electricity. The best conductors, or the most perfect anelectrics, are metallic bodies, charcoal, and saline fluids. (*See* ELECTRICITY.)

ANEMIDICTYON, *an-e-mi-dik'-ti-on* (Gr., *aneimon*, naked; *diktyon*, a net), an ornamental species of ferns, succeeding well in open loamy soil.

ANEMIOPSIS, *an-em-i-op'-sis* (Gr., *aneimon*, naked; *opsis*, appearance), so named in allusion to the appearance of the inflorescence. A genus of plants growing in marshes and pools of water in North India, North America, and China.

ANIMALCULES, *an-i-mal'-ku-lees* (Lat., *animalculum*, a little animal). This is a general term for animals so exceedingly minute that they cannot be studied without the aid of the microscope; such as the species of *Infusoria* and *Rotatoria*. (*See* INFUSORIA, PROTOZOA, ROTATORIA.)

ANIONS, *an'-i-ons* (Gr., *ana*, upward, *ion*, going), a term introduced by Faraday to distinguish the elements which go to the *anode*, or positive pole, in decomposing chemical compounds by the electric current. (*See* ELECTROLYSIS, CATHIONS.)

ANISE, *an'-eez* (Gr., *anison*, Lat., *anisum*), an umbelliferous plant, cultivated in Asia Minor, Egypt, Malta, Spain, and Germany, for the sake of its fruit, called aniseed, which is extensively used for flavouring liqueurs and confections, and medicinally as a carminative. The botanical name of the plant is *Pimpinella Anisum*. Star or Chinese aniseed is the fruit of the *Illicium anisatum*, a small tree in the natural order *Magnoliaceæ*. It has a starlike form—hence its name, and a flavour similar to that of the common aniseed. This is imported into Europe from China and Singapore. Oil of aniseed is obtained by distilling the fruit, and even the stems and leaves, of the common anise. For this, a similar product, yielded by the star aniseed, is frequently substituted. The true oil and its substitute have the aromatic properties of the fruits, and are employed for the same purposes. The anise of the New Testament is the Dill, the name of which is derived from an old Norse word, meaning to soothe.

ANISOMERUS, *an-i-som'-e-rus* (Gr. *ansios*, unequal, *meros*, a part), a term applied to a symmetrical flower, in which the number of parts in every whorl of organs is not the same, as in the flower of the *sedum*, which has five sepals, petals, and carpels, but ten stamens. (*See* ISOMEROUS, FLOWER.)

ANISOSTEMONOUS, *an'-i-sos-tem'-o-nus* (Gr., *anisos*, unequal, *stemon*, a stamen), a term applied to a flower in which the stamens are not equal in number to the sepals or petals. (*See* ISOSTEMONOUS.)

ANNELIDA, *an-nel'-i-da* (Lat., *annulus*, a ring), a class of animals of the sub-kingdom, *Annulosa*, the worm species, first proposed for distinct classification by Cuvier, who attached such importance to the fact of their possessing red blood that he placed them at the head of the articulate series, above the crustaceas, the arachnidas, and the insects. It is, however, generally agreed that the annelida represent but the larval condition of insects, and can hardly be regarded as higher in organization than the perfect insect. The name of the class is derived from *annulus*, a ring; because the animals arranged under this division always have their bodies formed of a great number of small rings, as in the earth-worm. (*See* EARTH-WORM.) For the most part, the annelida are oviparous. In their mode of life there is little variety; some live in fresh, others in salt water; some, like the hair-worm (*Gordius*), are amphibious. The body is divided into numerous segments, marked by transverse lines, and generally furnished with a series of bristly appendages, which serve as legs, are usually sharp, and sometimes barbed, serving not only to attach the animals to soft substances, and to hold firmly on to rocks and other solid bodies, but to aid their movements through the water. They are all hermaphrodite, but most require mutual fecundation. They feed in general upon other animals, and some (as the leech) live by sucking blood. Some of them bore and burrow in sand, mud, and earth, and even perforate rocks, shells, and stones; and their influence in disintegrating coral, limestone, and chalk is considerable.

ANNUAL, *an'-nu-al* (Lat., *annus*, a year), a plant which passes through all its successive stages of development in a single year. Such a plant produces flowers and fruit only once, and perishes when its fruit has become ripe. A plant which springs from the seed one year, but which does not flower until the next year, is called a *biennial;* and a plant which lives for several years a *perennial*. The duration of the life of a plant is greatly affected by accidental circumstances; and an annual is frequently converted into a biennial, and occasionally into a perennial. Some plants which are annual in one climate are perennial in another. The annuals cultivated in our gardens are very numerous, and many of them produce lovely flowers.

ANNULAR CELLS AND VESSELS, *an'-nu-lar* (Lat., *annulus*, a ring). The various parts of a plant are made up of little membranous sacs and tubes called *cells* and *vessels*. These are often strengthened by delicate threads or bands called fibres, formed by secondary deposits on the inner surfaces of the primary membranes. When these fibres exist as rings or hoops, the cells and vessels containing them are said to be *annular*.

ANNULAR ECLIPSE, an eclipse of the sun, in which the moon is wholly projected on the sun's disc, but, having a less apparent diameter, or ring of light from the outer parts of the sun's disc remains visible. (*See* ECLIPSE.)

ANNULATA SEDENTARIA, *an'-nu-lai'-ta sed'-en-tair'-i-a*, a carnivorous tribe of worm-like animals, inhabiting a tube-shaped shell, which they never quit. They are usually found adhering to marine substances.

ANNULATE, *an'-nu-lait* (Lat., *annulus*, a ring), a term applied to those ferns which have ringed sporangia (cases containing spores). The annulus or ring surrounding each sporangium is elastic, and its pressure causes the organ to burst when ripe, and release the spores. Those ferns which have sporangia not encircled by rings are said to be *exannulate*.

ANNULATED ROOT, *an-nu-lai'-ted* (Lat., *annulus*, a ring), a root having a number of ring-like expansions, so as to present the appearance of a string of thick rings, as in the ipecacuanha.

ANOBIUM. (*See* DEATH-WATCH.)

ANODE, *an-ode'* (Gr., *ana*, upwards, *odos*, a way), a term introduced by Faraday to designate the positive pole of any electrical arrangement for decomposing a chemical compound. The anode, or positive pole, is the surface by which the electric current enters the body undergoing decomposition. (*See* ELECTROLYSIS CATHODE.)

ANODYNE, *an'-o-dine* (Gr., *a*, without, *odune*, pain), a medicine which allays pain. The term is usually applied only to a medicine which acts upon the nervous system, so as to decrease sensibility and induce sleep, or a state of partial unconsciousness. The most important anodynes are preparations of opium.

ANOLIS, OR ANOLIUS, *a-no'-li-us*, a reptile peculiar to America, supplying in many respects the place which the chameleon occupies in the old world. The colour of the skin, especially that about its loose baggy throat, assumes an endless succession of ever-varying hues, as the animal is disturbed by love or anger. The anolis, however, is more slenderly built than the chameleon, and more active in its movements. It varies from seven or eight inches to a foot in length, and is extremely tame and harmless. Its food consists of flies and other small insects. The head is long, straight, and flattened; the body and tail slender; and both are covered with small round scales, which give the skin the appearance of fine shagreen.

ANOMALISTIC YEAR, *a-nom'-a-lis-tik*, (Gr., *anomalos*, irregular), in Astronomy, the time which the earth takes in passing through its orbit from its perihelion, at which it is at its least distance from the sun, until it again arrives at that point. Under the disturbing influences of the planets, the perihelion of the earth advances 11·8" yearly, following the direction of the earth's path. The anomalistic year is 25 minutes longer than a solar year, and 4 min. 39 sec. longer than a sidereal year.

ANOMALOUS, *a-nom'-a-lus* (Gr., *a*, without, *nomos*, a rule), this term is applied to all parts of a plant when they have very irregular or unusual forms.

ANOMALY, in Astronomy, the angle measured at the sun between a planet in any point of its orbit at the last perihelion. It is so called because it was in it that the full irregularities of planetary motion were discovered.

ANOMOPTERIS, *an-o-mop'-te-ris* (Gr., *anomos*, without rule, *pteris*, fern). This term is applied to a genus of fossil ferns peculiar to the new red sandstone. The plants differ from all recent and fossil ferns; hence the generic name, which signifies "anomalous fern."

ANONA, *a-no'-na*, the custard-apple, a genus of plants belonging to the natural order, *Anon-*

aceæ, and composed of small trees and shrubs growing in the West Indies and South America, where they are cultivated for the sake of their delicious fruits. The most important species are *A. squamosa* and *A. muricata*. The first, commonly known as the sweet sop, is found in all the West Indian islands. The fruit is covered with greenish scales, and has the appearance of a young pine-cone. The edible portion consists of a thick, sweet, and luscious pulp. *A. muricata*, the sour sop, which is also a native of the West Indies, is a picturesque small tree, bearing a yellowish-green fruit, weighing from 1 lb. to 3 lbs., and covered with weak prickles. Its pulp is perfectly white, and has a most agreeable acid taste. *A. reticulata* yields the netted custard-apple, a large, dark-brown fruit, filled with yellowish or reddish pulp of about the consistence of custard. *A. cherimolia* is cultivated in Peru, on account of the excellence of its fruit, which is called the cherimolia. Two other important species have been described—*A. sylvatica* (the *Araticu do Mato* of Brazil) and *A. palustris*, both of which furnish light and handsome wood, used for turnery.

ANONACEÆ, *an-o-nai'-se-e*, a natural order of dicotyledonous plants, of which the type is the genus *Anona*. They are trees or shrubs, with leaves alternate, simple, and without stipules. In the flower we find a calyx of three sepals, and a corolla of six leathery petals, arranged in two whorls. The carpels are usually numerous, distinct or united; the styles short, the stigmas simple, and the ovules inverted. The fruit is composed of a number of dry or succulent carpels, sometimes distinct, but oftener united, so as to form a fleshy mass. The plants of this order are almost entirely confined to the tropical regions of Asia, Africa, and America, none being found in Europe. They are generally aromatic and fragrant in all their parts, and some are very useful. There are about 300 known species, some of which are employed medicinally. The dry fruit of one species, *Xylopia aromatica*, was formerly imported into Europe as Guinea pepper. (*See* ANONA, CÆLOCLINE, DUGUETIA, XYLOPIA.)

ANOPLOTHERIUM, *an'-o-plo-the'-ri-um* (Gr., *a*, without, *oplon*, weapon, *therion*, beast), a genus of extinct quadrupeds, established by Cuvier from bones found in the gypsum strata of the upper Eocene formation near Paris. Several species have been determined, the smallest having been little larger than a guinea-pig, and the largest about the size of a small ass. From the situations in which their remains have been discovered, these ancient inhabitants of our globe appear to have lived in herds in swamps and marshes. Some had slender legs and feet, but others were firmly built and heavy. They had but two toes, as in the ruminants, and were the earliest bi-hoofed animals known to have existed on the earth; but in some specimens there are smaller supplemental toes. In some the tail was short and thick, and was probably made use of in swimming; in others it was short and slender. The dentition appears to have been very peculiar, each jaw having had six incisors, on each side of which was a small canine, and behind these, without leaving any interval, seven molars, resembling those of the rhinoceros. The common anoplothere (*A. commune*) has been taken as the type of a small natural family—the *Anoplotheridæ*, which appear to form a connecting link between the pachyderms, or thick-skinned mammalia, and the ruminants. Cuvier, in describing this typical species, showed that in one respect it stood between the rhinoceros and horse, and in another between the hippopotamus and camel. The name was given to the genus from the fact that all the species seem to have been destitute of organs of defence, as tusks, claws, or horns.

ANOPLURA, *an-o-plu'-ra*, a family of insects, in which are comprehended the *Aptera* of Linnæus and the many varieties of *Pediculus* or louse (*see* PEDICULUS), as well as the parasitic insects of other writers. About 500 different forms of *Anoplura*, all of them parasitic, have been described.

ANORTHITE, *an'-orth-ite* (Gr., *a*, without, *orthos*, right), a variety of felspar, without right angles in its crystals, composed of silica, alumina, magnesia, lime, and oxide of iron.

ANT, *ant* (Lat., *Formica*), a genus of hymenopterous insects, which from the very earliest period of the world's history have attracted attention on account of their social and industrious habits, their love of order and subordination, and unremitting economy. They are distinguished from other *Hymenoptera* by their habit of residing underground in numerous societies, and by the existence of *neuters* among them, by which class the labours of the community are chiefly performed. Although so small, their muscular strength is extraordinary, and they will carry loads at least ten times their own weight, displaying meanwhile considerable activity. They have triangular heads; the antennæ have joints; the jaws strong; the ligula, or lower lip, small, rounded, or spoon-like; the thorax compressed at the sides; the abdomen nearly oval, the pedicle which joins it to the thorax forming in some kinds a single and in some a double scale or knot. A community of ants, whatever the species may be, consists of males, which have always four wings; of females, much larger in size than the males, which only possess wings during the pairing season; and of a sort of barren females, which have been variously termed neuters, workers, or nurse-ants, and which, so far as is known, have never been observed to have wings in any stage of their existence. The nests of ants are differently constructed by the different species; all, however, are very curiously and regularly arranged. If an ant-hill be examined any time after midsummer up to the close of autumn, there may be seen mixed with the wingless workers a number of males and females furnished with white glistening wings. These are not allowed to move without a guard of workers to prevent them leaving the boundaries; and, if one straggles away unawares, it is for the most part dragged back by the vigilant sentinels, three or four of whom may in such cases be seen hauling along a winged deserter by the wings and limbs. The actual pairing does not seem to take place within the ant-hills; and scouts have been observed posted all around ready to discover and carry back to the colony as many fertile females as they could meet with. It is probable that, soon after pairing, the males die, as do the males of bees and other insects; for, as the workers never bring any of tnem back nor take any notice of them after leaving the ant-hill, they must perish, being entirely defenceless, and destitute of a sting and of mandibles to provide for their sustenance. The eggs of ants are so small as to be scarcely visible to the naked eye. When laid they are not glued to any fixed place, but are dropped at random by the mother in her progress through the nest, and carefully collected by the workers, several of whom sedulously attend her during her period of laying. The collected eggs are taken to the various apartments of the nest adapted for the purpose, and there left for hatching. Heat being indispensable, the eggs are placed carefully during the day near the surface of the ant-hill, but so sheltered from the direct influence of the sun, as to prevent the too rapid evaporation of their moisture. As night approaches, the experienced insects to whom the care of the precious ova is entrusted, remove the eggs to warmer quarters, to prevent the escape of the heat they naturally possess. Nor does the care of these tender nurses cease when the little ants come into life. At night they are carefully stowed away in the innermost chambers of the nest, every aperture being closed to prevent the ingress of cold air. But as soon as the rays of the morning sun fall upon the surface of the nest, the workers busily commence carrying their infants to the upper chambers, where, close under the roof, they may enjoy the genial warmth. Not unfrequently, they even place them for a time on the outside of the nest, exposed to the direct rays of the sun. During their grubhood, the little creatures are fed by the nurses, or by the mother herself, by a liquid disgorged from the stomach. When the grubs are full grown, they spin cocoons of a membranous texture, and of a brownish-white colour, in appearance not unlike barleycorns, for which, indeed, they were mistaken by early observers. Hence, doubtless, arose the belief that the insect laid up a store of grain in the summer season, to serve for its support in the winter. European ants are carnivorous in their habits, and do not, as has been frequently said, lay up stores of corn for the winter, for they are in a state of torpidity during the winter months, and require no food. In India, however, ants have been known to lay up large stores of millet-seed; and it is possible that other species may have the same habit. The vegetable substance which ants appear chiefly to use as food, is sugar, and to this, wherever it is to be found, they seem to be guided by a very acute sense of smell. *Honey-dew*, the saccharine excretion of the *aphides*, is a favourite food of many species. Not only do the ants climb plants on which *aphides* are to be found, but should they find the creature and not his saccharine produce, they will, with their antennæ, pat the aphis on either side of the abdomen until the desired drop is yielded, and then pass on to another. Linnæus quaintly styles the aphis the ant's *milch-cow*. The habitations of the ants are very curiously constructed, and display great ingenuity. Houses built by the common wood-ant (*Formica rufa*) are sometimes as large as a small haycock. They are generally found in the vicinity of some large tree on the bank of a stream; such a site affording them both food and the moisture requisite for building purposes. The ant-hill is of a conical shape, and composed of leaves, scraps of wood, earth, &c. At the commencement the nest is simply an excavation made in the earth; a number of the labourers wander about in quest of materials suitable for the superstructure, others carry out particles of earth from the interior, which are replaced by the bits of wood and leaves other labourers bring in, and which the builders properly arrange. Care is taken that space is left for the galleries that lead to the interior, while the dome contains a number of spacious apartments communicating with each other by means of galleries similarly constructed. To the superficial observer the exterior of an ant colony presents the appearance merely of a careless heap, the result rather of chance than of design. Minute inspection, however, would invariably discover it to be the very perfection of architecture, in which the attacks of enemies, the effect of wind and flood, and the rays of the sun, have been thoroughly provided against in the building. Some ants are popularly known as mason-ants for their skill in building; others, carpenter-ants, because they make their habitations in old trees, gnawing the wood into apartments and galleries with their partitions. Another species (*F. flava*) make partitions of a mixture of earth, sawdust, and spider's web. Cowdung and the leaves of trees are employed by other species. Ants are very pugnacious, and often fight fiercely. Party meets party, and after the fray may be found limbless trunks and trunkless heads, and combatants fast locked in each other's embrace, and quite dead. Most extraordinary than all, however, is the fact that some species of ants go on regular forays to carry off the eggs and grubs of other species, which they carry into captivity and rear as bond ants and slaves for the rest of their lives. The best known of these marauders are the Sanguinary Ant (*Formica sanguinea*) and the Amazon Ant (*Formica rufescens*). It has been noticed as a rather singular circumstance, that in both cases the kidnappers are red or pale-coloured ants, and the captives jet black.

ANT, WHITE, an extensive and important family of the *Neuropterous* order, chiefly confined to the tropics. They are very different from the ordinary ant. (*See* TERMITES.)

ANTARCTIC, *an-tark'-tik* (Gr., *anti*, against, or opposite to, and *arktos*, the Bear, or northern constellation), an expression applied to the south pole and Southern Ocean, as opposite to the north pole and Northern and Arctic Ocean, and especially to the region which lies around the antarctic or south pole, within a circle distant 23° 28′ from that pole; corresponding to an area similarly circumscribed which surrounds the north or arctic pole.

ANTARES, *an-tair'-ees*, a bright double star in the constellation Scorpio, marked α, and known as *Cor Scorpii*, the Scorpion's heart. It is remarkable for its brilliant red appearance.

ANT-EATER, GREAT (*Myrmecophaga jubata*, a genus of quadrupeds belonging to the natural order Edentata). This curious creature, sometimes called the ant-bear, is an inhabitant of most of the tropical parts of South America east of the Andes. It is the largest of the edentata, measuring four feet and a half from the tip of the snout to the root of the tail; while the latter member measures nearly three feet in length. The head of the great ant-eater extends to a long snout covered with skin, with only a very small opening at the tip for the protrusion of the tongue; its ears are very minute; its legs, especially the anterior ones, very stout and strong, and armed each with four long claws, which turn inwards against the sole of the foot. The hind feet are provided with a broad sole, and it is probably from this circumstance that the animal derives its occasional name of ant-bear. The body is covered with bristly hair, which, on the tail, grows to such a length as to sweep the ground. When composing itself for sleep, the ant-eater curls its body, and so enwraps itself in its bushy tail, as to present the appearance of a heap of withered grass rather than a living animal. Despite the animal's harmless appearance, it has a habit of suddenly rising, bear-fashion, and clasping its assailant round the waist, lacerating him fearfully with its powerful claws. The female produces one young at a birth, and carries it about for some time on her back. The natural food of the ant-eater is the white ant that abounds on the banks of lakes and rivers in tropical South America. Assailing the nests of the industrious insects with its heavy-armed fore-paws, it puts the entire colony in confusion, and then thrusting amongst them its nimble tongue, capable of protrusion to the extent of a foot and a half, withdraws the adherent ants, repeating the operation till they are all consumed, or the ant-eater's appetite satisfied. The ant-eater's tongue is composed almost solely of ring-like muscles, and is altogether worm-like in appearance. The surface is endued with viscous matter, to which the ants become helplessly attached at the slightest contact. The South African Aard-vark in some respects resembles the ant-eater. (*See* AARD-VARK.)

ANTECEDENTIA, *an-te-se-den-shi-a* (Lat., *antecedere*, to precede, to go before). When the motion of any heavenly body appears to be in a direction contrary to the course of the signs of the zodiac, or from east to west, it is said by astronomers to move *in antecedentia*.

ANTEDILUVIAN, *an-te-di-lu'-vi-an*. In Geology, the term is applied to the period before the final transformation of the surface of the earth by the action of water, but has no reference to the Mosaic deluge.

ANTELOPE, *an'-te-lope* (Lat., *antilope*), a large group of ruminating mammals, comprising many species, and classified together with sheep, oxen, and goats, as the family *Cavicornia* or hollow-horned ruminants. They are essentially distinct from the deer with which they are often confused; the horns of the deer being solid, composed wholly of bony tissue, and shed annually; while those of the *Cavicornia* are permanent through life. Although differing in many particulars from each other, all antelopes agree in certain important characteristics, as in the form of the horns, which are without angles and ridges, as is the case in the sheep and goat and other members of the *Cavicornia*, but of a round and annulated nature. Excepting in this particular, the horns of the antelope genus widely differ from each other; while those of one species are perfectly straight, another will exhibit curved or spiral horns. The female is usually endowed with these handsome appendages as well as its mate. All the antelopes are remarkable for their delicate sense of smell, and also for being the only family possessing the curious "lachrymal sinuses," or "tear-pits" of the eyes. These are small sacs situated beneath the eyes, and secreting a certain fatty substance. It was supposed that the possession of these tear-pits occasioned the very delicate sense of smell exhibited by all antelopes; but the anatomy of the parts fully proves that this theory is incorrect, and that there is no internal communication between the lachrymal sinus and the nose. The females are furnished with two and sometimes four teats, and the period of gestation varies from five to eight months. One, and occasionally two, are brought forth at a birth. From the most remote ages, the eyes of this genus have attracted notice. The Greek and the Roman name of the gazelle, *dorcas*, is derived from the verb *derkomai*, I see. Even the English name of the genus, antelope, is a corruption of the term *antholops*, literally "bright eyes." We are, moreover, informed by Bochart, that the Scriptural name, *tabitha*, is derived from *tzebi*, the Hebrew name of the gazelle, which alludes to the brightness of its eyes. The same image is frequently employed by poets. As a rule, the hair of the antelope is smooth and short, and of an equal length; but, in some species, they have manes on the neck and shoulders; others, as the gnu, are provided with a beard on the throat and chin. The ears are long and pointed, growing in the inside of which are long white hairs, forming five longitudinal lines, with four black spaces between. The tails are short, tufted at the extremity. This genus, as a rule, is gregarious, uniting in large flocks of thousands; but, in some instances, spending their lives in solitary pairs. When associating in large numbers, great caution is taken to prevent surprise, and sentinels are constantly kept on the alert. Their wariness in this particular, combined with their acute sense of smell and sight, renders them somewhat difficult game, tasking the patience and temper of the hunter to the fullest extent. The hunting-grounds of South Africa contain the largest number of these animals; Asia furnishes several species; Europe supplies but a small quota, the chamois being the best known; and the gigantic extent of pasture-land in the New World can boast of but two species, the so-called Rocky Mountain "goat," which is a true antelope, and the cabrit or prong-buck of the North American regions. Australia and Madagascar are totally destitute of antelopes, as of all indigenous ruminants. With regard to the habitat of the antelope, it is far from an uniform nature; the general characteristics are as variable as the structure of the animals. While some species delight in the parched and arid desert, feeding upon such bulbous plants as the nature of the soil affords, others find a home on the open plains, on the steppes of Central Asia, or karroos of Southern Africa. Another species prefers the mountainous districts, and exhibits all the ease and agility of the wild goat in their rocky home. The whole of the antelopes were at one time included under the general head *Antilopea*. Modern discoveries have so largely augmented the group, that it has been necessary to class them into subdivisions, as follows:—1, True antelopes; 2, bush antelopes; 3, capriform (or goat-like) antelopes; 4, bovine (or ox-like) antelopes. The two great divisions into which they are divided are, the *antelopes of the field* and the *antelopes of the desert*. They are principally distinguished in the former by the absence of hair on the nostrils, whilst the same organs of the latter division are covered within with hair or bristles. The antelope would appear to be the connecting link between the deer and the goat. In the peculiarity of never shedding their horns they resemble the goat; on the other hand, their fleetness, the colour and texture of their hair, their general structure, in fact, would place them near the deer tribe. The general colour of the antelope is brown on the back, and white under the belly, variegated with black stripes. With regard to the size of the antelope, while some of the largest species are some five or six feet in height, there is a singular little variety, the pigmy antelope, which scarcely measures nine inches. The whole tribe amount to about eighty species. Antelope flesh forms a considerable portion of the native's larder, as well as affording food to some thousands of the carnivora. In cases of severe drought, antelopes have been known to sweep down on the cultivated fields of the colonists in such flocks as to cause fearful devastations. The gazelle or North African or Barbary antelope has long been famed for its beauty; and from its extreme gracefulness of form, its gentleness of manners, and its bright black eye, it is and has long been a favourite subject of admiration by Eastern writers. Notwithstanding that it has often been spoken of as the wild gazelle, it has frequently been domesticated. The algazel is closely allied to the gazelle, and has graceful slender limbs, horizontal horns, obliquely annulated, nearly three feet in length. It is a native of Persia and Arabia. The addax is another North African antelope. The Chinese antelope, the *dzeria* of the Mongolian Tartars, is a native of the deserts lying between China and Thibet. It has short thick horns. The Chira, a native of Thibet, also of the Himalayas, possesses elongated and annulated horns, and a thick woolly coat. From the fact that one of its horns sometimes remains undeveloped, and, therefore, to the casual observer, the animal only appears to have one of these appendages, the mythical tales of the unicorn have arisen. The European representatives of the antelope are the chamois and the saiga. The latter, however, extends from Poland-Russia into Asia. But the principal home of the antelope is found in Southern Africa. Here are numerous varieties, perhaps the best known of which is the "spring-bok" of the Dutch settlers. The horns of this animal are curved like a lyre and annulate. It is famed for its great activity and powers of leaping great distances, hence its name "springer antelope," or spring-bok. It congregates in vast herds in the plains of Central and Southern Africa. "Bok" is the Dutch equivalent to "buck." The bontebok and the blesbok are two species closely resembling the spring-bok. Other species found in South Africa are—the blue antelope, the roan antelope, the water-bok (so called from its habit of frequenting rivers), the klippspringer (resembling our European chamois), the koo-doo, the eland, the wildebeest, the hartebeest, and the kudu.

ANTEMERIDIAN, *an-te-me-rid'-i-an* (Lat., *ante*, before, and *meridies*, noon or mid-day), before noon, or 12 o'clock in the day, used in its abbreviated form A.M. to denote any time between midnight and noon.

ANTENNÆ, *an-ten'-ne* (Lat., a yard-arm), the slender, jointed filaments with which the heads of insects are furnished, being synonymous with what are called feelers. It has been supposed that they are also organs of hearing, and without doubt it would appear that many insects possess the power of communicating, one with another, by means of them. (*See* INSECT, &c.)

ANTERIOR, *an-te'-ri-or*, designates before, either in time or place. In Anatomy, it is often used to designate parts which are situated before others, and is thus opposed to posterior; as, the anterior lobes of the brain, the *anterior intercostal nerve*

ANTHELIA, *an-the'-lia* (Gr., from *anti*, opposite to, and *helios*, the sun), luminous rings seen on clouds or fog lying opposite the sun, and usually attributed to the diffraction of light.

ANTHELIX, *an-the'-lix* (Gr., *antihelix*, from *anti*, opposite to, and *helix*, a spiral), an eminence on the cartilage of the ear, situated before, or more properly within, the helix, or outer circle of the ear. (*See* EAR.)

ANTHEMIS, *an'-the-mis* (Gr., the Chamomile plant), a genus of plants belonging to the natural order *Compositæ*, sub-order *Corymbiferæ*, and distinguished by having the scales surrounding the flower-heads membraneous at the borders, like those of a chrysanthemum, from which genus it differs chiefly in the receptacle of the flower being furnished with little chaffy projections. The most important plant of the genus is *A. nobilis*, the common chamomile, which is extensively cultivated for the sake of its flowers. It is an indigenous perennial, flowering from June to September, and growing on open gravelly pastures and commons. The *capitula*, which are commonly termed flowers, are each composed of a number of tubular yellow florets, arranged on a receptacle, and surrounded by a circle of ligulate white florets. The double variety is produced at the expense of the tubular florets, which become converted into ligulate florets. The single flowers are to be preferred for medical purposes, as the central yellow florets contain much more volatile oil than the white ones. Both leaves and flowers possess a strong but not unpleasant aromatic odour, and a nauseous bitter taste. The principal constituents of the flowers are volatile oil, tannin, and bitter resinous matter. The oil, which is procured by distillation, is stimulant and antispasmodic, and is frequently used in the preparation of tonic and cathartic pills, and to relieve flatulence. The dried flowers have the same properties as the oil, and are used for the same purposes. They are also employed externally for fomentations. A decoction of the flowers familiarly known as "chamomile tea" is a popular domestic medicine. The chamomile flowers of the German pharmacologists are the produce of a species of *Matricaria*, a genus very closely allied to the *Anthemis*. On the continent *A. nobilis* is called the Roman chamomile, to distinguish it from *M. chamomilla*, which is there generally known as the common chamomile. Great quantities of this plant are illegally used in the manufacture of beer. Two other species of *Anthemis* may be noticed—*A. Cotula*, the Mayweed, a common wild plant, sometimes mistaken for the chamomile, and so acrid as to blister the fingers if much handled; and *A. tinctoria*, which yields a yellow dye, much used in France by the dyers.

ANTHER, *an'-ther* (Gr., *antheros*, belonging to a flower), an essential portion of the stamen, being the bag or case which contains the pollen. It is generally supported on the summit of a little column or stalk called the *filament*. The pollen is discharged at certain periods through little slits or holes formed in the anther. (*See* STAMEN.)

ANTHERIDIUM, *an-the-rid'-i-um* (Gr., *anthos*, a flower), the general name applied to all the various structures in which, certainly or probably, the fertilizing function of reproduction resides in flowerless plants, and which consequently correspond physiologically to the anthers of flowering plants. All these organs have one character in common—namely, that of producing extremely minute bodies endowed with spontaneous motion when placed in water. These moving bodies from the antheridia are called spermatozoids, antherozoids, or spermatic filaments. (*See* SPERMATOZOID.)

ANTHESIS, *an-the'-sis* (Gr., flowering), a term sometimes used to indicate the period at which the flower-bud opens.

ANTHOCARPOUS, *an-tho-kar'-pus* (Gr., *anthos*, flower, *karpos*, fruit), a general term for fruits formed by the combination of several flowers. Such fruits usually consist not only of the carpels of the flowers, but of their bracts and floral envelopes as well, a fact indicated by the derivation of the term *anthocarpous*. The terms *multiple*, *aggregate*, ond *collective*, have also been applied to these fruits. The most important anthocarpous fruits are, the *cone*, which is seen in the fir, larch, spruce, and other plants of the order *Coniferæ*; the *galbulus*, seen in the cypress and juniper; the *strobilus*, seen in the hop; the *serosis*, in the pine-apple; and the *syconus*, in the fig. These fruits are described under their respective heads.

ANTHOCEROTÆ, *an-tho-se-ro'-te* (Gr., *anthos*, a flower; *kirkis*, a ray), a sub-order of the natural order *Hepaticaceæ*, the Liverworts, distinguished by having valved pod-shaped sporangia.

ANTHODIUM, *an-tho'-di-um*. (*See* CAPITULUM.)

ANTHOTAXIS, *an-tho-tax'-is*. (*See* INFLORESCENCE.)

ANTHOXANTHUM, *an-thox-an'-thum* (Gr., *anthos*, a flower, and *xanthos*, yellow), a genus of grasses. The species *A. odoratum* is commonly known as the sweet vernal grass, and greatly esteemed for its sweet smell, which causes much of the well known fragrance of new-mown hay.

ANTHOZOA, *an'-tho-zo'-a* (Gr., *anthos*, flower, *zooa*, animal), a class of that division of the animal kingdom termed *zoophytes* (animal-flowers). The *anthozoa* are divisible into three orders—*A. hydroida*, *A. asteroida*, and *A. helianthoida*. These so-called animal-flowers apparently, but not in reality, combine the animal and vegetable in their nature; for they possess the sense of touch, the power of voluntary motion, and usually feed on matters which they have swallowed or sucked in, digesting them in an internal cavity; thus completely exhibiting the attributes of an animal. (*See* ACTINIA and ZOOPHYTES.)

ANTHRACITE, *an'-thra-site* (Gr., *anthrax*, coal.—Anthracite, stone-coal, Kilkenny coal, culm, or coal-glance, is a very hard, lustrous variety of coal, found in the lowest parts of the carboniferous strata. It contains 90 to 96 per cent. of carbonaceous matter, and burns almost without flame, with a steady glow. Notwithstanding that it differs considerably from other kinds of coal, it is undoubtedly of vegetable origin like them, although it is nearly devoid of structure, and contains no impressions of plants. No distinct line of demarcation can be pointed out in the mine between the ordinary coal and the anthracite, as the one gradually merges into the other when they are found in the same seam. It has been spoken of as the ultimate product of the conversion of vegetable matter into coal. Its fracture is somewhat lamellar when broken in the direction of its bed, but irregularly conchoidal when broken across. Some specimens exhibit a beautiful play of colours, and are thence called peacock-coal. Being difficult of combustion, from its extreme hardness, it can only be burnt in a strong current of air. The coke obtained from it is very similar to the original coal both in bulk and weight. It is much used for steam boilers, and for various metallurgical operations, where a strong current of air is easily procured, and an intense heat is required. Anthracite is very abundant in the Welsh coal-fields, where excellent qualities are found. It also occurs in Kilkenny, and in enormous quantities in North America; but much of it is so compact that it cannot be used as fuel. In the neighbourhood of Bideford in North Devon, there occur a series of seams of clayey anthracite to which the name *culm* has been given.

ANTHRACOTHERIUM, *an'-thra-ko-the'ri-um* (Gr., *anthrax*, coal, *therion*, beast), a genus of fossil pachydermatous animals that seems to stand intermediate between the river-hog and the hippopotamus. The remains of the anthracotheria were first found in the tertiary lignites, or wood-coals of Liguria; hence the name given to this extinct animal.

ANTHRISCUS, *an-thris'-kus*, a genus of plants belonging to the natural order *Umbelliferæ*, and characterized by possessing little or no calyx, with heart-shaped petals bent down at their points; and by producing a fruit narrowed below the short beak, and without any ridges. The species *A. vulgaris*, the common beaked parsley, grows wild in waste places, and is sometimes confounded with hemlock, but may be easily distinguished by its paler colour, the slight hairiness of the leaves, and by the absence of spots on the stem, and the swelling under each joint. The species *A. cerefolium*, the garden chervil, was formerly cultivated as a potherb. *A. sylvestris*, the wild chervil, is a common weed in hedges and banks throughout England.

ANTHROPOLITE, *an-throp'-o-lite* (Gr., *anthropos*, man, *lithos*, stone), a term which has been applied to petrified human bones.

ANTHROPOLOGY, *an-thro-pol'-o-je* (Gr., *anthropos*, man, and *logos*, a discourse), is that science which in its widest sense treats of human nature both physically and mentally. It thus includes anatomy, physiology, psychology, ethnology, so far as they concern man, and even history, theology, æsthetics, &c. It is often, however, limited to the relations existing between the soul and body in man. This science has of late received much attention from some of our philosophers, and the word has come into very common use. The duty of anthropology is to gather from the various sciences before mentioned all the facts which they may be able to render concerning man, and elaborate from them, as completely as possible, a general view of human nature both physical and mental, also to present a theory of his life and actions from his first appearance here on earth. It was formerly the custom to exclude man entirely from other animals when pursuing these sciences, and to regard him as totally distinct from aught else; but of late years the human species has been regarded as the highest form and development of a long series of related organisms, and a much more perfect knowledge of man himself and his place in the universe has thus been gained. It is still a debatable subject, as to whether this plan shall be pursued with regard to the other sciences, and the mental, moral, and spiritual nature of man be regarded as wholly distinct from the lower animals, or as simply a higher development of them. Undoubtedly the break here between man and even the nearest animals to him in point of physical development is very vast, yet there are some philosophers who maintain that it is not absolute, and that germs of moral tendencies and of social law, reason, and noble instincts are to be discerned among the lower animals, and that the study of them may shed great light upon even the highest organization of man. (*See* EVOLUTION and ETHNOLOGY.)

ANTHROPOPHAGI, *an-thro-pof'-a-ji* (Gr., *anthropos*, and *phago*, I eat), cannibals, or man-eaters. (*See* CANNIBALS.)

ANTHYLLIS, *an-thil'-lis* (Gr., *anthos*, flower, *hulos*, beard), the kidney vetch, a genus of plants belonging to the natural order *Leguminosæ*. The silky appearance of the heads of flowers suggested the botanical name. *A. Vulneraria* is recommended as a herbage plant by some writers on agriculture.

ANTIARIS, *an'-ti-a-ris*, a genus of plants belonging to the natural order *Artocarpaceæ*. The species *A. toxicaria* is the celebrated antsjar, or upas poison-tree of Java, concerning which many fabulous and absurd stories have been told by travellers. (*See* UPAS.) The bark of *A. saccidora*, a tree growing in India, is used for cordage and matting. Sacks are also manufactured from it.

ANTIMOIC ACID. (*See* ANTIMONY.)

ANTIMONIOUS ACID. (*See* ANTIMONY.)

ANTIMONY, *an'-ti-mo-ne*, a brilliant bluish white metal, symbol Sb, from the Latin *stibium*; atomic weight 129, specific gravity 6·7. It fuses at 842° F. It is so brittle, that it may be reduced to powder by being pounded in a mortar. It occurs in commerce in crystalline cakes, and is generally very impure. It volatilizes at a red heat. It is a bad conductor of electricity and heat. When heated in air, it burns, and gives off copious white fumes, consisting of teroxide of antimony. It is also oxidized by nitric and sulphuric acid, and dissolved by aqua regia. In its chemical relations, it is allied to nitrogen, phosphorus, and arsenic, and forms, with the last, one of the connecting links between the metallic and non-metallic elements. Antimony is found pretty abundantly in nature, under the form of the grey ore, or tersulphide. The other ores of antimony are rare and unimportant.

ANTIPODES, *an-tip'-o-dees* (Gr. *anti*, and *pous*, a foot), is a term applied to those who live on opposite sides of the earth, and, consequently, have their feet turned towards each other. They are in similar but opposite latitudes, and their longitudes differ by 180°; and, consequently, while they have similar climates so far as dependant upon latitude, their seasons, as well as their days and nights, are reversed. The word is applied to places as well as to persons. The exact antipodes of London is a small island to the south-east of New Zealand, therefore known as London Island.

ANTIRRHINUM, *an-tir-ri'-num*, (Gr., *anti*, similar, *rin*, nose), a genus of plants, so named because the flowers of most of the species resemble the snouts of some animals. *A. majus* (commonly known as the snap-dragon), and its varieties, are popular border flowers, which can be cultivated without trouble in any dry soil. The genus belongs to the natural order *Scrophulariaceæ*, the Figworts.

ANTLER, *ant'-ler*, the term applied to the horn of the *Cervidæ*. Until the deer is a year old, nothing but a slight protuberance marks the place where the antlers sprout. In the second year the horn appears, and is called the *brow antler*; the next year it has a branch, and is known as the *bay antler*; the fourth year it has two branches, and is a *tray antler*; the fifth, another branch and a new name, *crockets*; and again, at the sixth year, when the antler is perfect and is called a *beam antler*. The deer's antlers are shed in spring; and, considering their size and weight, are renewed in an astonishingly short time. A full-grown stag's horn probably weighs twenty-four pounds; yet this large mass of true bone is reproduced in about ten weeks. The development of the deer's antlers is intimately connected with the sexual system. (*See* DEER.)

ANT-LION, *ant'-li-on* (*Myrmelon formicaleo*), an insect of the order *Neuroptera*, remarkable for its ingenuity in constructing a pitfall for the destruction of its prey. As soon as the young larvæ are hatched, they at once set about providing for their future sustenance. This is effected by turning round and round in the sand till a small cavity is made, which, as the animal increases in size and strength, grows broader and deeper, till it measures about thirty inches in breath and twenty in depth. If it meet with a stone it cannot remove, the excavation is deserted and another begun. At the bottom of this pit the ant-lion patiently remains, all its body, except the mandibles, buried in the sand, till some unsuspecting insect, arriving at the edge of the trap, thinks there can be no harm in exploring it. The sides of the pit, however, are so arranged as to afford foothold not even to the tiniest insect, and down rolls the little victim into the trapper's clutches; or, should it manifest any intention of escaping, a shower of sand, thrown up by a jerk of the ant-lion's head, at once arrests its progress, and brings it tumbling to the bottom again. It is entirely on the juices of insects that this voracious creature lives. The empty carcases are not allowed to encumber his abode. As soon as he has exhausted their fluids, he balances them in his strong jaws, and tosses them out. The larva remains in this condition during two years, being about half-an-inch long, with a large abdomen and small head; at the end of which time, having attained its full growth, it spins a cocoon, and takes the chrysalis form. Three weeks afterwards, it emerges a perfect insect. The ant-lion is, when full-grown, about an inch in length, and somewhat resembles the dragon-fly, except that it is much smaller. It has a very large abdomen and a very small head, which, however, is furnished with a pair of formidable incurved mandibles. It has six legs, but is incapable of rapid locomotion, and generally moves backwards. The perfect insect deposits its eggs in dry sandy situations. The *Myamelon foamiculeo* is not found in England, but occurs in many parts of the Continent, as France, Germany, Spain, &c.

AORTA. (*See* ANATOMY.)

APATITE, *ap'-a-tite* (Gr., *apatao*, I deceive). A mineral consisting mainly of phosphate of lime, and largely used of late years in the preparation of manures. It received its name from the fact that it is frequently mistaken for beryl, fluor spar, and other minerals, according to its colour and lustre, which vary considerably. It crystallizes in hexagonal prisms, modified sometimes on the edges, at others on the angles. It is a scarce mineral in England, though it occurs in some of the Cornish tin mines, and there is also a bed of it 18 inches thick at Llanfyllin in North Wales, from which large quantities have recently been taken. Fine specimens are found in Moravia, Bohemia, and Saxony, and extensive deposits have been found in various parts of the world: Krageroe in Norway and Estremadura in Spain have supplied great quantities. To fit it for the soil, it is reduced to a fine powder and then digested with sulphuric acid, which renders the phosphoric acid soluble in water, and facilitates its absorption by the corn or plant. Sometimes it is mixed with Peruvian guano, bones, blood, &c., and thus a mixed manure is produced which fertilizes the soil and enriches the corn much more than when the apatite or mineral phosphate is used alone. Different varieties contain a variable quantity of fluoride or chloride of calcium.

APE, *aip* (*Pithacus* of Linnæus), a genus of quadrumanous (four-handed) mammalia, most man-like in appearance and structure, such as the chimpanzee, the ourang-outang, the gorilla, &c. Formerly the term was almost synonymous with monkey and was used indiscriminately with it; now, however, according to the strict scientific zoological definition, the genus Ape, or *Pithacus*, comprehends only those four-handed mammals whose teeth are similar, both in number and form, to man's, and which have neither tails nor cheek-pouches. All the apes, however, present a striking difference from man in the formation of their great toe, which is so constructed as to resemble a man's thumb, the whole of the foot, moreover, is prehensile, like a hand, enabling them to clasp boughs. (For a notice of the most remarkable apes, *see* GORILLA, OURANG-OUTANG, CHIMPANZEE, &c.; for an account of species, &c., *see* SIMIADÆ, QUADRUMANA.)

APETALOUS, *a-pet'-a-lus* (Gr., *a*, without, and *petalon*, leaf), a term applied to a flower having but one whorl of floral envelopes; in other words, having a calyx, but no corolla.

APHAINTE, *a-faint'* (Gr., *a*, without, and *phaineia*, to appear), a tough compact rock, containing hornblende, quartz, and felspar, mixed so intimately as to be imperceptible—whence the name.

APHASIA, *a-fa'si-a.* Loss of speech in consequence of lesion of the brain. A much more serious disease than Aphonia (which *see*), for it is an absolute loss of the faculty of speaking. Perversion, or absolute loss of the power of expressing ideas by writing, is usually an accompaniment. It occurs in certain cases of paralysis of the right arm or leg. Often, after the lapse of a few weeks, recovery takes place if the patient is daily educated in simple words or short phrases, and the brain or paralytic affection improves.

APHELION, *a-feel'-yon* (Gr., *apo*, from, and *helios*, the sun), that point in a planet's orbit at which it is at its greatest distance from the sun. The rapidity of a planet's motion is least at its aphelion, and begins to increase after leaving that position, until it attains its maximum speed at the perihelion. (*See* PERIHELION, PLANET.)

APHIDÆ, OR APHIS, *af'-i-de* (Gr., *aphis*, a vine-fretter). A class of insects belonging to the order *Hemiptean*, sub-order *Homoptean*, and commonly known as plant-lice. They live by sucking the juices of plants, upon which they may be seen congregated in immense numbers. When attacked, the plant grows sickly, the leaves curl up, and the flowers and fruit, if not utterly destroyed, are certain to be seriously impaired. The cultivation of hops is notoriously an uncertain business, and this uncertainty may in great measure be attributed to the prevalence of the hop-fly (*Aphis Humuli*). So great are their devastations in some seasons, that the amount of duty paid upon hops has varied from £15,000 to £460,000; indicating, of course, a proportional variation in the crop. The Woolly Aphis, or American Blight, or Apple Aphis, was first observed in England in 1787, but it is not absolutely known whether it was actually imported from America, as has been supposed. It is, at times, very destructive to apple trees, and when once it appears, in garden or orchard, is very difficult of removal. It is a small insect, covered with a downy substance like cotton-wool; multiplies rapidly; clings to the chinks of the bark, and sucks the sap; causes diseased excrescences, and ultimately destroys the tree. There is an aphis that particularly affects turnips and cabbages, and one (*Aphis vastatoa*) that has earned for itself a world-wide notoriety as a blighter of potatoes. Most of the aphidæ are green; but that which attacks the bean (*Aphis Faba*) is black. They have a proboscis, by which they pierce and suck plants, and, at the extremity of the abdomen, two horn-like spines, from which exudes a saccharine fluid called *honey-dew*. The legs of aphides are long, and they move very slowly. Some are winged, and some are wingless, without distinction of sex. Their manner of propagation is very curious. In the autumn, male and female insects are found furnished with perfect generative organs, and the females lay eggs, which are hatched in the following spring. But, instead of producing insects of both sexes, these eggs give birth only to females, which, in their turn, produce living young without any congress with the male. The brood thus brought forth again produces young in the same manner; and this goes on throughout the whole summer, without the appearance of a single male insect. Happily their increase is kept under by the birds and by other insects which feed on them. Among the latter may be mentioned the familiar lady-bird.

APHONIA, *a-fo'-ni-a* (Gr., *a*, without, and *phone*, voice), loss of voice, very frequent in cases of common cold. There is no disease, simply a temporary mechanical defect, the muscles of the throat, brought into action by the mechanism of speech, being so affected by the cold, that for the time they refuse to perform their functions. A kind of aphonia sometimes appears in cases of hysteria.

APHRITE, *af'-rite* (Gr., *aphros*, foam), carbonate of lime occurring in scaly masses, having a peachy lustre and greasy feel; also called foam spa. This mineral must not be confounded with *meerschaum* (sea-scum), which is an amorphous carbonate of magnesia.

APHRODITA. (*See* SEA-MOUSE.)

APIACEÆ, *ai-pi-ai'-see*, a name sometimes given to the natural order *Umbellifeæ*, which *see*.

APIARY. (*See* BEES.)

APIOCRINITE, *ai-pi-ok'-ri-nite* (Gr., *anioa*, a pear), a term applied to a kind of encrinite peculiar to the chalk and oolitic formations, and distinguished by a pear-shaped receptacle. (*See* ENCRINITE.)

APIOS TUBEROSA, *a'-pi-us tu-ber-o'-sa*, a plant pertaining to the natural order *Leguminosæ*, sub-order *Papilionaceæ*. It is a native of Virginia, and has been cultivated in botanic gardens in Europe with some success. In many respects it resembles the potato, having similar tuberous roots, which taste like potatoes when cooked in steam. They are, however, more nourishing. Its ordinary cultivation is very difficult.

APIS, *ai'-pis*, the Bee. (*See* BEES.)

APIUM, *ai'-pi-um*, a genus of plants belonging to the natural order *Umbelliferæ*. The common celery, *A. graveolens*, is the only important species. This plant grows wild in almost every part of Europe; but it is quite unfit for food until cultivated with absence of light, when the stem and petioles become succulent, white, and wholesome.

APOCARPOUS FRUITS, *ap'-o-kar'-pus* (Gr. *apo*, separate, *karpos*, fruit), those fruits which are each formed of a single carpel, but of which several are produced by a single flower. The simple solitary fruits are generally included under the same head; but the most accurate botanists have kept them distinct. Three kinds of apocarpous fruits are distinguished, and these are respectfully termed the *Follicle*, the *Achæhium*, and the *Etærio*. (*See* these words.)

APOCOPE. (*See* APHÆRESIS.)

APOCRENIC ACID, *ap'-o-kre-nik*, an acid found in mould produced by the decay of leaves, wood fibres, and other plant textures. It retains ammonia with great tenacity, thus affording nourishment to the plants in its vicinity. Crenic, geic, ulmic and humic acids are found in similar situations, and possess similar properties.

APOCYNACEÆ, *a-po-si-nai'-se-e* (Gr., *apo*, against, *kuon*, dog), the Dogbane order of dicotyledonous plants, included in the sub-class *Corolliflorœ*, trees or shrubs generally having milky juices. The Dogbanes—of which there are 108 genera and 570 known species—are natives principally of tropical regions, a few only occurring in northern latitude. *Vinca*, the periwinkle, is the only British genus. The Oleander, however, is found in Southern Europe. Some of the plants of this order are intensely poisonous, of which the noted Tanghin tree of Madagascar is a famous example; all are to be suspected, though a few yield edible fruit. Some are drastic purgatives, and in some the bark is tonic and febrifugal. The milk of some of them, however, is bland and wholesome, as for instance Hya-Hya or Cowtree of Demerara. They have usually large showy flowers, and are on that account cultivated in our hothouses. Caoutchouc, or India-rubber, is prepared from the milky juice of several species.

APOCYNUM, *a-po-sy'-num*, the typical genus of the natural order of plants *Apocynaceæ*. *A. cannabinum* is the Canadian hemp, an herbaceous plant from four to five feet in height, with an unbranched stem bearing oblong leaves, and cymes of whitish flowers. It yields a very strong fibre which the Indians of North America employ for making twine and coarse cloth. The roots of this species and *A. androsæmifolium* are emetic, and slightly purgative.

APODAL FISHES, *ap'-o-dal*, fishes destitute of ventral fins; the eel is an example.

APOGEE, *ap'-o-je* (Gr., *apo*, from, and *ge*, the earth), means the greatest distance of any heavenly body from the earth; but it is applied more particularly to the sun and moon. The opposite condition is PERIGEE.

APONEUROSIS, *ap-o-nu-ro'-sis* (Gr., *apo*, from, *neuron*, a tendon), the membrane or tendon by which the muscles are attached to a bone, called aponeurosis of insertion. The term is also applied to a membrane within the substance of muscular fibres, called aponeurosis of intersection; also to a membrane surrounding a muscle and preventing its displacement, called enveloping aponeurosis.

APOPHYLLITE, *a-pof'-il-lite* (Gr., *apophullizo*, to strip of leaves), called also the "fish-eye stone," a mineral occurring in white, pearly, square prisms or pyramids. It is a silicate of lime and soda, and is found in the magnetic iron deposits of Sweden and Norway. So named from its tendency to exfoliate under the blowpipe.

APOPLEXY, *ap-o-plex'-e* (Gr., *apoplexia*, a sudden blow, a privation of sense and motion), is the name of a disease characterized by a sudden abolition or great diminution of the powers of sensation and voluntary motion, while the organic functions of the body—circulation, respiration, secretion, &c., are still carried on, but usually in a more or less impaired state. The attack is sometimes instantaneous; at other times it comes on by degrees. The face is generally flushed; the breathing slow, deep, and stertorous, the pulse fuller, stronger, and slower than natural, and the skin covered with a cold clammy perspiration; sometimes, however, the pulse, instead of being full and strong, is weak and intermitting, and the face pale and dejected. Apoplexy springs from a diseased condition of the brain, and is occasioned by whatever unduly impedes or accelerates the circulation of the blood within the brain, or exerts a certain degree of pressure upon it. Hence, violent exertion, either of mind or body, great mental anxiety, intemperance in eating or drinking, are among the exciting causes of it. Males are much more liable to it than females, and it is most common between the ages of fifty and seventy. Though the attack is usually so sudden, it is not without its premonitory symptoms, which, though numerous and diversified, are yet obvious and easily understood. Among these, are excessive drowsiness, giddiness and headache, with frequently dulness of hearing, imperfect or disordered vision, noise in the ears, loss of memory, &c. Sometimes the attack is preceded by paralysis affecting the speech, hands, feet, or other part of the body, and frequently it is succeeded by paralysis. When judicious remedies are adopted in time, an attack may generally be averted or rendered comparatively mild. Until medical assistance can be obtained, the patient's head should be raised, the head and neck bared, and the freest circulation of fresh air promoted; and, as soon as possible, purgative medicines should be administered. The attack may last from a few hours to two or three days; and, even when it does not destroy life, it usually gives a shock to the constitution, which is seldom entirely recovered from.

APOSTASIACEÆ, *a-pos'-ta-si-ai-se-e*, a natural order of plants, named after the genus *Apostasia*, and belonging to the class *Monocotyledones* and sub-class *Petaloideæ*. Herbs with regular hermaphrodite flowers, growing in the damp woods of tropical India. There are three genera and five species.

APOTHECIA, *a-po-the'-shi-a* (Gr. *apotheke*, a repository), the term applied to the spore-fruits of lichens. These contain the *thecæ*, or spore-cases, and occur either as little nodules and raised lines, or as round, shield-shaped, and cup-shaped bodies scattered over the fronds.

APPARENT, *ap-par'-ent* (Lat., *apparere*, to appear), an expression used in Astronomy to denote things as they seem to be to an observer, in contradistinction to their actual or real state. The term is applied principally to diameter, distance, figure, and motion.

Apparent Diameter of a body is the angle formed by two lines drawn from opposite points in the circumference of its disc to the eye; and the apparent magnitude of a body is similar, being the angle formed by two lines drawn to the eye from its opposite extremities. The apparent diameter and magnitude of bodies vary according to their distance from the eye.

Apparent Distance is the distance at which we judge or imagine heavenly bodies to be from us. The apparent distance of the heavenly bodies appears to us to be the same, or nearly so, in all cases, though really so widely different.

Apparent Figure is the shape which an object presents when viewed under different circumstances.

Apparent Conjunction is when one heavenly body comes directly in the line between another heavenly body and the eye of an observer.

Apparent Horizon is the circle which appears to bound the view on all sides, seen most perfectly at sea.

Apparent Noon at any place is the time when the sun is on the meridian of the place in contradistinction to true or mean noon, when the sun would be on the meridian if it moved in its apparent orbit with uniform velocity. (*See* EQUATION OF TIME.)

Apparent Motion is that which bodies appear to have to an observer who is himself also moving. The motions of the sun in the heavens are apparent motions.

Apparent Time. (*See* TIME.)

APPETITE, *ap'-pe-tite* (Lat., *appeto*, I desire), a desire of enjoying something that is apprehended or felt to be necessary or conducive to happiness. In its primary sense, and as used by the Latins, it comprehended every species of desire, whether of a mental or corporeal nature; now, however, it is usually applied only to corporeal desires. Appetites are distinguished from passions in being directed to general objects, while the latter are directed to special objects. Thus we speak of an appetite for fame, glory, or riches. They are also distinguished from passions in the latter having no existence till a proper object be presented; whereas, the former exists first, and then is directed to an object. Natural appetites are given for the preservation of the individual or the propagation of the species. Besides the appetites which nature has given to us for useful and necessary purposes, we may create others which nature never gave, and which are often very hurtful. Appetites seek their gratification without the aid of reason, and often in spite of it. In common language, the term frequently means a vigorous desire of food, and a healthy capacity for enjoying it.

APPLE, *ap'-pel* (Ang.-Sax., *appl*), the fruit of the *Pyrus Malus*, a tree belonging to the sub-order *Pomaceæ*, of the natural order *Rosaceæ* (*See* PYRUS.) All the different kinds of apple-trees now in cultivation are usually regarded as mere varieties of the one species which in its wild state is known as the crabtree. This plant is a native of Britain, and is found in most of the temperate parts of the northern hemisphere. Its fruit is uneatable, but is sometimes collected for the sake of its acid juice, which, when fermented, forms the liquid called *verjuice*, used in cookery and for purifying wax. The cultivated tree was probably introduced into Britain by the Romans, who are said to have had twenty-two varieties. At the present time it is, perhaps, the most widely-diffused, and most valuable of all fruit-trees; and the varieties, which are adapted to almost every soil, situation, and climate in the temperate zone, have become extremely numerous. The apple-tree seldom reaches a greater height than thirty feet, but its large round head makes up for the want of height; and, altogether, it is a noble-looking tree, especially when in full blossom. The flowers grow in bunches, and are very fragrant. They are white inside, and delicately tinged with pink externally. The tree is not always permitted to ramify in a natural manner, but is sometimes trained as an espalier, or as a wall-tree. New varieties are continually being developed; and, as they are generally propagated by grafting, the old ones gradually die out. The variety that produced the *costard*, which was formerly a favourite kind of apple, does not exist at the present time, though we still retain the name of costermongers (*costardmongers*) for itinerant sellers of apples and other fruits and vegetables. The apple is usually grafted on apple or crab stocks; but sometimes hawthorn stocks are used. For producing dwarf trees, stocks of the paradise apple, a very diminutive variety, are generally employed. The apple (we now allude to the fruit, and not to the tree producing it) varies greatly in size, form, and colour. It is regarded by botanists as the type of the kind of fruit to which they have applied the term *pome*. (*See* POME.) The eatable part has a more or less aromatic, sweet, or sub-acid taste, and contains starch, grape-sugar, and malic acid. Apples are commonly divided into dessert, baking, and cider fruits, the first being highly flavoured, the second such as become soft in baking or boiling, and the third those which are hard and austere. Apples are also classed under the general names of Pippins, Pearmains, Rennets, Calvilles, Russets, Codlins, &c. Large quantities of apples are imported into England from France, Canada, and the Northern States of America. The apple of Scripture, mentioned in the "Song of Solomon," was probably the citron. The uses of the apple—for the dessert, for puddings and pies, for preserving and making jelly—are sufficiently well known. Cider, the fermented juice of the apple, is a favourite drink in many parts of England and France. Malic acid, extracted from the apple, has long been used in medicine, and has latterly been largely employed as a mordant in dyeing. (*See* CIDER, MALIC ACID.)

Apple of Love. (*See* TOMATO.)

Appleberry. (*See* BILLARDIERA.)

Apple-Moth (*Carcocopsa pomonella*), one of the most destructive enemies of the apple crop in this country. It lays its eggs in the eyes of the newly-formed fruit, within which the larva feeds. The result is the premature falling of the apple.

Apples of Sodom.—A name given to a fruit, of somewhat fabulous properties, growing, or supposed to grow, "near that bituminous lake where Sodom stood." Josephus, in describing it, endows it with many marvellous characteristics; such as, that, on the fruit being plucked with the hands, it is dissolved into smoke and ashes. It is a kind of gall, about two inches long, growing on dwarf oaks, and produced by a species of gall insects known as *Cynips insana*. The apple is filled with a bitter poison, an easily pulverized substance surrounding the insect. (*See* SOLANUM.)

APPROXIMATION, *ap-prox'-i-mai'-shon* (Lat., *ad*, to, *proximus*, next), in Arithmetic and Algebra, the coming nearer and nearer to a root or other quantity sought, without finding, or expecting to be ever able to find it exactly. By approximation the value of a quantity may be found, if not to the utmost degree of exactness, sufficiently so for practice.

APRICOT, *ai'-pri-kot* (Lat. *præcox*, blossoming early), the popular name for *Prunus Armeniaca*, a fruit-tree belonging to the same genus as the plum. It is a native of Armenia, and the countries eastward, to China and Japan. It blossoms at the very commencement of spring, and bears a fruit resembling the peach, but with yellow flesh. It appears, from Turner's "Herbal," that the apricot was cultivated in Britain in 1562; and in Hakluyt's "Remembrancer," 1582, it is affirmed that it was first brought here from Italy, by Wolfe, a French priest, gardener to Henry VIII. Upwards of twenty varieties are now in cultivation. The trees are generally budded on plum or wild cherry stocks and trained against the walls. The dried fruits are exported from Italy and the south of France. From the bitter keracls which contain prussic acid, the *eau de noyaux* is distilled in France.

A PRIORI, *pri-or'-i*, is a term in Logic, taken from the Latin, and signifying, literally, "from a thing before" as opposed to *a posteriori*, "from a thing after." They distinguish the two different methods of reasoning, the former being applied to arguments from cause to effect, the latter from effect to cause; the one lays down some previous self-evident principles, and then descends to the several consequences that may be deduced from them; the other begins by regarding the phenomena themselves, traces them to the original, and, by developing the properties of these phenomena, arrives at the knowledge of the cause. Kant applies the term *a priori* to knowledge which is absolutely independent of all experience, as opposed to empirical knowledge, or knowledge derived *a posteriori*, through experience. In this sense, the terms are now commonly used by philosophers.

APSIDES, *ap'-si-dees* (Gr., *apsis*, arch, connection), the points in the orbit of a planet, or any heavenly body, at which it is at its least and greatest distance from the sun or body round which it revoles as a centre. The apsides of a planet are its aphelion and perihelion, and those of the moon, its apogee and perigee. (*See* APHELION, PERIHELION, APOGEE, PERIGEE.)

APTEROUS INSECTS, insects without wings; formerly considered as a separate order, but the distinction is not observed by modern naturalists.

APTERYX, *ap'-te-rix*, a genus of birds allied to the ostrich and emu, and, perhaps, more nearly to the extinct dodo. It has a long spike-bill, of which it makes use in supporting itself when at rest. Its wings are simple rudiments—a mere stump, terminated by a hook. Its feathers fall loosely, like those of the emu. Only one species is known (*A. Australes*), a native of New Zealand. It is a nocturnal bird, and preys on snails and insects. The feathers are much prized. The natives call it *Kivi-kivi*, from its peculiar cry.

APTHŒ, *ap'-the*, small vessels formed of the superficial layer of the mucous membrane, caused by fluid secreted by the latter; they are very painful. The complaint to which infants are liable, known as the thrush, is of this character. (*See* THRUSH.)

AQUAMARINE, OR BERYL, *ai-qua-ma-reen'*, a precious stone, much valued as a jewel. (*See* BERYL.) The name is sometimes given to green and blue varieties of the topaz. (*See* TOPAZ.)

AQUARIUS, *a-quair'-i-us* (Lat., water-bearer), a constellation, and the eleventh sign of the zodiac, giving a name to that part of the ecliptic in which the sun is in the latter part of January and the beginning of February. The sign is supposed to have been so called because the weather is generally rainy when it appears on the horizon.

AQUATIC, *a-quat'-ik*, a term applied to plants and animals that live either wholly or partly in water. All plants growing in water may be termed *aquatic;* but, by botanists, the term is usually applied only to those found in *fresh* water, either stagnant or running; as, *Sagittaria*, arrowhead; *Nymphæa*, water-lily; *Potamogeton*, pondweed; *Sabularia*, awlwort; *Utricularia*, bladderwort; *Stratiotes*, water-soldier; *Lemna*, duckweed; the *Confervæ*, and *Oscillatoriæ*. Some of these root in the soil, and appear above the surface of the water; others root in the soil and remain submersed; while others, again, swim freely on the surface, without rooting below. Aquatic animals must not only breathe air, but are adapted for spending great part of their existence on dry land, and are chiefly those that seek their food on water. The peculiarities of structure by which they are fitted for wading, for swimming, for diving, such as the web-feet and plumage of water fowls, the fur of the beaver and otter, and other animals of the clan, are very remarkable.

AQUEOUS HUMOUR, *ai'-que-us*, that watery fluid of the eye which is situated between the back of the cornea and the front of the lens. (*See* EYE.)

AQUEOUS ROCKS, are those which have been formed by deposition from water; in other words, they are the *sedimentary* or *stratified* rocks. Unstratified rocks which have arisen through fusion, are termed, in contradistinction, *igneous*.

AQUIFOLIACEÆ, *ai'-qui-fo'-li-ai'-se-e* (Lat., *folium*, leaf), the holly family, a natural order of dicotyledonous plants, in the sub-class *Corolliflora*. They are evergreen trees or shrubs, with coriaceous and simple leaves, which have no stipules. The flowers are small, axillary, and sometimes unisexual; the fruits fleshy and indehiscent. There are eleven genera and one hundred and ten species, which are widely, although sparingly, distributed over the globe, chiefly in America. Only one species, the common holly, is found in Europe. Bitter, tonic, and astringent properties are commonly possessed by plants of this order. Some are emetic and purgative, while others are largely used as substitutes for China tea. (*See* ILEX.)

AQUILA, *a'-qui-la* (Lat., eagle), the name of a constellation in the northern hemisphere, above the signs of Aquarius and Capricornus.

AQUILARIACEÆ, *a-qui-lair'-i-ai'-se-e* a natural order of dicotyledonous plants, in the sub-class *Monochlamydeæ* There are but six genera and ten species, all natives of tropical Asia. They are handsome trees, with smooth branches and very tough barks. The typical genus is *Aquilaria*, certain species of which yield the fragrant eagle-wood, or aloes-wood, supposed to be the calambac or agallochum of the ancients, the ahalim or aholoth of the Old Testament, and the aloe or aloes of the New. This wood was formerly held in high repute as a medicinal agent in Europe ; but its use is now obsolete.

AQUILEGIA, *a-qui-le'-ji-a* (Lat., a gutter), a genus of plants belonging to the natural order *Ranunculaceæ*. The name *Aquilegia* was given to the genus by the ancients, because the leaves are so shaped that they collect the rain which falls upon them, and retain it for some time. The species are commonly called Columbines, and several of them are cultivated in flower-borders, being handsome perennials. The petals are curiously formed, having each a long curved horn or spur at the base.

ARA, *air'-a* (Lat., altar), in Astronomy, a constellation in the southern hemisphere, not visible in our latitude.

ARACEÆ, *a-rai'-se-e*, the Arads or Arum family, a natural order of monocotyledonous plants, in the sub-class *Petaloideæ*—herbs or shrubs with acrid juices and subterranean tubers, corms, or rhizomes. Their leaves are sheathing, usually net-veined and simple, but in rare instances compound. Their flowers are monœcious (male and female organs in separate flowers), and they are arranged on a spadix within a spathe. The order embraces 30 genera and 170 species. The Arads abound in tropical countries, and some few occur in cold and temperate regions. They are all more or less acrid, and often highly poisonous. The type of the order is the genus *Arum* (which *see*).

ARACHIS, *ar'-a-kis*, a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Papilionaceæ*. The species *A. hypogæa*, a native of the tropical portion of America, is remarkable for ripening its legums under the surface of the ground, which characteristic is indicated by the names *underground kidney-bean* and *ground-nut*, commonly given to it. After flowering, the flower-stalks elongate and bend towards the earth, into which the pods penetrate. Each pod contains two, three, or four seeds, which, when ripe, are about the size of hazel-nuts. These seeds are used as food in various parts of the world; for the plant is now cultivated in Africa (very extensively on the west coast), Asia, and certain portions of Europe, especially France, as well as in its native regions. On being subjected to pressure, the seeds yield a fixed oil, which is extensively employed for cooking in India, where it is called katchung oil. Being a very liquid oil, it has been used in this country for watches, and other delicate machinery, as well as for burning and other purposes. It is also much used in Spain in the manufacture of soap and chocolate.

ARACHNIDA, *a-rak'-ni-da* (Gr., *arachne*, a spider, and *eidos*, form or likeness), a class of articulated animals generally regarded as intermediate between insects and crustacea, differing from the former in respect of having the head and thorax united in one piece ; and from both in having simple eyes and in the absence of proper antennæ. Some breathe by means of pulmonary cavities, others by trachæa like insects ; and upon this difference is founded the primary divisions into two orders—*Pulmonaria* and *Trachearia*. To the first of these orders, spiders and scorpians belong; acari to the the second. (*See* ACARUS, MITE, SCORPIAN, SPIDER, and TICK.)

ARACHNOID MEMBRANE, *a-rak'-noid* literally one of the three membranes which envelop the brain and spinal cord. It is situated between the dura and the pia mater, and is a thin glistening membrane. Between the pia mater and the arachnoid membrane there are in some places spaces filled with a fluid known as cerebro-spinal, the presence of which is necessary to the proper action of the nervous centres. (*See* CEREBRO-SPINAL FLUID.)

ARALIA, *a-rai'-li-a* a genus of plants belonging to the natural order *Araliaceæ*. It contains a considerable number of species—trees, shrubs, and herbs, some of which yield useful products. *A. nudicaulis*, is a native of North America, where its roots are used popularly in the treatment of rheumatic effections. They are commonly known as false or American sarsaparilla, and are sometimes forwarded to this country. The bark of *A. spinosa*, the angelica or toothache-tree, and also a native of North America, is used as a stimulant diaphoretic ; and the berries, infused in wine or spirits, are employed as a cure for rheumatism. *A. polaris*, a native of New Zealand, a shrub grown to the height of about five feet, is, from its orbicular masses of green foliage and waxy flowers, very handsome. From the pith of *A. papyrifera* the Chinese prepare their so-called rice paper. The roots of the *A. edulis* (or *Dimorphanthus edulis*), are eaten in Japan as carrots and parsnips are in Europe. Several species of *Aralia* yield aromatic gum-resins.

ARALIACEÆ, *a-rail-i-ai'-se-e*, Ivy-worts, a natural order of dicotyledonous plants, in the sub-class *Calycifloræ*—trees, shrubs, or herbs closely allied to the umbelliferous plants, but not possessing, in the slightest degree, the poisonous properties so commonly found in those plants. There are 21 genera and 160 species, which are universally distributed ; being found in tropical, sub-tropical, temperate, and the coldest regions. The most interesting genera are described under their respective botanical names. (*See* ARALIA, HEDERA, IVY, PANAX.)

ARAPAIMA, *a-ra-pai'-ma* a genus of fresh water fishes, the largest known sometimes attaining a length of 15 feet. They are found in the rivers of South America, and are taken with a harpoon. They are allied to the herrings, and belong to the family of *Clupesocidæ*. When salted, they are used as food. About six species are known.

ARAUCARIA, *a-raw-kair'-i-a*, a genus of plants belonging to the natural order *Pinaceæ* or *Coniferæ*, the Pines, consisting of gigantic trees, natives of the southern hemisphere, and distinguished by having the male and female flowers on separate plants. The species are all evergreen, and their leaves are considerably broader than those of the ordinary pines and firs. *A. excelsa* (more frequently named *Eutassa excelsa*), commonly called the Norfolk-Island pine, is a most majestic tree, growing to a height of from 160 to 220 feet, and having sometimes a circumference of more than 30 feet. Its timber is white, close-grained, but remarkably heavy, and seldom sound for a great length; the bark abounds in turpentine. This tree occurs in Norfolk Island, New Caledonia, and some parts of Australia. *A. imbricata*, the Chili pine, has been introduced into this country as an ornamental tree, and is now frequently planted on lawns and in shrubberies. Its seeds are edible, and are extensively used for food by the natives of Chili and Patagonia. It is said that the fruit of one large tree will maintain eighteen persons for a whole year. This tree was first found growing on the mountains of the Araucanian Indians, in South America: whence the name of the genus.

ARAUCARITES, *a'-raw-ka-rites*, a term applied to specimens of fossil wood, resembling in structure that of living Araucaria. These fossils are common in the carboniferous strata of Great Britain.

ARBORESCENT, *ar-bo-res'-ent* (Lat. *arbor*, a tree), a term applied to crystals that assume a tree-like form. A small quantity of milk added to a solution of any salt will alter its crystallization to the arborescent form. Very beautiful arborescent metallic crystals may be formed for the microscope by placing an atom of copper in a drop of nitrate of silver, placed on a glass slide. The Arbor Dianæ, or silver-tree, is made by dropping a few globules of mercury into a clean glass bottle, containing a solution of nitrate of silver. If left undisturbed for a few days, beautiful arborescent forms of metallic silver rise from the surface of the mercury, continuing to increase as long as there is any nitrate of silver left in the liquid. (*See* CRYSTALLIZATION.)

In Botany, the term is applied to plants possessing altogether, or in some measure, the character of trees. (*See* TREE.)

ARBOR VITÆ, *ar'-bor vi'-te* (Lat., tree of life). (*See* CONIFERÆ and THUJA.)

ARBUTUS, *ar-bu'-tus*, in Botany, a genus of plants belonging to the natural order *Ericeæ*, consisting of small trees and shrubs, most of them natives of America. The fruit is fleshy and many-seeded; in some species resembling in shape and colour that of the strawberry. The corolla is urn-shaped. The most remarkable species is *A. unedo*, which is a native of the south of Europe and the Levant, but now found also in Asia and America. It is cultivated as an ornamental evergreen-tree in Britain and in Ireland (especially near the lakes of Killarney), where it frequently attains the height of nearly twenty feet. It is commonly called the strawberry-tree. *A. andrachne*, the Oriental arbutus, is even more elegant than the common species; but, at the same time, it is much more delicate, and will not thrive in our variable climate. Its fruit is eaten in Oriental countries. *A. furens* is a small shrub growing in Chili, and yielding a fruit having strong narcotic properties. *A. aculeata*, is a beautiful shrub, which abounds at Cape Horn and on Staten Island, near New York. The red and black bearberries, growing in the north of Europe and Asia, belong to this genus.

ARC, *ark* (Lat., *arcus*, a bow), signifies any part of a curved line. The straight line which joins the extremities of the arc, is called its chord. The practical operation for finding the length of an arc is as follows:—Divide the arc into a number of smaller arcs, making the number large in proportion to the degree of accuracy required, then add together the chords of the smaller arcs. The sum of the chords will differ but little from the arc, even when the subdivisions are not numerous. For every practical purpose, an arc of a circle—and the same may be said of every other curve—is the polygon made by the chords of a moderate number of subdivisions of the arc.

Arc of the Meridian, the curve between any two points of a meridianal line on the surface of the earth, and the form of the curve indicates the size and configuration of the entire globe. Many measurements of arcs have been taken and very exact results arrived at. (*See* MERIDIAN.)

Diurnal and Nocturnal Arcs, the parts of a circle described by a celestial body between its rising and setting and setting and rising.

Arc of Progression, an arc of the zodiac which a planet appears to pass over when its motion is according to the signs.

Equal Arcs are those which contain the same number of degrees and the radii of which are equal.

ARCA, OR ARK-SHELL, *ar'-ka*, a genus of bivalve shells and mollusca, the type of the *Arcadæ*. One species is found on the British shores. Fossil *arcadæ* are very numerous.

ARCHÆOCIDARIS, *ar'-ke-o-sid'-a-ris* (Gr., *archaios*, ancient, *kidaris*, turban), a genus of turban-shaped sea-urchins, found in a fossil state, in carboniferous and Permian strata. (*See* CIDARIS.)

ARCHÆONISCUS, *ar'-ke-o-nis'-kus* (Gr., *archaios*, ancient; Lat., *oniscus*, woodlouse), a genus of fossil crustaceans, occurring in the Purbeck strata, and bearing considerable resemblance to the common woodlouse.

ARCHANGELICA, *ark-an-jel'-i-ka*, the herb Archangel, a genus of plants belonging to the natural order *Umbelliferæ*. The species are mostly herbaceous and perennial, natives of the cold and temperate regions of the northern hemisphere. *A. officinalis*, the garden angelica, is an indigenous biennial, growing in watery places, but somewhat rare in this country. It grows in moist situations, and flowers from June to September, the blossoms being greenish-white. Its root is large and fleshy, resinous, and pungently aromatic. It is imported from Hamburg in the dried state for medicinal purposes, being stomachic and carminative. The plant is cultivated for the purpose of candying in the neighbourhood of London. Large quantities of angelica are consumed by the rectifiers in the preparation of London gin and the liquor known as "bitters."

ARCHEGOSAURUS, *ar'-ke-go-saw'-rus* (Gr., *archegos*, leader, *sauros*, lizard), the name signifying "primeval lizard," given by Goldfuss to a reptile of the Carboniferous era, allied to the existing reptiles, the proteus and lepidosiren. It exhibits a blending together of the characteristics of reptile and fish in one animal. The first specimen, found in the coalfields of Bavaria, was described by Agassiz as a fish.

ARCHER FISH, a curious little fish, the *Toxotes jaculator* of the family of *Squamipennes*, or *Chætodontidæ*, inhabiting the Indian and Chinese seas. Lurking near the surface of the water, it awaits the approach of an insect, and then suddenly squirts at it a drop of water, which infallibly brings it down. It is about seven inches long, and has a wide mouth, with the lower jaw considerably prolonged. Another Javanese fish, the *Chelmon rostratus*, possesses the same power of forcibly ejecting a drop of water. The Chinese keep them in jars, and amuse themselves by watching the effect of suspending a fly above a jar with a thread.

ARCHIL PLANT. (*See* ROCELLA.)

ARCHIMEDES, *ar-ki-me'-dees*, PRINCIPLE OF, a celebrated principle in the science of Hydrostatics, the discovery of which is attributed to the Syracusan philosopher whose name it bears. This important theorem may be thus expressed: when a solid is immersed in a fluid, it loses a portion of its weight, and this portion is equal to the weight of the fluid which it displaces, that is, to the weight of its own bulk of the fluid. The application of this theory is one of the means by which the specific gravity of solids is ascertained. (*See* SPECIFIC GRAVITIES.)

ARCTIA CAJA. (*See* TIGER-MOTH.)

ARCTIC, *ark'-tik* (Gr., *arktos*, a bear), in Astronomy, a term applied to the north pole, or the pole raised above our horizon. It receives its name from the constellation of the Little Bear, the last star in the tail of which nearly points out the north pole.

ARCTIC CIRCLE, in Astronomy, a circle of the sphere parallel to the equator, and distant from the north pole 23° 30'. This and its opposite, the Antarctic Circle, are also called the Polar Circles, wherein the longest day and longest night are 24 hours, and within which at one time of the year the sun never sets, and at the opposite season never rises. (*See* PHYSICAL GEOGRAPHY.)

ARCTIC FOX. (*See* FOX.)

ARCTITIS, *ark-ti'-tis*, or weasel-bear, a genus of marsupial animals, consisting of two Indian species, *A. albifrons*, and *A. ater*. They are about the size of a terrier dog, and have long prehensile tails.

ARCTOMYS, *ark'-to-mes.* (*See* MARMOT.)

ARCTOSTAPHYLOS, *ark-tos-taf'-i-los*, a genus of plants belonging to the natural order *Ericaceæ*. The species *A. uva-ursi*, the common bear-berry, is found wild in the mountainous parts of England and Scotland, and generally over the whole of Northern Europe. (*See* ARBUTUS.)

ARCTURUS, *ark-tu'-rus* (Gr., *arktos*, the bear, and *oura*, tail), a star of the first magnitude, in the constellation Boötes, or *Arctophylax*. The star is so called because it is situated near the tail of the Bear.

ARDEA. (*See* HERON.)

AREA, *air'-e-a*, denotes the same thing as superficies, or quantity of surface; but is applied exclusively to plane figures: thus, we say, the *surface* of a sphere, the *area* of a triangle. In Mathematics, the measuring unit of every area is the square described upon the measuring unit of length: thus, we speak of the square inches, square feet, or square miles which an area contains.

In Building, the open sunken space giving access to the basement of a house.

ARECA, *a-re'-ka*, a genus of plants belonging to the natural order *Palmaceæ*—the Palms, containing two species, each remarkable for the purposes to which it is applied. *A. catechu*—the Pinang, or betel-nut palm, has been described as the most beautiful palm in India. The stem is remarkably straight, and often from 40 to 50 feet high, and generally about 20 inches in circumference. It is cultivated throughout India for the sake of its seeds, which are known as betel, areca, and pinang nuts. The nut, about the size of a hen's egg, is one of the ingredients in the famed masticatory of the East called betel (which *see*). Charcoal prepared from the nuts, and termed areca-nut charcoal, is used in this country as a tooth-powder. An extract is made from the nuts in the south of India; and this constitutes one of the commercial varieties of catechu (which *see*). The timber and leaf-stalks are made use of for various purposes; and in Malabar an inebriating beverage is prepared from the sap. *A. oleracea*, the cabbage-palm, is a native of Jamaica and other West-India islands. The trunk, which is seldom more than six or seven inches in diameter, grows to a height of from 100 to 200 feet. This majestic palm is frequently cut down for the sake of the single terminal bud, called the cabbage, which is eaten either raw or boiled as a vegetable. The nuts, about the size of a filbert, are very abundant. *A. sapida*, the New Zealand palm, is a small tree, but grows farther south than any other palm. *A. vestiari*, an Asiatic palm is so named because clothing is made from its fibres.

ARENACEOUS ROCKS, *a-re-nai'-shus*, are those composed of grains of sand, or which contain sand in any notable degree, as grits and sandstones. Mica or feldspar is frequently found in these rocks. When the rock is coarse-grained, it is called *grit*; when the grains are as large as pebbles, *conglomerate* or *pudding-stone*; and when the fragments are sharp and angular, *breccia*.

ARENARIA, *a-ren-air'-re-a.* (*See* SANDWORT.)

ARENG. (*See* GOMUTO.)

ARENICOLITES, *ar'-en-i-ko-lites*, a term applied to circular holes or markings which have been observed on the upper surface of many sandstones, and which are supposed to have been worm-burrows, like those of the arenicola or lobworm.

AREOLA, *a-re'-o-la* (Lat., a small open space or circle, diminutive of *area*), a term applied to the small interstices of minute cellular or other tissues, through which the smallest vessels and nerves pass, and to the small red or brownish circle which surrounds the niples of females, or the ring which surrounds the pustule of small or cowpox.

ARGALI, *ar'-ga-li* (*Ovis Ammon*), a species of wild sheep inhabiting the mountains of Siberia, Kamschatka, and the higher regions of the Himalayas. The horns of the male of this species of wild sheep are about 4 feet in length and 14 inches in circumference at their triangular-shaped base. The name of the animal is Mongolian, and was adopted by the Russian naturalist Pallas. The

Rocky Mountain sheep, or big-horn, has also been termed the American argali. (*See* SHEEP.)

ARGAN, *ar-gan'*, a small, spiny, evergreen tree, *Argania sideroxylon*, of the natural order *Sapotaceæ*. It is a native of the southern parts of Morocca, and bears an egg-shaped fruit, full of a white milky juice. From this fruit an oil is extracted used by the Moors in cookery.

ARGEL, OR ARGHEL, *ar'-gel*, a plant of the natural order *Asclepiadaceæ*, a native of Arabia. The leaves are frequently used for the adulteration of senna.

ARGEMONE, *ar-gem'-one*, in Botany, a genus of plants belonging to the natural order *Papaveraceæ*, the Poppy family. *A. mexicana*, the Mexican or gamboge thistle, is an annual herbaceous plant, with large yellow flowers, and sessile, waved, and sinuated spiny leaves. It is a native of Mexico and the south parts of the United States, but is cultivated in England and other parts of Europe as an ornamental plant. The seeds possess narcotic and purgative properties, and an oil is obtained from them which has been recommended as a remedy for cholera. In the West Indies the seeds are used as a substitute for ipecacuanha and opium, and the juice of the plant as a remedy for ophthalmia.

ARGENTIFEROUS, *ar-jen-tif'-e-rus*, silver-bearing. Applied to minerals, veins, or metals containing silver.

ARGENTITE, *ar'-jen-tite*, one of the most important ores of silver. It is occasionally found in crystals, but more frequently in malleable blackish lead-coloured masses. It is found in granite and porphyry, in different parts of the world, and consists of 86 parts of silver to 14 of sulphur.

ARGENTINE, *ar'-jen-tine*, a genus of small fishes of the family *Salmonidæ*, found chiefly in the Mediterranean, and occasionally in the British sea. They are remarkable for their silvery lustre, and the air bladder is covered with *nacra*, a coat of silvery fibres, used in making artificial pearls.

ARGES, *ar'-ges*, a genus of small fishes of the family *Siluridæ*, remarkable as being ejected in vast numbers by some of the South American volcanoes. It is supposed that they exist in lakes within the cavernous recesses of the mountains. Several species are known, to which the natives of the region give the name of *preñadittas*.

ARGILE PLASTIQUE, *ar'-zheel plas-teek'* (Fr., plastic clay), the term applied to extensive deposits of sand, with occasional beds of clay, used for pottery, near the base of the tertiary system in France. (*See* EOCENE.)

ARGILLACEOUS ROCKS, *ar-jil'-lai'-she-us* (Lat., *argilla*, clay), are those composed of clay, or having a notable proportion of clay in their composition, as roofing-slate and shale. All such rocks emit a peculiar odour when breathed upon. (*See* CLAY and CLAY SLATE.)

ARGO, OR ARGO NAVIS, *ar'-go*, the ship *Argo*, a constellation, the greater part of which lies in the southern hemisphere. It is of considerable extent, and is divided by astronomers into four parts or regions.

ARGONAUTA. (*See* PAPER NAUTILUS.)

ARGUMENT, in Astronomy, a quantity upon which an equation of other circumstance relating to the motion of a planet depends.

ARGUS PHEASANT, *ar'-gus* (*Argus giganteus*), a rare and beautiful bird, native of many parts of the Indian Archipelago, the peninsula of Malacca, and Siam, and said to exist in some parts of northern China. The tail of the adult male is nearly 4 feet long, and the plumage is wonderfully varied and elegant.

ARIADNE, *ar-i-ad'-ne*, one of the asteroids, or group of small planets, revolving between Mars and Jupiter. (*See* ASTEROIDS.) It is the forty-third in order of discovery, and was first noticed by Mr. Pogson, at Oxford, April 15, 1857.

ARIES, *air'-i-ees* (Lat., a ram), the first of the twelve signs of the zodiac, and a constellation giving its name to a space of 30° of the ecliptic, which the sun enters in March, measured from the vernal equinox. Owing to the constant change of the position of the vernal equinox, arising from the precession of the equinoxes, the sign Aries no longer corresponds with the constellation of that name, but has moved about 30° to the westward of it.

ARILLUS, *a-ril'-lus*, the term applied to an integument which is occasionally found covering, wholly or partially, the *testa*, or outer coat of a seed. The seed of the Passion-flower exhibits this covering, which commences at the base and proceeds towards the apex. In the nutmeg, the additional coat proceeds from above downwards, and constitutes the substance called mace, which is extensively employed as a spice.

ARISÆMA, *ar-i-se'-ma*, a genus of plants belonging to the natural order *Araceæ*, the Arum family. The species *A. atrorubeus*, Dragon-root, or Indian Turnip, is a native of North America. From the tuber a nutritious fecula is obtained. In medicine, the tuber is also occasionally used, being given internally as a stimulant in rheumatism and bronchial diseases, and being also employed as an application to apthous affections in children.

ARISTOLOCHIACEÆ, *a-ris'-to-lo-ki-ai'-se-e*, a natural order of plants of the class *Dicotyledones*, sub-class *Monoclamydeæ*, consisting of herbs or shrubby climbers, which are sparingly distributed in several parts of the world, but are very common in the tropical portion of South America. There are nine genera and 130 species. The typical genus *Aristolochia clematitis*, Birthwort, is distinguished by a tubular oblique perianth, generally inflated at the base, the mouth dilated on one side, and by stamens adherent to the style. Several species of this genus have been employed in medicine, principally on account of their supposed properties for regulating certain functions; and hence the name Birthwort. The roots of *A. longa*, *A. rotunda*, and *A. clematitis* are most commonly used. They have all stimulant and tonic properties. *A. anguicida* is supposed by Lindley to be the celebrated guaco of the Columbians. The juice of the root is said to stupefy snakes, so that they may be handled and played with. *A. serpentaria*, commonly called serpentary, or Virginian snake-root, was originally introduced as an antidote to snake bites, but it is now known that it has no efficacy in such cases. It is a valuable stimulant, tonic, and diaphoretic, and is especially useful in fevers of a low or typhoid character. The roots of *A. reticulata*, *A. tomentosa*, and *A. hastata* are said to be mixed in commerce with those of *A. serpentaria*. Several species of this important genus are cultivated in hothouses as ornamental plants.

ARISTOTELIA, *ar-is-to-te'-li-a*, a genus of plants belonging to the natural order *Tiliaceæ*, the lime-tree or Linden family. The most important species is *A. Maqui*, which produces an edible fruit, from which a kind of wine is prepared.

ARITHMETIC, *a-rith'-me-tik* (Gr., *arithmetike*, derived from *arithmos*), the science of numbers, or that portion of mathematics concerned with the properties of numbers. Every number is a ratio or relation; that is to say, every magnitude, compared with another magnitude, is either equal, or greater, or less, and, therefore, has a certain relation to that with which it is compared. Arithmetic is the art of combining these relations with one another, using for the purpose the signs themselves, by which the numbers are distinguished; thus, the four operations of addition, subtraction, multiplication, and division, include the entire science. For the facilitating of calculations and for commercial purposes, other useful rules have been invented; such as proportion, interest, discount, decimals, extraction of roots, &c.; but they are but different applications of the four elementary rules. The precise epoch in which numerical signs and the first methods of computation and calculation were discovered, is enveloped in mystery; but there can be little doubt that the decimal system, or method of calculation by tens, originated from the custom of children reckoning by the fingers. It was not till the commencement of the 13th century that the science of arithmetic became disseminated in Europe. The employment of the Arabic or Indian numerals, and the facilities afforded by algebra, have been the chief causes of the immense progress and development of modern mathematical calculations. (*See* ALGEBRA, DECIMALS, DUODECIMALS, and the various rules of arithmetic under their proper headings.)

Arithmetical Mean is that number which lies equally distant between two others, and is found by taking half their sum; thus the arithmetical mean between 10 and 16 is 13.

Arithmetical Progression. (*See* PROGRESSION.)

Arithmetical Signs, arbitrary marks or symbols to denote the operations to be performed on numbers. The same signs (+, −, =, &c.) are used in Algebra. (*See* ALGEBRA.)

ARM, *arm* (Lat., *brachium*), is that part of the upper extremity of the body which extends from the shoulder to the wrist. It consists of two portions—the arm, or *brachium*, properly so called, and the fore-arm, or *anti-brachium*; the former having one bone—the humerus; the latter two bones—the radius and ulna. (*See* ANATOMY.)

ARMADILLO, *ar-ma-dil'-lo* (*Dasypus*), a genus of mammiferous quadrupeds of the order *Edentata*, intermediate between the sloths and ant-eaters, and characterized by the possession of molar teeth only. Instead of hair, the armadillos are covered with a species of hard bony crust, forming three bucklers, on the rump, shoulder, and head, respectively; the two latter being connected by a number of transverse movable bands, very similar in form and appearance to the plate-armour of the Middle Ages, from which, indeed, these animals have acquired their name of armadillos—a name of Spanish origin, and adopted by English writers. The anterior surface of the body, not covered by the buckler, is clothed with coarse scattered hairs, of which some are also seen to issue forth between the joints of the armour. It has rather a pointed snout, long ears, short and thick limbs, and stout claws, which are in every respect adapted for digging and burrowing. So rapid, indeed, do the armadillos perform this operation, that they easily bury themselves in the earth beyond the reach of the hunter, who has no other resource but to smoke out his obstinate game. Once brought to the surface, however, the animal becomes an easy prey, as its only defence is to roll itself up hedgehog-wise, and await an assault. They are, however, by no means easily unkennelled, and have been known to allow a hunter to hack their tails off while they held on in the depths of their burrow by their powerful claws. The animal never attempts to bite any one by whom it is attacked. Its food consists of roots, fallen fruits, worms, and carrion if it can be obtained. The tropical and temperate regions of South America are the original and proper habitation of all the known species of the armadillo.

Crustacea.—Armadillo is the scientific name of a small animal of this genus, popularly known as the woodlouse, or fell-beetle, from its power of rolling itself into a ball when threatened.

ARMERIA, *ar-meer'-i-a*, a genus of plants belonging to the natural order *Plumbaginaceæ*. Thrift is the common English name for this genus. The dried flowers of the common thrift, *A. vulgaris*, are diuretic.

ARMILLARY SPHERE, *ar-mil'-la-re* (Lat., *armilla*, a bracelet), an instrument representing the great circles of the celestial sphere, the equator, ecliptic, tropics, equinoctial colure, &c. It is constructed of rings of metal, representing those circles, fastened together in their relative positions, and movable on an axis passing through the poles: it is furnished with a horizon and meridian similar to those attached to the terrestrial and the celestial globes. It was formerly much used by the early astronomers, but is now superseded by the celestial globe. The earth on which the observer stands is supposed to be in the centre of this skeleton sphere, the rings representing the imaginary circles above named, traced on the apparent sphere of the heavens around him, by which the position of any star may be determined. (*See* ASTROLABE.)

ARMORACIA, *ar-mo-rai'-si-a*, a genus of plants belonging to the natural order *Cruciferæ*. The species *A. rusticana* is cultivated for the sake of the root, which is the common *horse-radish*, so much used as a condiment. (*See* HORSE-RADISH.)

ARNEE, *ar-ne'* (*Bos Arnee*) an animal of the highlands of Hindostan, closely allied to the common wild buffalo. It is the largest animal of the ox kind known, and remarkable for strength and courage, qualities admirably seconded by a pair of horns measuring from four to six feet in length, and arching in the form of a bold crescent. In Bengal this animal is known as *Arria*.

ARNICA, *ar'-ni-ka*, a genus of plants belonging to the natural order *Compositæ*. The most important species is *A. montana*, known by the names of Mountain-tobacco, and German Leopard-bane. It is a perennial herbaceous plant, found growing in the meadows of the cooler parts of Europe, and also of the western states of North America. The florets are of a yellow colour, tinged with brown. The whole plant, when fresh, possesses a strong and disagreeable odour and an acrid, bitter taste. The plant has striking medicinal properties. The preparation known as tincture of Arnica, which is obtained by macerating the flowers with alcohol, is now largely employed as an external application for bruises. The flowers have been occasionally employed as a substitute for Peruvian bark, and are said to have proved beneficial in cases of amaurosis and chronic rheumatism. Preparations of arnica are much used by homœopathists.

ARNOTTO. (*See* ANNATTO.)

AROMA, *a-ro'-ma* (Gr., pleasant perfume), the principle in plants or other substances which constitutes their fragrance. In some plants this resides in a volatile oil; but in others the portion containing this principle cannot be detected.

ARRACACHA, *ar-ra-ka'-ka*, a genus of plants belonging to the natural order *Umbelliferæ*. It includes one species of great importance, namely, *A. esculenta*, a plant much cultivated in the tropical regions of South America for the sake of the root, which is a valuable article of food. This is about the size of a parsnip, which it somewhat resembles in flavour. The starch obtained by rasping and washing the root is similar to arrowroot.

ARROWHEAD, a genus of aquatic plants. (*See* SAGITTARIA.)

ARRHENATHERUM, *ar'-hen-a-the'-rum* (Gr., *arrhen*, mole, and *ather*, awn, or hairy pointed beard of corn or other grasses), a genus of grasses, of which the *A. avenaceum*, a common grass in Britain, sometimes known as oatlike-grass, is a familiar specimen.

ARTANTHE, *ar-tan-the*, a genus of plants belonging to the natural order *Piperaceæ*. The species are natives of the tropical regions of America. The dried leaves of *A. elongata* are much used in medicine. (*See* MATICO.) The dried fruits of *A. adunca* are employed as a substitute for pepper. The spikes of fruit of *A. crocata* are used for dyeing yellow.

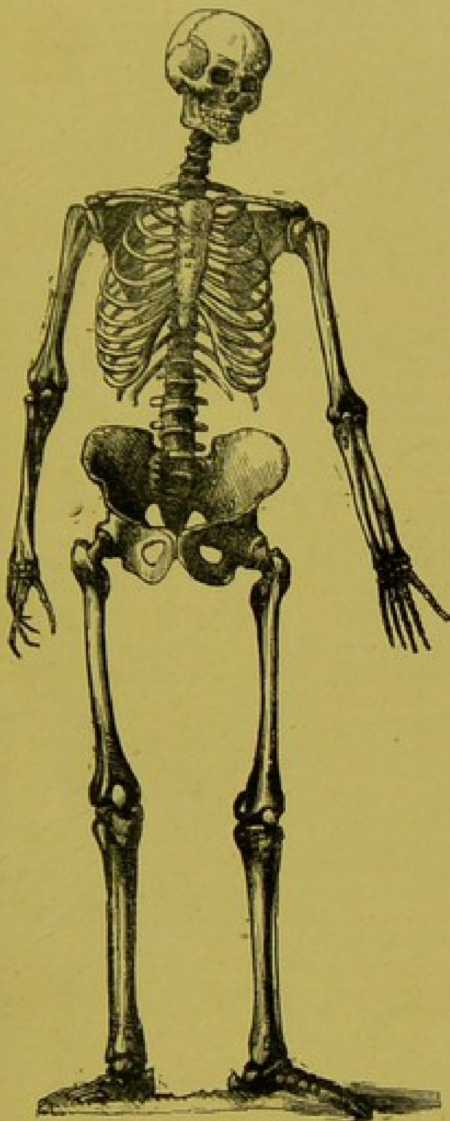
ARTEMISIA, *ar-te-mis'-i-a* (from *Artemis*, one of the names of the goddess Diana), a genus of plants belonging to the natural order *Compositæ*, sub-order *Corymbiferæ*, and comprehending several interesting and valuable species. *A. absinthium*, the common wormwood, is an indigenous perennial, often met with in waste places and by roadsides. The flowers are arranged in globular heads, and are of a buff or yellowish colour, blossoming in August. The principal constituents are a volatile oil, a bitter principle called absinthin, and carbonate of potash. The latter was formerly known as "salt of wormwood;" but it possesses no specific virtue other than belongs to carbonate of potash generally: it is still, however, regarded as a patent remedial agent by the ignorant. The dried herb, or flowering-top, under the name of wormwood, is used as an aromatic bitter tonic, and as an anthelmintic. It is also employed in the preparation of liqueurs. The species *A. abrotanum* is the familiar southernwood, a fragrant plant employed on the Continent in making beer. The Persian species *A. acetica* is said to have the odour of strong vinegar; hence its name. The species *A. alba* and others are said to serve as nourishment to the herds of the Kirghese and Calmucs. The anthelmintic known by the names Semen-seriphii and Barbotine consists of the flower-heads of *A. cœrulescens*, a Mediterranean plant. *A. chinensis*, and other species, are stated by Lindley to yield the Moxa of China. It is prepared from the cottony or woolly covering of the leaves, and used as a cautery, by burning it upon parts affected with gout and rheumatism. (*See* MOXA.) *A. dracunculus* is the tarragon, the leaves of which are used for flavouring vinegar in pickles and salads. *A. gallica*, termed in France sanguerie or sanguerite, possesses similar properties to the species *cœrulescens*. *A. indica* and *madraspatana*, both Indian species, are much used by the native doctors. *A. mutellina* and *spicata*, both Alpine plants, are said to furnish between them the famous liquor called *crême d'absinthe*, which a modern French writer styles "the emerald poison." The substance sold as wormseed, and known under the names of semen-contra, semen-cinæ, and semen-santonicum, consists of the broken flower-stalks, involucres, and flower-buds of *A. contra*, *pauciflora*, *lercheana*, *sieberi*, and *valiana*. It is employed as a vermifuge.

ARTERY, *ar'-te-re* (Gr., *aer*, air, and *tereo*, I keep), is literally an air-duct, and was a name applied by the ancients to certain vessels of the human body, which were believed by them to contain air, from their being found empty after death. The arteries are those vessels which convey the blood from the heart to all parts of the system. They are membraneous cylindrical tubes, composed of three coats; viz., the external, which is firm, strong, and elastic; the middle, which is muscular, contractile, and brittle; and the internal, which is brittle, smooth, and transparent, and lined with epithelium on the side washed by the blood. The action of the arteries called the pulse corresponds with that of the heart, and is effected by the contraction of their muscular coat and the great elasticity of their outermost one. Besides the arteries which carry the purified blood from the heart to all parts of the body, there is the pulmonary artery, which emerges from the right ventricle of the heart, and carries the impure blood from the heart to the lungs. The other arteries all spring from the aorta. (*See* ANATOMY.) The principal arteries will be found noticed under their respective names.

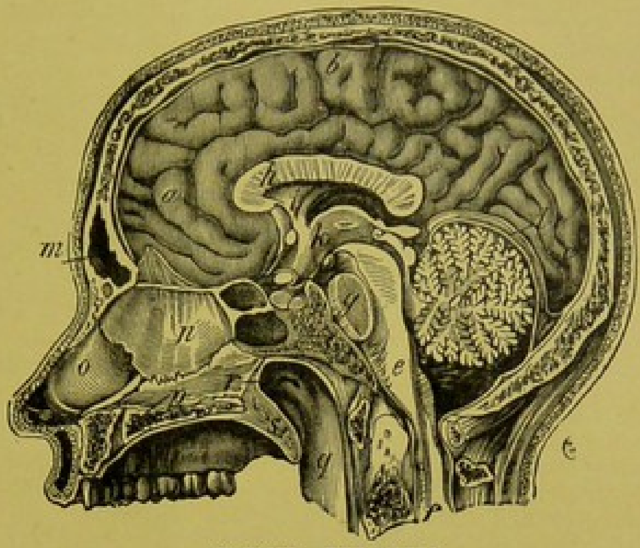
ARTHRON, *arth'-ron*, is a Greek word signifying a joint, and, in composition, is used in a number of medical terms; as, *arthrosis*, an articulation; *arthritis*, inflammation of a joint, the gout; *arthrodynia*, pain in a joint; *arthropuosis*, a collection of pus in a joint; *arthrodia*, a species of articulation, in which the head of one bone is received into the superficial cavity of another, so as to admit of motion in every direction.

ARTHRODIC, *ar-thro'-dik* (Gr., *arthrosis*, articulation), in Anatomy, a term applied to a connection of bones, in which the head of one fits into a shallow cavity in another; by which means motion in nearly every direction is admitted of; as, for example, in the joint between the humerus and the scapula.

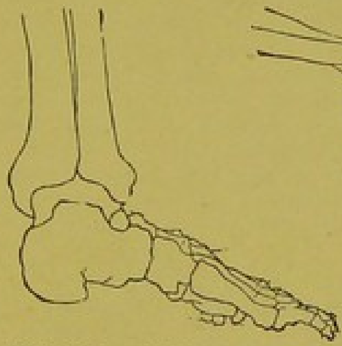
ARTHRODIEÆ, *ar-thro-di'-ee* (Gr., *arthron*, a joint), a term applied to such algæ as possess an articulated structure, like *Conferva* and *Oscillatorias*.



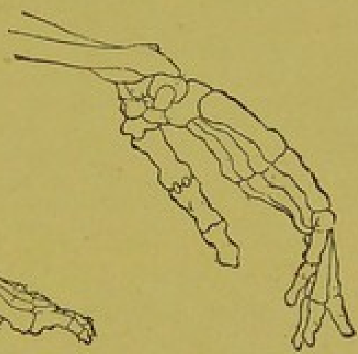
ANATOMY.—THE HUMAN SKELETON.



ANATOMY.—THE SKULL.



ANATOMY.—BONES OF THE FOOT.



THE HAND.

ARGUS PHEASANT.

ANTEATER.

ARTICHOKE, *ar'-ti-choke* (Fr., *artichaut*). This esculent is the young succulent receptacle of the flower-head of *Cynara Scolymus*, a perennial plant growing wild in the south of Europe, and extensively cultivated in this country. On the Continent, the artichoke is frequently eaten raw with salt, pepper, and oil; but in England it is generally boiled before it is sent to the table. (*See* CYNARA.) The esculent tubers of a species of sunflower, *Helianthus tuberosum*, are known as Jerusalem artichokes; the term Jerusalem being a corruption of the Italian *girasole*, "sunflower." (*See* HELIANTHUS.)

ARTICULATA, OR ARTICULATED ANIMALS, *ar-tik-u-lai'-ta* (Latin, *articulatus*, jointed), according to the classification of Cuvier, the third great division of the animal kingdom. Arthropoda is the designation now generally adopted. (*See* ARTHROPODA.)

ARTICULATION, *ar-tik'-a-la-shun*, in Anatomy, the connection of the bones of the skeleton by joints. (*See* ANATOMY.)

ARTOCARPACEÆ, *ar'-to-kar-pai'-se-e* (Gr., *artos*, bread, *karpos*, fruit), a natural order of dicotyledonous plants, consisting of 30 genera and about 60 species—trees or shrubs, found only in tropical regions, having a milky juice, which contains caoutchouc, or India-rubber, dense heads of unisexual flowers, and, generally, fruits of the sorosis form. The typical genus, *Artocarpus*, or bread-fruit, includes two very important food-producing trees, namely, *A. incisa* and *A. integrifolia*. The first species is a native of the Moluccas and islands of the Pacific; it yields the nutritious bread-fruit which supplies the place of corn to the natives of the regions in which it flourishes. The milky juice of some species yields CAOUTCHOUC, and from one, popularly known as the Cow-tree, a substitute for milk is obtained. The species *A. integrifolia* yields the Jak, or Jack-fruit, which is largely used as food in Ceylon and some other parts of the East. (*See* SOROSIS.) The natural order *Artocarpaceæ* includes other interesting genera, which are noticed under the botanical names. (*See* ANTIARIS, BROSIMUM, PHYTOCRENE.)

ARUM, *air'-um* (formerly *aron*, supposed to be an ancient Egyptian word), the typical genus of natural order *Araceæ*. The only British species is *A. maculatum*, the common cuckoo-pint, wake-robin, or lords-and-ladies, and probably the long purples of Shakspeare. This curious perennial is found growing in shady places, hedge-banks, rough grounds, and groves. The flowers, which come to perfection in April and May, are monœcious; that is, the sexes are contained in different flowers on the same plant. They are arranged on a succulent axis, terminating in a club-shaped receptacle termed a spadix, of a purple or yellowish-white colour, and inclosed in a membranous sheath denominated a spathe. The berries are of a fine scarlet colour, and help to adorn our hedges in autumn. They are very poisonous, and the whole plant contains acrid and poisonous juices. The tubers, which are filled with starch, are dried, powdered, and used in France as a cosmetic, under the name of cypress powder. The starch, separated from acrid juices, forms Portland arrowroot, which was formerly prepared in large quantities in the island of Portland, where the plant grows in great profusion. In the fresh state, the tubers are stimulant, diaphoretic, and expectorant, and were formerly used in the form of an emulsion in obstinate rheumatism.

ARUNDO, *a-run'-do* (probably Lat., *arundo*, reed, or from Celtic *aru*, water), a genus of grasses, the species of which frequently attain a considerable size, and are found in many climates. *A. phragmites*, the common reed, is a well-known species, the culms being largely employed for thatching and other useful purposes.

ARYAN RACE, *a'-re-an* (Sanscrit, "honourable"), the name generally given by ethnologists to that division of mankind otherwise called Indo-European or Indo-Germanic. The first traces of the race are found in Central Asia, eastward of the Caspian Sea, and north of the Hindoo-Koosh mountains. From this centre migrations took place, probably impelled by the necessity arising from increased numbers, the movement beginning about two thousand years before the Christian era. Large numbers moved towards the north-west, probably reaching Europe; others crossed the Indus and penetrated into the great peninsula of Southern Asia. The three higher castes of India still claim to be of Aryan descent, as superior to the lower or subjugated castes, the Sudras, and the third caste is specially named Aryan. From India, the Aryans reached Persia, and others settled in Asia Minor, from which a further migration took place to Southern and Central Europe. In the Veds the sacred books of the Hindoos, Arya is the name by which the believers in the gods are distinguished from their enemies, who are called Dasas. Iran, the old name assumed by the dominant races of Persia, is evidently derived from the same root. In the Persian cuneiform inscriptions, Darius claims, with apparent pride, that he was of Aryan descent.

ASAFŒTIDA, OR ASSAFŒTIDA, *as-sa-fe'-ti-da* (Persian, *asa*; Lat., *fœtidus*, fetid), the name of a fetid gum-resin, used in medicine on account of its anti-spasmodic and more or less stimulating properties, and extensively employed in Persia and the adjacent countries as a condiment, just as garlic and other allied plants are employed in Europe. The umbelliferous plant *Narthex*, or *Ferula asafœtida*, yields the greater part of the asafœtida of commerce. The peculiar, and, to Europeans, offensive odour of asafœtida, is attributed to the presence of sulphur in combination with allyle. (*See* ALLYLE.)

ASAGRÆA, *as-a-gre'-a*, a genus of plants belonging to the natural order *Melanthoceæ* or *Colchicaceæ*. The most important species is *A. officinalis*, a native of Mexico, and the principal, if not the only source of the *Sabadilla*, *Cevadilla*, or *Cabadilla* of the shops, which consists of the fruits and seeds. The seeds yield any alkaloid, which has been used externally as a remedy for rheumatism, gout, and neuralgic affections, and also internally in similar cases, in doses of one-twelfth to one-sixth of a grain. It is a most powerful poison. Sabadilla seeds, when powdered and applied externally, destroy vermin.

ASAPHUS, *as'-a-fus* (Gr., *asaphes*, obscure), in Geology, a genus of trilobites. (*See* TRILOBITE.)

ASARABACCA. (*See* ASARUM.)

ASARUM, *as'-a-rum* (Gr., *a*, not, *saron*, feminine), a genus of plants belonging to the natural order *Aristolochiaceæ*. The species *A. europæum*, a native of Europe, is a rare plant in the woods of Britain. The root which forms the drug asarabacca contains a camphor-like principle, and a bitter principle called *asarin*, which is combined with gallic acid. It was formerly much employed as an emetic; but has been superseded by ipecacuanha, which is milder and safer. It is still occasionally used as an errhine—that is, a medicine to be snuffed up the nose in headache and ophthalmia. The species *A. canadense*, the Canada snake-root, or wild ginger, is another medicinal plant, the rhizome being used in the United States as a tonic, diaphoretic, and aromatic stimulant.

ASBESTOS, OR ASBESTUS, *as-bes'-tos* (Gr., *asbestos*, incombustible), a fibrous variety of hornblende, so soft that it can be spun and woven into fabrics. It is remarkable for being incombustible; and for this reason it was used by the ancients for wrapping up their dead before placing them on the funeral pile, in order that none of their ashes might be lost. They also used it for napkins, which, when soiled, were passed through the fire. They likewise used it for lamp wicks, composed chiefly of silica, magnesia, alumina, and ferrous oxide. The finest variety is known as Amianthus, from a Greek word signifying "unpolluted." It is very plentiful in Corsica, and is found also in Savoy, Scotland, the Shetland Islands, and many other places. Common asbestos, inferior in quality, is found in serpentine rocks; and other varieties of small value are known as mountain leather, mountain cork, and mountain wood. The latter melts before the blowpipe. Fireproof cloth has been woven from asbestos fibre, but its feeble consistency is an objection to its use for that purpose. Paper has also been made from it, and it was supposed that it would be invaluable for the preservation of important documents in case of fire, but it was found that, although flames could not destroy the paper, they effectually obliterated the writing. More practical use is made of the fibre as a packing for fireproof safes and pistons of steam engines.

ASCARIDES, OR ASCARIS, *as-kar'-i-dees* (Gr., *askarizo*, I jump), parasitic worms which inhabit the intestines of animals. They belong to the genus *Entozoa*, and are ranked in the order *Nematoidoa*. One of the commonest species, the *A. lumbricoides*, which is very like the common earthworm, is found frequently in the intestines of men, and of horses, oxen, &c. They have been observed fifteen inches in length, and they are often the cause of severe disease, which has sometimes proved fatal. The mouth of this worm is only formed for suction; hence it is unable to injure the coating of healthy intestines. In a very young state, ascarides have never been found either in man or the other animals. Persons living in damp valleys are said to be most liable to suffer from them. The *A. vermicularis*, or threadworm, is very common among young children. It is white, and about half-an-inch long. It infests the lower part of the intestines in great numbers, causing much irritation. Though so small, it possesses a highly developed nervous system. (*See* VERMIFUGE, THREADWORM.)

ASCENSION, RIGHT, *as-sen'-shun* (Lat., *ascensio*, a rising, a term in Astronomy. The right ascension of any heavenly body is the arc of the celestial equator intercepted between the first point of Aries and the meridian, or circle of declination passing through the object, or the distance east from the meridian, passing through the first point of Aries measured on the equinoctial or celestial equator. It corresponds with longitude on the terrestrial globe; and as the position of any place on the earth is determined by its longitude and latitude, so the position of any object in the heavens is determined by its right ascension and declination. (*See* DECLINATION.) The right ascension of any heavenly body is ascertained by the aid of a transit-instrument and sidereal clock, the former showing its passage across the meridian, and the latter indicating the time when the passage takes place. The sidereal clock beats seconds, and is so constructed and regulated, that the hour hand describes a complete revolution in 24 hours from the time of the passage of any star across the meridian to its return to the same point.

Oblique ascension is the arc of the celestial equator intercepted between the first point of Aries and that point of the equator which rises at the same time with any heavenly body.

Ascensional difference is the difference between the right and oblique ascension of any object.

ASCIANS, *ash'-i-ans* (Gr., *a*, not, and *skia*, shadow), a term applied to those inhabitants of the globe who at certain times of the year have no shadow. Such are the inhabitants of the torrid zone, where the sun being twice a year in its zenith,—in other words, being vertically above their heads,—no projecting shadow is thrown.

ASCIDIANS, *as-sid'-i-ans* (Gr., bottle-shaped, from *askos*, a leather bottle), a term usually employed to distinguish a genus of molluscan animals, found in all seas. The type of the family *Ascidiadæ*. They are acephalous; that is, without heads, and are encased in a kind of elastic tunic, inclosing a second mantle or tunic, which is muscular, and adheres to the first only near two orifices. Their nature is very apathetic, and they remain fixed to a rock or a piece of seaweed, living upon the animalculæ which are drawn in with the water that is constantly passing through their ciliated respiratory organs. The action of the *cilia* seems to be involuntary. The sexes of ascidians are distinct; and their chief nervous centre is situated between the openings of the muscular tunic. In 1828 MM. Milne-Edwards and Audouin discovered that an ascidian does not begin life as a fixed animal, but was able to move about like tadpoles, by means of a vibrating tail. After a time it attaches itself to a plant or rock, and the tail disappears. Many of the ascidians are splendidly coloured, and often cling about seaweed like bunches of strange fruit. They are divided into two classes—compound and solitary ascidians. (*See* POLYPE, ZOOPHYTE.)

ASCITES, *as-si'-tees* (Gr., *askites*, from *askos*, a bottle), a term employed to denote abdominal dropsy, or dropsy in the belly. (*See* DROPSY.)

ASCLEPIADACEÆ, OR ASCLEPIADEÆ, *as-kle-pi-a-dai'-se-e*, the *Asclepias* or Milk-weed order of dicotyledonous plants, included in the sub-class *Corolliflorœ*—shrubs or trees commonly lactescent, and frequently with twining stems. The order is at once distinguished by a curiously-formed five-cornered stigma, and by the grains of pollen cohering in wax-like masses, which, when the anther dehisces, become attached to glands at the angles of the stigma. There are

157 genera and about 930 species, which are mostly tropical, abounding in South Africa, India, and equinoctial America. Some are cultivated in British gardens and hothouses for the sake of the beautiful or curious flowers they bear. (*See* ASCLEPIAS, CALOTROPIS, CYNANCHUM, HEMIDESMUS, GYMNEMA, and MARSDENIA.)

ASCLEPIAS, *as-kle'-pi-as* (Gr., name of Æsculapius, the god of medicine), a genus of plants, the type of the natural order *Asclepiadaceæ*. The common English name for the genus is Swallow-wort. The species are mostly American, and many of them possess powerful medicinal qualities, as one might expect from the generic name. They are herbaceous plants, seldom of a twining habit, with opposite, whorled, or alternate leaves, and flowers arranged in simple umbels between the leaf-stalks. The corolla is five-parted and reflexed. The stamens, five in number, alternate with the lobes of the corolla, and have curious horn-like appendages. The species *A. syriaca*, Syrian or Virginian swallow-wort, was formerly thought to be a native of Syria, but is now regarded as an American plant. The white acrid juice of this plant contains caoutchouc. The seeds are covered with down, which is frequently employed in America for making wadding and for stuffing pillows and mattresses. The stalks furnish a very tough fibre, which is used for the manufacture of thread, cloth, ropes, and nets. Sugar has been prepared from the flowers. *A. curassavica*, the bastard ipecacuanha, is another important species. It is a native of the West-Indian islands, where the root is employed by the negroes as an emetic, and is occasionally sent to England as ipecacuanha. From the stems of *A. tenacissima* the Jetee or Tongoose fibres are obtained. The root of *A. tuberosa* is sometimes used as a diaphoretic and expectorant. The last-named plant, which is commonly known as the butter-fly weed or pleurisy-root, is frequently cultivated as an ornamental garden flower. In Arabia the young shoots of *A. stipitaceæ* are eaten like asparagus.

ASH, (Ger., *esche*,) a genus of trees belonging to the natural order *oleaceæ*. The botanical name is *Fraxinus*. There are about fifty species, mostly natives of Europe and North America. The leaves are deciduous, and are pinnate, with a terminal leaflet. The flowers are very imperfect, the calyx being obsolete, and the corolla either wanting or 3—4-partite. The fruit is a *samara* (which *see*). *F. excelsior*, the common ash, a native of Britain, is a beautiful and umbrageous tree, rising to the height of 100 to 150 feet. The wood is white, tough, hard, and light, much valued by wheelwrights, coachmakers, and turners. It is peculiarly adapted for agricultural implements, handles for tools, and ladders. Sometimes it is irregular in the disposition of its fibres and finely veined, and is then prized by cabinet-makers. Some interesting varieties have been developed by cultivation: the weeping ash, with branches drooping to the ground; the curled-leaved ash, with dark green wrinkled or curled leaves; and the entire-leaved ash, with many or all the leaves simple. *F. americana*, the American or white ash is a very fine tree, common in Canada and New Brunswick, with wood similar to that of *F. excelsior*. The sweet concrete exudation known as *manna* is procured by making incisions in the stems of certain species of *Fraxinus*, chiefly *F. ornus* and *rotundifolia*, natives of Calabria, Apulia, and Sicily. Manna is a mild agreeable laxative. It owes its properties to a peculiar resin called mannite. The insect which produces the white wax of China feeds upon the species *F. chinensis*. The mountain ash belongs to a different natural order. (*See* ROWAN.)

ASOCA, *a-so'-ka*, an Indian tree (*Jonesia asoca*) of the natural order *Leguminosæ* sub-order *Cæsalpineæa*, remarkable for the beauty of its red and orange flowers. It is often mentioned in Indian poetry, and figures in the Hindoo mythology.

ASP, *asp* (Lat. *aspis*), a name confined by naturalists to the *Vipera aspis*, a venomous snake peculiar to the European Alps, but commonly applied to several species of poisonous serpents. The asp is often mentioned by both Greek and Roman writers; but the most common and celebrated would seem to be that called by the Arabs Haje Nasher. This animal measures from three to five feet in length, is of a dark green colour, marked obliquely with bands of brown. The haje is closely allied to the cobra di capello, or spectacled snake of India. Old writers give the name to several kinds of poisonous snakes; and the asp by which Cleopatra is said to have ended her life is generally supposed to have been the cerastes, or horned viper, a much smaller snake. The asp, four times mentioned in the Old Testament is generally considered to be synonymous with adder.

ASPARAGUS, *as-par'-a-gus*, a genus of plants belonging to the natural order *Liliaceæ*, the Lily family. The species are herbaceous, or shrubby plants, growing wild in the southern parts of Europe and in Africa. *A. officinalis*, the common asparagus, has long been cultivated for the sake of the young succulent shoots, which form a much esteemed article of food, on account of its delicate flavour. There are many local varieties of asparagus, but they may all be regarded as slight modifications of two well-marked sorts, namely, the red-topped and the green-topped. In the kitchen-garden asparagus is generally grown in beds four feet broad, and in rows a foot or eighteen inches apart, with the space of nine inches between every two plants in the rows. The plants are either raised from seed where they are to remain, or raised on a seed-bed the preceding year, and transplanted. The value of the crop depends on the soil being dry, sandy, well trenched, and powerfully manured. The trenches should be from two and a half to three feet deep. Asparagus-shoots contain a peculiar crystalline principle, to which the name *asparagin* has been given: this has a specific action on the urinary organs, and its properties have caused asparagus to be popularly employed as a lithic; but it is a somewhat dangerous remedy, and is now obsolete. The shoots, roots, and flowering stems of *A. officinalis* are, however, occasionally employed as diuretics. The roasted seeds have been used as a substitute for coffee. The young shoots of the species *A. tenuifolius*, *A. acutifolius*, and especially *A. albus*, are eaten in the south of Europe. Under the name of Prussian asparagus, the spikes of an allied plant, *ornithogalum pyrenaicum*, are sometimes used.

ASPECTS, *as'-pects*, in Astronomy, certain positions of planets with respect to one another as seen from the earth. Astrology ascribed to these aspects great influence over the destinies of individuals and nations.

ASPEN, *as'-pen*, the trembling-leaved poplar (*Populus tremula*), a tree, a native of northern Europe and Asia, found sometimes in Scotland, at a considerable elevation above the sea; and in favourable moist soils reaching a height of 80 to 90 feet, but in other places dwarfish. The name is derived from the almost continued movements of the leaves, suspended by flattened leaf-stalks. The wood is soft, light, and porous, readily worked at the turning lathe, and well adapted for arrows. In France, sabots are made of it. Charcoal made from the wood is used in the manufacture of gunpowder; and, in some parts of Europe, cattle, sheep, and goats are fed on the leaves. There are trees of a similar species in North America. (*See* POPLAR.)

ASPERGILLUM, *as-per-gil'-lum* (Latin, *aspergo*, to sprinkle, a genus of conchiferous mollusca, in which the shell has the form of an elongated cone, terminating at the larger end in a disc, with numerous small tubular holes, from which the popular name, the watery-pot, originated. A remarkable feature in the structure of the shelly tube is the presence of two rudimentary valves, which are in themselves useless, but show an affinity with mollusca inhabiting bivalve shells.

ASPERGILLUS, a genus of plants, containing many of the small fungi, commonly known as mould, which appears in decaying vegetable and animal substances.

ASPERULA, *as-pe-ru'-la* (diminutive of Lat., *asper*, rough), a genus of plants belonging to the natural order *Galiaceæ*, the Madder family. The species *A. adorata*, the woodruff, is one of the most fragrant plants found in our woods: it contains the natural perfume to which chemists have given the name of *coumarin*. *A. cynanchicha*, another indigenous species, is commonly called quinsey-wort, on account of its supposed value as a remedy in sore throat.

ASPHODE, *as-fo-de* (Gr., *a*, not, and *sphallo*, I supplant), a genus of plants belonging to the natural order *Liliaceæ*, the Lily family. It includes several beautiful perennials, with fleshy finger-like roots and upright annual stems covered with long leaves. The yellow and white asphodels, *A. luteus* and *A. albus*, have long been cultivated in Britain as garden-flowers. Immense tracts of land in Apulia are covered with the latter species, which affords good nourishment to the sheep. In ancient days it was sacred to Proserpine, and used in funeral ceremonies.

ASPHYXIA, *as-fix'-ia* (Gr., *a*, not, and *sphuxis*, pulsation), literally signifies cessation of pulsation, and is used to denote that state of body during life in which the pulsation of the heart and arteries cannot be perceived. The action of the lungs is suspended, and the blood no longer undergoes that purifying process so necessary to life. Hence the body becomes filled with impure blood, the powers of sensation and voluntary motion are suspended, and, if the proper means of restoration are not resorted to, death will speedily ensue. Asphyxia may be produced by various causes; as by whatever prevents the access of air to the lungs, strangulation, drowning, choking, &c.; or whatever interferes with the action of the nerves that are concerned in respiration, as paralysis, cold, stroke of lightning, &c. It may also be produced by breathing an impure or a too rarified atmosphere.

ASPIDIUM, *as-pid'-i-um* (Gr., *aspidion*, a little buckler), a genus of ferns (which *see*). The fronds of the species *A. fragrans* possess aromatic and slightly bitter properties, and have been used as a substitute for tea.

ASPIDURA, (*as-pi-du'-ra* (Gr., *aspis*, shield, *oura*, tail), a genus of fossil star-fishes, so named from the buckler-like arrangement of the bony plates which protect the arms.

ASPLENIUM, *as-ple'-ni-um* (Gr., *a*, not, *splen*, spleen), a genus of ferns, included in the sub-order *Polypodieæ*. Many species are common in Great Britain, being known as spleen-worts. They were formerly used in medicine, but have now fallen into disuse. *A. ruta-muraria* is popularly known as wall-rue. *A. trichomanes* is an elegant little fern, common on rocks and old walls: it is often cultivated in cases and on garden rockwork.

ASS, *ass*, (Lat., *asinus*), *Equus asinus*, an animal too well known, at least in a domestic state, to need description here. It is found wild in the same parts of Asia as the horse, and it is there that we find it make the best figure in a state of domestication. In those countries it would seem that the ass was tamed before the horse; and to this day, in the East, asses are far more generally used as beasts of burden and draught than horses. There, however, instead of being despised and neglected, care is taken to cultivate the breed, by crossing the finest specimens. Even the wild ass is procured for this purpose. The ass is, properly speaking, a mountain animal. Its hoofs are long, and furnished with an extremely hard rim, leaving a hollow in the centre, by which means it is enabled to tread with more security on the slippery sides of hills and craggy places. The ears are larger when in a domesticated state than when wild. Its most general colour is mouse-colour, with a blackish stripe extending along the spine to the tail, and crossed by a similar stripe over the shoulders. The female goes with young eleven months, and seldom produces more than one foal at a time. In eastern countries the domesticated ass is generally a much finer animal than it is in this country. The stupidity and obstinacy with which it is credited here may, doubtless, be attributed to systematic ill treatment. The milk of the ass, highly esteemed as nutritious in cases of consumption and weak digestion, contains more sugar of milk and less caseine than that of the cow. The hide makes excellent leather for shoes and the best material for drums; and, by a peculiar process, shagreen leather is made.

ASSIMILATION, *as-sim-i-lai'-shon* (Lat., *adsimilatio*, from *ad*, to, and *similis*, like), the act of organized bodies, by which they convert foreign substances into their own proper substance, by which food is converted into nutriment. (*See* NUTRITION.)

ASTEROIDS, *as'-ter-oids* (Gr., *aster*, a star, and *eidos*, like), a number of small planets revolving around the sun, between the orbits of Mars and Jupiter, four of which were discovered in the first decade of the present century, and the remainder since 1845. They are sometimes called *planetoids*, an expression meaning "like a planet," which conveys a better idea of their character, in contradistinction to fixed stars; and *extra-zodiacal planets*, because their orbits, unlike those of the larger planets, are not confined within the zodiac, The entire number discovered up to the present time is about 150. Flora, the eighth in order of discovery, is nearest to the sun, with a mean distance of 209,170,000 miles; and Euphrosyne, the thirty-first, the most distant, being about 300,000,000 miles from the centre of our solar system. They are all extremely small, seldom exceeding in brightness stars of the eighth magnitude; and the eccentricities of their orbits and the inclination of their planes to the plane of the ecliptic are much greater than those of the larger planets.

ASTEROLEPIS, *as-ter-o-le'-pis* (Gr. *aster*, a star, *lepis* scale), the star-scale, a gigantic fossil ganoid fish of the Old Red sandstone, so named from the star-shaped markings on the strong plates which protect the head. The structure of this creature is minutely described in Hugh Miller's work "Footprints of the Creator; or the Asterolepis of Stromness."

ASTEROPHYLLITES, *as'-ter-of'-il-lites* (Gr., *aster*, star, *phullon*, leaf), fossil plants found abundantly in the Coal-measures, Lias, and Oolite, characterized by star-like whorls of narrow leaves surrounding the jointed stems, as in the existing genera *Hippuris* and *Equisetum*.

ASTHMA, *asth'-ma* (Gr., *asthmazo*, I breathe with difficulty), is a disease of the lungs, characterized by difficulty of breathing, which comes in paroxysms, accompanied by a wheezing noise and a feeling of tightness across the chest. The fit occurs most frequently during the night suddenly awaking from sleep the patient, who is obliged to assume an upright posture, to prevent suffocation, and to struggle and pant for breath while the paroxysm continues, which is usually for two or three hours. Though a terrible, it is seldom, in itself, a fatal disease. It is frequently hereditary, or it may arise from some inflammatory affection of the respiratory organs. Among the other causes that may give rise to it, are dwelling in a moist or impure atmosphere, cold, indigestion, mental anxiety. The paroxysms are generally preceded by languor, flatulency, headache, sickness, a feeling of anxiety, and a sense of tightness and fulness about the chest. Physicians usually distinguish three kinds of asthma—the humid, dry, and spasmodic, according as they are, or are not, attended with cough and expectoration. During the paroxysm, gentle aperients and anti-spasmodic medicines are recommended. A blister on the chest, bathing the feet in warm water, a cup of hot coffee, or the smoking of stramonium, are frequently of use. To prevent the return of a paroxysm, the exciting causes are to be avoided; the bowels to be kept gently open, the food to be light and nourishing, sudden changes of temperature to be avoided, regular and moderate exercise to be taken, and a change of climate or of situation to be tried. As regards this last, it has been found that some have been least subject to asthma in the country, others in the centre of a town.

ASTIGMATISM, *as-tig'-mat-ism* (Gr., *a*, without, *stigma*, a mark or spot), a defect in the eye, which consists in its refracting the rays of light in different planes. The defect may be detected by looking at a small pinhole in a card held up against any bright object, and moved to different distances from the eye. To an ordinary eye the image of the hole remains circular at all distances, but to an eye having the peculiar defect in question the image of the hole, as the card is moved away, becomes elongated, and, at a certain distance, passes into a straight line.

ASTRÆA. (*See* CORAL, MADREPORE.)

ASTRAGALUS, *as-trag'-a-lus* (Gr., *astragalos*, a die), the name of the ankle-bone, or first bone of the foot, upon which the tibia moves. The lower surface rests on the *os calcis*, or heel-bone, to which it is attached by a strong ligament. It is a bone of great importance, as it supports the weight of the body in standing, and partakes of most of the movements of the foot.

In Botany, a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Papilionaceæ*. More than 250 species have been described, and most of them are hardy plants, either shrubby or herbaceous. The best-known British species are *A. hypoglottis*, the purple milk-vetch, and *A. glycephyllos*, the liquorice-vetch. The species *A. verus*, *A. gummifer*, *A. creticus*, and some others, furnish gum-tragacanth, or, as it is frequently termed in the shops, *gum-dragon*. Tragacanth exudes naturally from all parts of the above plants, or from wounds made in the stems. *A. boeticus*, an annual species, is cultivated in Hungary, Germany, and other parts of Europe, for the seeds, which are roasted, ground, and used as a substitute for, or an improver of, coffee.

ASTRINGENTS, *as-trinj'-ents* (Lat., *ad*, to, and *stringo*, I tie fast), substances which have the property of contracting or drawing together the muscular fibre, and which are employed medicinally for the purpose of checking fluxes, hæmorrhage, and diarrhœa. The drugs most commonly used as astringents are alum, acetate of lead, catechu, oak-galls, and rhatany-root. Most vegetable astringents contain tannin.

ASTROCARYUM, *as-tro-kair'-i-um* (Gr., *astron*, a star, *karuon*, a nut), a genus of palms, including about sixteen species, all natives of tropical America, and remarkable for the formidable spines with which the stems, leaves, and other parts are armed. The fruits of *A. Tucuma* and *A. Murumuru*, are eatable. The species *A. vulgare*, the Tucum-palm, is cultivated by the Indians of the Amazon for the sake of the epidermis of the unopened leaves, which they make into strong and fine thread by twisting thin strips together. Beautiful hammocks are made of this tucum thread. The tucum-palm is much more lofty than the tucuma-palm.

ASTROLOMA, *as-tro-lo'-ma* (Gr., *astron*, a star, and *lobos*, a pod), a genus of plants belonging to the natural order *Epacridaceæ*. The species *A. humifusa* yields the Tasmanian cranberry. This fruit is about the size of a black-currant, but is of a green or yellowish colour, sometimes tinged with red, and consists of a viscid apple-flavoured pulp, inclosing a large seed. The flowers are of a beautiful scarlet.

ASTRONOMY, *as-tron'-o-me* (Gr., *astron*, a star, *nomos*, a law), the science which treats of the mechanism of the universe and the motions and positions of the heavenly bodies. Originally, astronomy formed part of the supposed science astrology, and men studied the stars in order to discover their influence upon future events. Thus the true science sprang out of the false. The difference between the two may thus be stated:—Astronomy was the knowledge of the laws regulating the motions of the stars, and astronomy was the interpretation of their supposed language. In process of time, the new science exposed the falsity of the old. The science of astronomy may be divided into three great branches:—*Geometrical* or *Mathematical*, *Physical*, and

Sidereal. The first relates to the magnitudes, shapes, and relative distances of the heavenly bodies, their orbits and the mathematical calculations required to ascertain the periods of their movements. The second branch relates to the nature of the forces operating in the universe, the composition and physical properties of the systems. Sidereal astronomy deals with the fixed stars, or those which do not form a part of our solar system. Practical astronomy is the application of the knowledge thus gained, the preparation and use of instruments for making observations, and the record of the results of observations. (*See* various headings.) Astronomical science has revealed to us "an innumerable company" of stars and nebulæ, to the number of which no limit can be set, diffused through an inconceivable extent of space. From 5,000 to 8,000 stars can be seen by the unassisted eye of an observer, and the most powerful telescopes have revealed the existence of nearly 50,000,000 of heavenly bodies; and there can be no reasonable doubt that still more powerful instruments would reveal millions more. Of these stars, our sun, the centre of our system, is one, and certainly not one of the largest; at the average distance of stars of the first magnitude, he would appear as only a star of the third or fourth magnitude. The more immediate and practical object of astronomical science is to ascertain the distances, movements, magnitude, and density of the members of our solar system; but, beyond that, there is an illimitable field for investigation.

History.—Astronomy is the most ancient of all the sciences. Long before the Christian era the Chinese, Chaldeans, Hindoos, and Egyptians are known to have studied the movements of the stars, and, according to the unanimous testimony of the Greek writers, the earliest traces of the science are to be found among the two latter peoples. The broad plains and extensive horizon of Chaldea afforded great facilities for astronomical observations, while their simple pastoral life gave them ample time for such studies. The Greeks, also, in their day, were efficient astronomers, and did much for the advancement of the science; they also have the merit of having studied for the sake of the science itself, while all the above-named people mingled it with astrology. The Chaldean priests observed and placed on record the rising and setting of the celestial bodies, and eclipses of the sun and moon, as stated by Diodorus; and they understood the Metonic cycle (*see* METONIC CYCLE); they used the clepsydra, or water-clock, to mark the lapse of time, and the gnomon and hemispherical dial, for determining solstices and the positions of the sun respectively. Alexander the Great found at Babylon a list of eclipses from 2234 B.C., more than 1900 years before the conquest of Babylon by that monarch, and sent them to Aristotle. The division of the ecliptic into twelve equal parts (the twelve signs of the zodiac), and that of the day and night into twenty-four hours, are ascribed to the Chaldeans. The Chinese records of astronomical observations claim to go back to the year 2857 B.C.; but they are very incorrect. The Chinese were acquainted with the Metonic cycle and the motions of the planets, and they had divided the year into 365¼ days; but they knew nothing about the precession of the equinoxes until about 400 A.D. In the year 221 B.C. the emperor Tsin-Chi-Hong-Ti barbarously ordered nearly all scientific books to be burned. In this manner it is said that a great mass of astronomical knowledge was lost. The Hindoo records are a series of observations known as the "Tables of Tirvalore," which are assumed to date from the year 3102 B.C., but are believed to have been fabricated from data derived by the Hindoo astronomers from the Greeks and Arabs. The Greeks derived their astronomical knowledge from the Egyptians in the first place; but the Egyptians have left no records of their observations. With the Greek philosopher Thales, who flourished about 640 B.C., the real and reliable record of facts connected with the history of astronomy may be considered to commence. Thales is said to have predicted a total eclipse of the sun, and was the first to show that the earth was a sphere, and not a plane surface, as the ancients imagined; and he also gave the Grecian sailors some idea of shaping their course by the stars. Pythagoras, who flourished about 500 B.C., did not consider the earth to be the centre of the universe, but, as it was afterwards shown by Copernicus, that the earth and other planets revolved round the sun. With the astronomers of the Alexandrian school, which flourished about 300 years before Christ, a regular system of observation was commenced. The paths of the planets in their orbits were determined; the relative positions of the fixed stars clearly laid down, and the constellations duly mapped out and catalogued. The first Alexandrian school of philosophy may be considered to have existed for 175 years, until the death of Hipparchus of Bithynia, the greatest of all the astronomers that lived before the Christian era. The second school commenced with Ptolemy, about 130 A.D., and ended with Pappus and Theon of Alexandria, early in the 5th century. The most celebrated astronomers in the first of these Alexandrian schools were Timocharis and Aristyllus, whose joint observations proved of much importance to Hipparchus, enabling him to discover the precession of the equinoxes. Contemporary with these was Euclid, better known to us as a mathematician; his clear and logical reasoning did much to pave the way for future discoverers, particularly those who turned their attention to the theory of the science. Some years later came Aristarchus of Samos, remarkable for being the first who attempted to ascertain the magnitude of the earth and its distance from the sun and moon; he was also a believer in the Pythagorean theory, that the earth revolved round the sun. Another celebrated astronomer of this school was Eratosthenes, who observed the obliquity of the ecliptic, and obtained some idea upon a true principle of the magnitude of the earth; he also made observations with astrolabes of his own construction, which existed at Alexandria in the time of Ptolemy. But the master mind of the first Alexandrian school was Hipparchus of Bithynia, the Newton of his age, who flourished from 160 to 125 B.C. He made a catalogue of 1,081 stars, determining the latitude and longtitude of each, which is the first list on which any reliance can be placed, as those attributed to Eratosthenes and others are devoid of bearings by which they can be recognized and identified. From his death to the time of Ptolemy, with whom the second school of Alexandrian philosophy commenced A.D. 130, no astronomer of eminence is met with. Ptolemy followed closely in the footsteps of Hipparchus, substantiating or altering the various theories which his predecessor had propounded. Among his chief discoveries were the libration of the moon and the refraction of light. He made a catalogue of the stars, based, most probably, on that of Hipparchus, with the positions corrected by the improvements he had been enabled to effect: he also invented a planetary system known as the Ptolemaic system (*see* PTOLEMAIC SYSTEM), which was generally considered to be the true principle of the motion of the universe, until Copernicus revived and extended the system originated by Pythagoras. His successors, with the exception of Pappus, who wrote a commentary on his works, and Theon of Alexandria, were men of little or no note. After the death of these philosophers, the second school of Alexandrian philosophy may be considered to have ceased, or, perhaps, to have languished until its total destruction by the Arabs, then called Saracens, about the middle of the 7th century. Fortunately, the Arabs preserved the writings of Ptolemy, and, in the year 762 A.D., commenced a diligent prosecution of the study of astronomy. Although they did not make any great discoveries, yet their careful observations led to the correction and more accurate determination of many facts that had been sought out by the inquiring minds of the old Greek astronomers. The most distinguished of the Arabian astronomers were Albategnius, or Al Batani, who flourished about 880, Ebn-Yunis, and Abul-Wefa. In Persia, Nasireddin compiled tables of observations, and gave them to the world in 1270; while Uleg Beg, a grandson of Timour the Tartar, made observations at Samarcand about the year 1433, and constructed the most correct catalogue of stars that had appeared up to his own time. This prince was as eminent as a geographer as he was as an astronomer. From this time, however, the study of astronomy has declined among Asiatic nations; their pursuit of the science being solely kept up for the sake of the study of astrology. In the early part of the 13th century, the attention of European nations was again turned to astronomy. Frederick II., emperor of Germany, ordered a translation of the *Almagest* to be made; and Alphonso X., king of Castile, collecting a great number of the most notable astronomers of the age about him, caused a set of tables to be compiled in the year 1252, which are known as the Alphonsine tables. (*See* ALONSINE OR ALPHONSINE TABLES.) From this time until 1500, when we come to the great name of Copernicus, no new discoveries were made, although many astronomers laboured and wrote. Copernicus completely revolutionised the science. He showed the fallacy of the Ptolemaic system, and introduced what has since been known as the Copernican system (*see* COPERNICAN SYSTEM), which is now known to be the true theory of the motion of the universe. He met with great opposition, and his theory was not esteemed at its true value, because he was unable to answer certain objections that were made to it, which have since been fully explained. The next famous astronomer was Tycho Brahe, born 1546. Commencing the study at a very early age, he soon determined to devote his life to it; and in 1582 he began his observations, on an island in the Baltic, near Copenhagen. He did not adopt the Copernican system, but substituted a theory of his own, known as the Tychonic System, in which he asserted that the earth was the centre round which the sun moved, but that all the other planets moved round the sun, continually circling about him as he moved onwards in his course round the earth. This theory was received more favourably than that of Copernicus, especially as it explained all the natural phenomena then known quite as well. In addition to the invention of the Tychonic system, he effected great improvements in the instruments then in use. He produced a catalogue of the fixed stars considerably more accurate than any which had preceded it, and made the first table of refractions. He also added greatly to what was already known of the motions of the moon, discovering the moon's variation and annual equation, the changing motion of her nodes, and the inclination of her orbit. He also made very important researches into the nature, course, and distance from the earth of comets, which were previously imagined to be atmospheric bodies. The next astronomers of eminence were Kepler and Galileo; the former of whom was born 1571, died 1630, and the latter born 1564, died 1642. The lives of these philosophers bring the history of astronomy to the middle of the 17th century. Building on the discoveries of Tycho Brahe, and his own investigations of the orbit of the planet Mars, Kepler was led to the conclusions demonstrated in what are called his First and Second Laws (*see* KEPLER'S LAWS), that the courses in which the planets move round the sun are ellipses, having the sun as one of the foci, and that the areas of the orbits are proportional to the times of revolution. His Third Law, that the squares of the periodic times of the planets are proportional to the cubes of their relative distances from the sun, was enunciated in 1618, nine years after the discovery of the first and second laws. Kepler did much to establish the system of Copernicus, to divest it of some of its errors, and to answer the arguments that had been previously urged against it. His last work was the compilation of the Rudolphine Tables, published about four years before his death. The telescope was first constructed in Holland by an optician named Lipperhey, and Galileo availed himself largely of the telescope. He greatly improved its construction and made one which magnified a thousand times. With the aid of this instrument, he soon discovered the satellites of Jupiter, the ring of Saturn, and the phases of Venus, as well as the hills and valleys on the moon's surface. He also asserted the truth of the system of Copernicus, which drew on him the displeasure of Paul V., of Rome, and in the subsequent reign of Urban VIII., in 1633, he was subjected to the tortures of the Inquisition which wrested from him a recantation of the Copernican system he had so ably advocated. After Galileo, the knowledge of astronomy was largely increased by the labours of various men, thus—Gassendi, in 1631, watched the transit of Mercury across the disc of the sun; Descartes, an eminent mathematician, published his Cartesian theory; Vernier invented the instrument which bears his name, to determine the smallest subdivision of space; Norwood had measured the meridian from London to York with great accuracy; Gascoigne, Auzout, and Picard independently of each other, applied the telescope to the quadrant, and the micrometer to the telescope; Huyghens constructed the first pendulum clock, and Moreton made use of the pendulum to assist him in his observations of the differences of the right ascension of the heavenly bodies; Gregory, in 1663, constructed a reflecting telescope; and Cassini, with many other valuable discoveries, ascertained the period of the rotation of Jupiter, and compiled the earliest tables of the satellites of that planet. The illustrious Newton, who was born in the year in which Galileo died, now brought forward the theory of gravitation. (*See* GRAVITATION.) It was many years before he could satisfy himself of the truth of his speculations, and determine the laws on which his wonderful discovery rested; but he ultimately published them in his *Principia*, in 1687. This discovery is perhaps the grandest effort of human genius that the world has yet witnessed. It completely revolutionised physical science. By observations of the comet of 1680, Newton found that in accordance with the laws propounded by Kepler, the orbits of comets about the sun were elliptic. He also invented fluxions, proved the form of the earth to be an oblate spheroid, and showed the influence of the moon upon the ebb and flow of tides. In 1669, he constructed his first reflecting telescope. Contemporary with Newton were Halley and Flamsteed. The latter held the post of first astronomer royal in the Observatory at Greenwich, founded in 1675. He was as eminent a practical astronomer as Newton was skilled in physical astronomy. In 1680, he determined the laws of the moon's annual equation; and fourteen years later, in conjunction with Newton, he commenced a series of observations for the improvement of the theories then held respecting the moon's motions, and the laws which Newton had arrived at respecting the reflection and refraction of light. He made a long catalogue of stars, in which important additions were made to those that had already been published, and many series of astronomical observations, which were given to the world in his valuable *Historia Celestis*. His successor, Halley, discovered the accelerated mean motion of the moon by the aid of the eclipses recorded at Babylon, and preserved in the great collection of Ptolemy. He also added considerably to our knowledge of the revolutions of comets and their nature. He was succeeded by Bradley, who discovered the aberration of light in the year that Newton died. This discovery furnishes incontrovertible proof of the truth of the Copernican system, by determining the fact of the earth's annual revolution round the sun. (*See* ABERRATION.) Bradley also observed the phenomenon of nutation, and at the time of his death he left behind him upwards of 60,000 observations. In 1731, Hadley invented the quadrant; later, Lacaille, Euler, D'Alembert, and Cassini produced valuable tables, and extended the researches that had already been made in the theories of the motions of the planets, precession, nutation, libration, and the advancing motion of the sun's apogee. Maskelyne, the fourth astronomer royal, originated the *Nautical Almanac* in 1767. In 1781, Herschel discovered the planet Uranus, and Laplace calculated the elements of its orbit. Six years after, Herschel constructed his 40-foot telescope, with which he discovered two of Saturn's satellites and the rotation of his ring, as well as the satellites of Uranus. He also found that the Milky Way consisted of closely-serried groups of countless stars, and that the motion of the satellites of Uranus was retrograde. The astronomical labours of the 18th century may be considered to be closed with the catalogue of nebulæ and clusters of stars found by Herschel, and the commencement of the great work of Laplace, the *Méchanique Céleste*. In the opening years of the present century, the discovery of the first four asteroids (*see* ASTEROIDS), between the orbits of Mars and Jupiter, was made by Piazzi, Olbers, and Harding; and since that time no less than 150 have been added to this group, fully substantiating the speculations on this subject entertained by Kepler. In 1846, the planet

Neptune was discovered almost simultaneously by a Frenchman, M. Le Verrier, and Mr. Adams, of the University of Cambridge: but M. Galle, of Berlin, was the first to place his observations of the newly-discovered heavenly body on record. Among the principal astronomical publications of the present century may be enumerated Piazzi's *Catalogue of the Stars*, the most complete that we have; Herschel's *Catalogues of Stars and Nebulæ*, and Brisbane's *List* of the same. Lubbock's *Researches on the Lunar Theory* and his star maps are equally important; as also are the numerous publications of Airy, Laplace, Challis, Lalande, and Arago. Among the principal instruments constructed since the year 1800 may be noted Troughton's mural circle, put up at Greenwich in 1812, and the telescope erected at Parsonstown by Lord Rosse. (*See* TELESCOPES.) In recent years, great numbers of observations have been published in relation to the sidereal heavens, multiple stars, and nebulæ. Chiefly by means of spectrum analysis, our knowledge of the physical nature of the sun, sun spots, &c., and of the other heavenly bodies, has also been largely increased. Every year our numerous and laborious astronomers are adding to our knowledge of this science. Other parts of this extensive subject will be found treated separately under their distinctive headings, such as Comets, Solar System, Spectrum Analysis, &c.

AS'TUR. (*See* GOSHAWK.)

ASYMPTOTE, *as-im'-tote* (Gr., *asumptotos*, not falling together), in Geometry, a line which approaches continually nearer and nearer to some curve, whose asymptote it is said to be, without ever meeting it. It is a property appertaining to the hyperbolic curve. (*See* HYPERBOLA.)

ATACAMITE, *a-ta'-ka-mite*, an ore of copper, found as a crust on lava thrown out by volcanoes, especially Vesuvius and Etna. It is also found in the volcanic regions of South America, and takes its name from Atacama, in Peru. In Bolivia it is found associated with veins of silver. Chemically it is regarded as a combination of protoxide of copper with chloride of copper. It is worked in South America as an ore of copper, and large quantities are sent to England to have the metal extracted. Atacamite frequently forms on the surface of copper exposed to the air or sea-water, and it forms the greenish incrustation observed on antique bronzes, commonly known as the *ærugo nobilis*.

ATAVISM, *at'-av-ism* (Lat. *atavus*, a great-grandfather), the re-appearance in animals or plants of traits belonging to their remote progenitors, which their immediate parents did not present.

ATAXIA, *a-tax'-i-a* (Gr., *a*, not, *taxis*, order), a term used in Medicine to denote want of regularity in the symptoms of a disease or in the functions of the body.

ATAXY, LOCOMOTER, *a-tax'-e*, a disease of the nervous system, otherwise known as *tabes dorsalis* or *posterior spinal acterosis*, manifesting itself principally by disordered movements of the limbs in locomotion. It arises from loss of the power of using the muscles harmoniously, and so properly performing the voluntary motions of the body, and maintaining its equilibrium. Until recently, it was supposed to be a form of paralysis, but that is not the case. The symptoms make their appearance slowly, and are now understood by pathologists to originate in a diseased condition of the posterior columns and posterior nerve-roots of the spinal cord. In some cases, ataxy appears to be hereditary, and it is more common with men than with women, and mostly affects persons of middle age. The cause is obscure, but supposed to be exposure to cold and privation, excessive sensual indulgence, or mental anxiety.

ATELES, *at'-e-lees* (Gr., incomplete), a genus of American monkeys, of that division of the Quadrumana termed *Sapajons*. The most distinctive characters of the genus are long, slender, but powerful prehensile tails; fore-hands almost entirely without thumbs, or possessing only the merest rudiment of the organ—whence the name of the genus; a dental system which, in common with all the American Quadrumana, consists of two molar teeth more than are possessed either by man or by corresponding genera in the Old World. Other prominent characters of the ateles are round small heads, limbs remarkably long and slender, corpulent bodies. These characteristics have obtained for the genus the name of spider-monkeys. (*See* SPIDER-MONKEY.) The genus comprehends the following species:—1, *Ateles paniscus*, or quata; 2, *Ateles marginatus*, or chuva; 3, *Ateles ater*, or cayou; 4, *Ateles Belzebub*, or marimonda; 5, *Ateles melanocheir;* 6, *Ateles arachnoides*, or brown quata; 7, *Ateles hypoxanthus*, the mono or miriki; 8, *Ateles subpentadactylus*, or chameck.

ATEUCHUS. (*See* BEETLE and SCARABÆUS.)

ATHERINE, *ath'-e-rin* (Lat., *atherina*), a genus of fishes, formerly classed with the Mullet family, but now separated from them. They rarely exceed six inches in length, and have a rather flat upper-jaw. Some possess very small teeth, while others are entirely toothless. All the known species have a silvery stripe on each side of the body. In the Mediterranean they are very numerous, and they also abound on the southern coast of England, as well as in certain parts of Ireland. At Brighton the atherine is called the sand-smelt; and in several market-towns of England where the smelt is unknown, the atherine is commonly sold under that name. It is generally caught by anglers from the shore, as it rises readily almost to any bait.

ATHEROMA, *a-ther-o'-ma*, a fatty deposit found in the tissues of aged persons, or those who have lived dissipated and ill-nourished lives. It arises from a diseased state of the blood vessels. The name is derived from a Greek word meaning porridge of meal, which the deposit somewhat resembles.

ATHEROSPERMACEÆ, *ath'-e-ro-sper-mai'-se-e*, the Plume Nutmeg family, a natural order of dicotyledonous plants in the sub-class *Monochlamydeæ*. Only four species are known, and these are all handsome and fragrant trees. Each produces fruit, consisting of a number of achænia inclosed in the tube of the calyx, and having persistent styles which have grown into feathery awns. The achænia of *A. Laurelia*, a native of Chili, have an odour very similar to that of the common nutmeg. *A. moschata* furnishes valuable timber, also an aromatic bark, which is used in some parts of Australia as a substitue for China tea.

ATMOSPHERE, *at'-mos-feer* (Gr., *atmos*, vapour, and *sphaira*, sphere), the name given to the gaseous envelope of the earth. It consists of two distinct portions, the permanent atmosphere, the amount of which does not depend on ordinary variations of temperature; and the vaporous portion, the amount of which is far less considerable than that of the permanent portion, and is varia-

ble with changes of temperature, &c. The form of this gaseous envelope of the earth is that of an oblate spheroid, more flattened at the poles than the earth is. This is the result of centrifugal force, which is enormously great at the equator and scarcely perceptible at the pole. The *height* of the atmosphere—that is, the thickness of the atmospheric belt—varies therefore, being in addition affected by the less density of the air at that part where its motion is most rapid. Many observations have been made to determine the height of the atmosphere. At one time, taking the duration of twilight as a test, it was considered to be about 45 miles. Observations of luminous meteors and auroral arches have also been made, and the best authorities now agree that the height of the atmosphere is at least 120 miles, and that in an extremely attenuated form above the equatorial regions of the earth, it may even extend to 200 miles. That the atmosphere has weight can be practically and very easily demonstrated. A hollow glass globe filled with air weighs more than the same globe does after the air has been extracted by the air-pump, the difference, of course, being the weight of the quantity of air withdrawn. A column of air is equal to a column of water of similar horizontal section very nearly 34 feet high, or a column of mercury of about 30 inches. The mercury weighs a little more than 14¾ lbs., consequently that is the weight of the corresponding quantity of air. The pressure of the atmosphere on a square inch being thus ascertained, the multiplication of the number of square miles on the earth's surface by the atmospheric pressure is a simple arithmetical operation, the result showing that the weight of the entire atmosphere is 11·67085 trillions of pounds (about 500 billions of tons), or rather would be if the pressure of the mercurial column were a constant quantity; but, in fact, it varies somewhat in different latitudes, at various seasons of the year and even hours of the day, owing in a great degree to the pressure of watery vapours, and the accumulation of air by the action of winds. The *density* of the atmosphere diminishes with distance from the earth. All gases are elastic, and those portions of the atmosphere in contact with the earth are pressed upon by all the air above them. The variations of density, though according generally with the deductions from theory, are yet marked by peculiarities of a somewhat complex nature, resulting from the duplex character of the atmospheric constitution. The following statement is approximately correct—at a height of seven miles the density of the atmosphere is reduced to one-fourth the density at the sea-level, and for every increase of height by seven miles, the rarity of the air is similarly quadrupled. The *chemical composition* of the atmosphere varies slightly (as compared with the entire mass) from different causes. The mean composition of 100 parts is about 79 nitrogen, 20 oxygen, and ·04 carbonic acid, and minute proportions of other gaseous matters as ammonia, carbonetted and sulphuretted hydrogen, hydrochloric acid, carbonic oxide, sulphurous and sulphuric acid, nitric acid, and probably iodine. The amount of carbonic acid increases with elevation, being nearly doubled at a height of 10,000 feet. Carbonic acid is being continually produced by the respiration of animals, the processes of combustion, and the decomposition of organic substances; so that there is no danger of the supply required by growing plants ever falling short. Boussingault has estimated that the quantity of carbonic acid produced in Paris every twenty-four hours amounts to nearly a hundred and six millions of cubic feet. The atmosphere, as a chemical agent, acts principally by oxidizing bodies exposed to its influence, more especially metals. The amount of moisture in the air increases its chemical effect. It varies according to weather and locality. The chemical influence of the air is seen in the disintegration of the hardest granitic and felspathic rocks, which gradually crumble away under its action, forming the kaolin or China clay of the potter. Metals for the most part rust, or become converted into oxide, in moist air; giving rise to precisely the same compound, as if they were burnt in the fire. The action of the air on metallic paints containing lead is very marked; they become speedily tarnished by the absorption of sulphur. Even glass is affected in this way, lead-glass especially becoming covered with a film of oxide or sulphide, from prolonged exposure to air and damp. Gold, aluminum, and one or two other metals, remain untarnished by exposure to air; but silver soon becomes covered with a film of sulphide. In addition to its gaseous constituents, the atmosphere contains watery vapour, drawn up by the action of heat, varying, as noticed above, in different localities, and at different seasons, and in the lower strata solid substances in extremely minute particles, the presence of which is revealed in the sunbeam. It is customary to estimate the force of steam and other fluid pressures by *atmospheres*—that is, in round numbers, at the rate of 15 lbs. per square inch for every atmosphere. (For information respecting other points connected with the atmosphere, *see* FLUID, ACOUSTICS, METEOROLOGY, DEW, RAIN, TEMPERATURE, WIND, ANEMOMETER, BAROMETER, HYGROMETER, RAIN-GAUGE, THERMOMETER.)

ATMOSPHERE OF THE PLANETS. From a great variety of analogous circumstances proving the common origin of the earth and the other heavenly bodies, there is strong reason for believing that many, if not all, of the planets are surrounded with gaseous envelopes or atmospheres. It is not, however, assumption alone that leads to this opinion; the telescope reveals to us such changes in the appearance of many of the planets as can only be accounted for by the fact that they have atmospheres. Mars, Jupiter, and Saturn have, in this way, been proved to possess a transparent atmosphere, varying at different times and places, like that of our own planet.

ATOLL, *a-tol'*, a peculiar form of coralline island, common in Polynesia and the Indian Ocean, consisting of a circular reef enclosing a sheet of water, or lagoon, connected with the ocean by an open passage. The reefs generally support vegetation, and are sometimes inhabited.

ATOM, *at'-om* (Gr., *atomos*, not to be divided). The finite or the infinite divisability of matter, and the consequent existence or non-existence of atoms which do not admit of farther division, were discussed in the earliest times of philosophical speculation. About four centuries before the Christian era, Democritus (commonly spoken of as "the laughing philosopher," but really a very acute observer of physical phenomena) held that the only existing things are innumerable indestructible atoms, varying in form and combined in obedience to mechanical laws. Epicurus (also a speculative philosopher of great powers, and certainly not, as ordinarily supposed, the propounder of the doctrine that sensual pleasure is the great end of life), adopted the views of Democritus, and they were supported also by the Roman poet Lucretius, in *De Rerum Naturâ*. The atomic theory received the support of Gassendi, in the middle of the 17th century; and the illustrious Newton was disposed to accept it and extend its signification. He says, "It seems probable to me that God, in the beginning, formed matter in solid, massy, hard, impenetrable, movable particles of such sizes and figures, and with such other properties, and in such proportions to space, as most conduced to the end for which he formed them. . . . That nature may be lasting, the changes of composed things are to be placed only in the various separations and new associations and motions of these permanent particles." The theory was elaborately expounded in a remarkable address delivered by Professor Tyndall, as President of the British Association for the Advancement of Science, at the Belfast Meeting of 1874. He said, "The atomic doctrine, in whole or in part, was entertained by Bacon, Descartes, Hobber, Locke, Newton, Bayle, and their successors, until the chemical law of multiple proportions enabled Dalton to confer upon it an entirely new significance." (*See* ATOMIC THEORY.) Endeavours to ascertain the limit of the size of atoms have occupied the attention of many of the most accomplished physicists of our time, especially Loschmidt of Vienna, Stoney the American, Williamson, Maxwell, Tomlinson, and Sir William Thomson. By calculations, founded on the thickness of a soap bubble, it has been found that an atom of soap, in the solid state, "cannot possibly occupy so much as the hundredth of a cubic, 2,600,000th of an inch." There we may well stop, keeping in view the possibility that these atoms are not final, but that each may be capable of still more minute sub-division. Beyond the point reached by scientific demonstration, there is abundant room for abstract speculation, of which the theory of Boscovich, which has found many advocates, may be taken as a specimen. "Matter consists not of solid particles, but of mere mathematical centres, from which proceed forces according to certain mathematical laws, by virtue of which such forces become at certain small distances attractive, at certain other distances repulsive, and at greater distances attractive again." In Chemistry, an *atom* is the smallest quantity of matter that can exist in combination, and a *molecule* (containing two atoms) that can subsist by itself.

ATOMIC THEORY.—To Dalton, the eminent chemist and mathematician of Manchester, is due the formulation of a theory of atomic proportions. The subject had previously been discussed, but no certain results arrived at. He began his investigations in 1803, and in 1808 and 1810, developed his theory in his "New System of Chemical Philosophy." He announced four laws:—1, *Definite proportions*, in accordance with which the nature and proportions of the constituent elements in every chemical compound are definite and invariable; as, for instance, in water, obtained from any source, the proportion of oxygen to hydrogen is invariably as 8 to 1 by weight, and in every carbonate of lime, however differing in form and other physical properties, there are 56 parts of lime to 44 of carbonic acid. 2, *Multiple proportions*, by which, when one substance unites with another in several proportions, the highest proportions are multiples of the first or lowest; thus, nitrogen and oxygen combine to form five chemical compounds, in all of which the properties of nitrogen remain constant, but that of oxygen is a constantly increasing multiple of its atomic weight. 3, *Equivalent* or *reciprocal proportions*, which means that each element, in combining with other elements, or in displacing other elements from combination, does so in a fixed proportion, which may be stated numerically, of which (to quote a recent authority) this example may be given:—"We have a compound of oxygen and iron containing these elements in the proportion of 8 to 28; we have also a compound of sulphur and iron in the proportion of 16 to 28; and sulphur and oxygen unite together to form sulphurous acid gas, which contains equal weights of the two elements—the proportion of 1 to 1 having a simple arithmetical relation to the proportion of 8 to 16." 4, *Compound proportions*, the law that the combining proportion of a compound substance is the sum of the combining proportions of its components; or, to quote an illustration from the same authority, the compound body, carbonic acid, which consists of 6 of carbon united with 16 of oxygen, has the combining proportion 22, which is the sum of the combining proportions of the carbon and oxygen composing it; and 22 is the proportion in which carbonic acid will form compounds with every other substance of similar chemical constitution.

Atomic Heat.—Equal weights of different bodies require different amounts of heat to raise them through the same number of degrees of temperature; but if, instead of using equal weights of the bodies, quantities in proportion to their atomic weights are employed, and the amounts of heat required to raise these quantities through one degree of temperature are determined, they will be found to be nearly identical. Regnault calls the number got by multiplying together those which express the atomic weight and specific heat of a body, its *atomic heat*. Taking sulphur as an instance, the atomic weight is 32, the specific heat 0·1776 of a unit of heat, and those numbers multiplied give 5·6832.

Atomic Volume.—Atomic volume is the relative *size* of the combining proportions or atoms of bodies, just as atomic weight is the relative *weight* of their combining proportions or atoms. It is determined by dividing the atomic weight by the specific gravity, which gives the atomic volume or space occupied by the aggregate of atoms as well as the interstitial spaces, the weight of the volume being proportional to the atomic weight of the body. The atomic volume, or its multiple, shows the proportions in which one body will unite with another body by volume.

Atomic Weight is the relative weight of the atoms of bodies, or, which is the same thing, the proportion in which they unite. Tables have been constructed of the atomic weights of all the elements, the atomic weights of compounds being evidently the sum of the atomic weights of their constituents. Hydrogen has been taken as the unitary body by English chemists, from being the lightest of all known substances. The continental chemists have taken 100 parts of oxygen as the standard number. There is great diversity in the relative sizes of elementary atoms, those of carbon being only half the size of those of iron. The weight of an atom of carbon would be 6, and that of an atom of iron would be 28; but the quantity of carbon would only take up half the space of the quantity of iron.

ATONY, *at'-o-ne* (Gr., *a*, not, and *tonos*, tone), is a term used to denote deficiency in power or tone, generally applied to muscular power.

ATROPA, *a tro'-pa* (Gr., *Atropos*, the name of one of the Fates), a genus of plants, formerly included in the order *Solanaceæ*, but now regarded as the typical genus of a natural order to which the name *Atropaceæ* has been given. The most important species is *A. belladonna*, the common Dwale, or Deadly Nightshade. This plant is a native of Greece, and also indigenous to Britain, but not common. It is perennial, and grows in hedges and waste grounds on a calcareous soil, but is only met with in a comparatively few localities. It blossoms from June to August, the flowers being about an inch long, drooping, bell-shaped, and of a lurid purple colour. The fruit is a berry of a shining violet black colour when ripe, about the size of a small cherry. The berries have a most tempting appearance, and children have frequently been poisoned by them. The are powerfully narcotic; and one of the first symptoms of their deadly action on the human frame is an appearance of the most besotted drunkenness. The dried leaves, or an infusion of the leaves, will act in a similar manner. The best antidote to the virulent effects of this poison is *vinegar*, when promptly administered; but, if practicable, the stomach-pump should be at once used. When death ensues from its effects, the body soon putrefies, and swells in a remarkable manner, being covered with livid spots; and blood sometimes exudes from the mouth, nose, and eyes. Extract of belladonna is employed to dilate the pupil of the eye during surgical operations, to allay pain and nervous irritation, and as an antispasmodic. A homœopathic preparation is administered to relieve neuralgia. The active principle of the plant is the alkaloid ATROPIA.

ATROPACEÆ, *a-tro-pai'-se-e*, a natural order of dicotyledonous plants, of the sub-class *Corolliflorœ*. The thirty-eight genera included in this order were separated by Miers from the *Solanaceœ* and *Scrophulariaceœ*. The species are very numerous, and abound in tropical regions; but some are found in most parts of the world. Many have powerful narcotic properties. (*See* NICOTIANA, DATURA, HYOSCYAMUS, ATROPA, and MANDRAGORA.)

ATROPHY, *at'-ro-fe* (Gr., *a*, not, and *trophe*, nourishment), a wasting, from deficient nutriment, either of a part or of the whole body. In order to the maintenance of the healthy state of the body or any of its organs, a certain supply of nutrition is required to meet the waste that is constantly going on. When, from any cause, the supply of nutrition is not able to meet this waste, the natural dimensions of those parts are reduced. In a healthy condition of body, an exact balance is maintained between the waste and the supply; but in every morbid condition this balance is more or less disturbed, in consequence of which the whole body, or certain parts of it, receive too little or too much nourishment. The first state, from whatever cause it arises, is termed *atrophy*, the latter *hypertrophy*. Progressive muscular atrophy (commonly described as wasting or creeping palsy) is an affection of the muscular system, characterized by the atrophy and subsequent paralysis of certain muscles, and is associated with morbid changes in the anterior roots of the nerves of the spinal cord. In all cases, atrophy arises from the diminution or perversion of the vital energies, generally the former; and hence, by exciting the natural vital energies of an organ, we tend to remove atrophy. In order to its cure, it is necessary to discover in what organ or organs the deficiency or perversion exists. The discovery of this is often difficult, and the removal of it, when discovered, is often more difficult.

ATROPIA, ATROPINE *a-tro'-pi-a*, a vegetable alkaloid found in the deadly nightshade (*Atropa belladonna*), and the seeds of the *Datura Stramonium*. It is extracted by adding sulphuric acid to a strong decoction of either plant; filtering, saturating with potash, and dissolving the precipitate, which is the atropia, in hot water, from which it crystallizes in long silky needles. (*See* ATROPA.)

ATTALEA, *at-tai'-le-a*, a genus of palms comprising numerous species, nearly all natives of the tropical parts of America. They have, in general, tall and smooth cylindrical stems; but a few species are stemless. The leaves are large and pinnate; the fruit a nut, with three seeds and three cells, enclosed in a dry husk. The species *A. funifera* is the most important member of the group. The fruits constitute the Coquilla nuts of commerce, which are largely imported into this country. The pericarp of this fruit is very hard, and forms a kind of vegetable ivory. The pendulous fibres of the leaf-stalks are much used for cordage, the ropes made from them being very strong, and extremely durable in salt-water. From the seeds of *A. Cahouni* a fatty oil may be obtained. *A. compta*, the Pindova palm, a noble tree, produces a fruit about the size of a goose's egg, the kernals of which are eatable.

ATTENUANTS, *at-ten'-u-ants* (Lat., *attenuo*, I make thin), a term applied to those remedies which, it is supposed, have the power to impart to the blood a thinner or more fluid consistence.

ATTRITION, *at-trish'-on* (Lat., *attritus*, worn or rubbed down), the wearing and smoothing of rock-surfaces by the passage of water charged with gritty particles, by the descent of glaciers, or by the passage of sand-drift.

AUCKLANDIA, *awk-land'-i-a*, a genus of plants belonging to the natural order *Compositæ*. The most interesting species is *A. costus*, a native of Cashmere, the root of which is supposed to have constituted the *costus* of the ancients. This root is commonly known in the north-western parts of India by the name of orris-root. It must not, however, be confounded with the true orris-root, which is furnished by a plant belonging to a very different order. (*See* IRIS.)

ATTRACTION, *at-trak'-shon*, the force or forces by which all bodies, of whatever size, exhibit a tendency to approach each other, and are held together when in contact. The attraction of the magnet for iron is a familiar instance. Newton, in his "Principia," published in 1687, was the first to suggest a theory of attraction to explain the phenomena of the universe. The nature of the power is considered under the headings, ADHESION, AFFINITY, CAPILLARY ATTRACTION, COHESION, ELECTRICITY, GRAVITATION, and MAGNETISM.

AUCUBA, *aw-ku'-ba*, a genus of plants belonging to the natural order *Cornaceæ*. The only known species is *A. Japonica*, which, as its name implies, is a native of Japan. It was introduced into Britain as a hothouse plant, but was soon found to be hardy enough to flourish in exposed situations. It is now a very common ornamental shrub, especially in the parks and suburban gardens of large towns. It is remarkable for its shining pale-green leaves mottled with yellow, which have obtained for it the common name of Variegated Laurel; but the female plant is alone known in this country; hence, it never yields seed, and can only be propagated by layering, or by slips or cuttings.

AUDITORY, *aw'-di-to-re*, is a term applied to certain parts of the organs of hearing; as the auditory nerve, *meatus auditorius*, &c. (*See* EAR.)

AUGITE, *aw'-jite* (Gr., *augé*, brilliancy), a mineral nearly allied to horneblende, known also as *pyroxene*. It is found in many volcanic rocks, such as basalt and porphyry, and consists of silicate of lime and magnesia. It is greenish-black or entirely black, and is generally more or less translucent, according to the amount of manganese and iron contained in it. It crystallizes in six or eight-sided prisms. A transparent green variety found in the Tyrol is used in jewellery.

AUK, *awk*, a name common to several species of web-footed birds, really all belonging to the family *Alcidæ*, the largest species, the Great Auk, is now supposed to be extinct, not having been seen for about thirty years. The last specimen captured is now in the British Museum. The wings of the great auk are but partially developed. In length it measures about three feet, and its wings scarcely exceed four inches. Though the wings are almost useless for aërial locomotion, they are well adapted for assisting the bird's progress under water. The food of auks consists of fish and crustacea, and other marine productions. The common puffin is sometimes called the Labrador auk.

Auk, Little (*Mergulus Alle*), is the most diminutive of the auk tribe, and the hardiest. The colder and wilder the region, there do they seem to congregate in larger flocks, and enjoy the inclement weather with as much relish as their human companions the Esquimaux. In the locality of Baffin's Bay they are found in large flocks; also at Melville Island. On the inhospitable wilds of Spitzbergen and Greenland thousands of these birds find a home. It very rarely visits this country; indeed, those that have been seen are more probably storm-blown castaways. The little auk is a compact, stout bird, about nine inches in length. The upper parts of the plumage are mostly black, the cheeks and under-parts white, the legs yellowish-brown, the bill black. In summer the front of the neck, which during the winter is black, assumes a paler hue. It lays one egg, of a pale-bluish green, and, like the preceding, affects the highest cliffs.

Auk, Razor-billed (*Alca torda*), larger than the preceding; when full grown, it measures about fifteen inches in length and twenty seven across the wings. This species is found also in the Arctic regions; but, unlike the great auk, is a frequenter of warmer climates, including the coasts of Great Britain, France, Holland, and Germany. These birds take up their abode on the highest cliffs attainable, and live together in large flocks. About May the auk colonies begin their task of incubation, sitting closely together in rows, one above the other. It is very remarkable, that, although the razor-billed auk lays but one egg, and so many hundreds are accumulated on the cliffs at one time, without any kind of covering to denote their respective owners, no inconvenience is occasioned; every auk knows its own egg, and probably in no instance is the paternity of a young bird questionable.

AURANTIACEÆ, *aw'-ran-ti-ai-se-e*, the Orange family, a natural order of dicotyledonous plants, consisting of trees and shrubs, often of great beauty. The order is included in the subclass *Thalamifloræ*. There are twenty-three genera, and about ninety-five species, chiefly natives of the East Indies, but generally distributed by the agency of man throughout the warmer regions of the globe. Their flowers are regular, and usually odoriferous; their fruits succulent and sub-acid, being examples of the *hesperidium* (which *see*). The plants abound in receptacles containing essential oils, which are much used in perfumery, for flavouring, and for other purposes. The oils are especially abundant in the leaves, the petals, and the rind of the fruit. The latter also contains a bitter tonic principle. The edible fruits known as the orange, lemon, lime, shad dock, citron, pompelmoose, forbidden fruit, Indian bael, and wampee-fruit, are the produce of this order. (*See* CITRUS, ÆGLE, FERONIA, COOKIA.)

AURELIA. (*See* CHRYSALIS.)

AURICLES, *aw'-rikls*, is the name given to two of the cavities of the heart. (*See* HEART.)

AURICULA, *aw'-rik-u-la* (Lat., *auris*, an ear), the name given to a species of Primrose (*see* PRIMULA) much cultivated in flower-gardens. It grows wild in the Alpine and sub-Alpine regions of Italy, Switzerland, and Germany; also on the Caucasus and the mountains of Syria. In the wild state it has comparatively small flowers, generally yellow, but occasionally red or purple. These have short stalks, and grow in an umbel on one scape or leafless stem. The leaves, which spring from the crown of the root, are of a dark green colour, and are usually covered with a mealy powder. The scape and the flowers are also dusted over with this peculiar meal. The auricula has been cultivated in Britain since the close of the 16th century; and an immense number of varieties, many of exquisite beauty and fragrance, have been developed.

Auricula, a plant-eating molluscous animal, comprehended in that class of Gastropods to which the common snail belongs. Its organs of respiration are formed for breathing air, but some have the power of living in water for a long time. It inhabits a shell somewhat oval in shape, and marked by wide plaits. *A. Midæ*, a native of the East Indies, is from the fancied or real resemblance of the shell to the ears of an ass, commonly known as Midas's ear.

AURICULATE, *aw-rik'-u-lait* (Lat., *auricula*, little ear), a term applied to a leaf having two small ear-like lobes at the base. The leaf of the Woody Nightshade (*Solanum Dulcamara*) is an example.

AURIFEROUS, *aw-rif'-e-rus* (Lat., *aurum*, gold, *fero*, I yield), a term used to signify that certain rocks and veins yield or contain gold; hence the terms "auriferous veins," "auriferous sands," &c.

AUROCH, *aw'-rok*, the *Bos bison* of Europe, a large animal of the ox family, very similar to the American bison, once abundant, but now existing only in the forests of Lithuania, and possibly the Caucasus. The fossil animal of the same kind (perhaps identical) the ure-ox (*Bos urius*, or *B. sprim genius*) found in the post-tertiary deposits, existed in Switzerland as late as the 16th century. It was a contemporary of the mammoth.

AURORA BOREALIS, *aw-ror'-a bor'-e-ai'-lis* (Lat., *aurora*, the morning, or light preceding sunrise, *borealis*, belonging to the north), a magnificent luminous phenomenon which appears in the northern heavens, and is commonly known as the Northern Lights. In this country it is rarely seen, and never in its full splendour; still the appearances observed are sufficiently striking and beautiful to excite our wonder and admiration. Very beautiful exhibitions were witnessed in this country in September, 1870 and 1872. Long shooting streamers are seen to dart across the sky, and these are generally attended by a beautiful glow of diffuse light, varying from green to deep purple, violet, and red. In days gone by, the *merry dancers*, or *northern lights*, as these appearances were commonly named, gave birth to many absurd superstitious terrors; and even now they are regarded as evil omens by some country folk. In the Arctic zone the aurora is frequently seen; indeed, it serves to break the monotony of the long dreary night, of some months' duration, which falls upon the inhabitants of that gloomy region every winter. There the meteor assumes a character of the greatest imaginable splendour. It first appears as an arch of light of a bluish-white colour, resting at each end on the horizon, and enclosing a dark segment. This luminous arch, which remains visible for several hours, may be considered to be a part of a luminous ring, elevated at a great distance above the earth's surface, and having its centre corresponding with some point near the North Pole. The bow of light does not remain stationary, but rises and falls, extends towards the east or the west, and breaks, now in one place, and then in another. After a while it generally shoots forth quivering rays towards the zenith. When such rays are projected from every part of the arch, and do not rise too high, the aurora presents the appearance of a comb. When the rays are of great length, they culminate in a point near the zenith, and form what is called the *boreal crown*. Then the whole heavens towards the east, west, and north present the appearance of a vast cupola of fire, supported by columns of coloured light. These phenomena are said to be accompanied by a crackling sound, like the crackling of sticks when fractured, and very like the sound produced when a powerful electrical machine is excited. The aurora borealis is intimately connected with the magnetism of the earth. The centre of the boreal crown is invariably found at a point in the heavens indicated by the prolongation of a freely-suspended magnetic needle; and during the occurrence of the phenomenon the magnetic needle is always greatly disturbed, sometimes deviating several degrees from its normal position. There seems, moreover, to be a connection between the magnetic poles of the earth in regard to the aurora, for, so far as can be ascertained, the meteor occurs simultaneously at both. The southern auroras have been witnessed by many navigators, and closely resemble the auroras of the north, and the name *Aurora Polaris*, or Polar Lights, might appropriately be given to both displays. The spectrum of the aurora is almost mono-chromatic, consisting of a single bright line. (*See* SPECTRUM.)

AURO-TELLURITE, *aw'-ro-tel'-lu-rite* (Lat., *aurum*, gold, and modern Lat., *tellerium*), an ore of tellurium containing gold and silver.

AUSCULTATION, *aws'-kul-tai'-shon* (Lat., *auscultare*, to listen), is a term applied to the method of ascertaining the healthy or diseased state of certain organs, by attending to the sounds they produce, either on being struck, or in the natural performance of their functions. In a stricter sense, the term auscultation is confined to the latter of these cases, the former being termed percussion. Auscultation is either immediate or direct, by the unassisted ear, or mediate, by the stethoscope. (*See* STETHOSCOPE.) It is chiefly valuable as aiding the physician to understand the character of diseases of the organs of circulation and respiration in the chest. It is also valuable in the investigation of many obscure internal affections, such as aneurisms and diseases of the æsophagus and stomach, in the detection of uterine tumours and in the diagnosis of pregnancy.

AUSTRALIAN MANNA, *aws-trai'-li-an man'-na*, a saccharine substance, exuded spontaneously by the leaves of several species of *Eucalyptus*, or gum-tree, natives of Australia. It resembles manna, but does not contain mannite, the sweet principle being a peculiar kind of sugar, to which the name *melitose* has been given. It is said to drop from the leaves of *E. mannifera* in pieces sometimes as large as almonds.

AUSTRAL SIGNS, *aws'-tral* (Lat., *australis*, southern; *signum*, a sign), an expression applied to the last six signs of the zodiac—namely, the autumnal signs Libra, Scorpio, and Sagittarius, and the winter signs Capricornus, Aquarius, and Pisces, because they lie to the south of the equinoctial.

AUTOMALITE, *aw-tom'-a-lite*, a species of corundum, found in octohedra. It consists principally of alumina and oxide of zinc, and generally occurs associated with zinc-blende and glance.

AUTOMATIC ACTIONS, *aw-to-ma'-tik*, is a term applied to certain muscular movements which are influenced simply by sensation, and not at all by the will.

AUTUMN, *aw'-tum* (Lat., *autumnus*), is the name of one of the four seasons of the year—that in which the fruits of the earth are gathered in. Astronomically speaking, it is the period during which the sun is passing from the autumnal equinox to the winter solstice (from 23rd September to 21st December). The inhabitants of the southern hemisphere have spring when those of the northern have autumn.

AUTUMNAL EQUINOX. (*See* EQUINOX.)

AVALANCHE, *av'-a-lansh* (Fr., from the Lat., *ad*, to, and *valles*, valley), an accumulation of snow descending from precipitous slopes of a high mountain into the valley below. Avalanches generally result from the partial melting of the snow in spring. The earth, warmed by the rays of the sun, melts the under layer, and thus destroys the adhesion of the mass to the surface. The least agitation of the air will sometimes cause the fall of an avalanche; and for this reason experienced Alpine travellers generally preserve strict silence when in the neighbourhood of dangerous masses of snow. In Switzerland, avalanches are common, and sometimes destroy entire villages. Four kinds of avalanches are distinguished. A *drift* avalanche consists of loose and powdery snow, set in motion by a strong wind; a *rolling* avalanche is that produced by a detached mass of snow rolling down the steep, and licking up the snow over which it passes; a *sliding* avalanche consists of an immense mass which has lost its adhesion to the surface through partial melting; lastly, a *glacial* avalanche is that made up of masses of frozen snow and ice from the higher reaches of the mountain.

AVANTURINE, *a-vant'-u-rine*, a variety of quartz, containing spangles of gold-coloured mica, which give it a peculiar play of colour, as if metallic particles were dispersed through its mass. It is of a yellow, red, and gold colour. It is now made artificially by mixing copper filings with glass while in a state of fusion. Artificial avanturine is far more lustrous than the real mineral. It is found in India, Spain, and Scotland, and is used in the manufacture of cheap jewellery.

AVENA, *av-e'-na*, the Oat, a genus of grasses (natural order *Graminaceæ*). (*See* OAT.)

AVERRHOA, *av-er-ro'-a*, a genus of plants belonging to the natural order *Oxalidaceæ*, and consisting of two species, both being small trees growing in the East Indies. They produce sour fruits, which are much eaten by the natives, but which are not relished by Europeans, except when in pickles. The botanical names of the species are *A. bilimbi* and *A. carambola*, and the fruits are known respectively as the Blimbing and the Carambole.

AVES, *ai'-veez* (Lat., birds), in Natural History, the second class of vertebrata. (*See* BIRDS.)

AVICENNIA, *av-i-sen'-ni-a*, a genus of plants belonging to the natural order *Myoporaceæ*. The species are natives of Australia and America, and grow, like the mangroves, in salt marshes. The bark of *A. tomentosa*, commonly called the white mangrove, is much used in Brazil for tanning. *A. resinifera*, which grows in New Zealand, yields a green resinous substance, which is eaten as food by the natives.

AVICULA, *a-vik'-u-la*, a genus of marine conchifera, the shell of which is imported in considerable quantities, and used, under the name of mother-of-pearl, in the construction of buttons, knife-handles, &c. The real commercial value, however, of this peculiar oyster rests on the real pearls often found in its interior. (*See* PEARL.)

AVICULOPECTEN, *a-vik'-u-lo-pek'-ten*, in Geology, a genus of fossil bivalve molluscs, peculiar to the carboniferous limestone, and often so well preserved that even the colours of the living shell are retained.

AVOCADO PEAR. (*See* PERSEA.)

AVOCET, OR AVOSETTA, *av'-o-set*. An aquatic bird which has a very thin, flexible bill, of a substance like whalebone, and turning hookwise, but in an opposite direction from the hawk and other tribes. The plumage of the avocet is black and white. It is usually ranked among the *Grallæ*, on account of the length of its legs, the long slender bill, and general similarity to the snipe. For scooping, probing, and beating the water, while the mandibles act as a strainer and retain the finny prey, the avocet's bill is most admirably adapted. The common avocet, *Recurvirostra avocet* is about the size of a lapwing, is strong on the wing, but not much addicted to swimming. It is found nearly all over the world.

AWN, a solitary pointed bristle in the flower of grasses. The character of genera and species are often derived from it, but it is not invariable, even in the same species, and the cultivated varieties of wheat and oats differ much in being more or less "bearded." There appears to be a tendency to the diminution or disappearance of the awn through cultivation.

AXE-STONE, a green variety of jade found in New Zealand and on the banks of the Amazon, and used by the natives for making hatchets.

AXIL, AXILLARY, *ax'-il* (Lat., *axilla*, armpit), the upper angle formed by the leaf with the stem is called the *axil*, and everything arising at that point is said to be *axillary*. Buds are usually axillary. Anything springing from the stem, either above or below the axil, is *extra-axillary*; if above, it may be described as *supra-axillary;* if below, as *infra-axillary*.

AXILLA, *ax-il'-la* (Lat.), is applied to that cavity under the upper part of the arm called the armpit. Hence the term axillary is applied to the arteries, veins, glands, &c., of this part.

AXINITE, *ax'-e-nite* (Gr., *axine*, an axe), a variety of garnet found in mica-schist in Dauphiné and Cornwall; so called from the axe-like form of its crystals.

AXIS, *ax'-is* (Lat., a pole, or axle-tree), a term applied to any line which divides a curve into two equal ymmetrical parts.

In Astronomy, the term is applied to an imaginary line passing through the centre of a heavenly body, around which it revolves. The axis of the earth is the line about which it revolves with an uniform motion from west to east. The poles of the earth are the points where the axis meets the surface.

In Botany, the term is applied to the central part both above and below ground, around which the whole plant may be said to be arranged. The stem is called the *ascending axis;* the root, the *descending axis*.

In Geometry,, the word axis is used to denote a right line around which a plain figure revolves to produce a solid. Thus, a semicircle, by moving round its diameter, describes a sphere, the axis of which corresponds to the diameter; a right-angled triangle, by turning round on its perpendicular, in like manner describes a cone, of which the axis is that perpendicular. The word is generally employed to designate a line which we may conceive to be drawn from the summit of a regular figure to the centre of its base.

In Physical Science, the word is used in many different senses. The *axis of a lens* is an imaginary line joining the centres of the two opposite surfaces of the glass. The *axis of a telescope* or *microscope* is a right line which passes through the centres of all the lenses in the tube. The *axis of the eye*, or *visual axis*, is the right line passing through the centres of the pupil and crystalline lens. The *axes of a crystal* are imaginary lines, about which the planes are symmetrically arranged. The *axis of rotation* is the line around which a body turns when revolving. The *axis of oscillation* is a line passing through the point about which an oscillating body—a pendulum, for instance—makes its vibrations.

AXIS DEER, *ax'-is* (*Cervus axis*) known also as the Chittra and Spotted Hog-deer, chiefly found in India, and also in many islands of the Eastern Archipelago. It is about the size of the fallow-deer, which it much resembles in size. It is of a rich fawn colour, spotted with white. The under parts are white; while a stripe of black runs along the back. The horns of the male are slender, sharp, and palmated. The female has no horns. Hunting the axis is a favourite sport, and its flesh is esteemed a great dainty.

AXOLOTL, *ax'-o-lotl* (*Siren pisciformis*), an amphibious animal, possessing both gills and lungs, thus being able to breathe either air or water. It is about 9 inches long; head broad and flat; the eyes situated near the muzzle; four legs with toes not webbed; the tail nearly as long as the entire body, and compressed at the sides, like that of the common water-newt. It is of an uniform brown colour, thickly mottled with small black spots. The axolotl is very common in the lakes of Mexico, and, according to Humboldt, inhabits the cold waters of mountain lakes. Dressed after the manner of stewed eels, it is often sold in the market-places of Mexico, in which country it is esteemed a great delicacy.

AXOTOMOUS, *ax-ot'-o-mus*, a term applied to minerals cleavable in the direction of their axis.

AYE-AYE, *ai-ai* (*Cheiromys madagascariensis*), a quadruped, about the size of a hare, often confounded with the *ai*, or sloth. It is now regarded as a connecting link between the Rodents and the Quadrumana. When first discovered, it was supposed to be a species of squirrel. It burrows underground, and is altogether a nocturnal animal. It has large flat bat-like ears, and its tail is long and bushy. Each fore-hand has five fingers, the third being singularly attenuated, and provided with a strong claw. The hind-legs are also furnished with prehensile hands. The entire body is clothed with long smooth hair, beneath which is an under-coat of a woolly nature. It measures about eighteen inches from nose to tail, and is found only in the forests of Madagascar, where it feeds on worms and insects. In confinement it will subsist on boiled rice and fruits.

AZALEA, *a-zai'-le-a* (Gr., *azaleos*, dry, arid —the habitat of the plant), a genus of plants belonging to the natural order *Ericeæ*, sub-order *Rhododendreæ*, remarkable for the beauty and fragrance of their flowers. Many of the species are extensively cultivated as ornamental plants: of these, the most common is *A. pontica*, a shrub from three to five feet high, with orange, red, or nearly white flowers. It is a native of the countries around the Black Sea, growing luxuriantly on the mountain-slopes, and often giving great brilliancy to the landscape. The whole plant is narcotic, and Trebizond honey owes its poisonous properties to the bees feeding on the flowers. Some of the finest species in cultivation are natives of North America; of these, the most deserving of notice are *A. nudiflora*, called, on account of its sweet odour, the upright honeysuckle, and *A. viscosa*, which, with *A. pontica*, have become the parents of numerous beautiful hybrids. *A. calendulacea* is a very beautiful plant. It is a native of the southern parts of the United States, where it is described as often clothing the mountain sides with a mantle of rich scarlet. The delicate azalea of the greenhouse, *A. indica*, is, as its name implies, a native of India. This species has lately met with a rival in *A. ledifolia*, an evergreen, which has been brought to this country from China. The azaleas are closely allied to the rhododendrons, from which they chiefly differ in having thin deciduous leaves, and by the flowers having five stamens only instead of ten.

AZIMUTH, *az'-e-muth* (Arab., *al samt*, the way, tract, or quarter). The azimuth of any heavenly body is the angular distance between the north or south point of the horizon and the point where it is cut by a vertical circle, or circle of altitude, passing through the heavenly body itself and the zenith. It is taken by aid of an altitude and azimuth instrument and a theodolite. The term *azimuth circle* is sometimes applied to vertical circles, the planes of which are perpendicular to the plane of the horizon. The *magnetic azimuth* is the angular distance between the point in the horizon cut by the azimuth circle of any heavenly body and the meridian of the magnetic pole. The sun's magnetic azimuth is found at sea by means of an azimuth compass. (*See* COMPASS.)

AZOBENZIDE, *a-zo'-ben-zide*, a substance obtained by the action of an alcoholic solution of potash on nitrobenzole. Its crystals are large and of a reddish-yellow colour. It must not be confounded with nitrobenzole or nitrobenzide, which is benzole in which an atom of hydrogen is replaced by an atom of peroxide of nitrogen; whereas, in azobenzide, it is replaced by an atom of nitrogen only.

AZOIC, *a-zo'-ic* (Gr., wanting life), a term applied to objects entirely destitute of organic life. The name *Azoic Age* is given by geologists to that period of the earth's history preceding the appearance of vegetable and animal life.

AZOLITIUM, *a-zo-li'-ti-um*, the principal constituent of litmus: it is amorphous, of a brown-red colour. It is insoluble, or nearly so, in alcohol and water, but dissolves readily in ammonia.

AZOTE, *az'-ote* (Gr., *a*, not, and *zoe*, life), the old name for nitrogen, so called from being destructive to life; as numerous other gases have the same fatal properties, the word has been almost given up by English chemists, except in such words as *azotized*, *azobenzole*, &c. The French, however, still use *azote*, *azotique*, *azotate*, &c., for nitrogen, nitric acid, and nitrate.

AZURE SPAR, a generic term sometimes applied to any and all minerals of an azure colour.

AZURE-STONE. (*See* LAPIS LAZULI.)

AZURINE, *a'-zhur-ine*, a fresh-water fish closely resembling and of the same genus as the roach, chub, &c. Its back is slate-coloured, its abdomen and fins, white. It was first described by Yarrell. In Lancashire it is known as the blue roach. It is also found on the Continent, especially in the Swiss lakes.

AZURITE, *a'-zhur-ite*, a mineral found in mica-schist of a beautiful azure hue. It is also called *lazulite*, from its faint resemblance to *lapis lazuli*, with which it must not be confounded. It consists of phosphate of alumina, magnesia, and protoxide of iron. The name is also applied to an ore of copper, closely allied to malachite, and sometimes known as *blue copper*.

AZYGOS, *az'-e-gos* (Gr., *a*, not, and *zugos*, a yoke), in Anatomy, is applied to certain parts of the human body that have no yoke or fellow— that, in other words, are single.

B.

BABIANA, *bab-e-a'-na*, a genus of plants belonging to the natural order *Iridaceæ*, and including numerous species, all natives of the Cape of Good Hope. The name is derived from *Babianes*, a word employed by the Dutch colonists to distinguish these plants, because their round subterraneous stems are greedily devoured by baboons. The leaves of all the species are narrow, plaited, and sword-shaped; the flowers are very similar to those of the genus *Gladiolus*, and are usually yellow, but sometimes purple, or even scarlet.

BABOOL, *ba-bool'*, the Indian name for the astringent barks of the *Acacia arabica* and *A. Catechu*. (*See* ACACIA, CATECHU.)

BABOON, *ba-boon'* (Fr., *babouin*) (*Cynocephalus*), a genus of Quadrumana, in which the tail is short and the nose prolonged uniformly with the jaws, the nostrils being open at the end of it, exactly as in the dog. The resemblance the baboon's head bears to the dog is its chief distinctive peculiarity. Its dentition agrees with that of the other monkeys; it has a long and truncate muzzle, cheek-pouches, and sharp claws, and is the fiercest and most repulsive of the Quadrumana. The common baboon (*Cynocephalus papio*) is a native of the coast of Guinea. It is of a uniform yellowish-brown colour, with a shade of light red on the head, shoulders, and extremities, the face, ears, and hands being naked and entirely black. It is furnished with whiskers, which have a backward direction, but do not conceal the ears. The rib-nosed baboon, or mandril, is the most remarkable of the genus. Its head is grotesquely large, its face long; it possesses scarcely any forehead, and its snout is blunt and abrupt. The eyes, which are very small, are sunk deeply in the head, and the cheek-bones very prominent and tinted with violet, purple, and scarlet. The hair rises above the forehead to a peak; and beneath the chin there is a small beard of orange-colour. Round the back of the neck the hair is long and inclines forward. The hinder parts of the animal's body, commencing from the loins, are marked with a soft violet, which gradually expands to the most vivid red. The tail is very short. Besides the baboons mentioned, there are the zelada of Abyssinia, the chacma of the Cape of Good Hope, and several others.

BABYROUSSA, *bab-i-roos'-sa* (*Sus Babirussa*), a large tusked hog, found in a wild state in India and the Indian islands. Its chief peculiarity is the possession of two protruding and curved tusks, turned upwards and backwards, so as very nearly to describe a semi-circle. The animal is further distinguished from the common hog by its slender build and the fineness of the bristles that cover its body. It is said that, when closely pursued, the babyroussa will, without hesitation, take to the water, and, by alternately swimming and diving, speedily elude its enemy. Its food is vegetable, and its flesh, according to travellers, superior to dairy-raised pork. It is sometimes called the Horned Hog.

BACCA, OR BERRY, *bak'-ka*, a many-seeded pulpy fruit, such as the gooseberry, *inferior* (adherent to the calyx) and *indehiscent* (not opening to allow the seeds to escape). The fruit of the grape is called a *nuculanium;* but it only differs from the bacca in being *superior* (free from the calyx). The name bacca is applied by some botanists to any fruit of a pulpy nature.

BACILLARIA, *ba-sil-lair'-i-a* (Lat., *bacillum*, little stick), a genus of *Diatomaceæ* (which *see*), consisting of silicious frustules of a prismatic form united into a brilliant chain, often in a zig-zag manner. They form beautiful microscopic objects.

BACK, *bak* (Ang.-Sax.), that portion of the human body which extends from the neck to the loins, and includes the dorsal vertebræ, the posterior portions of the ribs, and the muscles and skin pertaining thereto.

BACON-BEETLE. (*See* DERMESTES.)

BACTERIA, *bak-te'-re-a* (Gr., *bakterion*, a club), a name given by microscopists to certain plant cells, which are cylindrical, spherical, or oblong, but sometimes distorted in shape. They occur either single or compound, and multiply by transverse division; are propagated in water, and are not capable of transmission through the air. They are found very extensively, if not universally, in the vegetable and animal kingdoms, and play an important part in both healthy and morbid processes. Many of the phenomena of so-called spontaneous generation are due to these minute organisms.

BACTRIS, *bak'-tris*, a genus of palms consisting of nearly fifty species, all natives of tropical America. They are mostly small trees, with slender reed-like stems, some of which are no thicker than a goose-quill. The fruits, which are small, soft, and sub-acid, are greedily devoured by small birds. Tough fibres, used for making nets, are obtained from the stems of some of the species. The leaves of some are pinnate, while those of other species are entire.

BACTRITES, *bak-tri'-tes*, a genus of fossil *ammonitidæ* of which five species have been described. The shell is straight, and the septa ramified.

BACULITE, *bak'-u-lite* (Lat., *baculus*, a staff), a straight, many-chambered, conical shell, of the chalk epoch. In its internal structure it resembles the ammonite. From its prevalence in the chalk of Normandy, that rock has been termed the baculite limestone.

BADDERLOCKS, *bad'-der-locks*, sometimes called Henware, a seaweed (*Alaria Esculenta*), of the sub-order *Fucaceæ;* grows on rocks in deep water on the shores of Britain, Iceland, and other northern countries of Europe. Its stem is from 4 to 8 inches long, and is pinnated with a few short leaflets, which contain seeds. It has also a membranous olive-green frond which grows from 2 to 12 feet long, and has a stout mid-rib. The frond is stripped off, and the mid-rib is used as an article of food.

BADGER, *badj'-er* (*Meles Taxus*), a carnivorous quadruped inhabiting most parts of Europe and Asia. It was classed by Linnæus among the bears, but separated from that group by succeeding naturalists. It is now regarded as forming a connecting link between the bears and the *Mustelidæ*, or otters and weasels. It bears the greatest resemblance to the skunk, the dentition and habits being almost identical, moreover, both animals possess the power of secreting a disagreeable odour, which they can give forth at will. The teeth of the badger differ from those of the bears in the large size of the tuberculous molars, which shows that they are more adapted to vegetable food. It is almost omnivorous in its diet, eating indiscriminately roots and fruits of all kinds, eggs, birds, frogs, snails, worms, honey, and strawberries. It is also extremely partial to the larvæ of wasps and bees, to obtain which, it frequently digs up their nests, its thick hide rendering it careless of the stings of the infuriated insects. It is a slow and heavy animal, passing the day in sleep within its complicated burrow, and emerging at night in search of food. Its size is about two and a half feet in length ; its legs are very short, and its body flat; its eyes are very small, its neck short and thick, its tail stumpy, and its hide loose and tough. It was this last quality that in ancient times recommended the badger to folks of brutal mind as a fit subject to pit against mastiffs. Badger-baiting used to be a very favourite sport in England; and the badger's strong jaws and loose skin made it a formidable antagonist for a dog. No matter what part of the badger's body was seized, it could turn and fix its its teeth in its assailant, and inflict on it a terrible bite. The flesh of the badger is eaten in Italy, France, and China, and may be converted into hams and bacon. The skin, when dressed with the hair on, is impervious to rain, and is, therefore, very commonly used in covering travelling boxes. Its bristles are made into artists' and shaving brushes. The American badger (*M. Labradorica*), closely resembles the European species, but is, perhaps, more carnivorous. To this family also belong the ratels, or honey badgers (*Mellivera*). The best-known species is the Cape ratel (*Mellivera capensis*), which closely resembles the badger both in size and form, but is, perhaps, heavier in its appearance, and has the nose less developed. Its colours are grey above and black beneath. It burrows like the badger, not only to provide itself with a habitation, but also in search of the nest of the wild bees, of whose honey it is passionately fond. It has the same loose hard skin as the European badger, and in this leathery armour it is said to attack the citadels of these irritable insects with impunity. The verb *to badger* comes from the old cruelty of badger-baiting, and is expressive of annoyance and worrying by numerous assailants.

BAGSHOT SANDS, *bag'-shot*, a series of lower tertiary beds, consisting chiefly of light yellow sands reposing on the London clay, and occupying extensive tracts around Bagshot, in Surrey, and in the New Forest, Hampshire. They correspond to the Brocklesham beds (which *see*).

BALÆNA. (*See* WHALE.)

BALÆNOPTERA. (*See* RORQUAL.)

BALA LIMESTONE, *ba'-la* (from Bala, n Merionethshire), a series of limestone beds about 20 feet in thickness, alternating with slaty shales, and constituting a portion of the Lower Silurian formation of Wales.

BALANCERS, *bal'-an-sers*, a term applied to two slender membranous appendages, inserted on either side of the metathorax of insects belonging to the class *Diptera*. They are always small and movable, and vary much in size and form, according to the class of insects by which they are possessed. They usually consist of an elongated style with a small rounded head. Entomologists differ greatly as to the use of these organs. It is generally supposed they are the representatives of the posterior pair of wings, and are attached to the true metathorax. All dipterous insects possess balancers ; and as they keep them in constant motion, they are evidently of great importance.

BALANITE, *bal'-a-nite* (Lat., *balanus*, a barnacle), any fossil of the Barnacle family. The cirripeds, or barnacles, are not found in a fossil state beneath the Oolite.

BALANITES, a genus of plants belonging to the natural order *Amyridaceæ*. The most important species is *B. Ægyptiaca*, which is cultivated in Egypt for the sake of the seeds, which yield, by expression, a fixed oil called *zachun*. The leaves are slightly acid, and are reputed to be anthelmintic. The fruits when unripe are bitter and purgative, but when ripe, are eatable.

BALANUS, *ba'-la-nus*, a genus of *Cirrhopoda* (cirrhus-footed crustaceans), resembling barnacles, but distinguished from them by being destitute of a flexible stalk, and having a symmetrical shell. Popularly they are known as acorn shells. There are many species, and they are found in all seas attached between low and high water-mark to rocks, timber, &c., where they resemble a calcareous incrustation. When under water, they present a very pleasing sight, their valves and feathery cirrhi moving prettily and regularly, but out of water they appear quite dead. The larger species were esteemed a great delicacy by the ancient Romans. In the earlier stages of their existence they are not fixed to rocks as in their adult state, but swim actively in the water.

BALANOPHORACEÆ, *bal'-a-no-fo-rai'-se-e*, a natural order of dicotyledonous plants in the sub-class *Monochlamydeæ*. They are parasites, found growing on the roots of various woody plants, in the tropical and sub-tropical mountains of Asia and South America. They have no leaves ; their stems are of various colours, but never green ; their peduncles are naked or scaly, bearing spikes of flowers, usually white. Dr. Hooker enumerates thirty-seven species, which are divided into fourteen genera. Many are remarkable for their astringent properties ; others are edible, and a few secrete a kind of wax. Two plants of this order are worthy of note—namely, *Cynomorium coccineum*, and *Langsdorffia hypogæa*. The first is the *fungus melitensis* of pharmacologists, formerly highly valued as a styptic ; the second yields large quantities of wax, which is used for making candles by the inhabitants of New Granada.

BALANTIUM, *ba-lan'-ti-um*, a genus of ferns. The species *B. chrysotrichum* is a native of Java, and furnishes the silky hairs which are imported under the name of *Pakoe Kidang*, and occasionally used as a styptic.

BALAUSTA, *ba-laws'-ta*, the name given to a kind of fruit of which the pomegranate is the only example. It is inferior (*i.e.*, adherent to the calyx), many-celled, many-seeded, and indehiscent, and has a tough rind. It is formed of two rows of carpels placed above each other, and surrounded by the calyx; the seeds are attached irregularly to the walls or centre.

BALDNESS, *bawld'-ness* (Ang-Sax.), the loss of hair on a portion or on the whole of the head. It sometimes occurs in early years, but more frequently in old age. It also occurs after febrile or other severe illnesses. It is caused by an atrophy of the follicles on which the hairs depend for nutrition, and generally commences on the crown of the head. Many nostrums are recommended for the cure of baldness; but they are seldom attended with any good result, and frequently do harm.

BALDWIN'S PHOSPHORUS, *bawld'-wins*, nitrate of lime, which, when fused and exposed to the sun's rays, emits a phosphorescent light for a long time if taken into the dark. This phenomenon was first discovered by Baldwin in 1675, and is supposed to be caused by evaporation of the water of crystallization. The reaction is as yet unexplained. (*See* FLUORESCENCE, PHOSPHORESCENCE.)

BALEARIC CRANE, *ba-le-ar'-ic* (*Balearica pavonia*), a beautiful crane of Northern and Western Africa, conspicuous for its crown of golden plumes and scarlet cheeks. It is of bluish slate colour, and about four feet high, with a shorter and thicker bill than that of other cranes. It is easily tamed and of a gentle and playful disposition.

BALISTES, *ba-lis'-tees*, popularly known as the *File Fish*, a genus of osseous fishes, inhabiting the tropical and sub-tropical seas. They belong to the order *Plec tognathi*, and like the other members of the same genus, the skeleton is very incomplete. The body in some of the genera is covered with large rhomboidal scales, and in others with small rough scales, with stiff bristles densely crowded together. The most notable feature of these fish is the power of instantaneously raising or lowering the first dorsal spine.

BALLOTA. (*See* HOREHOUND.)

BALM. (*See* MELISSA.)

BALM OF GILEAD. (*See* BALSAMODENDRON.)

BALSAM, *bawl'-sam* (Gr., *balsamon*), a name formerly given to almost every oily or resinous aromatic substance exuding from trees, or to any healing application to wounds and sores; but now used by scientific men to denote a vegetable product containing either benzoic or cinnamic acid. The true balsams are much used in medicine on account of their stimulating, expectorant, and tonic properties. The most important are the balsams of Peru and Tolu (*see* MYROSPERMUM), benzoin (*see* STYRAX), storax, and gum-wax (*see* LIQUIDAMBER). All those substances are very fragrant. They vary much in their consistence. Thus benzoin is solid, hard, and brittle; Peruvian balsam is fluid; and Tolu is intermediate, being a very soft and readily-fusible solid. Copaiva, commonly called balsam copaiva, is not a true balsam, but belongs to the class of oleo-resins. Several medicinal mixtures, in which oils enter, are commonly included under the head of balsams. Thus, the preparation known as balsam of sulphur, used as an application to foul ulcers, consists simply of flowers of sulphur in olive-oil.

In Botany, the name is also applied to a natural order of herbaceous plants, the Balsamineæ of botanists. (*See* BALSAMINACEÆ.)

BALSAMIFLUA, *bal-sa-mif'-lu-a*, a natural order of dicotyledonous plants, consisting of only one genus. The species are balsamiferous trees found in the warmer parts of India, North America, and the Levant. By some botanists the order is named *Altingiaceæ*. (*See* LIQUIDAMBER.)

BALSAMINACEÆ, *bal'-sa-mi-nia'-se-e*, the Balsam family, a natural order of dicotyledonous plants, in the sub-class *Thalamifloræ*. There are but two genera, *Impatiens* and *Hydrocera* (*see* these words), which include 110 species. These are scattered over the globe, but are chiefly natives of India, growing in damp shady places, and where the temperature is moderate. They are all herbaceous plants, with succulent stems containing much watery juice. The flowers are very irregular, and the petals often finely coloured. The most familiar example is the beautiful *Balsamina Impatiens*, so often cultivated in our greenhouses. The fruit is five-celled, and usually bursts with elastic force so as to scatter the seed over a considerable area. The plants are said to have diuretic properties, but they are never used in medicine.

BALSAMODENDRON, *bal-sa-mo-den'-dron*, an important genus of plants or shrubs, belonging to the natural order *Amyridaceæ*. The species are natives of the East, and are remarkable for the odoriferous gum-resins which exude from their trunks. They have small green flowers, little oval fruits, and pinnated leaves with 4 or 5 leaflets. *B. myrrha*, a small tree growing in the north-eastern parts of Africa, and in the adjoining parts of Arabia, is believed to be the principal, if not the only source of the fragrant gum-resin known in commerce under the name of *myrrh*. It is at first soft, oily, and of a yellowish-white colour; on exposure to the air it soon acquires the consistence of butter, and in time becomes much harder, and changes to a reddish hue. Medicinally, myrrh is regarded as a tonic, stimulant, expectorant, and antispasmodic, when taken internally; as an external application, it is astringent and stimulant. It is an ingredient of the incense burnt in Roman Catholic chapels, and of some kinds of pastiles which are used for fumigation. The substance called *balm of Gilead*, or *balm of Mecca*, and which is supposed to be the *balm* of the Old Testament, is obtained from trees of this character. This substance was, in ancient times, regarded as a cure for almost every disease; but it is seldom used at the present day. The finest variety is obtained by making incisions in the stem, when a turbid white liquid appears, which, on exposure, becomes of a golden yellow colour, and of a like consistence to honey. The gum-resin, known as *Indian bdellium*, or *false myrrh*, and supposed to be identical with the *bdellium* of Scripture, is the produce of two species of this genus. It is the *googul* or *guggur* of the Beloochees, and the *mokul* of the Persians. It is very similar to myrrh. *African bdellium*, another of the gum-resins of commerce, is said to be an exudation of the species *A. Africanum*.

BALTIMORE BIRD, OR BALTIMORE ORIOLE, *Bal'-ti-more* (*Icterus Baltimorii*), a very beautiful bird found in all parts of North America, except the extreme north. In summer it flies as far north as 55° N. lat., but migrates to warmer climates during winter. It belongs to the natural family of *Sturnidæ* (of which the starling is our most common representative), and is quite distinct from the true Orioles (q.v.). The plumage of the Baltimore Bird is very brilliant, and its song is very agreeable. In size, it is a little less than the starling; its beak is slightly curved and very acute, the tail is slightly forked. It is very active, and builds a curious pendulous nest, usually seven inches long, and suspended from two twigs of a lofty branch.

BAMBOO. (*See* BAMBUSA.)

BAMBUSA, *bam-bu'-sa*, the Bamboo, a genus of plants found in tropical and sub-tropical countries throughout the world, and belonging to the natural order *Graminaceæ*, the Grass family. There are many varieties, all of which are graceful and noble-looking plants; for though they are merely grasses, according to the botanical meaning of the term, their thick, jointed stems sometimes reach the height of from 20 to 100 feet. The stems in each species arise from a strong-jointed subterranean-creeping root-stock, which shoots up from 10 to 100 stems. These are hard externally, being coated with flint; for instance, the stem of the *Bambusa tabacaria* (a native of Amboyna and Java), is so silicious that it strikes fire when struck with a hatchet. The stems of all the species are hollow, except at the nodes or joints, where strong partitions exist, and so divide the interior into a number of closed up cylinders. The cavities thus formed are usually filled up with soft loose pith. A peculiar flinty secretion, called *tabasheer* (which *see*), is found in the joints of some species, while others yield a saccharine juice called Indian honey. The stems of the different species of bamboo are applied to a multitude of useful purposes. Good paper is made from them in China and other parts of the world. The very young shoots are boiled and eaten like asparagus, and are also used for pickles and sweetmeats. The hollow stems are used as materials for houses, furniture, clothing, musical instruments, tools, and weapons, in all the countries where they flourish. Dr. Hooker says that in some districts a very large kind of bamboo is used for water-buckets, another kind for quivers, a third for flutes, a fourth for walking-sticks, a fifth for basket-work, a sixth for arrows, a seventh for tobacco pipes, and so on. In China we find the bamboo used for water-pipes and fishing-rods, and for making hats, shields, umbrellas, soles of shoes, baskets, ropes, paper, scaffold-poles, trellis-work, sails, covers of boats, and katamarans. The seeds of some species are cooked and eaten like rice, and are also used for making a sort of beer. The leaves also are used for thatch and for making hats. The bamboo is usually of rapid growth, and is often found in very arid soil. Some species have been found growing in the Himalayas, at an altitude of 12,000 feet.

BANANA. (*See* MUSA.)

BANANA BIRD (*Icterus Xanthornus*), an active and beautiful bird closely allied to, but larger than, the Baltimore bird (q.v.) It inhabits the West Indies and warmer parts of America, is gregarious, and builds a pensile nest like its cogener the Baltimore Bird. Its plumage is very beautiful, and, as it is easily domesticated, it is often kept in houses where it is useful for destroying insects.

BAND-FISH, OR SNAKE-FISH (*Cepola*), a genus of fishes related to the ribbon-fish, are remarkable for singularity of form and beauty of colour. The body is much elongated and compressed. The red band-fish (*C. ruberceus*) found in the Mediterranean, is about 15 inches long.

BANDICOOT, *ban-di-koot* (*Perameles*), a marsupial animal, indigenous to Australia. In some respects it is analogous to the opossum and kangaroo; but its hinder legs, though much longer than the anterior ones, do not present so great an apparent disproportion as in the last-mentioned animal. It is a nocturnal animal, and burrows for itself a dwelling in the soft earth, for which purpose its claws are well adapted. The flesh of the bandicoot is said to resemble that of the rabbit; but the food of the former is generally of a very different nature, consisting chiefly of insects and grubs. Its gait consists of a series of hops, in which, like the rabbit, it uses its fore feet. The long-nosed bandicoot (*P. nasata*) is about 18 inches long from the extremity of the snout to the root of the tail. Another species, *P. Gunnii*, is found in Tasmania.

Bandicoot, or Malabar Rat, *Mus giganteus*, sometimes known as the pig-rat, a native of India and Ceylon. It is the largest known species of rat, and not unfrequently is nearly 30 inches long. The natives eat its flesh, which is said to resemble young pork in flavour It feeds chiefly on grain and roots, and in wet weather stores up rice ready for the dry season.

BANEBERRY, *bain'-ber-e*, a name given to a species of *Actæa*, the root of which is sometimes used medicinally, on account of its antispasmodic, expectorant, and astringent properties. It is a perennial herbaceous plant, from one to two feet high, with triternate leaves, the leaflets of which are deeply cut and serrated. The flowers are in racemes; the berries are black and poisonous. This plant (*A. spicata*) is also known by the name of Herb Christopher. It belongs to the natural order *Ranunculaceæ*.

BANIAN TREE. (*See* BANYAN.)

BANKSIA, *bank'-si-a*, a genus of plants belonging to the natural order *Proteaceæ*, and so named in honour of Sir Joseph Banks. The species are bushes and small trees, found in all parts of Australia. They have hard, dry leaves, dull green above and almost white beneath. The branches bear, towards their extremities, long heads of very numerous flowers. The flowers secrete much honey; hence the name honey-suckle-trees commonly given to these plants by the colonists. One kind, the *P. grandis*, attains a height of 50 feet. Several species are much cultivated in British conservatories.

BANTAM FOWL, *ban'-tam*, a variety of the common fowl, first brought from the East Indies, and deriving its name from Bantam, Java. It is remarkable for its small size and its courage.

BANTENG, *ban'-teng* (*Bos Banteng or Bos Sondaicus*), an animal belonging to the ox family, the peculiarity of which is that the back rises into a high arch immediately behind the neck. It is a native of Borneo and Java, and in colour, formation of horns, and shape, it bears some resemblance to the Indian ox or Gaur. The formation of the skeleton is, however, somewhat different. Its colour is generally black with white legs, its limbs slender, and its sleek coat is covered with short hair.

BANXRING, *banks'-ring* (*Tupaia*), a genus of insectivorous animals, of which there are but a few species known, inhabiting the Indian archipelago. They present remarkable points of differences from other *insectivora* in having very elongated muzzles, and are more like lemurs or squirrels than any other animal, as they have soft glistening fur, a long bushy tail, and are able to run up trees with great agility.

BANYAN-TREE. (*See* FICUS.)

BAOBAB-TREE. (*See* ADANSONIA.)

BAPHIA, *baf'-i-a*, a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Cæsalpinieæ*. The species *B. nitida* yields the dye-wood known in commerce as bar-wood or cam-wood. This dye-stuff is employed, in conjunction with sulphate of iron, to produce the dark-red colour of the English bandana handkerchiefs.

BAPTISIA, *bap-tis'-i-a*, a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Papilionaceæ*. The species are numerous, and chiefly natives of North America. *B. tinctoria* is the wild indigo of the United States, yielding a blue dye, resembling, but much inferior to, indigo. This plant is used medicinally; the root and herbage being stated to possess antiseptic, sub-astringent, cathartic, and emetic properties.

BAR, in Physical Geography, an obstruction, consisting of sandbanks or rocks, which prevents the entrance of vessels into a harbour at low water. They are, for the most part, formed by the accumulation of earth, mud, and sand, washed away and brought down by the water of a river on its way to the sea. The rush of water, however, generally keeps clear one or two deep, narrow channels in the mass, which can be used for the entrance and exit of vessels; but, in some cases, the entrances to rivers have to be kept open by the continual removal of the accumulating detritus by dredging-machines constructed for the purpose.

BARB, *barb*, the name given to a fleet and vigorous breed of horses reared by the Moors of Barbary, and introduced by them into Spain. They are unusually nervous and long-winded, but, as a rule, are not remarkable for symmetrical beauty.

BARBADOES CHERRY. (*See* MALPIGHIA.)

BARBADOES GOOSEBERRY. (*See* PERESKIA.)

BARBARY APE, PIGMY APE, MAGOT, *bar'-ba-re*, a species of ape, interesting as being the only kind now left in Europe. It is about the size of a large cat, and is greenish-grey in colour, paler underneath. It has no tail, and is sometimes called the tailless monkey. The muzzle is not so much elongated as in the baboons, and the facial angle is much higher than theirs. It has small, round, reddish, lively eyes, and its ears resemble those of a human being. The face is nearly naked, and somewhat wrinkled. It usually walks upon four feet; but it can be tamed and taught to walk, though clumsily, on two. They are found in large numbers at Gibraltar, and inhabit the precipitous sides of the rock. They are gregarious, and live in parts of the rock inaccessible to man; but they are often seen in great numbers, the females carrying their young ones on their backs. They are very seldom destroyed, on account of the amusement they afford by their gambols and tricks. The Barbary ape probably came to Gibraltar from the north of Africa, where it is very abundant, and inhabits rocky mountains. Bands of them will often plunder gardens, while one of the number keeps a keen look-out. This species of ape possesses a considerable amount of intelligence, and is often seen tame in this country. They must, however, be taught when young, as they often grow sullen and vicious as they grow old; moreover, they are very unclean in their habits. They feed on roots, fruits, berries, &c., and their fondness for eggs has doubtless given rise to the ancient story of the pigmies and cranes.

BARBASTELLE. (*See* BAT.)

BARBEL (*Barbus*), *barb'-el*, a genus of fish of which there are several species, belonging to the *Cyprinidæ*. They frequent the quiet and deep parts of rivers, and swim with considerable strength and activity. The name is derived from the barbs or wattles attached about its mouth. Barbel have been found measuring three feet in length; but the average is two feet, and weight about ten pounds. The Thames produces barbel of a large size. They are fond of muddy pools and deep rivers, where they seek food by pushing in the mud with their snouts like swine. They feed on worms, insects, small fish, and the roots and leaves of aquatic plants. Only one species is found in England, the *Barbus vulgaris*. It is not good for the table, being very coarse eating, and poor persons boil bacon with it to give it flavour. Another kind, called the Binny, is found in the Nile, where it is very abundant and grows to a great size.

BARBERRY. (*See* BERBERIS.)

BARBET, *bar'-bet*, a family of birds, belonging to the *Picidæ*, and distinguished by their large conical beaks, and by being bearded with fine tufts of bristles directed forward. They exhibit points of resemblance both to the cuckoo and the woodpecker. They prey on insects and young birds, and also fruits and berries, and being of short wing, they generally wait with great patience on a branch and snap up the insects as they pass by. They inhabit warm climates in both hemispheres, and there are several species all of which are remarkable for gay plumage. The American puff-bird belongs to this family.

BAREGINE, *bar'-a-geen*. A deposit found in hot springs, and particularly in those at Barèges in France—whence the name. This deposit is the product of certain Algæ which grow in these springs. It imparts a meat-like flavour and odour to the springs, which is highly prized.

BARITAH, *ba-ri'-ta*. The name given to a genus of large birds found in Australia, and of which there are several species, the best known being the Piping Crow or Jar-ra-var-nang of New South Wales. Sometimes these birds are classed among the Crows (Corvidæ), and sometimes among the Shrikes (*Laniadæ*). The Baritah present points of resemblance to both.

BARIUM, *bair'-i-um* (atomic weight 68·5, symbol Ba), the metallic base of the alkaline earth *baryta*, which latter substance was first recognized by Scheele in 1774, the metal barium being first obtained by Davy in 1808, who named it *barium*, from the Greek word *barus*, heavy, on account of the excessive density of its compounds.

It may be formed by voltaic decomposition, from the anhydrous chloride, or by passing the vapour of potassium over red-hot baryta contained in an iron tube, a mixture of oxide of potassium and barium is formed, which is amalgamated with mercury. On distilling off the mercury in an atmosphere of hydrogen, the metal barium is left behind in a somewhat impure state. Owing to the difficulty with which it is prepared, little is known of its properties. Its specific gravity is said to be 4. It is of yellowish colour, and slightly malleable, rapidly oxidising in air, and decomposing water at ordinary temperatures. It has never yet been obtained in a mass but only in powder. It quickly tarnishes in the air, from the absorption of oxygen. When moderately heated, it burns with a deep-red flame.

BARK, *bark* (Dan.), the external coating of an exogenous or dicotyledonous stem and its branches. It is distinguished from the *rind* or *false bark* of an endogenous (such as palms, &c.), or of an acrogenous stem, by its mode of growth, and by the ease with which it may be separated from the wood beneath. The bark presents three distinct layers, independently of the epidermis which is common to it, with other external parts of the plant. These three layers, proceeding from within outwards, are known as the *liber*, or *inner bark*; the *cellular envelope*, or *greenlayer*; and the *suberous*, or *corkylayer*. Some botanists apply to these three layers, respectively, the Greek terms, *endophlœum*, *mesophlœum*, and *epiphlœum*. The bark is connected organically with the wood by means of the medullary rays and cambium-layer. (*See* STEM.) It develops in an opposite direction to that of the wood; for while the latter increases by additions to the outer surface, the bark increases by additions to the inner. Each layer of the bark grows separately; the two outer layers, constituting the cellular system of the bark, rarely continue to grow after a few years, but become dead structures on the surface of the tree. The inner bark, however, continues to grow throughout the life of the individual, by the addition of annual layers on its inner surface from the cambium-layer of the wood. In some trees, the oak for example, up to a certain age, these liber layers may be readily observed. (*See* LIBER.) The outer layers of the bark, from the distension to which they are exposed by the growth of the wood beneath, generally become cracked in various directions, and give a rugged look to the trunk, as in the elm and cork-oak. In some trees, however, as the beech, the bark always remains smooth, owing partly to the small development of cellular layers, and partly to the great distensibility of the layers. There are several kinds of bark which enter largely into commerce, being used for processes in the arts, or for medicines. These will be found noticed in separate articles, under the botanical names of the genera which include the plants producing them. For oak-bark, qeurcitron-bark, and cork (*see* QUERCUS); Peruvian bark (CINCHONA); cabbage-bark, Surinam bark (ANDIRA); cascarilla bark (CROTON); wild-cherry bark (CERASUS). (*See* also TANNING.)

BARK BEETLE, OR BARK CHAFER, a name given to many of the family of coleopterous insects known to naturalists as Xylophage, or wood eaters. They are all small, and generally of uniform colour, have hard bodies, and club-shaped antennæ. They bore holes in the bark, and deposit their eggs. Sometimes they appear in immense numbers and commit dreadful ravages.

BARKING-BIRD, *bar'-king* (*Pteroptochos*). A native of the South-American archipelago, building its nest close to the ground, among the underwood and fallen branches. Says Mr. Darwin, "Its name is well applied: I defy any one, at first, to feel certain that a small dog is not yelping somewhere in the forest."

BARLEY. (*See* HORDEUM.)

BARNACLE, OR BERNICLE, *bar'-na-kel* (Port., *bernaca*), a marine animal, which attaches itself to ships' bottoms and other submarine substances. It belongs to the genus *Cirrhopoda*, and is the type of a family of articulate animals distinguished by a long flexible stalk, which is provided with muscles upon the summit of which are five shelly valves, enclosing the principal organs of the animal, and opening and closing on one side. Barnacles abound in almost all seas.

Barnacle Goose. (*See* BERNICLE GEESE.)

BAROLITE, *bar'-o-lite*, (Gr., *barus*, heavy, *lithos*, stone), carbonate of baryta, or witherite. It contains 80 parts of barytes and 20 of carbonic acid. It is found at Alston Moor, in Cumberland, and at Anglesack, in Lancashire. It is much used in the North for poisoning rats.

BAROMETZ, *bar'-o-metz*, the prochate stem of a fern (*Aspidium barometz*), growing in the salt plains near the Caspian Sea. It has a sort of general resemblance to an animal with a silken down; and in past times was known as the Tartarian or Scythian lamb, and believed to partake of the vegetable and animal natures, and to eat grass.

BAROSELENITE, *bar'-o-sel'-e-nite* (Gr., *barus*, heavy, *selene*, lustre), native sulphate of baryta, or heavy spar. It occurs in modified rhombic and rectangular prisms; also in compact granular or fibrous masses. It is much used when ground for adulterating white lead. It contains 66 parts of baryta and 34 of sulphuric acid.

BAROSMA, *bar-os'-ma*, a genus of plants belonging to the natural order *Rutaceæ*. The leaves of several species, such as *B. crenata*, *crenulata*, and *serratifolia*, are used in medicine for their aromatic, stimulant, antispasmodic, and diuretic properties. They seem also to have a specific influence over the urinary organs. The plants yielding them are natives of the Cape of Good Hope. In commerce they are known as Buchu-leaves, and are thus named in the British Pharmacopœias. They contain a peculiar bitter principle called *Diosmin* or *Barosmin*, and a powerfully-scented volatile oil.

BARRICARRI SEEDS, *bar'-ri-kar-re*, the produce of the *Adenanthera pavonia*, a leguminous plant. They are of a bright red colour, and are employed in the northern parts of South America as beads for making necklaces.

BARRINGTONIA, *bar-ring-to'-ni-a* (in honour of the Hon. Daines Barrington), the typical genus of the natural order *Barringtoniaceæ*, consisting of small trees conspicuous for their beauty. *B. Speciosa*, the Moordilla, a native of Ceylon, has dark glossy leaves, and white flowers delicately tinted with crimson. Sir Emerson Tennent says that the stamens, of which there are nearly a hundred to each flower, when they fall to the ground, might almost be mistaken for painters' brushes.

BARRINGTONIACEÆ, *bar'-ring-to'-ni-ai'-se-e*, a small natural order of dicotyledonous plants, in the sub-class *Calyciflorœ*. They are usually placed among the *Myrtaceœ*, which they resemble in most essential particulars. The species are all natives of tropical regions, and most of them have poisonous properties. The bark of *Stravadium racemosum* is said to be febrifugal; the fruit of *Careya arborea* is edible; while that of *Gustava braziliana* is emetic, and produces an intoxicating effect upon fish.

BARTON BEDS, *bar'-ton*, a group of tertiary beds forming part of the Middle Eocene formation, included in the Bagshot series. They consist of greenish-grey sandy clay below, passing up into bluish-green and brown clay, interstratified occasionally with beds of sand and loam.

BARU. (*See* SAGUERUS.)

BARWOOD. (*See* BAPHIA.)

BARYSTRONTIANITE, *bar-i-stron'-shan-ite*, a mineral found in Orkney, containing a mixture of carbonate of strontia and sulphate of baryta. It is also known as Stromnite.

BARYTA, OR BARYTES, *ba-ri'-ta* (Gr., *barus*, heavy), one of the alkaline earths, discovered by Scheele, in 1774. It is met with, combined with sulphuric acid, in *cawk* or *heavy spar*, and combined with carbonic acid in *witherite*. It may be formed by decomposing the nitrate by a red heat. It is very similar in its properties to caustic lime. It is greyish-white; becomes hot when moistened with water, falling to a fine white powder, forming the hydrate. Its specific gravity is about 4. It has an extremely acrid caustic taste, and is very poisonous. It dissolves in 20 parts of water, forming baryta-water, much used as a chemical re-agent. Boiling water dissolves half its weight of baryta, and deposes, on cooling, four or six-sided prismatic crystals, containing 10 equivalents of water.

Baryto-Calcite, *ba-ri'-to-kal'-site*, a mineral containing carbonate of baryta and carbonate of lime; also called Alstonite, from being found in the lead mines of Alstone Moor.

BASALT, *ba-zawlt'* (from *basal*, an Ethiopian word for iron), a close-grained, hard, black, or dark-brown rock, of igneous origin, occurring both in the Trap and Volcanic series. It is one of the Dolerites or Augitic lavas, and consists essentially of augite and felspar, the former being in excess. It often contains crystals of the olive-green mineral *olivine*, grains of magnetic iron, and other bodies. Masses of basalt are frequently found divided into columns or prisms, with three, five, or more sides. That this columnar structure is the result of contraction on consolidation, is shown in the prisms usually being at right angles to the greatest extension of the mass—that is to say, being vertical in a horizontal bed, and horizontal in a vertical dyke—proving that the fissuring commenced at the cooling surfaces, and struck thence directly towards the centre of the mass. The pillars of basalt are usually from six to eighteen inches in diameter, and vary in length from five or six to 100 or 150 feet. Basalt is rarely, if ever, found as an underlying rock, but generally occurs as a dyke or as an overlying mass. The most celebrated plateau of basalt is that in the north-east of Ireland, covering almost the whole county of Antrim. This entire mass is 300 or 400 feet in thickness, and 50 miles long by 30 wide. The basalt occurs in three or four sheets, in many places beautifully columnar, and interstratified with beds of volcanic ash, or "ochre," as it is called. One of the columnar beds dips gradually into the sea on the north coast, and is known as the Giant's Causeway. The basalt of the west of Scotland is very remarkable for the beauty and regularity of its columns. At Fingal's Cave, in the island of Staffa, the arrangement of these basaltic columns was long regarded as the masonry of a race of giants.

BASE, *baiss* (Lat., *basis*, a foundation; Fr., *bas*, low), that part of a column on which the shaft is placed, consisting generally of a square plinth and mouldings, formed of tori, fillets, cavettos, and astragals, in various combinations, between the plinth and the bottom of the shaft. The height of the whole base, including plinth and mouldings, is about half the diameter of the shaft at its lowest or broadest end. The Greek Doric column is the only form of pillar that has no base. In Gothic architecture, the base became higher and more varied in form than in examples of orders of the classic period.

BASELLACEÆ, *bas-el-lai'-se-e* (from *basella*, its Malabar name), the Basella family, a small natural order of dicotyledonous plants, in the sub-class *Monochlamydeœ*. They are climbing herbs or shurbs, closely allied to *Chenopodiaceœ* (which *see*), but readily distinguished by having a coloured calyx, with two rows of sepals and perigynous stamens. There are four genera and twelve species, all of which are tropical plants. *B. rubra* and *alba* are used in the East Indies as substitutes for spinach. From the former species a purple dye may be obtained. The fleshy roots of *Ullucus tuberosus*, or *Melloca tuberosa*, a native of Peru, contain a great deal of starch, and are edible.

BASIL. (*See* OCYMUM.)

BASILISK, *bas'-i-lisk* (*Basiliscus*), a genus of Saurian reptiles, found in South America, and occasionally attains a length of three feet. Instead of the comb-like ridge of the iguana, the basilisk is furnished with a broad membrane running down its back, and a second, still broader, on the upper surface of its tail. This process is capable of either expansion or contraction. The hind part of the basilisk's head bears a remarkable pointed hood. Notwithstanding its unsightly appearance, the basilisk is a perfectly harmless reptile.

BASILOSAURUS. (*See* ZEUGLODON.)

BASIN, *bai'-sin* (Fr., *bassin*), a term applied to any dipping or disposition of strata towards a common centre, which has resulted from the upheaval and subsidence of the earth's crust. The tertiary formations often occupy limited areas, and fill up the basins of the older strata; hence the use of such phrases as "London basin," "Paris basin," &c. The *basin of a river* implies the area of drainage; the *basin of a dock*, a place where the water is confined by double floodgates, or a caisson, and thereby prevented from running out at ebb tide. The use of it is to contain ships either before they enter, or after they come out of the dock in which they are repaired. Basin also implies some part of a haven, which opens from a narrow channel into a spacious receptacle for shipping.

BASKING SHARK, *bas'-king shark*, a large, immensely strong, but still harmless species of shark. By the Irish it is called the sunfish. (*See* SHARKS.)

BASSE, OR SEA-PERCH, *bass*, a marine fish, the *Labrax Lupus* of Cuvier. The fishes of this genus belong to the family *Percidæ*, or Perches, with whom they are closely allied. The basse is to be met with along the British and Dutch shores, and abundantly in the Mediterranean. By the ancient Greeks aud Romans it was highly esteemed as an article of food. On account of its voracity, it was called by the Romans *lupus* (wolf), a name still retained as a designation of the species. Its length is generally from a foot to a foot and a half; but it has been found of a much larger size. There is an American species of basse, which is termed by Cuvier *Lupus macronatus*.

BASSET, *bas'-set*, a term applied by miners to the emergence at the surface of different mineral strata from beneath each other. It is also applied to openings from or into mines from the surface.

BASSIA, *bas'-si-a*, a genus of plants belonging to the natural order *Sapotaceæ*. The species are trees, natives of tropical or sub-tropical regions. They are remarkable for their fleshy flowers and oily seeds. In India, the fatty oils procured from the ripe kernels of *B. latifolia*, the Madhuca-tree, and *B. longifolia*, the Elloopa-tree, are made use of for burning in lamps, for culinary purposes, for making soap, and, medicinally, for external applications in cutaneous affections. The fleshy flowers and fruits are used as food, and from the former an alcoholic liquor is distilled. The wood of *B. longifolia* and other species is very hard and durable.

BASSORA GUM, *bas'-sor-a*, a whitish or yellowish substance brought from the neighbourhood of Bassora. It differs from most gums in being nearly insoluble in water. The plant yielding it is believed to be a species of *Mimosa*. It contains a peculiar principle, called Bassorin, which also exists in gum-tragacanth.

BAST, OR BASS, *bass*, a name commonly given to the inner bark of trees. Russian mats are manufactured from the bast of the lime-tree, and more than 3,500,000 are annually exported. (*See* LIBER.)

BAT, *bat*, the common name of a group of the class Mammalia, forming the order *Cheiroptera*, "wing-handed." Naturalists of an ancient date experienced a difficulty as to the proper classification of bats in the system of nature. The anatomical and intestinal structure of bats, combined with their viviparous nature, their hair, &c., without doubt entitles them to be ranked as quadrupeds. The anterior members are as completely organized for true flight as those of a bird. As in the birds, the bones supporting the anterior members are large, the humerus rather short, and the bones of the fore-arm long; but the latter are quite separate and movable, as in the human arm. The bones of the fingers, however, instead of being amalgamated, so as to form a single series, are all quite distinct, and, when extended, radiate widely from the wrist, the bones of which are of small size. The thumb is short, but the other four fingers excessively elongated: the first finger is the shortest, and the others of nearly equal length. The four long fingers and the bones of the arm are united by a delicate leathery membrane, which is also united to the sides of the body as far as the extremities of the hind-legs, and sometimes fills up the space between them; and it is by the agency of the broad wings, formed by the extension of the arms and fingers, that the bats are enabled to flutter through the air. The thumbs of the anterior feet are small, free, and furnished with sharp curved claws, by which the animals can suspend themselves to any convenient projection. The thumbs of the anterior hands and the hind feet are the only means by which the bat can progress along the ground, where, as might be expected, it is very awkward in its movements. The body is covered with a soft down, but the membrane of the wings only exhibits a few scattered hairs. The teats are placed on the breast, and the young, when sucking, cling to that part of the mother's body, and are carried about by her. Their senses of smell, hearing, and feeling, are very acute, and in some the nose is furnished with a membraneous foliation of most delicate structure, by which the sense of smell is greatly enhanced. The ears, in many kinds, are expanded, and capable of being folded down; while their full wings and the tissues of the ear and nose are so amply furnished with nerves as to enable them, even though deprived of sight, to pursue their flight through the narrowest passages without danger. On the approach of winter, the bat relapses into a state of lifeless inactivity, and in selecting a spot for hybernation, appears to regard security from molestation before any other consideration. At an earlier or later period of autumn, according to their species, they retreat, generally in large congregations of various species together, to the most retired places, as under the roofs of houses and churches, in caverns, in the hollows of trees, and similar situations, where they suspend themselves by their hinder claws, with their heads downwards. Here they crowd together, holding not only by the surface of the walls of their retreat, but by each other, one crowding over another so closely that it appears scarcely possible for such numbers to occupy so small a space. The common bat, or "flitter-mouse" (*Vespertilo pipestrellus*), is more frequently seen in this country than any of the others. It makes its appearance in the twilight of fine summer evenings in lanes and shady places, or haunts the vicinity of quiet streams, where any sort of nocturnal insects abound. Although not more than two and a half inches long, or about the size of the common brown mouse, it is very voracious, and must in a single evening consume a vast number of insects. The long-eared bat (*Plecotus auritus*), is the most elegant of the bats, and most easily tamed, learning to come at a whistle and take flies from the hand. The mouse-coloured bat (*Vespertilio murinus*), and the great bat (*Vespertilio noctula*), also count among the well-known British bats. The horse-shoe bat (*Rhinolophus*) resembles the common bats in its general habits, but is even more nocturnal, being satisfied with nothing short of absolute darkness for its place of retreat. The animal derives its name from the possession, above its nose, of a singular leaf-like membraneous appendage, shaped somewhat like a horse-shoe. The horse-shoe bats are abundantly distributed over the warmer regions of the earth, but Britain numbers but two of them—the great and little horse-shoe bat. The largest of these two measures two and a half inches in length, while the lesser is one of the smallest British species of the order. The most terrible of all the bats is the one that has earned for itself the title of Vampyre (*Phyllostoma spectrum*). Like the horse-shoe bat, it is furnished with a nose-crest; the canine teeth are large, and in almost all the species there are four incisors in both jaws. Some of them are so large as to measure two and a half feet across the extended wings. There can be little doubt that their favourite food is blood; but many of the stories respecting them are probably greatly exaggerated. The fruit-eating bats (*Pteropus*) are limited to the warm regions of Asia and Africa, the largest known bat is the Kalong of Java (*Pteropus Javanicus*), which measures four feet between the tips of its wings. About 130 species of bats are known.

BATATAS, *ba-tai'-tas*, a genus of plants belonging to the natural order *Convolvulaceæ*. The most important species is *B. edulis*, the Sweet Potato, a native of the East Indies, but now cultivated in all tropical and sub-tropical countries for its tubers, which, when roasted or boiled, form a wholesome and highly-nutritious article of food. Next to maize, the sweet potato is the principal food of the poorer classes in America.

BATHYBIUS, *bath-ib'-e-us* (Gr., *bathus*, deep, *bios*, life), the name given by Professor Huxley to a gelatinous substance found at the bottom of the sea, supposed to exhibit the lowest form of animal life. Many naturalists, however, deny that it exhibits any traces of life.

BATH STONE. A building stone extensively used on account of its beauty, is obtained from quarries in Wiltshire and Somersetshire. It belongs to the Lower Oolite, is five-grained, and, although easily cut in the quarry, hardens on exposure to the air; but is not very durable.

BATIDEÆ, *bat-i'-de-e*. A succulent and shrubby plant, *Batis maritima*, a native of the West Indies, where it is occasionally used as an ingredient in pickles. The order is closely allied to *Empetraceæ*, the Crowberries.

BATRACHIA, *ba-trai'-ki-a* (Gr., *batrachos*, a frog), soft and naked-skinned reptiles, such as frogs and toads, who in the early stage of existence respire by means of gills. (*See* AMPHIBIA, FROG, NEWT, REPTILE, &c.)

BATRACHOLITES, *bai-trai'-ko-lites*, in Geology, fossil remains of frogs and other animals of the same order. The skeletons, vestiges of the soft parts, and imprints of the feet of several genera of true batrachians, occur in the tertiary strata. In the pliocene deposits on the banks of the Rhine at Œningen and in the paper-coal of the Eifel, several species of frog, toad, and newt, have been found. Fossil frogs of a small species very similar to the recent abound in a dark shale overlaid by basalt in the vicinity of Bombay.

BATRACHOMYOMACHIA, *bat-ra-ko'-mi-o-mai'-ki-a* (Gr., *batrachos*, a frog; *mus*, a mouse; *mache*, a battle), literally signifies a battle of frogs and mice, and is the title of a Greek mock heroic poem usually ascribed to Homer, but without any good foundation. It seems to be indeed a parody upon the Iliad; and the contests of the beasts, their single combats, the intervention of the gods, and other Homeric incidents, are described with much humour. The authorship has been attributed to Pigres of Caria, who lived in the time of the Persian wars.

BATRACHUS. (*See* FROG-FISH.)

BAUHINIA, *baw-hin'-i-a* (so named in honour of the brothers Bauhin, botanists of the 16th century), a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Cæsalpinieæ*. The species are natives of the warmer regions of both hemispheres. Most of them are twining plants, which stretch from tree to tree in tropical forests, like living cables; but a few are small trees, with erect self-sustaining stems. The leaves are generally divided into two equal globes, which circumstance is said to have suggested the idea of naming the genus after the two brothers. The flowers of some are large and very beautiful; but they rarely show themselves in the hothouse. The genus contains several very useful species. Thus *B. parviflora*, *racemosa*, and *valilii* yield tough fibres employed for making ropes; *B. retusa* and *emarginata* each produce a kind of gum; *B. variegata* has an astringent bark used in medicine, and for tanning and dyeing leather; the buds and dried flowers of *B. tomentosa* are also astringent, and are much employed by the Indian doctors in dysenteric affections. The snaken rod of Æsculapius is said to have had its origin in a portion of the stem of *A. scandens*, which had twined around a smaller stem. The Mopané-tree of South Africa is a species of *Bauhinia*. During the heat of the day the leaves of this tree fold up and become almost erect, so as to afford but little shade to the sun-oppressed traveller.

BAY, *bai* (Fr., *baie*), an arm of the sea extending into the land, not of any definite form, but smaller than a gulf, and larger than a creek. The term is, however, often applied to large tracts of water around which the land forms a curve, as Hudson's Bay.

BAY. (*See* LAURUS.)

BDELLIUM. (*See* BALSAMODENDRON.)

BEACH, *beech*, (Ang.-Sax.), a shelving tract of sand or shingle washed by the sea or a fresh-water lake, interspersed between the water and the land on which vegetation grows. The sea-beach is the space between low and high water-mark, particularly that part of it which is dashed by the waves; and the beach of a lake lies between the highest and lowest water-marks of its ordinary level.

Beaches, Raised. Banks of sand and shingle, with shells, found following the bays and recesses of the coast, at various heights above the existing beach or sea-margin. These give evidence of either elevation of the land or depression of the ocean, and point to times when sea and land stood at these successive levels. Along the coasts of Great Britain there are several notable examples, at heights about 10, 20, 40, and even 60 feet above the present sea-level.

BEADS, ST. CUTHBERT'S, a popular term for the detached bead-like joints of the fossils called *encrinites* (which *see*). They are found in great abundance on many parts of our coasts. The legend associating St. Cuthbert with these fossils is thus alluded to by Sir Walter Scott:—

"On a rock by Lindisfarne,
St. Cuthbert sits and toils to frame
The sea-born beads that bear his name."

BEAGLE, *bee'-gl*, a small hound, more remarkable for perseverance than speed, formerly employed in hare-hunting, but now superseded almost entirely by the harrier. The true beagle is rarely more than eleven inches high to the top of the shoulder, and in many cases much smaller. It has long ears: smooth-haired, and the colour is dark brown, or white, with black or reddish spots. Some breeds of beagles are very small. Queen Elizabeth had little "singing beagles" (so named from their very musical cry when hunting), one of which could be placed in a man's glove. Colonel Thornton, an eminent English sportsman, owned a valuable breed of minute lapdog beagles, and George IV., while prince of Wales, was in the habit of hunting with packs of well-selected dwarf beagles. Another well-known English sportsman, the late Colonel Hardy, once had a pack of beagles amounting to ten or twelve couples, and so diminutive in size that they were always carried to and from the sporting field in a large pair of panniers slung across a horse.

BEAK. (*See* BILL.)

BEAM-TREE. (*See* PYRUS.)

BEAN, *been* (Sax.), the common name for several leguminous plants yielding pulse. These will be described under the names of the genera to which they belong; thus, for broad-bean, *see* FABA; kidney-bean, scarlet-runner, and haricot (PHASEOLUS); ordeal-bean (DOLICHAS); Tonquin-bean (DIPTERYX).

BEAN-CAPER. (*See* ZYGOPHYLLUM.)

BEANS, IGNATIUS. (*See* STRYCHNOS.)

BEAR, *bair*, a general name of the *Tersidæ*, a family of plantigrade mammals distinguished by massive bodies, short limbs, and almost rudimentary tails, they belong to the order *Feræ*, and sub-order *carnivora*. Bears are generally inhabitants of the wooded districts of mountainous countries, and occur in all parts of both hemispheres, with the exception of Australia. Of all the carnivora, they are the most omnivorous in their diet, some of them living almost entirely on animal food. Roots, berries, worms, insects (especially ants), are equally relished by the bear; but, more than all, he delights in honey, to get at which he will climb trees and assault the strongholds of wild bees, though not uncommonly compelled to beat a retreat before the tiny sting-bearers. Generally, the bears are large heavy animals, with an awkward and shuffling gait. Their anterior limbs, however, are possessed of considerable mobility, and, despite their bulk and great weight, they exhibit great dexterity in climbing. The feet of the bear are armed with formidable curved claws, equally available for tearing a carcass or digging up a root. Bears are found in Europe, Asia, and North and South America, and in all climates, the species belonging to cold regions being generally most fierce and carnivorous. Old writers speak of them as being found in Africa, but, as far is known, no species is now to be met with in that continent, except in the north-western corner. Six species are European, six American, eight Asiatic, and one, the Polar bear, is common to the Arctic regions of both hemispheres. In northern countries, the bear retires during the winter season into caves and the hollows of trees, and remains dormant till the opening of the spring season, the vital action being sustained by the absorption of the fat, which, in their time of activity, acumulates rapidly. Young bears are born naked and blind, and remain in that condition for about five weeks, after which time they can see and the fur grows. The common or *brown bear* (*Ursus Arctæ*), is found in the temperate regions of Europe, Asia, and South America, and was in former times an inhabitant of Britain. It is generally about four feet long and two and half feet high. It is an animal of solitary habits. This bear is hunted for the sake of its fur and fat (the bear's grease of hair-dressers), and as food, bear-hams and bear-paws being considered a delicacy. The American *black bear* (*U. Americanus*) is large, and its fur is of considerable value, and about 10,000 skins are annually imported into Great Britain. The largest and most ferocious animal of the species is the North American *grisly bear* (*U. ferox*), found chiefly in the Rocky Mountains and the plains to the eastward. It measures about nine feet in length, has enormous claws, and can overpower and carry away a bison. All narratives of travel in the Far West abound with stories of encounters with the terrific "Grisly." The claws possess the singular property of independent action (not retractible like those of feline animals), each separate claw being as capable of distinct movement as the fingers of the human hand. The strength of this last-mentioned animal is so prodigious, that it can bear off an ox or bison weighing a thousand pounds. Should it find a carcass, and, being already full, have no immediate appetite for it, the grisly bear will dig a pit and bury it. This propensity to bury is very peculiar. Bear-hunters suddenly overtaken by the animal have stretched themselves along the earth and feigned death; whereon the shaggy sexton has immediately set about excavating a pit, into which the hunter was rolled and covered with earth. It is said that wolves, however famished, will not touch a body buried by a grisly bear, though they will devour any and the vilest offal chance may throw in their way. Another peculiarity of the animal in question is, that he does not hug his prey. His claws are broad, of great length, and edged like a chisel. Eyeing the object of attack intently for a moment, he rushes at it, rears, and strikes with his tremendous fore-paws. Sir John Richardson mentions the case of a hunter who was completely scalped, the skull being laid bare, and the hair turned right over the face, by a blow from the grisly bear's paw. The *Syrian bear* (*U. Syriacus*) is most probably the bear mentioned in the Scriptures. It is of a dingy white or brown colour. The *Polar bear* (*U. maritimus*) is a very large animal. The neck is long, the head flat, and the fur smooth and white. It is marine in habits, and never found far from the sea, living chiefly upon seals, fishes, and birds.

BEARD MOSS. (*See* USNEA.)

BEATSONIA, *beet-so'-ni-a*, a genus of plants belonging to the natural order *Frankeniaceæ*. The leaves of one species are used at St. Helena as a substitute for tea.

BEAVER, *bee'-ver* (*Castor fiber*), an animal of the order *Rodentia*, easily distinguished from the rest of the order by its peculiar tail, which is of a nearly oval form, horizontally flattened. The usual length of this animal is about two feet, exclusive of its tail. In colour, the beaver is reddish-brown, sometimes deepening into black; the coat consists of two kinds of hair, the longer comparatively coarse, smooth, and glossy; the under coat dense, soft and silky. The hind-feet are webbed, and adapted to the element in which the animal usually lives. There are two large glandular pouches near the tail, containing a substance known as *castoreum*, which emits a pungent odour. The incisor teeth are remarkably hard and sharp, and act like a chisel. According to Sir John Richardson, the Indians always used these teeth to cut bone and other substances, until the introduction of iron caused their disuse. The same authority says, "When the beaver cuts down a tree, it gnaws it all round, cutting it, however, somewhat higher on the one side than the other; by which the direction of its fall is determined. The stump is conical, and of such a height as a beaver sitting on his hind-quarters could make. The largest tree I observed cut down by them was about the thickness of a man's thigh, that is, six or seven inches in diameter; but Mr. Graham says that he has seen them cut down a tree which was ten inches in diameter." The sagacity and industry of the beaver have been the favourite theme of naturalists from the time of Buffon to the present day. As food the beaver chiefly prefers the bark of trees and such shrubs as the willow, poplar, and birch. It will eat berries in the summer. It lays up stores of food for the winter in the same manner as other rodents. This winter supply mainly consists of the bark and branches of trees. The northern part of North America is the great breeding-place of the beaver. The American species is known as the *Castor Canadensis*. In consequence of the use of silk and other materials in the manufacture of hats, the demand for beaver skins is much less than was the case some years back, when the eagerness with which the beavers were captured threatened the extinction of the animal. Some thousands of their skins are annually imported into this country. Beavers inhabit lakes, ponds, and rivers, as well as those narrow creeks which connect the numerous lakes with which North America abounds; but the two latter are chosen by them when the depth of water and other circumstances are suitable, as they have then the advantage of a current to convey wood and other necessaries to their habitations, and because, in general, they are more difficult to be taken than those that are built in standing water. The materials made use of are driftwood, green willows, birch, and poplars, if they can be got; also mud and stones intermixed in such a manner as must evidently contribute to the strength of the dam; but there is no other care or method observed in constructing the dams, except that the work is carried on with a regular sweep, and all the parts made of equal strength. The beaver-houses are built of the same materials as their dams, and are always proportioned in size to the number of inhabitants, which seldom exceeds four old and six or eight young ones. Instead of order or regulation being observed in rearing their houses, they are of a much ruder construction than their dams; for, notwithstanding the sagacity of these animals, it has never been observed that they aim at any other convenience in their houses than to have a dry place to lie on; and there they usually eat their victuals, which they occasionally take out of the water. So far are the beavers from driving stakes into the ground when building their houses, that they lay most of the wood crosswise and nearly horizontal, and without any other order than that of leaving a hollow or cavity in the middle. When any unnecessary branches project inward, they cut them off with their teeth, and throw them in among the rest, to prevent the mud from falling through the roof. It is a mistaken notion to suppose that the woodwork is first completed and then plastered; for the whole of their houses, as well as their dams, are, from the foundation, one mass of mud and wood, mixed with stones if they can be procured. The mud is always taken from the edge of the bank, or the bottom of the creek or pond, near the door of the house; and though their fore-paws are so small, yet it is held close up between them, under their throat. Thus they carry both mud and stones; while they always drag the wood with their teeth. All this work is executed in the night; and they are so expeditious, that in the course of one night they will collect as much as amounts to some thousands of their little handfuls. As they are frequently seen to walk over their work, and sometimes to give a flap with their tail, particularly when plunging into the water, this has, without doubt, given rise to the vulgar opinion that they use their tails as a trowel with which they plaster their houses; whereas that flapping of the tail is no more than a habit, which they always preserve, even when they become tame and domesticated, and more particularly so when they are startled. The beaver is found in Europe, chiefly near the banks of the Rhone, the Weser and the Elbe, in Russia and Poland, and in the rivers which flow into the Caspian Sea, as well as America, although differing in one important respect—viz., in the building of its house. Until very recently, it was supposed that the European species did not build its habitation like the American beaver, but burrowed along the banks of rivers. It is, however, now known that the American beaver living near the settlements acts in precisely the same manner as its European brethren, and, moreover, that in certain places which are secluded, the latter build their houses after the fashion of their transatlantic friends. At some remote period, beavers are supposed to have been common in Scotland; and tradition implies that Beverley, in Yorkshire, took its name from the circumstance of beavers abounding in the neighbouring river Hull. Giraldus Cambrensis briefly alludes to the Welsh beaver in the 12th century. Indeed, considering all the evidence, traditionary and recorded, there is little doubt that the beaver at one time was common in Britain, and recent efforts have been made to re-introduce it. Fossil remains of beavers, apparently of the same species as those now existing, are found in the deposits of the Pliocene and Pleistocene periods.

Beaver-Tree. (*See* MAGNOLIA.)

BEBEERU OR BIBIRI. (*See* NECTANDRA.)

BECCAFIGO, OR BECCAFICO, *bek-ka-fee'-ko* (Ital., the fig-pecker), the *Sylvia hortensis*, is a migratory song-bird, which feeds upon insects, figs, currants, and other fruits. It is very nearly the size of a linnet. During the summer it is a visitor to England, and even Scotland; but it always departs for a southern climate in September. Its voice resembles that of a nightingale; it lurks shyly in the thickest foliage, whence its piercing notes issue, though the tiny warbler is seldom seen, and flies with singular grace. With the ancient Romans it was a highly prized morsel, and in our own day it is one of the rarest autumnal delicacies of the Italians, the Greeks, and the French. The term beccafico is applied rather indiscriminately to different kinds of the *Sylviadæ*, or Warblers, when they are fat enough to serve at table. Birds of this kind are commonly named in France *bec-fin*.

BED, in Geology, the term usually applied to a stratum of considerable thickness, and of uniform homogeneous texture; as "bed of sandstone," "bed of clay," &c. Originally, however, the term *bed* referred to the surface-junction of two different strata.

BED-STRAW, (*See* GALIUM.)

BEE, *be* (Ang.-Sax.)—Under this name, in England alone, are included about 250 species of insects of the order *Hymenoptera*. The name *Anthophila* (flower-loving), or *Mellifera* (honey-bearing) is given to the family they constitute; and there is a subdivision into *Andrenetæ* and *Apiariæ*. The former are solitary in their habits. The females construct their nests underground in a singular manner. Usually selecting a sandy situation, they burrow in the ground to the depth of about eight or nine inches. This hole, which is cylindrical, is only of sufficient dimensions to admit the bee. The bottom, with the aid of some glutinous substance, is made tolerably smooth. This labour accomplished—and, considering the soil is only removed a grain at a time, it is no small labour—it sets forth in search of pollen. This the bee procures from flowers, and carries to her cell on her hind legs, which are thickly covered with long hairs. With the addition of a little honey, the pollen is made into a small paste-ball, in which the egg is deposited, and the mouth of the cell hermetically sealed. In time the egg becomes a larva, and devours the pollen in which it has been enveloped; the larva turns to a pupa, and then the next transformation produces a bee. It, however, remains in a torpid state till the next year. The *Apiariæ* are a more important group; and the habits of the species belonging to it are more variable than those of the *Andrenetæ*. To this group belongs the hive or honey-bee, which demands particular attention. In the earliest records may be found notices of this insect. Xenophon, who lived more than 2,000 years ago, and who is famous for his remarkably clear and perspicuous narrative, makes particular mention of it in connection with the injury his men received by eating honey of bees which had fed on deleterious plants. Both Aristotle and Virgil were observers of its habits. Pliny tells us that the philosopher Aristomachus spent fifty-eight years in investigating bee-nature; and Philiscus devoted the whole of his life to this branch of study. A beehive contains three classes of inhabitants—the *working-bees*, the *drones*, and the third order, represented by only one member —the *queen-bee*. The first class is the most important. They are believed to be undeveloped females; consequently, incapable of taking part in the reproduction of their species. The drones are the males, and exist but for the propagation of their kind. The queen-bee is the *mother-bee* of the whole colony, and lays about 200 eggs a day through the whole season, from early spring to September. The anatomy of the working-bee forms one of the most interesting portions of entomology. Its body is about half an inch in length, of a blackish-brown hue, and is covered with thick hairs, which serve the insect for the purpose of collecting pollen. The most singular part of the body is that which is called the *proboscis*. This instrument, if casually observed, appears to be a single tail, and formerly it was considered so to be by naturalists. Examined through the microscope, however, it appears a slender projection composed of some forty cartilaginous rings, fringed with fine hairs. It is formed of five parts, a central stalk, and four lateral ones—two on each side. The central part used for collecting honey, is aided by the fringed hairs lapping up, like a tongue, anything to which the proboscis is applied, and then conveyed to the pharynx, or honey-bag, whence, in due time, it is disgorged into the cells of the comb. The structure of the other portions of the mouth are beautifully adapted to their several uses. The bee has three pairs of legs, the anterior ones being the shortest, and the posterior the longest. The latter have a cup-like cavity on the fore-leg, which the bee uses to contain the pollen it collects. The legs are all covered with hairs, and more particularly the ones which carry the pollen. There is a pair of hooks attached to each foot, which enable the bee to walk on the roof of the hive. It was clearly demonstrated by Huber that respiration was as essential to the bee's existence as that of any warm-blooded animal. Situated behind the wings are *spiracles*, or air-openings, which admit air for the purpose of oxygenating the circulating system. That these *spiracles* were the instruments of respiration, Huber proved by immersing a bee in water; so long as the air-openings were free, the insect lived; immediately they were placed under water, the bubbles which escaped from them proved their use, and the bee ceased to exist. The abdomen contains the honey-bag, the stomach, the wax-bag, the venom-bag, and the sting. The honey-bag, though occasionally called the first stomach, is not used for the purpose of digestion; it is a small bag, about the size of a pea, with two pouches behind, and is properly only an enlargement of the gullet. This receptacle receives the honey from the proboscis, as already stated. A small passage thence leads to the stomach, which receives and digests the food of the bee. It was formerly supposed that the wax of the bee was the pollen elaborated in the stomach, and afterwards ejected by the mouth. The celebrated anatomist, John Hunter, discovered two small pouches in the lower part of the abdomen; and it was found that the wax is derived from the saccharine matter consumed by the bee, and that it is secreted from vessels on the surface of these pouches. After the wax has remained there for a time, it appears externally in scales, usually eight in number, below the medial rings of the abdomen, and is removed by the bee itself or one of its fellows. One of the most important and beautifully developed organs is the *sting*, which lies close to the abdomen. Viewed through the microscope, it presents one of the most elaborate and exquisitely defined pieces of mechanism to be found in the wondrous workshop of Nature. It consists of two long darts, adhering longtitudinally, and protected and encased by one sheath. The fineness of this apparatus may be shown by the fact that the sheath itself, which is not nearly so sharp as the darts, placed under a magnifying lens exaggerating its proportions some two hundred fold, is, towards the point, quite invisible. When wishing to use the sting, the sheath is first protracted and inserted; then the two fine darts follow, and are also inserted. The puncture being made, the poison is conducted in a groove to the end of the sheath. And now the most singular part of the business follows. The long darts are armed with nine or ten barbs at the end, and this prevents them from being too quickly withdrawn. Immediately the poison flows in, the darts are withdrawn, and the deadly liquid has a cavity to enter, which soon festers, and produces death. The nature of the poison is not known; it possesses, however, a certain acidity, which will redden vegetable blues. With regard to the other senses of the bee, the evidence is far from satisfactory. It has five eyes in all—three on the top of the head, and two in front. Springing from between the latter are two tubes, curving outwards on each side: these are called the *antennæ*, and serve the insect for the ordinary purposes of vision. The *antennæ* are extremely sensitive, and, indeed, the most useful organs of the bee. By their aid it builds its cells, feeds the young, and stores the hive. They are also used as a medium of recognition with its kind. The combs of a beehive comprise a congeries of hexagonal cells, built by the bees as receptacles for honey and for the nurseries of their young. Each comb in a hive is composed of two ranges of cells backed against each other: the base, or partition, between the double row is so disposed as to form a pyramidal cavity at the bottom of each. There is a continued series of these double combs in every well-filled hive, the spaces between them being just sufficient to allow two bees, one on the surface of each comb, to pass without touching. Each cell is hexagonal, the six sides being perfectly equal. This figure insures the greatest possible economy of material and space. The outer edges of the cells are slightly thickened, in order to gain strength. The same part is also covered with a beautiful varnish, which is supposed to give additional strength. The construction of several combs is generally going on at the same time. No sooner is the foundation of one laid, with a few rows of cells attached to it, than a second and a third are founded on each side, parallel with the first; and so on, till the hive is filled, the combs which were commenced first being always in the most advanced state, and, therefore, the first completed. The design of every comb is sketched out, and the first rudiments laid, by a single bee. This foundress bee forms a block out of a rough mass of wax, drawn partly from its own resources, but principally from those of other bees, which furnish wax from small sacs, in which it has been secreted, that are situated between the segments of the body of the bee, taking out the plates of wax with their hind-feet, and conveying it with their fore-feet to their mouths, where it is moistened, and rendered soft and ductile. The mass of wax prepared by the assistants is applied by the foundress bee to the roof or bottom of the hive, and thus a slightly double convex mass is formed. When of sufficient size, a cell is sculptured on one side of it by the bees, who relieve one another in the labour. The cells intended for the drones are considerably larger, and more substantial than those of the workers, and being formed subsequently, they usually appear nearer the bottom of the comb. Last of all are built the royal cells for the queens: these are situated in the very centre of the hive, and number from three to twelve. When the cells are ready, the queen begins to lay her eggs. The fecundation of the queen-bee is very extraordinary. It has been pretty clearly ascertained that no connection takes place with the drones *in the hive*. The question naturally arises, why this large number of drones in a hive? Huber's investigations have, to a certain extent, cleared away the mystery. According to this eminent naturalist, fecundation takes place by contact in the air; and it is consequently essential that the number of drones should be large, that the queen-bee may be sure of meeting them when going abroad. One intercourse is sufficient to render the queen-bee fruitful for two seasons. It is estimated that she gives birth to 100,000 bees in a single season. The eggs which are to produce working-bees are laid first. These are carefully watched; and, when they are hatched, the larva is fed with mixed honey, pollen, and water, by what are called *nurse-bees*, whose whole work is to *nurse* the young bees. Not until eleven months have elapsed in laying working-eggs, does the *mother-bee* commence laying the male and royal eggs. The *nursing* of the latter is managed on a grand scale. The royal larva disdains simple honey or pollen; it must have rich *jelly*, and in such quantities that her highness's cell is saturated with it. This waste is rather contradictory of the bee's frugality; but bees are wonderfully loyal creatures. From the egg to her majesty bee, the whole time occupied in the metamorphosis is about sixteen days. It is a remarkable fact, only recently demonstrated, that the queen-bee has the power of laying eggs without the intervention of a male, and these eggs laid by an unimpregnated virgin-bee become drones. If the queen-bee is not impregnated before she is twenty-one days old, she becomes incapable of impregnation, and lays only drone eggs for the rest of her life. The bees only require one queen at a time. So these newly-hatched majesties must be kept confined until the throne is vacant. There is also another important reason why they are not set at large. When two queen-bees meet it is certain death to one. The queen of a hive appears to be terribly jealous of the royal infants, and makes desperate efforts to destroy them; but the working-bees surround her, and keep her out of mischief, and the particular object of her jealousy, the "young queen," is also carefully guarded. The queen then becomes restless, the bees are divided into parties, one taking the part of the reigning monarch, and the other supporting the young claimant. At length the queen abdicates, is released from her cell, and with a large following of faithful attendants, quits the hive to seek a new habitation. This exodus is known as *swarming*. The throng of bees, forming a compact, buzzing cloud, at length settles on a bush or on the top of a tree. Sometimes they settle on the grass near the old hive. The bee-owner follows them with a new hive, which he endeavours to place over them. A great clatter is made with shovels, pokers, frying-pans, and other available instruments of noise, and the bees, frightened by the clamour, allow themselves to be secured. A full healthy hive will throw off two, and sometimes three swarms in the course of the summer, the first swarm being always the most valuable, on account of the bees having had the whole summer to collect their stores, which is called very often by the sellers *virgin honey*, while the late swarms often require to be fed in winter. Sometimes the first swarm throws off one from itself, which is called a *cast*, and the produce of this is the true *virgin honey*, but it is only in exceptionally favourable seasons that a cast can collect sufficient honey to carry the hive through the winter without feeding. Perhaps the most singular phenomenon in bee history is the *making of a queen*. On extraordinary occasions, when the hive by some accident is deprived of a queen, and destitute of royal larvæ, a wonderful provision is resorted to. One of the working-larvæ is selected, deposited in a royal cell, fed on the same food which is administered to the royal larvæ, and it ultimately becomes a queen. The only explanation that can be given is, that the peculiar food provided has the effect of rendering the honoured insect fertile. Towards the beginning of August, a good stock of eggs having been laid, the drones are no longer required; and winter, long and dreary, is before the industrious bees. What must be done with the lazy ones? They are massacred by the workers. A buzzing commences in the hive; the heavy drones and the nimble workers grapple and hug; but the strength of the lazy drones avails them nothing; the sharp stings of the workers' pierce them through and presently the ground is heaped with the slain. The working-bees are partially torpid in cold weather, and consume very little food; but they are readily aroused from this state.

Varieties of Bees.—About 250 species of bees are known as natives of Britain, and bees are found in almost all parts of the world, particularly in warm climates. The Ligurian, or Yellow Alp bee (*Apis Ligustica*) has been recently introduced into this country, and is reported to be less sensitive to cold than the ordinary black bee; the queens also are more prolific, and they swarm earlier and more frequently. This bee is a mountain insect; it is found between two mountain chains to the right and left of Lombardy and the Rhætian Alps, comprising the whole territory of Tessin, Vethin, and South-Graubunden. It thrives up to the height of 4,500 feet above the level of the sea, and appears to prefer the northern clime to the warmer, for in the south of Italy it is not found. The further one goes from the Alps, the less handsome it is found—as, for example, in Nice—until it is entirely lost, in Lower Italy, in the black species. The heath-bees, common in some parts of England, and met with in Schleswig and Holstein and other places, although closely resembling the black European bee in appearance, never seem to complete their labours in accumulating a store of honey, and having a well-governed community, with a queen at its head, appearing to consist principally of drones, which move about in the aimless manner peculiar to drones in an ordinary hive, which we shall refer to again. The Carniolan variety appear to be of the same genus as the ordinary black European honey-bee, with the exception that the rings on the abdomen are whiter in colour than the marks on the ordinary honey-bee. The Greek, or Crecopian, are of an order which seem to partake of a cross between the Italian, as they are commonly designated, and the black European bee. They are said to be more indefatigable than the common bee, the drones being somewhat smaller in size. The Cyprian and Smyrnæan bees appear to be also a mixed race, such as would result from the union or grafting of a Ligurian queen to a common stock, of which we shall speak again. Egyptian bees (*Apis fasciata*) appear to be the same variety as the common black honey-bee, only somewhat smaller in size, and having small white hairs about them, the first two-and-a-half rings of the abdomen being of a reddish-yellow colour, the queen being remarkably handsome. Wild honey-bees generally make their nests in hollow trees, or among the branches of trees, sometimes under ledges or in clefts of rocks; and their stores of honey afford food to numerous animals, some of which also prey upon the larvæ.

The Humble-bee derives its name from the humming noise produced by the wings when in motion. There are about forty different species of humble-bees in Great Britain. They are larger than the ordinary hive-bee; their communities are not so large, and the females are not so prolific. One species (*Bombus terrestris*) make nests in holes in the ground, at the depth of about a foot, floored with leaves and lined with wax, and often entered by a winding passage; another species (*B. lapidarus*) among stones; and a third (*B. muscorum*) in moss. Humble-bees do not swarm, the females do not seek to destroy each other, and the males and workers die on the approach of winter, the females remaining in a torpid state until the ensuing spring, when they lay eggs and found new communities. In rural districts, the name is often perverted into "Bumble-bee."

Solitary Bees, or those which do not live in communities, have no neuter sex, or working-bees; there are only perfect males and females. They make nests in holes of the ground, or by excavation in old wood. One European species (*Xylocopa violacea*) drills holes, or tunnels, twelve or fifteen inches long, divided into ten or twelve cells, in each of which an egg, with a store of pollen and honey for food, is deposited. The soft pith of brambles is, by some of these bees, scooped out to make room for a nest, and oak-galls, and even snail shells, have been known to be made available; and one species (*Megachile muraria*) glue together grains of sand, with a viscid saliva, as a covering to their nests, and the compound is so hard as not to be easily penetrated by a knife.

BEECH. (*See* FAGUS.)

BEE-EATER, *be-e'-ter* (*Merops apiaster*), a genus of birds of the order *Insessores* and tribe *Fissirostres*, nearly allied to the King-fishers. They are found in large numbers in the southern and eastern provinces of Europe and the northern districts of Africa. They build their nests in clay and sand banks, and associate so closely together that the earth appears like a honeycomb. There is some analogy between these birds and the swallows; indeed, in the neighbourhood of the Cape, where they most abound, they are called by the Dutch mountain swallows. In certain parts of Africa, they are much respected by the natives, who have a belief, that by following one of them, the discovery of a store of honey will be the certain result. They are larger than the common swallow, and have a long and slightly-curved beak. Their colour is a blending of white, and brown, and green.

BEEF. (*See* FOOD, ANIMAL.)

BEEF-EATER, a genus of birds only found in Africa. This bird belongs to the order *Insessores*, tribe *Conirostres*. They have short bills, swelling towards the point, and square at the base. They subsist upon the larvæ of gadflies, which they find in the hides of buffaloes, camels, and other large quadrupeds. They perch upon the back of these animals, and Dr. Livingstone states, with regard to one of the species—the buffalo-birds, that as their sight is keener than that of the buffalo, they see the approach of danger first. When the buffalo perceives that the birds are flying away, he is warned that he is in peril, and begins to look around him. The beef-eaters are sometimes called ox-peckers.

BEEF WOOD. (*See* CASUARINA.)

BEESHA, *be'-sha*, a genus of grasses nearly allied to the Bamboo, but differing from it in having the seed enclosed in a fleshy pericarp. Only a very few species are known, all natives of the East Indies

BEET. (*See* BETA.

BEET-FLY (*Anthomyia Betæ*), an insect not so large as a common fly, which deposits its eggs on the leaves of beetroot, or mangel-wurzel. When the larvæ leave the eggs, they devour the soft parts of the leaves, giving the plant a scorched and blistered appearance. It is a dipterous or two-winged insect of the great family *Muscides*, the type of which is the common house-fly, and belongs to a genus whose larvæ infest and feed upon the roots of cabbages, turnips, &c. (*See* CABBAGE-FLY, TURNIP-FLY, POTATO-FLY.)

BEETLE, *bee'-tl*.—This term is frequently used to designate the large tribe of insects called *Scarabæides*, but it is more frequently and correctly used as the name of those insects which are covered with a strong horny substance, and have the abdominal part of the body guarded by two sheaths, under which the wings are folded. Hence the word is often used in works on natural history as the ordinary designation for coleopterous insects. This, however, is not correct, as it would bring under the title of Beetle, cantharides, weevils, fire-flies, &c. (*See* the articles COLEOPTERA, SCARABÆIDES, STAG-BEETLE, TIGER-BEETLE, BOMBARDIER-BEETLE, BURYING-BEETLE, GOLIATH-BEETLE, ROSE-BEETLE, &c.)

BEETLE-STONES.—In a cliff composed of shale, at Newhaven, as well as upon the beach in the vicinity, there are found certain indurated nodules of clay iron-stone. These minerals are selected by the lapidaries of Edinburgh to be fashioned into articles of ornament; as, letter-weights, &c. When highly polished, these stones present a very attractive appearance. The term is said to have owed its origin to a fancied resemblance of the nodules to a fossil beetle. Although some of these minerals exhibit proofs of an animal origin—a fossil fish, for instance—the nucleus of the nodules is never that of a fossil beetle.

BEGONIA, *be-go'-ni-a* (so named after Michel Bégon, a French botanist), the typical genius of the natural order *begoniaceæ*. The species (about 160 in number) are natives of tropical regions, but many are now cultivated as ornamental plants throughout Europe. The leaves are oblique or unequal (more developed on one side of the midrib than on the other), and are often richly tinged with crimson. The flowers are of a delicate pink colour, and grow in cymes. The young stems and leaves of the species *B. malabarica* and *tuberosa* are used as potherbs in the countries where they grow wild. Of the numerous species which adorn our conservatories, *B. argyrostigma* and *discolor* are perhaps the most beautiful. The first of these, the silver-spotted begonia, was brought to this country from Brazil in the early part of the present century; the leaves, which are long and pointed, are red beneath and spotted with white above. *B. discolor*, or two-coloured begonia, is a Chinese species, and is remarkable for the very rich crimson of the under-surface of the leaf, which is short and broad.

BEGONIACEÆ, *be-go-ni-ai'-se-e*, the Begonia family, a natural order of dicotyledonous plants belonging to the sub-class *Monochlamydeæ*, consisting of four genera and 160 species, natives chiefly of India, South America, and the West Indies. The species are herbs, or low succulent shrubs, with alternate leaves which are oblique at the base and have large dry stipules. The flowers, which growi n cymes, are unisexual, the perianth coloured with four unequal divisions in the male flower, and five or eight in the female. The stamens are numerous; the fruit is membraneous, winged, three-celled, bursting by slits at the base; the seeds are very small. The plants are more remarkable for their handsome leaves and neat flowers than for useful properties. They are reputed, generally, to possess astringent and bitter qualities, and occasionally to be purgative.

BEJAN, OR BAJAN, *be'-jan* (Fr., *bec-jaune*, yellow beak, an unfledged bird), a nickname given to new students, or freshmen, in some of the Scotch and many continental universities.

BELEMNITES, *bel'-em-nites* (Gr., *belemnos*, a dart), fossil remains of extinct naked cephalopods allied to the squid and the cuttle-fish. They are found in large numbers in the chalk and oolite, generally as straight, solid, dart-like stones. These relics of creatures which thronged the seas of the secondary period have ever been objects of wonder, and the wildest speculations have been advanced to explain their origin. The popular names for them, such as devil's fingers, spectre-candles, arrow-heads, picts, and thunderbolts, indicate the different views taken of their nature by the ignorant. To the philosophers of the last century, the belemnite was a standing puzzle, and the guesses which were called forth from time to time appear to us to be scarcely less absurd than the popular beliefs. It was said to be a product of electric action, and given the learned name of *lapis fulminans*, or thunder-stone. According to other hypothesis it was a stalactite, a crystal, petrified amber, and lastly, when fossils began to be looked upon as actual organic remains, it was held to be the tooth, or perhaps the spine, of some unknown creature. It is now known to be the internal bone or shell of a cephalophod, and corresponds to the slender and insignificant *pen* of the common squid. Although the most common belemnites are mere tapering stones, some have been found so well preserved that naturalists have been able to form from them a vivid image of the living mollusc. "The belemnite," writes the author of "Vestiges of Creation," "is an elongated conical shell terminating in a point, and having at the larger end, a cavity for the residence of the animal, with a series of air-chambers below. The animal placed in the upper cavity, could raise or depress itself in the water at pleasure, by a pneumatic operation upon the air-tube pervading the shell. Its tentacula sent abroad over the summit of the shell searches the sea for prey. The creature had an ink-bag, with which it could muddle the water around it, to protect itself from more powerful animals; and, strange to say, this has been found so well preserved that an artist has used it in one instance as a pigment wherewith to delineate the belemnite itself." One genus of the belemnite family, called *Belemnoteuthis*, and occurring in the lias and oolite, is occasionally discovered with the remains and impressions of the soft parts; namely, the mantle, body, and tentacles.

BELLADONNA, *bel-la-don'-na*. (*See* ATROPA.)

BELLADONNA LILY, a very beautiful species of *Amaryllis* (which *see*). It is a native of the Cape of Good Hope, and was introduced into England in the early part of the last century. The flowering-stem is about eighteen inches in height, and bears at its summit a cluster of drooping flowers of a delicate rose-colour.

BELL-BIRD (*Arapunga alba*), a native of Guiana, South America, and distinguished by a fleshy tubular appendage above the base of the bill of the male bird. When empty, this tube, about three inches long, is pendulous, but it can be filled with air by a communication from the palate, and then rises erect. Generally, this appendage is decorated with a few fine feathers. Its voice is very peculiar, and much resembles the tolling of a bell. Waterton asserts that the sound it emits may be heard at a distance of three miles. The bird is of a pure white colour, and about a foot in length.

BELLE-DE-NUIT, *bel'-de(r)-nwe* (Fr., beauty of night), the name given by French travellers to some tropical species of *Convolvulaceæ*, with extremely beautiful and fragrant flowers, which open only at night time. They are natives of the West Indies and South America. (*See* MIRABILIS, CONVOLVULUS.)

BELLEROPHON, *bel-ler'-o-fon*, a genus of fossil shells occurring in the Silurian, Devonian, and Carboniferous strata. As in the existing argonaut, the shell consists of a single chamber.

BELL-FLOWER. (*See* CAMPANULA.)

BELLIS, *bel'-lis*, the Daisy, a genus of plants belonging to the natural order *Compositæ*, sub-order, *Corymbiferæ*. The receptacle is without scales, and upon it are arranged two kinds of flowers—ligulate, or strap-shaped, and tubular. The ligulate flowers, which are white in the common daisy, form the ray, or outer circle. They have no stamens, but each has a single pistil, which, at the top, divides into two branches, forming stigmas. The yellow tubular flowers clustered together within the ray are hermaphrodite; that is to say, they have both stamens and pistils. The involucre is composed of two rows of bracts. The fruit found at the base of every little flower, whether ligulate or tubular, is without a pappus, and contains a single seed. The best known species is *B. perennis*, the common daisy. The roots of this are perennial. It blossoms nearly all the year round, and is constantly found with open flowers from March to October. Few of the poems of Burns are better known and admired than his address to the daisy, the "wee modest crimson-tipped flower."

BELLY. (*See* ABDOMEN.)

BELOPTERA, *be-lop'-te-ra* (Gr., *belos*, arrow, *pteron*, wing), a fossil resembling a belemnite, but less pointed, and having a wing-like projection or process on each side. It occurs in tertiary strata, and was evidently the internal bone of a cephalopod. The name *Belosepia* (Gr., *sepia*, cuttle-fish) is given to another kind of belemnite found in tertiary deposits; and that of *Beloteuthis* (Gr., *teuthis*, squid) to one shaped like a spear-head occurring in the lias.

BELUGA, *be-lu'-ga*, a genus of *Cetacea*, belonging to the *Delphinidæ*, or Dolphins. It has a broad blunt head, and no produced snout; thus differing from the rest of the family to which it belongs. Its form is principally characterized by the softness of its curves, and the clear white colour of its skin, which is so tender that it often fails to retain the harpoon. The beluga also differs from the ordinary family of dolphins in having fewer teeth, which fall out before the animal is old, and it has no dorsal fin. It usually attains the length of thirteen feet. It is gregarious, and shoals of fifty or sixty are often met with in the Arctic seas. Belugas have been captured on the coast of the British Isles; and, in 1846, one was killed in the Medway. The Greenlanders eat the flesh, and convert the skin into leather. The oil is of very fine quality.

BELVISIACEÆ, *bel'-vis-i-ai'-se-e* (from the genus *Belvisia*, named after its discoverer, P. de Beauvois), a small natural order of dicotyledonous plants, in sub-class *Calycifloræ*, comprehending only two genera, namely *Asteranthos* and *Napoleona*, or *Belvisia*. These include four species, which are large shrubs, with smooth leathery leaves, all growing in tropical Africa. The flowers grow in threes, sessile in the axils of the leaves, and are extremely curious. The calyx is a thick leathery cup, divided into five segments. The corolla consists of three distinct whorls of united petals; the outer one turning back over the calyx; the second one is a narrow membrane divided into numerous segments; and the third forms an erect cup, and contains the stamens, which are united, so as to make a sort of inner cup. The fruit is a soft berry, with large kidney-shaped seeds. The pulp of the fruit is edible, and the pericarp contains much tannin.

BEMBECIDÆ, *bem'-be-si-de*, a family of hymenopterous insects, commonly known as sand-wasps. They resemble wasps in appearance, and some are remarkable for emitting an odour similar to that of roses. The females are furnished with stings.

BEMBRIDGE BEDS, *bem'-bridj*, the name given to an important group of upper eocene strata, resting on the Osborne or St. Helen's series, and capped by the Hempstead beds. In the Isle of Wight this group is principally developed. Beginning at the bottom, we find the Bembridge limestone. This bed consists of a pale yellow or cream-coloured limestone, interstratified with clay or crumbling marl, and is from 20 to 25 feet thick. Upon this we find the oyster-bed, a few feet of greenish sands, containing oysters (*Ostræa vectensis*) in great abundance, capped by a band of hard septerian stone. Resting on this are unfossiliferous mottled clays, alternating with fossiliferous laminated clays and marls. The latter contain the characteristic shell *Cyrena pulchra*. Lastly, we come to marls and laminated grey clays containing *Melania turritissima*; for immediately above these we find the *black band*, forming the base of the Hempstead series.

BENJAMIN TREE. (*See* BENZOIN.)

BENT GRASS, the common name for the genus *Agrostis* (which *see*.)

BERBERIDACEÆ, *ber'-ber-i-dai'-se-e*, the Barberry family, a natural order of dicotyledonous plants, in the sub-class *Thalamifloræ*, consisting of shrubs and herbaceous perennials. The order includes twelve genera, which together contain 100 species, natives of the temperate parts of Europe, Asia, and America, some being exceedingly common in the mountainous regions of the north of India. The plants have acid, astringent, and bitter properties; their acidity is due to the presence of oxalic acid.

BERBERIS, *ber'-be-ris*, the typical genus of the natural order *Berberidaceæ*, consisting of numerous species, found in temperate climates in most parts, except Australia. The most interesting species is *B. vulgaris*, the common barberry, which is usually a bush from four to six feet high, but which, in Italy, sometimes becomes as large as a plum-tree. It is a very ornamental plant, especially when covered with fruit. The berries are of an oval shape, and, when ripe, generally of a bright-red colour, but sometimes whitish, yellow, or almost black. They are very acid, and not fit to be eaten raw; but when boiled with sugar, they form a most refreshing preserve. They are sometimes pickled, to be used for garnishing dishes, and occasionally they are put into sugar-plums or comfits. The bark and stem are very astringent, and yield a bright yellow die. Of the numerous species of *Berberis* which are cultivated in Britain as ornamental shrubs, the finest is *B. aristata*, the bristle-leaved barberry. This is a hardy evergreen, producing excellent fruit. It is a native of Nepaul.

BERGAMOT, *ber'-ga-mot*, the popular name of nearly fifty different kinds of pears. The one best known is the *Bergamot Crasanne*, a flattish, rough-skinned pear, with a very juicy pulp and agreeable flavour.

BERG-MEHL, *bairg'-mal* (Swedish, mountain-meal), the name given to a whitish earth, consisting almost entirely of the flinty shields of microscopic plant-growths. (*See* DIATOMACEÆ.) It occurs in bog and ancient lake deposits in many parts of Northern Europe, and, during times of great scarcity, it has been, mixed with flour, eaten as food. The amount of nutriment contained in it is very minute.

BERNICLE GOOSE, *ber'-ni-kl*. The bernicle goose (*Anser bernicla*, or *leucopsis*), is marine in its habits, and feeds almost entirely on algæ and grass-wracks. Like the common goose, it is only a winter visitor to our climate, and passes during the summer to the highest northern latitudes. The bird owes its name to a ridiculous notion. It was formerly believed (it can scarcely be said that the belief is to this day entirely abandoned) that these birds were produced from the common bernacle, or barnacle, the latter originating, in their turn, from the fruits of a particular tree, whose branches dipped into the water. It is smaller than the common goose, has the forehead, cheeks, and throat white, and the bill black, with a black stripe extending to the eye. The crown of the head, the neck, and the upper part of the breast are black. The plumage on the upper part of the body is chiefly ash-grey and black in undulating bars. (*See* GOOSE.)

BERÖE, *be-ro'-e*, a genus of *Acalephæ*, of higher organization than the Medusæ. The beröe are characterized by a nearly globular or oval body of a jelly-like substance. On the body are bands covered with rows of large cilia, the rapid motion of which is controlled by the will of the animal, and causes a beautiful iridescence. The *Beröe pileus*, a beautiful little creature, is very abundant off the British coasts. It has two long slender tentacula, covered with fine filaments.

BERRY, a description of fruit more or less fleshy and juicy, and not opening when ripe. (*See* BACCA.)

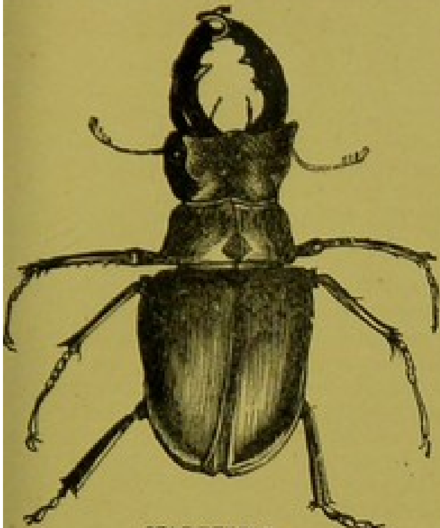
BERTHOLLETIA, *ber-tol-le'-ti-a* (so named in honour of Berthollet, the French chemist), a genus of plants belonging to the natural order *Lecythidaceæ*. The only species known is *B. excelsa*, a majestic tree, growing to the height of 100 or 120 feet, which forms vast forests on the banks of the Orinoco. (*See* BRAZIL NUTS.)

BERYL, *be'-rel*, a mineral which in many respects resembles the emerald, but is of a yellowish or blue colour, and somewhat harder. The finer varieties, transparent and of beautiful colour, are known as precious beryls or aquamarines (*See* AQUAMARINE), and occur in crystals or modified hexagonal prisms. Beryl occurs most frequently in veins that traverse granite or gneiss, or imbedded in granite. It is found in many places in Europe; and the precious beryl chiefly in Brazil and Siberia, but occasionally in the mountains of Aberdeenshire and the Mourne mountains, Ireland, and in New England, North America.

BESSEMER FLAME, SPECTRUM OF THE. (*See* SPECTRUM.)

BETA, *be'-ta*, the Beet, a genus of plants belonging to the natural order *Chenopodiaceæ*, found in Europe, the north of Africa, and the western parts of Asia. *B. vulgaris*, the common beet, grows along the whole coast of the Mediterranean, and is cultivated in European gardens for its sweet, tender, and dark-red root, which is chiefly used in England as a salad, but in France and Germany as a common table vegetable. It is also cultivated on a large scale in many parts of the world as a source of sugar; and it is believed at the present time that about 1,200,000 tons of beetroot sugar are annually produced in Europe. (*See* SUGAR.) The beet used for this purpose is considered to be a variety of *B. vulgaris*, and is known as the sugar-beet. The mangel wurzel, so valuable as a field-crop for feeding cattle, is another variety and is distinguished by botanists as *B. vulgaris*, variety *campestris*. The white beet, cultivated in gardens for the sake of its leaves, which are used as a substitute for spinach, is also merely a variety of the same plant.

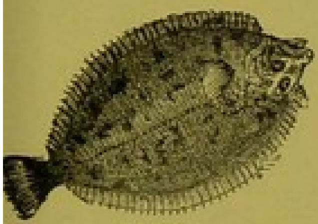
BETULA, *bet'-u-la*, the Birch, a genus of trees or shrubs belonging to the natural order *Betulaceæ*. With the exception of *B. antarctica*, an evergreen shrub found in Terra del Fuego, all the species flourish beyond the tropic in the northern hemisphere. *B. alba*, the common birch, is one of the most beautiful of our forest trees, and is found in most of the northern parts of Europe, Asia, and America. Under favourable circumstances, it grows to the height of 60 or even 70 feet; but as it approaches both the northern and southern limits of its native region, it gradually decreases in size, and ultimately appears as a mere bush. The leaves are small, of an ovate-triangular shape, and doubly serrated. The bark is smooth and silvery white, and the outer layers are thrown off as the trunk increases in diameter. This tree yields useful timber for turnery, hoops, fish-barrels, cattle-yokes, and other articles in which lightness is of more importance than durability; the wood is also employed for making charcoal. The bark is valuable as a dye-stuff and for tanning, and, being exceedingly tough, is turned to a variety of uses by the poor of Northern Europe. Light boats, or canoes, are formed of it by the Russians on the Volga; it is sometimes employed instead of slates for roofing houses, sometimes twisted into ropes, and is even used for making hats, shoes, and drinking-vessels. The outer layers yield an oil which is much prized by the tanner; it is this which gives Russia leather its peculiar odour. In the spring the sap of the birch contains much sugar, and forms, when fresh, an agreeable beverage; when fermented, it constitutes what is called birch wine, a liquor employed medicinally in domestic practice for stone and gravel. The young twigs are in general use for besoms, and birch-rods were once recognised aids to education. The graceful tree known as the weeping-birch is generally regarded as a mere variety of *B. alba*; but a few botanists view it as a distinct species, and name it *B. pendula*. *B. nigra*, the black birch of North America,



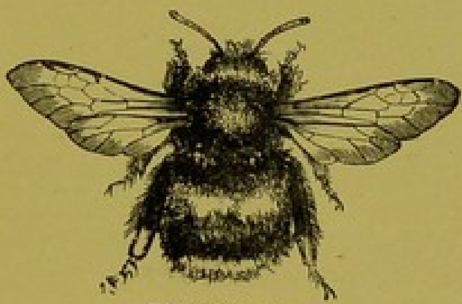
STAG-BEETLE.

BAMBOO.

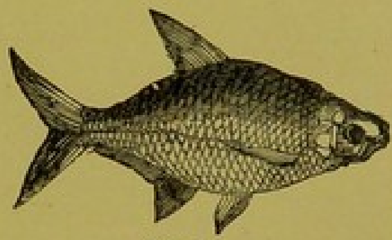
ERRATIC BOULDERS.



BRILL.



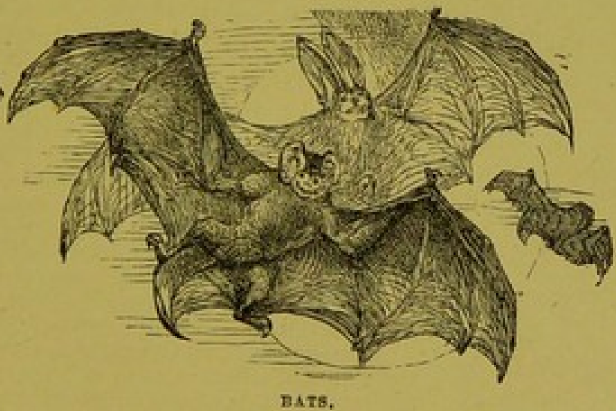
HUMBLE BEE.



BREAM.

BAY.

BRYONY.



BATS.

BORASSUS PALM.

BIRD OF PARADISE

BRAZIL-NUT

yields a fine-grained valuable timber, and, like the common birch, a saccharine juice. *B. papyracea*, the paper birch, is a native of the more northern regions of the same continent; it is remarkable for its tough bark, which is used by the Indians as a substitute for paper, and for constructing canoes, boxes, and baskets. *B. excelsa*, the yellow birch of North America (Maine, Nova Scotia, New Brunswick, &c.), is a very beautiful tree attaining a height of 70 to 80 feet, and destitute of branches for about 30 feet. The bark is of a brilliant yellow colour, and the leaves are very large. The wood is used for ship-building purposes. *B. lenta*, another American species, commonly known as the cherry-birch, yields the timber called mountain mahogany: its bark is one of the sources of the volatile oil called oil of winter green. (*See* GUALTHERIA.) The bark of the Asiatic species, *B. Bhajaptraut* (growing on the Himalayas, sometimes at an elevation of 9,000 feet) is used in India as paper, and for lining the tubes of hookahs.

BETULACEÆ, *bet-u-lai'-se-e*, the Birch family, a natural order of dicotyledonous plants, in the sub-class *Monochlamydeæ*. All the species are either trees or shrubs. The flowers are unisexual, the fertile being in one catkin, and the barren in another. In each, small scales take the place of a true calyx. The fruit is dry, indehiscent, and one-celled, with a single seed. There are but two genera, *Betula* and *Alnus* (which *see*), and about sixty-five species, almost all natives of the colder regions in the northern hemisphere. Many of these are very valuable either for their timber, or for their astringent, tonic, and febrifugal barks.

BEZOAR STONES, *be'-zor* (Persian, *pazahar*, antidote to poison), concretions found in the stomachs of various animals. They are brittle egg-shaped masses, about the size of a small walnut, and are mostly dark olive in colour. On being cut open, they present the appearance of a nucleus surrounded by concentric deposits. They occur principally in the stomachs of oriental goats, deer, and antelopes, and were formerly looked upon as possessing supernatural properties, being able to cure all diseases, and act as antidotes against every poison. They were so much sought after as to be worth ten times their weight in gold. The most valuable of these was obtained from the wild goats of Persia, and was called the *Lapis Bezoar Orientalis*. They are found, more or less, in all herbivora, and sometimes occur in the stomachs of persons living much on farinaceous food. They contain litho-fellic and ellagic acids.

BHANG, *bang*, the common Indian name for the seed-capsules and larger leaves of the native hemp employed for making the celebrated narcotic called *Haschisch* (which *see*). The Indian hemp is a species of the genus *Cannabis* (which *see* also).

BIBIRU. (*See* NECTANDRA.)

BICAPSULAR, *bi-kap'-su-lar* (Lat., *bis*, twice, *capsula*, a capsule), having two capsules containing seeds to each flower.

BICEPS, *bi'-seps* (Lat., *bis*, twice, *caput*, a head), a common name applied to several muscles of the human body, from their having two distinct origins or heads. The principal of these are the *biceps flexor cruris* and the *biceps flexor cubiti*, the former situated on the hind part of the thigh, the latter on the fore part of the os humeri.

BICORNIS, *bi-kor'-nis* (Lat., *bis*, and *cornu*, a horn), is a term sometimes applied in Anatomy to the hyoid bone, from its having two processes like horns. Formerly, it was also applied to muscles that had two terminations.

BICUSPIDES, OR BICUSPIDATI, *bi-kus'-pids* (Lat., *bis*, and *cuspis*, a spear), is applied to the two first pairs of molars in each jaw, from their having two spearlike tubercles.

BIELA'S COMET, *be'-la's* (Gr., *kome*, hair), a comet discovered in the month of February, 1826, by a Prussian named Biela, at Josephstadt, in Bohemia. It accomplishes its elliptic revolution round the sun in rather more than six years and a half. It approaches the earth's orbit more closely than any other cometary body that has yet been observed. In 1846, the comet was observed to be separated into two parts, which travelled in company, at a distance of about 950,000 miles apart. It was not seen in its perihelion passage in 1859, as the circumstances attending its motion were unfavourable for its observation; but this also occurred in 1839, when it passed without notice. When last observed, in 1852, the two fragments into which it had been divided by some inexplicable means, were plainly noticed travelling onwards through space, at the same relative distance from each other as in 1846.

BIENNIAL, *bi-en'-ni-al* (Lat., *bis*, twice, *annus*, year), a term applied to a plant which springs from the seed one year, but does not flower and seed until the second year, when it perishes. The biennial root is commonly enlarged at the close of the first season by an accumulation of nutriment intended for the support of the plant during its flowering and fruiting. Under changed circumstances of soil and culture, some biennials become annuals.

BIGNONIA, *big-no'-ni-a* (named after the Abbé Bignon, librarian to Louis XIV.), the Trumpet-flower, the typical genus of the natural order *Bignoniaceæ*. The species are trees or shrubs, usually of a climbing habit, and furnished with tendrils. The leaves are opposite, and generally ternate, pinnate, or conjugate. The flowers are mostly in terminal or axillary panicles. The corollas are trumpet-shaped, and are coloured variously, white, yellow, orange, purple, or rose. All the species are magnificent plants when in blossom, and have long been cultivated by florists. They are, with few exceptions, too delicate to withstand our climate, and will only grow freely in stoves. From the leaves of the species *B. chica*, the Indians of South America obtain a red dye called *chica*, or *carajura*, which they use for painting their bodies and their arrows.

BIGNONIACEÆ, *big-no-ni-ai'-se-e*, in Bot., a natural order of dicotyledonous plants, in the sub-class *Corollifloræ*. They are usually trees or shrubs, often twining or climbing; rarely herbs. They flourish in the hotter parts of Asia, Africa, and America, being unknown in Europe except in a cultivated state. The chief interest of these plants lies in their beautiful trumpet-shaped flowers. There are about 500 species.

BIKH. (*See* ACONITUM.)

BILBERRY. (*See* VACCINIUM and WHORTLEBERRY.)

BILE, *bile* (Lat., *bilis*, said to be derived from *bis*, twice, and *lis*, contention, as being the supposed cause of anger and dispute), it is a peculiar oily fluid secreted from the blood by the liver. In man it is generally of a yellowish-brown colour, and has a bitter taste. According to Berzelius, its constituents are, in 1,000 parts, 908·4 water, 80 picromel, 3 albumen, 4·1 soda, 0·1 phosphate of lime, 3·4 common salt, and 1 phosphate of soda. The primary cells of the liver separate the bile from the blood of the portal vein, and discharge it into small ducts, which unite to form larger ones, terminating in the ductus communis choledochus, whence it is conveyed into the duodenum. It there mixes with the digested food, and performs the important office of fitting it for absorption into the system. The bile thus mixed with the elements of nutrition becomes in part also absorbed; the excrementitious portion passing out of the body, with the other indigestible materials. When digestion is not going on, the bile ascends through the cystic duct to the gall-bladder, where it is stored for future use. The principal use of the bile is to separate the chyle from the chyme. It also aids in exciting the peristaltic motion of the intestines, and thus causes them to evacuate their contents sooner than they would otherwise do; for, when there is a deficiency of bile, the bowels are in general extremely torpid. When, owing to some functional derangement, the bile is absorbed into the blood and carried through the system, it imparts a yellow tint to the surface of the skin. (*See* JAUNDICE.) The solid portions of the bile may be in excess, and solidifying, produce biliary calculi, or gall-stones. (*See* BILIARY CALCULI.) When from any cause the bile is in excess in the blood, or when the liver only imperfectly performs its function of secreting it, the person is said to be bilious. (*See* LIVER.)

BILIARY CALCULI (Lat., *calculus*, a small stone).—These are sometimes called gall-stones, and are often found in the human gall-bladder in large quantities. They are either semi-transparent and crystalline, or strongly coloured with the bile. They mostly consist of cholesterin deposited on a nucleus of phosphate of lime. (*See* CALCULIS.)

BILIARY DUCTS, those ducts or canals which convey the bile from the liver to the duodenum.

BILL, *bill* (Ang.-Sax., *bill*, a beak), the beak or hard horny mouth of a bird, consisting of two mandibles. There is no appearance of lips either in the upper or lower jaw. A portion of the bill at the base of the upper mandible is covered with a membrane, which is called the *cere*, from the waxy appearance which it presents in some species of birds. It is sometimes covered with feathers, and sometimes it is naked; but it is often found protected by hairs or bristles. The nostrils of a bird are usually situated in the *cere*, but in some cases they are placed so far forward as hardly to be observable. The bills of birds vary in shape according to their habits and the different substances upon which they feed. The bills of birds of prey are very strong, the upper part being hooked, and very sharp, so as to be able to tear and cut to pieces the flesh of the animals upon which they seize. A strong short bill, with the edges sharp and notched, is the usual indication of courage in a bird, and a sign that it preys upon living animals. The great variety in the modification of the forms of bills is very interesting, and is treated of under the names of the different species of birds; such as crop-bills, spoon-bills, horn-bills, parrots, &c. In the case of those birds which live upon insects, the bill is very seldom found hooked, but usually short and slender. The bills of those birds which catch insects flying, are remarkable for their deep division, which enables them to gape widely. Birds which live upon seeds have short but powerful bills, with which they can crush their food. Aquatic birds have, as a general rule, broad sensitive bills, which are provided with laminæ on the inner edge, for the purpose of straining the muddy water, from which they take the principal part of their food. The bills of every species of bird which extracts its food from mud, are modified according to the nature of the food it seeks. Besides the general use of tearing or crushing food, the bills of birds are used when fighting with each other, and also for the purpose of dressing their plumage, building their nests, and for other functions. Many fishes and reptiles have mouths resembling bills, and the *Ornithorhynchus paradoxus* is a singular specimen of a quadruped with a bill.

BILLARDIERA, *bil-lar'-de-air'-a* (from the French botanist Labillardière), a genus of plants belonging to the natural order *Pittosporaceæ.* The species are climbing shrubs, natives of Australia and Tasmania, where they are commonly known as apple-berries. They have simple alternate evergreen leaves, and axillary pendulous flowers. The fruits are soft berries, which, when ripe, are of a bluish colour, and have a pleasant sub-acid taste. A few species are cultivated in the conservatories of this country for the sake of their handsome flowers.

BILLBERGIA, *bil-ber'-ji-a* (from the Swedish botanist Billberg), a genus of plants belonging to the natural order *Bromeliaceæ.* The species are all natives of South America. From the roots of *B. tinctoria* the Brazilians obtain a yellow dye.

BIMANA, *bi-mai'-na* (Lat., *bis*, twice, *manus*, a hand), the first order of Mammalia, reckoning in its number the human species only; no other animal possessing only two hands. The monkey tribes are distinguished by having thumbs at each of the four extremities of their limbs, and are consequently called *quadrumana*, or four-handed animals.

BINARY ARITHMETIC, *bi'-na-re*, a kind of notation in which only unity, or 1 and 0, is used. It was the invention of Leibnitz, who proves it to be an expeditious method of discovering properties of numbers and of constructing tables. M. Dangecourt, in the History of the Royal Academy of Sciences, gives a specimen of its operation in arithmetical progressionals, in which he shows that, as in binary arithmetic only two characters are used, the laws of progression may be more easily discovered by it than by common arithmetic. In binary arithmetic, all the characters used are 0 and 1, and the cipher multiplies everything by two, as in the ordinary arithmetic is done by 10. Thus, 1 is 1; 10, 2; 11, 3; 100, 4; 101, 5; 110, 6; 111, 7; 1,000, 8; 1,001, 9; 1,010, 10. It is remarkable that this system is identical with that used 4,000 years ago by the Chinese, and left as an enigma by Fo-Hi, the founder of their empire.

Binary Compound. (*See* CHEMICAL NOMENCLATURE.)

BINARY NUMBER is that which is composed of two units.

BINARY THEORY, in Chemistry. (*See* SALTS.)

BINDWEED. (*See* CONVOLVULUS.)

BINOMIAL, *bi-no'-mi-al*, in Algebra, an expression consisting of two members, connected by the sign + or −. Thus, $a+b$ and $8-3$ are binomials, consisting of the sum and difference of these quantities. The powers of any binomial are found by a continual multiplication of it by itself. For example, the cube or third power of $a+b$ will be found, by multiplication, to be $a^3+3a^2b+3ab^2+b^3$; and if the powers of $a-b$ are required, they will be found the same as the preceding, only the terms in which the exponent of b is an odd number will be found negative. Thus, the cube of $a-b$ will be found to be $a^3-3a^2b+ab^2-b^3$; where the second and fourth terms are negative, the exponent of b being an odd number in these terms. In general, the terms of any power of $a-b$ are positive and negative by turns.

BIOLOGY, *bi-ol'-o-je* (Gr., *bios*, life, and *logos*, a discourse), is the science of life. In its widest sense, it includes life in all its forms on earth, and thus comprehends within its sphere all living organized beings. Within the last few years no department of science has been more energetically pursued, and many of the most acute intellects of the age have been engaged in the investigation of the phenomena exhibited by living matter, and the endeavour to discover an approximation to a reply to the great question, "What is life?" The phenomena of life, however, are distinct from life itself; and what life does, or produces, is not identical with what life is. Living matter, as distinct from non-living matter, has three distinctive properties—1, chemical composition, for it contains a complex compound of carbon, oxygen, and nitrogen, known as protein, which has never been obtained otherwise than from living bodies; 2, integration and waste, supplied by the formation and development of new matter; 3, tendency to undergo cyclical changes. The protein is the chief constituent of a substance known as protoplasm, which appears to be the very basis of physical life, and is found in all animal and vegetable structures; the addition of new protoplasm causes growth, not by a secretion or addition to the surface as in the case of non-living matter, but by a process described as molecular intersusception, or interposition of new matter between the existing molecules of the living mass. The cyclical changes are exhibited in the power of propagation and creating new living masses, which take the character of those from which they originated. "Thus," says a recent able writer, "an individual living body is not only constantly changing its substance, but its size and form are undergoing continual modifications, the end of which is the death and decay of that individual, the continuation of the kind being secured by the detachment of portions which tend to run through the same cycle of forms as the parent." Another distinction between living and non-living bodies is that, in nearly every known instance of the former, even the most minute, the character of which is revealed by powerful microscopes, there are visibly different parts which possess different powers or functions, and such living things are described as *organized*. That this cannot be said of all living matter is perhaps due to the deficiency of our powers of investigation, and there may be a complex molecular structure beyond the reach of vision. A mass of living protoplasm is simply a molecular machine of great complexity, the total results of the working of which, as its vital phenomena depend, on the one hand, on its construction, and on the other on the energy supplied to it. So far as science has been able to reach, the morphological, or form, unit, the primary and fundamental form of living matter, is merely an individual mass of protoplasm, in which no farther structure is discernible; and these form-units are of the nature of cells, spheroidal masses of protoplasm, surrounded, in most cases, by what is known as a cell-wall. The ultimate conclusion which has been arrived at is that no cell has arisen otherwise than by becoming separated from the protoplasm of a pre-existing cell. Here we must stop, not because there is nothing beyond, but simply because, with all the appliances at our disposal, we can see no farther, and are still without any satisfactory definition of what life is. We can, within certain limits, discover results of the primordial vital force, but only results. The development of a living organism is thus described by the writer already quoted (Professor Huxley, in the *Encyclopædia Britannica*)—"However complicated one of the higher animals or plants may be, it begins its separate existence under the form of a nucleated cell. This, by division, becomes converted into an aggregate of nucleated cells; the parts of this aggregate, following different laws of growth and multiplication, give rise to the rudiments of the organ; and the parts of these rudiments again take on those modes of growth and multiplication and metamorphosis which are needful to convert the rudiment into the perfect structure. The development of the organism as a whole, therefore, repeats in principle the development of the cell. It is a progress from a general to a special form, resulting from the gradual differentiation of the primitively simple morphological units of which the body is composed." The theory of life, known as abiogenisis, or the derivation of living from non-living matter, which has found many advocates, is not sufficiently supported by the results of experiments to justify its acceptance. The experiments have been conducted in accordance with the hypothesis that all living matter is killed by being heated to a certain degree. In solutions, which have been so heated and kept closed from contact with the external air, living organisms have been found; and, therefore, argue the abiogenisists, living matter has been obtained from non-living. Their first proposition, however, is not established as an axiom, as it is yet uncertain what amount of heat, if indeed any, is sufficient to destroy the molecules of protoplasm, which are the rudiments of organization; whether, in fact, intense heat may not be a means of producing new cellular arrangements, and resultingly, new forms. The Darwinian theories of evolution, and origin of species, are branches of the science of biology. (*See* EVOLUTION, ORIGIN OF SPECIES, &c.)

BIPED, *bi'-ped* (Lat., *bis*, twice, and *pes*, *pedis*, a foot), an animal having two feet; as man, bird. It is applied also to a few species of reptiles, some of which are batrachian, some saurian, which may be regarded as forming connecting links between saurians and serpents, and between batrachians and fishes. One of the species of saurians, the *Bipes lepidopodus* of Lacépède, was dissected by Cuvier, who found that though its posterior and only apparent pair of feet had merely the external form of two scaly plates, the integument, in reality, covered a famur or thigh-bone, a tibia and fibula, leg-bones, and four metatarsal or finger-bones. The colour of the Bipes is greenish, with small black blotches scattered over it. It is a native of Australia. Lacépède says of it, "This reptile, like the other species of bipes, ranks between the oviparous quadrupeds and the serpents. It is related to the latter by its general form as well as by the figure, proportion, and distribution of the scales, while it approaches the former by its auditory apertures, and by the hollow tubercles near the anus."

BIPUPILLATE, *bi-pu'-pil-lait* (Lat., *bis*, twice, *pupilla*, a pupil), a term applied to that spot upon the wing of a butterfly resembling an eye, and having two dots or pupils of different tints within it.

BIQUADRATIC POWER, *bi-quod-rat'-ik* (Lat., *bis*, twice, and *quadratus*, squared), in Algebra, the fourth power or squared square of a number or quantity; as 16 is the biquadratic power of 2; for 2×2 is 4, and 4×4 is equal to 16.

Biquadratic Root of a Number is the square root of its square root: thus the biquadratic root of 81 is 3; for the square root of 81 is 9, and the square root of 9 is 3.

Biquadratic Equation, an equation where the unknown quantity of one of the terms has four dimensions. Any biquadratic equation may be generated by the multiplication of four simple equations; or by that of two quadratic equations. (*See* EQUATIONS.)

BIRCH. (*See* BETULA.)

BIRD-CATCHING SPIDER (*Mygale avicularia*), an immense black hairy spider, a native of Cayenne and Surinam. It is nearly two inches in length, and its feet, when stretched out, cover a surface of nearly a foot in diameter. The hooks of its mandibles are conical and very strong. It does not construct a web for the capture of its prey, as do other spiders, but builds in clefts of rocks, or hollows among trees, a funnel-shaped cell of a transparent tissue, resembling fine muslin, and which it itself provides. There it lurks till insects, or even the tiny humming birds, approach, when the spider darts out and secures its victim. There are several bird-catching spiders besides the one in question, and they are found in America, the East Indies, and Africa. As a rule, they make a web like the common European spider, but of such tough threads, that a thrush would scarcely be able to force a passage through. It is even declared, that in certain tropical forests where these spiders abound, their nets will often impede the progress of the traveller. The bite of the larger species of this genus is said to be dangerous to human life.

BIRD-CHERRY. (*See* CERASUS.)

BIRD OF PARADISE, *par'-a-dise* (*Paradisea major*), a name popularly given to the *Paradiseidæ* family of birds, which may be justly regarded as the most beautiful of the feathered tribes. They are found chiefly in New Guinea and the neighbouring islands. Except in the splendour of their plumage, they are closely allied to the crow family, in general form, habits, and voice. Concerning them the most fanciful conjectures have been indulged in, not the least curious being one, that the bird, having no feet, and being unable to walk or swim, was compelled to live entirely on the wing. This error, doubtless, took root in the fact that the legs of the bird being its least ornamental parts, were detached from the skins of the earliest known specimens before they were prepared for exportation. In some localities where they are found, the natives call them *Manuco Denata*, or birds of God, and in other places they are known as birds of the air, birds of the sun, &c. They have great diversity of beauty. Some of them have thinly-barbed feathers to cover the closed wing, so prolonged as to form immense tufts, and extending far backward beyond the body. The Greater Bird of Paradise is rather longer than the common thrush. Its general colour is a deep cinnamon, with the exception of the top of the head and the back of the neck, which is a deep yellow; the feathers which decorate the base of the breast, and cover the whole of the throat, are of a pure emerald green. In the male bird, there springs from each side of the chest a full plume, from sixteen to eighteen inches long, composed of slender shafts, with loose, delicate webs. In some speci mens they are bright yellow at the base, fading gradually into straw-colour. From the tail-coverts spring two slender, naked shafts of great length, which taper gradually to a point, and are of a rich brown. The *Magnificent Bird of Paradise* (*magnifica*) is somewhat smaller than that above described, and is chiefly distinguished by a double sort of ruff, composed of slender plumes that spring from the back of the neck. More of purple and blue enter into the plumage of this bird than the former. The *King Bird of Paradise* (*cincinnurus regius*) is the smallest and the most precious of the family, both on account of its rarity and its splendid colours. It is scarcely as large as a sparrow. The upper parts of its body are of the richest chestnut-brown, and the under parts dazzling white. A zone of golden green extends across the chest; from the sides spring two fan-like plumes, consisting of six or seven dusky feathers of the richest golden green. From the tail-coverts spring two long, slender shafts, each elegantly terminating in a broad emerald web, rising from one side only of the shaft, and disposed into a flat spiral curl. The breast and legs are yellowish-brown. These birds fly in flocks of about thirty or forty, led, it is said, by a single bird. They fly against the wind, lest their plumage should be discomposed. When flying, they make a noise like starlings; but their common cry is little more melodious than that of the raven. They are captured by bird-lime and blunted arrows. In their wild state, they feed on the fruit of the teak tree, figs, and butterflies. In confinement, they are fed on rice and insects. They are unfitted for any other than a tropical climate, and only a very few specimens have been preserved alive in this country. The young male birds at first resemble the females, which are of a dusky brown, and possesses neither plumes nor lengthened tail feathers; but after the fourth moulting, the gorgeous plumage appears. At the breeding season, the males assemble in groups of twelve or fourteen, on the branches of trees, and "dance" so as to display their magnificent plumage to attract the females.

BIRD'S FOOT, *ornithopus*, a genus of plants of the natural order *Leguminosæ*, sub-order *Papilionaceæ*. The botanical and the popular names are alike derived from the resemblance of the curved pods to birds' claws. The British species (*O. perpusillus*) is a small plant with white and red flowers. A much larger species (*O. sativus*) named Serradilla, is cultivated in Portugal as food for cattle.

Bird's-foot Trefoil (*Lotus corniculatus*), a plant very abundant in pasture lands in this country, resembling in some respects the trefoils or clovers, but with clusters of pods resembling a bird's foot. It is a favourite food for cattle. There is a larger species (*Lotus major*) with more compact heads of smaller flowers and much smaller seeds, also a native of Great Britain, and generally found in moist places where there is much underwood. In some of the southern parts of Europe, a species known as the winged pea (*Lotus tetragonobulus*) has four membranous wings connected with the pods. The seeds are used occasionally as substitutes for coffee. The name Lotus has been given to this genus of plants because one of the species is supposed to have been one of the plants so named by the Greeks. (*See* LOTUS.)

BIRD'S-EYE LIMESTONE, a division of the Trenton group of the Lower Silurians of North America, containing many fossils.

BIRDS (Ang.-Sax.), feathered, vertebrated, and oviparous bipeds, which are generally so constructed as to be able to support themselves in the air, and make progress through it. *Aves*, or birds, are the second class of vertebrated animals, and the first of oviparous animals, including all those which have warm blood. About 5,000 different birds are known. Elegant and symmetrical as the outward form of the bird is, it is surpassed by the internal construction, which is peculiarly adapted to its habits and mode of living. The large head, broad shoulders, deep chest, and sinewy limbs of the quadruped, are replaced in birds by the pointed beak, the long supple neck, the gently-swelling shoulder, the expansive wings, the tapering tail, and the light, bony feet, all of which assist them in their motion through the atmosphere. Their bodies are protected from the intense cold in the air by a soft and delicate plumage, and their wings, although made of the lightest materials, are so powerful as to be able to strike the air with great force; their tails also serve as rudders, steering them in any direction they please. Internally, the frame of a bird is quite as wonderfully and appropriately constructed. All the bones are thin and delicately formed, except the sternum, or breast-bone, which is very large and strong. The clavicles, or collar-bones, are generally joined, forming the bone called the merrythought, which, together with two bones called the coracoid bones, keep the shoulders apart, and serve to resist the compressing action of the wings. All the muscles, except the pectoral muscle, are small and light. In men and in quadrupeds, the pectoral muscles are small when compared with those of birds, which are very strong, and are situated on either side of the breast-bones. These muscles are used for moving the wings. The anterior extremities of birds are always wings, and never arms or legs. In the cases of birds whose wings are too small to enable them to fly, they are used either as paddles in the water or to assist them in running. The great auk is an instance of the former, and the ostrich of the latter. The lungs of a bird are situate close to the backbone and ribs. The air, entering them from the windpipe, passes through, and is conveyed to a number of membranous cells which lie upon the sides of the pericardium, and communicate with those of the sternum. These cells are in some birds continued down the wings, and even to the pinions and thighs and other parts of the body. They can be filled with air at pleasure, and by this means the bird can render his body heavy or light, when necessary, either in flying, swimming, or running. The vertebral column in birds is usually rigid in the central parts and flexible at both extremities. By this means the ribs are strengthened, and the free motion of the neck and tail assisted. In birds which do not fly, the vertebræ retain some amount of motion throughout the back; but, in general, they become ankylosed, or firmly united and cemented together by bone. The skull differs from that of the mammalia; the cranial bones are consolidated, and there are no sutures in the skull of a bird. It is articulated to that part of the vertebral column called the neck by one condyle or joint, which is situated at the front margin of the great occipital opening, through which the brain descends into the vertebral column, being prolonged as it were into the spinal cord. It is by this peculiar formation that birds have so free a motion of the head and neck, especially in a horizontal direction. The wryneck is a special instance of this faculty. Birds generally sleep with the head turned back and nestled under the wing. In mental capacity, birds fully equal quadrupeds, and in some respects, indeed, surpass them. In some of the songsters, the brain has been said to exceed that of man, when considered with reference to the comparative size of the head and body. The size of the brain of an eagle in relation to its body has been reckoned to be $\frac{1}{260}$th part, that of a canary-bird $\frac{1}{14}$th, and that of a man $\frac{1}{22}$nd to $\frac{1}{33}$rd part. Parrots and starlings retain many words and phrases fixed in their memories, and some singing-birds remember whole melodies. Birds of passage, after travelling thousands of miles, and after being absent for a great length of time, remember the exact spot where their nests were previously located, or where they were reared. Prudence, cunning, and docility, are practically exemplified in the different positions in which birds build their nests, some in the neighbourhood of human beings and some in uninhabited places. Sight, smell, and hearing, are the most acute senses in birds. There are two classes of birds—the carnivorous and the granivorous; and there is a middle kind, as in quadrupeds, which partakes of the nature of both. The carnivorous class is provided with long wings, furnished with very powerful muscles, in order to be able to fly great distances. They have strong hooked beaks, and sharp formidable claws; they have large heads, short necks, and strong, sinewy limbs; their sight is wonderfully acute, so as to enable them to see their prey at a great height in the air; and they swoop down upon their victims with an unerring aim. Carnivorous birds are solitary and sullen, and seldom live together in flocks. Granivorous birds, whose food consists of grain of various sorts, have larger intestines than carnivorous birds, and their digestive organs are more complicated. The form of the bill varies, according to the kind of food which the bird subsists on. (*See* BILL.) The food is passed from the bill into the stomach, which consists of three parts—

the crop, which lies in front of the breast-bone, the membranous stomach, and the gizzard. In the crop, the food undergoes a partial dilution from a fluid furnished by the glands. In the membranous stomach it is still further diluted, and then passes into the gizzard, which acts as a powerful mill, and in which the food is ground down and triturated. The action of the gizzard is strengthened by small hard stones, which many birds swallow with their food. The digestive powers of the gizzard are very extraordinary. An experiment was tried upon a turkey-cock, when a ball of lead, studded with twelve small lancets, was forced down his throat. After eight hours had passed, the gizzard was opened, and the ball was found by itself, the whole of the lancets being broken to pieces. In the London museum of the College of Surgeons there is a large bottle entirely filled with pebbles, &c., taken from the stomach of an ostrich. In some experiments tried upon a hen, it was found that a louis d'or, after being swallowed for four days, lost sixteen grains; and the weight of an onyx was diminished one-fourth. In carnivorous birds the muscles connected with the gizzard are very weak. The liver of domestic birds is much larger than that of wild birds. The eyes of birds are admirably adapted for sight. The impression of external objects is rendered more vivid and distinct by a particular modification of the optic nerve. They have three eyelids, two of which, the upper and lower, are closed in most species by the elevation of the lower one. This may be noticed in domestic fowls. A small number of birds, such as the owl and goat-sucker, can depress the upper eyelid. The third eyelid, a thin semi-transparent membrane, lies, when at rest, in the inner corner of the eye, with its loose edge nearly vertical. It can be drawn over the eye like a curtain; and by its means the eagle is said to be able to look at the sun. Were the eyes of birds less perfectly formed, on account of the rapidity of their flight, they would be liable to fly against any object in their way. The voices of birds distinguish them from all the rest of the animal world. The organs of the voice closely resemble certain musical instruments. At the bifurcation of the windpipe is a glottis furnished with appropriate muscles, where the voice is formed. The gift of song is only possessed by male birds, and their notes are generally expressive of love. They are silent when in ill health, in sadness, or during rough weather; but when they are cheerful they always sing. They express different feelings with varied modulation; and the fear of approaching danger, hunger, love, longing for their mates, &c., are all expressed by changes in the tone of the song. This faculty is possessed by no other animal. Every form which the most lively fancy could create, and every hue that the imagination could conceive, are to be found in the feathers of birds. Two changes occur in the feathers—one in the spring and another in the autumn. In the former case, the changes occur just before the breeding-time, and the bird gains a number of new feathers without losing the old ones. In the latter, or moulting season, the old feathers fall off and new ones appear. The feathers of the wings are larger and stronger than those on other parts of the body. They are called wing-feathers, quill-feathers, or quills. At the base of each quill are small feathers called wing-coverts. The tail-feathers are also provided with coverts above and below. Many birds have very ornamental plumage in their tails; and the feathers often take other remarkable forms in different parts of the body; such as shoulder-tufts, ruffs, crests, &c. When spring approaches, wild birds begin to pair and to make arrangements for their young. The notes of the male bird at this time are very loud. The marriage contract then entered into is for the season faithfully adhered to; and in case one of the pair dies, its mate does not survive it long. The reproduction of the species among birds is carried on by means of eggs, which pass from the body of the female and are afterwards hatched. The warmth necessary for incubation is usually derived from the body of the bird, which sits upon the eggs. This duty is generally performed by the female bird; but in some cases it is undertaken by the male. (*See* EGG, HATCHING, REPRODUCTION.) Many sea-fowl make no nests, but deposit their eggs on the bare rock, or in rough holes scratched out of the earth or sand. The ostrich allows her eggs to be hatched by the heat of the sun in warm climates; but she sits and broods over them where the temperature is colder. Birds generally brood once in the year, but some brood twice; and the number of eggs they lay varies from one to twenty. The cuckoo and a small number of other birds lay their eggs in the nests of other birds, in order to be hatched by them; and several birds are able to run about and find food as soon as they leave the nest, while others remain in the nest for days and weeks before they can venture out. During this period the parent birds find food for them. At the breeding-season, birds are often gregarious, and sometimes live together in one large nest. Birds' nests are constructed with such delicate and exquisite art and ingenuity, as to call forth the admiration of every observer. Birds of the same species, wherever they may be found, build their nests with the same kind of materials and in the same manner. The situations they select, the materials they use, and the form in which they build, are wonderfully adapted to the particular nature and necessities of the bird. They are generally lined with moss, wool, fine hair, or down, and have an exterior composed of straws, twigs or roots, and dry grass, mixed with clay. Birds that build early in the spring, such as the blackbird and thrush, line their nests with loam, in order to keep out the cold air. The common sparrow, which builds four or five nests in the year, is not particular as to the situation he chooses. Sometimes he locates himself in ivy, sometimes in trees and hedges, and often under the eaves of houses. Some birds carefully conceal their nests, and some leave them open and apparent; some, like the jay, build them so loosely that the eggs can be seen through the twigs; and some very compactly, such as the golden-crested wren, which constructs its nest with small pieces of moss and spiders' web interweaved. It is nearly an inch in thickness, and is lined with a profusion of soft downy feathers. While hatching, all birds, as a general rule, resort to those places where their particular food is plentiful, and where there is an abundance of the proper material with which to construct their nests. Some water-fouls pluck the down from their own breasts, in order to line their dwellings; but they usually build in out-of-the way places, since their food is not that which is gathered by ordinary birds. While hatching, the female bird is remarkably patient. She is usually plump when she begins to sit; but before the eggs are hatched she is almost reduced to a skeleton. Neither hunger nor danger will make her leave her post of duty; but if, after being absent, the male and female birds perceive that their nest has been meddled with, they will often leave, and build in a more secure place. After the young are fledged and flown, the nest is generally deserted. Many small birds live upon worms, caterpillars, &c.; and it has been remarked, "that a single pair of sparrows, during the time they are feeding their young, will destroy about four thousand caterpillars weekly: they likewise feed their young with butterflies and other winged insects, each of which, if not destroyed in this manner, would be productive of many thousands of caterpillars." It is only of late years that the value of small birds as destroyers of vermin has been recognised; previously, farmers destroyed birds, supposing that they spoiled the crops. That they do commit ravages is beyond question, but the advantage they confer by destroying other ravagers more than counterbalances. Whilst moulting or changing their feathers, many birds turn sickly, and often die. Every country and climate have birds which are peculiar to them; but many migrate to distant lands when the season becomes too severe for them. Near the equator, the birds are remarkable for their brilliant and varied plumage; but their voices are usually harsh and discordant. In the frigid zone, where fish is plentiful, they are mostly aquatic, and their plumage consists of soft, warm, downy feathers. In all countries birds live longer, comparatively, than either men or quadrupeds in the same place. Many kinds of birds are important in an economical sense. A large profit is derived from the rearing of domestic fowls; and the flesh and eggs of some birds can be eaten, common birds, however, being generally an exception. Feathers are employed in many useful and ornamental ways, and the dung of birds is useful for manure. (*See* GUANO.) For mention of the labours of naturalists and writers in relation to birds, *see* ORNITHOLOGY.

Classification of Birds.—The following classification of birds by Professor Owen is that now generally accepted by naturalists:—*Raptores* (birds of prey)—eagle, hawk, vulture, owl, &c.; *Scansores* (climbers)—woodpecker, cuckoo, parrot, &c.; *Passeres* (from the Latin *passer*, a sparrow)—sparrow, thrush, swallow, blackbird, lark, &c.; *Columbidæ* (*columba*, a pigeon)—pigeon, dove; *Gallinæa* (*gallus*, a cock)—domestic fowl, grouse, partridge, turkey, peacock, &c.; *Cursoria*, (runners)—ostrich, emu, buzzard, apteryx, &c.; *Grallatores* (waders)—crane, heron, stork, snipe, plover, sandpiper, &c.; *Palmipedes* (web-footed)—duck, gull, albatross, pelican, &c. (*See* various headings.)

Birds of Passage are those birds which migrate from one country to another at certain times, depending on the seasons. Availing themselves of their power of flying, many birds remove themselves, at certain periods of the year, to places where the temperature is more congenial and the supply of food more abundant. Even in the tropics, some birds, like the bird of paradise, migrate from island to island, according to the change of seasons from the dry to the wet monsoon. In the temperate and colder regions, however, birds of passage usually migrate from south to north or from north to south, as winter passes into summer or summer into winter. They are usually divided into two classes—winter and summer birds of passage, the term being applied according to the time when they make their appearance. Hence, the summer birds of passage in one country are the winter birds of passage in another. The approach of spring is always heralded by the arrival of summer birds of passage, and their appearance is always connected with pleasant and cheerful associations. During the winter season, large numbers of winter birds of passage, such as wild swans, geese, and other water-fowls, leave the frozen waters of the north and migrate to the shores of Great Britain. Woodcocks, fieldfares, redwings, and many other birds which breed in northern countries, also make their appearance regularly. The migrations of the pigeons in America are very extraordinary, on account of the vast numbers which compose the flocks. The return of some birds of passage can be depended on almost to a single day; and in some places, such as St. Kilda, where the inhabitants depend for their existence on the sea-fowl, their return is almost punctually on the same date every year. It has been observed that some birds of passage leave at the regular time, while others seem dependent on the weather and temperature. Nearly all birds of this species have long and powerful wings; but some are short-winged. They can pass over great distances in a very short period of time; and as they can fly with ease at the rate of 50 to 150 miles an hour, they often arrive at their destination with comparative ease; but some birds, such as the woodcock, are often found much exhausted after their flight. That birds of passage return to the same places which they formerly inhabited, has been clearly proved in the case of swallows.

Birds of Prey, a term usually employed to distinguish the order of birds called *Raptores*. They have remarkably keen sight, and great perfection in the sense of smell. Many birds, however, which follow and prey upon other birds, do not belong to this order; and those which live upon fishes, worms, and insects, are not reckoned as birds of prey. There are two sections into which birds of prey are divided—the diurnal and the nocturnal: the latter division is composed entirely of fowls.

BIRTHWORTS. (*See* ARISTOLOCHIA.)

BISH. (*See* ACONITUM.)

BISON, *bi'-son* (Lat., *Bos Bonassus*).—The principal European regions where this animal is found are the marshy forests of Poland, the Carpathian mountians, and Lithuania. (*See* AUROCH.) The American bison (*Bos Americanus*, or *B. bison*), commonly called the American buffalo, is larger, shaggier, and fiercer even than the European species. It possesses immense strength, and can sometimes hold its own even against the grisly bear. Weaker foes it tramples beneath its feet. The hair about its neck and shoulders is bushier, and of a fine texture. The hump, which is oblong, diminishes in height towards the tail, lending a considerable obliquity to the outline of the back. On the crown of the head the hair rises in an immense mass, and shows in thick, close curls before the horns; below the chin the hair grows like a beard, and falls as low as the knees. Its flesh affords food for the roaming Indian tribes, the hump being considered a great delicacy; its skin serves them for coats, and beds, and boots; and walls for their tents, and tiles for the roof; and for saddles, and bridles, and lassos. The bones are converted into saddle-trees, into war-clubs, into whistles, and into musical instruments. Of the horns are made pins, needles, ladles, spoons, and spear-heads; the sinews serve as strings to their bows, thread to stitch their buffalo-robes and to form their tent-cloths, and for the attachment to their persons of scalps and such pleasing nic-nacs as they may set store by. The bison's feet and hoofs, when stewed down, yield a superior glue, largely used in the construction of hunting-spears and arrows. The tallow is an important article of trade, and one animal will sometimes yield as much as 150 lbs. The mane of the animal is twisted into ropes and horse-halters, and the tuft at the extremity of its tail is used as a fly-brush. The brains even are not wasted, but used in the preparation of leather from the bison's hide. The number of bisons roaming the vast North American prairies is rapidly diminishing, so eagerly has it been hunted by white men and redskins. During the pairing season, the roaring of the bulls is terrific, and the combats that take place between them are unequalled even among the carnivora. They swim broad rivers in nearly the same order as they traverse plains—viz., in a dense animated mass, pressing so close at each others' heels that the foremost dare not stop from peril of being trodden to death. The Indians profit by this peculiarity, and, creeping up to a herd, drive them forward, with hideous shouts and yells, to the verge of a precipice, over which a score or so will certainly topple.

BISTORT. (*See* POLYGONUM.)

BITTERN, *bit'-tern* (Du., *butoor*) (*Botaurus stellaris*). A genus of wading birds, comprising several species closely allied to the heron, from which, however, they are distinguished by the long, loose plumage of the neck, which can be erected at pleasure, and the greater length of the toes. The common bittern (*Botaurus stellaris*) is generally found throughout the entire Eastern hemisphere. In summer it chiefly affects the north of Europe and Siberia, at other seasons the mild regions skirting the Mediterranean, in China, India, and even in Southern Africa. It was formerly plentiful in this country; but the universal drainage of marsh land has driven it to seek a locality more congenial to its nature. When alarmed, the bittern emits a peculiar cry, by no means pleasant to hear; but on the approach of the breeding season the sounds it utters are of the most hollow and melancholy kind. The provincial English names are "Mere-drum," "Night-raven," and "Bull of the Frog." The length of the common bittern is about thirty inches, and its voracity remarkable. Mr. Yarrell found in the stomach of one the bones of a good-sized pike. The little bittern (*B. minutus*) is also a summer visitor to these islands, and is the smallest variety of the family to which it belongs known in Great Britain. It is an inhabitant of a wide range of countries, as it has been met with in south-western Asia, in Holland, Germany, southern France, and Italy, and even as far north as Sweden. The American bittern (*B. lentiginosus*) is somewhat smaller than the common bittern. On the other side of the Atlantic this bird has different names in the different states which it inhabits, being called, among other titles, Indian-billet, Indian-hen, and Dunkadoo. The Australian bittern (*B. Australis*) very closely resembles the bittern of Europe. The bittern once afforded great sport to falconers in England, and it was protected by severe penalties. Any one who destroyed or took away the eggs of a bittern was liable to a year's imprisonment and a fine of eightpence for each egg, by a statute of Henry VIII. Yarrell, in his *History of British Birds*, informs us that "the bittern was formerly in some estimation as an article of food for the table. The flesh is said to resemble that of the leveret in colour and taste, with some of the flavour of wild fowl." Sir Thomas Browne says that young bitterns were considered a better dish than young herons. Turning to Yarrell once more, we find that "the bittern constantly feeding at night, is, therefore, seldom seen on wing in the day, but remains with head erect in thick beds of reeds, or conceals itself among flags, rushes, or other rank aquatic vegetation which afford it a solitary and secure retreat:" from such situations it is with difficulty made to take flight; and when at length obliged to get on wing, the pace is dull and flagging, and seldom sustained to any great distance. M. Viellot says that in France it is occasionally found in woods. Neither females nor the young differ much in their plumage from the male bird.

BITTERSWEET. (*See* SOLANUM.)

BITTERWOOD. (*See* XYLOPIA.)

BITUMEN, *bit'-u-men* (from Gr., *pitus*, the pitch-tree, because it resembles pitch), is a term which includes many fossil bodies of a resinous nature. True bitumen is fossil tar, and is the product of the action of an elevated heat upon vegetable bodies. The surrounding stratum, which is generally tertiary, is mostly impregnated with bitumen, giving rise to bituminous clay, shale, or coal, according to its nature. In many cases, bitumen occurs in nature as a regular deposit, forming beds like true coal. Lignites (which *see*) contain bitumen imbebbed in them in small quantities. Asphalt is a finer sort of bitumen, much used in the preparation of paving-material. Bitumen is closely allied in its properties to coal-tar, which is produced by the destructive distillation of coal. The first process for obtaining pictures by means of light was founded upon the fact that the bitumen of Judea when exposed to the sun's rays became insoluble in oil of lavender, whilst those parts remaining in shadow preserve their solubility. Elastic bitumen, or mineral Caoutchouc is an interesting variety of the mineral. (*See* ELATERITE.)

BIVALVE, *bi'-valv* (Lat., *bis*, double, *valvæ*, valves), in Conchology, a term given to those kinds of shell-fish which possess two shells, in contradistinction to those which possess but one, and which are termed univalve. (*See* MOLLUSCA.) As familiar examples of bivalves may be mentioned the mussel, cockle, and oyster. Bivalve shells form the testaceous envelope of mollusks, and are composed of two concave plates connected by a hinge, having an elastic ligament.

BIXACEÆ, OR FLACOURTIACEÆ, *bix-ai'-se-e*, a natural order of dicotyledonous plants in the sub-class *Thalamifloræ*. They are shrubs or small trees, with alternate leaves, usually entire and leathery, and very often dotted. The flowers are polypetalous or apetalous, the stamens being hypogynous, and equal in number to the petals, or some multiple of them. The fruit is one-celled, dehiscent or indehiscent, having a thin pulp in its centre. The seeds are numerous, usually enveloped in a covering formed by the withered pulp. The plants of this order are almost confined to the hottest parts of the East and West Indies and Africa. There are 34 genera and about 90 species. Many are feebly bitter and astringent, and have been used as stomachics. The bark of *Aphloia* is said to be emetic. The fruits of *Oncoba* and of some species of *Flacourtia* are edible and wholesome. The most important plant of the order is *Bixa orellana*, which yields a red dye. (*See* ANNATTO.) The reddish pulp covering the seeds is the source of this colouring matter.

BIXIN, *bix'-in* (from *bixa*, the name of the tree whence annatto is derived), an orange-red colouring matter, found in annatto, to which it owes its dyeing properties. It is a resinous substance, soluble in alcohol and ether, but sparingly so in water. The alkalies dissolve it, producing a deep red colour, but, on neutralizing, it falls as an orange precipitate. It is also soluble in fixed oils.

BLACK ALDER. (*See* RHAMNUS.)

BLACK ANT. (*See* ANT.)

BLACK BAND, a clayey carbonate of iron containing sufficient carbonaceous matter to allow of its being calcined without any additional fuel. It is found principally in the Scotch coal-fields, and is the most important ore of iron in those districts. (*See* IRON.)

BLACK-BEETLE, *be'-tel* (*Blatta orientalis*). This insect, though now common throughout Europe, is supposed to have been originally a native of India, and, by the progress of commerce, carried thence westward. On board merchant ships, the black-beetle is very commonly found; and it is said to be more plentiful in seaport towns than other places. All sorts of matter, vegetable or animal, suits the appetite of this insect. The curious way in which insects of this genus lay their eggs is worth mention. Instead of emerging singly from the abdomen of the female, they are inclosed in a horny case almost half as large as the abdomen of the parent. Within this the eggs are ranged in two rows, separated by a partition which runs down the middle of the case; each egg is also separated from the next by a similar partition. This egg-case is attached to the wall or floor with a strong adhesive liquid furnished by the mother. When the larvæ are hatched, they emit from their mouths a fluid which dissolves the walls of their prison, and they are set free.

BLACKBERRY. (*See* RUBUS.)

BLACKBIRD, *blak'-bird* (*Merula vulgaris*). —This familiar bird furnishes a fair example of the general size and appearance of the typical thrushes. Like the corvine or crow family—of which, indeed, the thrushes are but representatives—these birds make their way upon the ground, in the air, and among trees, with equal facility; and this perfection of foot is more or less prevalent throughout the family. It builds a large cup-shaped nest, composed of grass, roots, and stems externally, coated inside with mud, and lined with soft grasses. It lays four or five eggs, generally of a light blue. There is sometimes, however, so little difference between the eggs of the blackbird and the common thrush, as to make it impossible for any one but an accomplished ornithologist to distinguish between them. The blackbird has a powerful voice and great power of song and imitation, and it is asserted, has been trained to utter words.

BLACKCAP, (*Curruca atricapilla*), one of the *Sylviadæ*, or Warblers, and allied to the nightingale, by which bird only is it surpassed as a sweet singer; indeed, some persons prefer its shake or trilling note. The back, wings, and tail are of an ash-brown colour; the chin, throat, and breast grey; the belly white. The upper part of the head in the male is jet black. The feathers of the head, both in the male and female, are somewhat erected, giving the bird a hooded appearance, whence the popular name, "the monk," given in Germany. It is a bird of passage, arriving in Britain (mostly in the southern counties) early in spring, and leaving in September. As a cage bird it is greatly admired, not only on account of its beautiful song, but for its intelligence and affectionate nature.

BLACKCAP TITMOUSE. (*See* TITMOUSE.)

BLACK CHALK, a variety of clay-slate, containing a large amount of carbon, found on a rock of a slatey texture and bluish-black colour, chiefly in the island of Islay, Carnarvonshire, and Spain. It is used for draining, and, when ground down, for a black pigment.

BLACKCOCK, *blak'-kok* (*Tetrao tetrix*), a species of the grouse family, rarely seen in England, but abundant in Scotland, and found also in various parts of Europe, especially in Sweden and Lapland. The male (much larger than the female) sometimes weighs four pounds, and is of a bright bluish-black colour with a white bar on the wings, and a mixture of black and white on the legs; over the eye is a piece of scarlet skin. The outer feathers on each side of the tail have a peculiar curve outwards. It is frequently known as the heath-fowl, or black grouse. In its habits the blackcock closely resembles the capercalzie, inhabiting the low-lying districts, and feeding chiefly on the young shoots of shrubs, and seeds, and berries. According to Yarrell, in the winter time the bird's crop is frequently found filled with the young shoots of fir.

BLACKFISH (*Centrolophus Moris*), a fish of the dolphin kind, found in the Mediterranean and on the western coasts of Europe. It is nearly thirty inches long; it has a dorsal fin rising from a thin elevated ridge. It is remarkable for strength and velocity of movement. The flesh is said to be of delicious flavour.

BLACK-JACK, a name given by miners to sulphide of zinc, or zinc-blende. (*See* ZINC.)

BLACK-JACK TREE. (*See* OAK.)

BLACK-LEAD. The common commercial name for graphite, or plumbago, given to that substance from its metallic leaden-grey lustre. It is, however, nearly pure carbon, and contains no lead. (*See* GRAPHITE, PLUMBAGO, CARBON.)

BLACK QUARTER, an apoplectic disease peculiar to cattle, otherwise known as Black Leg, Quarter Evil, and by various other names. It is not contagious, but limited to districts, but attended in hot weather by the development of a fatal blood-poison. (*See* MALIGNANT PUSTULE.) The chief causes are rich pasture on undrained or retentive soils, and sudden changes from poor to rich feeding. Death generally follows the first appearance of the disease in a few hours.

BLACK SNAKE. (*See* COLUBER.)

BLACKTHORN. (*See* PRUNUS.)

BLACK WAD.—A dense black earthy mineral used as a pigment, also in glazing pottery, and in the manufacture of glass and chlorine. It is a hydrated peroxide of manganese mixed with various impurities.

BLADDER, *blad'-der* (Sax., *blader*, from *blawan*, to blow), is a thin membraneous bag, which serves as a receptacle for the urine secreted by the kidneys, until it is voided through the urethra. It is situated in the pelvis, and is kept in its place by ligaments, which are usually divided into true and false, the latter being formed of folds of the peritoneum. It is composed of three coats or membranes—the external or fibrous membrane, the middle or muscular membrane, and the internal or mucous membrane. Its figure is nearly that of a short oval. It is broader on the fore and back than on the lateral parts; rounder about than below, when empty; and broader below than above, when full. It is divided by anatomists into the fundus or upper portion, the body, and the neck —that portion which is constricted by a sphincter muscle, and communicates with the urethra. On each side, rather below its middle, it receives the two ducts called ureters, which convey the urine from the kidneys into the bladder. The bladder, like every other organ of the body, is liable to certain diseases, one of the most common of which is inflammation, or cystitis. It chiefly affects the mucous coat of the bladder; but all the other coats may be implicated; and it is either chronic or acute. The acute form is known by great pain in the region of the bladder, attended with fever and hard pulse, and a frequent and painful discharge of urine, or a retention. The disease runs its course with rapidity, and subsides, or carries off the patient, in a few days. It is to be treated by local bleeding and hot fomentations, together with opiates. The chronic form of this disease is best treated by tonics and sedatives. The causes of this disease are various. It often arises from calcarious secretions, which in that case must be removed. Irritability may exist in the bladder, unaccompanied by inflammation, and may arise from over-distension or from nervousness. It is to be treated by the administration of tonics. The bladder may be affected with paralysis, resulting either from accident, from disease of the nervous centres, or from over distention. It gives rise to incontinence of urine, which, however, is to be distinguished from that which sometimes arises from irritability, inasmuch as in this case the bladder is full, and has no power to evacuate properly; so that it must be drawn off by the catheter. Retention of urine may be caused by mechanical obstacles to its exit, by paralysis, or by a want of power over the muscles.

BLADDERLOCKS. (*See* ALARIA.)

BLADDER-NUT (*Staphylea pinnata*), a genus of plants classified by some botanists as a small natural order, but by others united with *Celastraceæ*. About fourteen species are known, found in very different climates, and scattered over the world. They are mostly small trees of elegant appearance. The common Bladder-nut (which derives its name from the curiously inflated capsule and the hard seed) is an ornamental tree, a native of Eastern Europe and the temperate regions of Asia. The seeds have a slightly aperient quality, and the flowers are pickled as copeia.

BLADDER SENNA. (*See* COLUTEA.)

BLADDERWORT, a genus of plants (*Utricularia*) of the natural order *Lentibulariaceæ*. They grow in lakes and marshes in almost all parts of the world, especially in the tropics. The roots, stems, and leaves are furnished with little bladder-like vessels, which are filled with water till it is necessary that the plant should rise for the expansion of the flowers, when they become filled with air; and they again give place to water, after flowering is over, so that the seeds ripen at the bottom of the water. Only three species, all having yellow flowers, are known in Britain.

BLADE, a term generally applied to the expanded portion of a leaf. It is the part which is usually the most highly developed, and which is popularly known as the leaf. The terms *lamina* and *limb* are also applied to this part. (*See* LEAF.)

BLAPS, *blaps*, the typical genus of the family *Blapsidæ*, of that order of insects named *Coleoptera*. The blaps is the only insect of the family *Blapsidæ* to be met with in this country. Its scientific name is *Blaps mortisaga*, its common one the Churchyard Beetle. It is about an inch long, sometimes of a dark, but more frequently of a black colour, and is generally to be found in murky, damp situations, or the dirty parts of dwelling-houses. *Blaps sulcata*, cooked with butter, is eaten by Turkish women in Egypt in order to attain that corpulent condition of body so highly esteemed as an element of female beauty in the east.

BLATTA. (*See* BLATTIDÆ.)

BLATTIDÆ, *blat'-ti-de* (Lat., *blatta*, an insect that eats away clothes), a family of insects belonging to the order *Orthoptera*. The insects of this family are extremely active and voracious. According to Mr. Stephens, there are only seven species indigenous to this country, among the most disagreeable of which is the well-known Cock-roach, or Black-beetle. (*See* BLACK-BEETLE.) In hot climates, where the number of species of this family is very large, their ravages are exceedingly great. The largest of the genus is the *Blatta gigantea*, which is indigenous to the warmer parts of Asia, South America, and Africa, where they plunder and erode all kinds of victuals, dressed and undressed, and damage all sorts of clothes, especially such as are touched with powder, pomatum, and similar substances; everything made of leather, books, paper, and various other articles. In old timber and deal houses, when the family is retired at night to sleep, this insect, among other disagreeable properties, has the power of making a noise which very much resembles a pretty smart knocking with the knuckle upon the wainscoting. The *Blatta gigantea*, in the West Indies, is therefore frequently known by the name of the Drummer. The *Blatta Americana*, or American cockroach, is another member of this troublesome family. Its size is somewhat larger than that of the black beetle; but its destructive powers are little less. It is now becoming common in England, especially in seaport-towns, where it is brought with merchandise from abroad. The *Blatta lapponica* is a smaller species, which is to be found in Lapland in great numbers. When very numerous, instances have been known where they have devoured the whole of the natives' winter provision of dried fish. Perhaps the most singular circumstance connected with these insects consists in the manner in which they deposit their eggs. Instead of laying her eggs singly, as most insects do, the female drops an oblong mass, which serves as a case for an entire family of young Blattæ. From this prison Nature has provided the young insects with a means of escape at the fitting moment. This consists of a fluid which they emit, and which softens the cement of the denticulated margins of the case, or cocoon, as it might be termed, in which they have hither to been enclosed. The cocoon of the blattæ contains about sixteen eggs, of an oblong oval form, arranged in a double series. In this protecting case the young insects are brought to a considerable state of maturity ere they emerge into freedom.

BLEAK, *bleek* (*Leuciscus alburnus*), a little silvery-scaled fish, well known to British anglers. It belongs to the family of *Cypeinidæ*, and is of the same genus as the roach, dace, and minnow. It is six or seven inches long, and is more elongated than the dace, and the dorsal fin is farther back. The back is of an olive-green colour; the sides, belly, and gill-covers, silvery white. If well cooked, they afford delicate eating. It is said that the scales of the bleak are used in the manufacture of imitation pearls.

BLENDE, *blend* (Ger., *blenden*, to dazzle), a term applied to several minerals possessed of a peculiar glittering lustre, such as *hornblende*, *bismuth-blende*, &c. When used alone it generally designates zinc-blende, or *garnet blende*, or *sulphuret of zinc*. (*See* BLACK JACK.)

Antimony Blende, a rare mineral with a shining surface, known also as Red Antimony, and composed of sulphur and antimony.

Manganese Blende, similar to the above, but composed of manganese and sulphur.

Ruby Blende sometimes used indiscriminately to designate any glistening mineral of a ruby colour, but applied particularly to Pyrargyrite on the ores of silver.

BLENHEIM SPANIEL. (*See* SPANIEL.)

BLENNIUS, OR BLENNY, *blen'-ni-us* (Gr., *blenna*, mucus), a genus of fishes belonging to the section *Acanthopterygii* and the family *Goboidæ*, principally recognizable from their having the ventral fin placed before the pectoral. Their skins are frequently destitute of scales but are covered with an abundance of slimy matter. Their eyes are shaded by a fringed appendage; their bodies elongated. They congregate in small shoals upon rocky coasts, where, upon the reflux of the tide, they may be often found in pools among the crevices of the rocks. Five species frequent the English coast—Montagu's, or the Diminutive Blenny; the Ocellated Blenny, or Butterfly-fish; the Gattoruginous Blenny; the Shanny; and the Crested, or Yarrell's Blenny.

BLENNORRHŒA, *blen-nor-re'-a* (Gr., *blenna*, mucus; *rheo*, I flow), a term used to denote an unusual discharge of mucus from any of the mucous membranes. (*See also* MUCOUS.)

BLENNY. (*See* BLENNIUS.)

BLESBOK, *bles'-bok* (*Gazella albifrons*), a fleet antelope of Southern Africa. (*See* ANTELOPE.)

BLETS.—Spots of rottenness in fruit. Hence the term *bletting*.

BLIGHT, *blite* (Sax., *belihtan*, to fall upon), a general term for a certain class of diseases which affect the cultivated grasses, especially the cerealia. It is generally limited to the disease to which wheat and other grains are liable, when the outside of the plant remains green and flourishing while the interior is filled with a powder having a very fœtid smell. This powder consists of a microscopical fungus in the shape of balls, so minute that four millions of them may be present in a grain. This disease is also called smut-balls, bunt, pepper-brand, and stinking rust. The name of blight has been applied to every kind of disease incidental to plants through changes in the state of the atmosphere, the condition of the soil, ravages of insects, parasitic fungi, &c. The name has also been given to diseases of plants which have arisen through errors in cultivation. Insects and parasitic fungi attack unhealthy plants first; and often when the evil has been ascribed to them, the true cause has been some mistake in manuring the soil. There is a kind of blight sometimes very prevalent, which has been referred to fungi, but which is, in fact, nothing more than an excessive development of the epidermal cells, which are no longer kept within bounds by the real cuticle, but become elongated, and frequently branched in various ways, so as to form spongy or mealy patches, which are sometimes in such abundance as from their bright colour or peculiar aspect to attract general notice. This species of blight does little damage to the plant on which it is found, and is most commonly observed on woody plants, such as vines and hawthorn. A similar effect sometimes appears on a few herbaceous plants.

BLIND COAL, a common name for those varieties of coal containing little or no bituminous matter, which are said to burn blindly, because they give out neither flame nor light. (*See* ANTHRACITE.)

BLINDNESS, *blind'-ness*, is a more or less complete deprivation of vision in consequence of a diseased state of the organs of sight. Some of the blind retain a slight perception of light, or are able to distinguish the general outlines of bodies, or very bright colours, while others are entirely deprived of the faculty. Some are blind from birth; others become so in consequence of disease. In those that are born blind, the eyelids are sometimes united to each other, or to the eyeball itself; sometimes a membrane or film covers the eye; sometimes the pupil is closed, or adheres to the cornea; and sometimes the opening of the pupil is not in the right place, so that the rays of light do not fall in the middle of the eye. It may also arise from some defect of the optic nerve, or of the brain in connection with it. Blindness may result from disease of the optic nerve, or of the brain; or from an abnormal condition of the humours or coats of the eye, intercepting the passage of the light to the optic nerve. Among the diseases of the brain that may produce blindness are hydrocephalus, inflammation, congestion, softening or wasting of that organ. The eye itself may be injured by inflammation, suppuration, or cancer; spots, films, or tumours may form on the cornea, and so destroy its transparency; the humours of the eye may become thick and turbid; or the opening of the pupil may be destroyed. Blindness often arises from debility of the optic nerve, occasioned frequently by long-continued overstraining of the sight. It is in this way that certain kinds of occupations are so injurious to the sight, and often cause blindness. Hence it is, too, that in the northern regions, where the country is long covered with snow, which reflects the sun's rays, and in the sandy deserts of Africa, blindness is a common affliction. *Congenital Blindness*, that is, blindness at birth, is generally caused by some deficient development of the nerves of the eye, and may be detected by the indifference of the child to the light. In old age, blindness is usually occasioned by a drying up of the humours of the eye, a thickening of the cornea or crystalline lens, or atrophy of the optic nerve. *Day blindness* is an inability to see during the day in a bright light. Those who have been long immured in dark cells are often affected in this way. *Night blindness* is that state in which blindness comes on towards evening. This may be continued for some time; but at length the eyes become weak during the day also, and it terminates in amaurosis. Proceeding as blindness does from such a variety of causes, it is impossible to say anything here regarding its treatment, which will be found noticed in other parts of the work. (*See* AMAUROSIS, CATARACT, OPHTHALMIA, EYE, SIGHT.)

BLINDNESS, COLOUR. (*See* COLOUR BLINDNESS.)

BLINDWORM, also called the Slow-worm, a small reptile belonging to the family *Anguidæ*. There are many varieties of the species in Europe, and one of the genus is well known in many parts of Britain. It is perfectly harmless, and in no species are their any poison-fangs. Its teeth are very small, and, when irritated, it attempts to bite, but is unable to pierce the skin. Its eyes are very small, and in consequence it is popularly believed to be blind; hence the name. The blindworm lives in holes, in rocks, under stones, &c., and feeds on live worms and insects. It will not touch them when it finds them dead. Its length varies from 11 to 16 inches, and its thickness is equal throughout its length. Its colour is silvery grey, with a black line along the back, and frequently rows ot dark spots along the sides. The body is singularly brittle; the tail is blunt and easily broken off, but soon sprouts out afresh, and at the end of the year is quite renewed. The scales are small and nearly equal; the tongue is notched at the end, but not pointed and fanged. During the winter it remains torpid, and casts its skin at the beginning of summer. It is ovoviviparous, and the number of young varies from seven to twelve at a birth. One of the most interesting facts in connection with the blindworm is that it forms one of the connecting links between lizards and serpents. The bones of the head of a blindworm connect it with the lizard family; and although there are no external traces of limbs in the skeleton, there are the bones of the shoulder, the sternum or breastbone, and the pelvis, all existing in a rudimentary state.

BLISTER, *blis'-ter*, (Ang.-Sax.), a pustule or thin watery bladder on the skin containing serum. It is formed by raising the cuticle, and may be occasioned by a burn or other injury, or by a vesicatory. The term is also applied to the separation of the film or skin of plants.

BLISTER-FLY (*Cantharis vesicatoria*), an insect common to the south of Europe. Its body is used for medicinal purposes, having the effect of raising a blister when applied to the skin. It has been observed that the efficacy of the insect increases according to the heat of the country inhabited by it. (*See* CANTHARIDES.)

BLOOD, *blud* (Sax., *blod;* Germ., *blut;* Lat., *sanguis*), a red fluid circulating through the heart, arteries, and veins of animal bodies, serving for the nourishment of all their parts, and the support of life. "The blood is the life," is a Scriptural axiom. This nutritive fluid, called scientifically the *liquor sanguinis*, consists firstly of water, holding, in a dissolved condition, fibrine, albumen, potassium, and sodium, together with phosphoric acid and other substances; secondly, of corpuscles, or globules, which float in the *liquor sanguinis*. When drawn from the body, the blood undergoes a remarkable change. By degrees it gelatinizes, and forms spontaneously coagulum and serum. Coagulum consists of the fibrine and the corpuscles; serum, of water, albumen, and the various saline matters. The corpuscles are of two kinds—red and white, the red being the more numerous. The size of a red corpuscle of human blood is $\frac{1}{3200}$th of an inch in diameter. The largest corpuscles are those of reptiles. The discovery of the globules of the blood is due to Leuwenhoeck and Malpighi, whose researches were made soon after the microscope was invented. Blood is termed arterial or venous, according to the vessel in which it circulates. Arterial blood is a florid red, with a stronger odour and less specific gravity than the venous fluid. Venous blood is of a dark purple. The chief difference between arterial and venous blood, is that the former contains more oxygen and less carbonic acid than the latter. The scarlet, or arterial blood, which is one degree warmer than venous blood, owes its colour to is undergoing contact with atmospheric air in the lungs; it circulates in the pulmonary veins, the left cavities of the heart, and the arteries, by which it is distributed to the different organs throughout the body. The dark purple blood circulates in the veins, in the right cavities of the heart and lungs. (*See* CIRCULATION OF THE BLOOD, RESPIRATION.) There is, again, a difference between arterial and venous blood in respect to the gases which they contain: the first holds a supply of oxygen, the second is rendered impure by the carbonic acid with which it is loaded. (*See* ARTERY and VEIN.) Blood is the product of the elaboration of chyle; it acquires all its nutritive and life-giving qualities in respiration. By means of arterial vessels, it penetrates to all the organs, distributing nutrition to every organic tissue. It is, moreover, the principal source of animal heat: from it, also, the secretive organs derive their various products, such as saliva, bile, urine, &c. The average quantity of blood in an adult man has been calculated at 28 lbs. or pints. It has been shown that the composition of the blood undergoes a change in various diseases; and, after repeated bleedings, the number of corpuscles becomes permanently diminished. The colour, as well as the composition of the blood, varies in different sections of the animal kingdom: red in the Vertebrates and Annelides; it is white and transparent as water in Insects and Crustaceans; bluish-white in Mollusca; yellowish in Holothurians and some other Invertebrates. This difference in colour arises from the corpuscles, which are red in some cases, and in others white or straw-coloured, or bluish-white. The temperature of human blood is 90° Fah., and from 30 to 120° lower than that of other animals, the blood of birds being the highest in temperature. The chemical constituents of blood, when in a healthy condition, are—albumen, fibrin, hæmatin or colouring matter, oleic, stearic, lactic, phosphoric, sulphuric, and hydrochloric acids, in combination with soda, potash, ammonia, lime, magnesia, and a small portion of phosphorized fat. The blood also contains oxygen, nitrogen, and carbonic acid. In considering the chemical constitution of the blood, it may be regarded as consisting of two parts—the *liquor sanguinis*.

and the blood corpuscles floating therein. The *liquor sanguinis* is composed of serum, holding a small quantity of fibrin in solution. Taking the blood as a whole, Liebig gives its component parts as follows: water, 80; solid matter, 20. The solid matter, on being incinerated, give 1¼ to 1½ per cent. of ash, which consists of one-half sea-salt, one-tenth of peroxide of iron, and the rest of lime, magnesia, potash, soda, phosphoric acid, and carbonic acid.

Blood, Absorption Lines in. The colouring matter in red blood gives two wide indistinct bands in the red part of the spectrum, while deoxidised blood gives only one black band. In cases of poisoning by inhalation of carbonic oxide is found to give another set of bands. (*See also* SPECTRUM, SPECTRUM ANALYSIS, &c.)

Blood, Transfusion of.—An opinion was largely prevalent in the 15th century that the decaying vigour of the infirm might be repaired by the transfusing into their veins of the blood of young persons. It was so often fatal that it was at length suppressed; but the practice has been occasionally revived in recent times.

BLOOD-BIRD, a beautiful little bird found in New South Wales, having its head, neck, breast, and back of a rich scarlet colour. It belongs to the genus Honeysuckers (*q.v.*).

BLOOD-FLOWER. (*See* HÆMANTHUS.)

BLOOD-HORSE. (*See* HORSE.)

BLOODHOUND, *blud'-hound*, (blood; and Dan., *hund*, hound), *Canis sanguinarius*, a dog gifted with such exquisite and peculiar scent as to be able to follow the trail, for many miles, of any body bearing about it traces of fresh-shed blood, or indeed of any object to the pursuit of which it has been trained. It is also known as *Sleut* or *Sleuth* hound from the Saxon word *Sleut*, the track of a deer, in the chase of which animal it was largely used in former times. The genuine bloodhounds are large, strong, and broad-chested; the upper lip large and pendulous; the general colour a deep tan, marked with a spot of black over each eye. Formerly this creature was used in recovering escaped criminals, and it is still sometimes so employed, but very rarely, a recent instance being the capture of Fish, who murdered a girl at Blackburn. It was also used to track fugitive slaves in America and Cuba.

BLOOD-ROOT. (*See* SANGUINARIA and HÆMODORACEÆ.)

BLOODSTONE, *blud'-stone*, a variety of chalcedony, of a fine dark green colour, variegated with small bright-red spots; whence its name. It is also called *heliotrope*. Being very hard and compact, it is highly valued by seal-engravers, the devices engraved upon it being much sharper and finer than those engraved on other stones of a similar kind. Hæmatite, a brown-red mineral, consisting of sesqui-oxide of iron, is sometimes erroneously called *bloodstone*.

BLOW-FLY, *blo'-fli* (Ang.-Sax.) (*Sarcophaga carnaria*; Gr., *sarx*, flesh, *phago*, I eat). A dipterous, or two-winged insect, of the family *Muscides*, of which the common house-fly is the most familiar example. The blow-fly, which is very common in Britain on heaths, in gardens, &c., has a hairy body, with wings that have an expanse of an inch. The face is silky and yellow, the thorax grey with three small black stripes, and the abdomen is of a shining dark brown, which in certain lights has a blue tinge, and is covered with shining yellow spots. The eyes are always widely separated in both sexes. The larvæ of the blow-fly feed upon the flesh of animals, either living or dead. Sometimes they are found in meat, the carcasses of dead animals, the bodies of living earthworms, and very often upon sheep. The maggots eat their way into the skin of the sheep, which soon die, after suffering great torment. A wash of corrosive sublimate may be applied, and when the skin is much broken the wool should be clipped and an ointment of grease and tar used. Some parts of England are more infested with these pests than others, and their appearance requires the most untiring attention of the shepherd. Many blow-flies are ovoviviparous, the eggs being hatched within the body of the insect, and their reproduction is very rapid. There is a particular species of this genus which haunts burial-vaults: it is called *Sarcophaga mortua*. It differs slightly from the above, in that the abdomen is of a shining steel blue and there is on the forehead a reddish-brown line.

BLUBBER, *blub'-ber* (Ang.-Sax.), the fat of whales and other large sea-animals. Properly speaking, it is the *adeps* of the animal, and lies immediately beneath the skin and over the muscular flesh. In the porpoise it is a firm and fibrous mass, usually about an inch thick; in the whale its thickness is generally six inches; about the under lip it is two or three feet thick. The quantity of blubber yielded by one of these animals is generally from twenty to thirty tons, from which from fifteen to twenty-two tons of oil may usually be extracted. The use of the blubber to the animal seems to be partly to poise the body, and render it equiponderant to the water, partly to keep the water at some distance from the blood, and so prevent chill, and partly to reflect the hot steams of the body, and so redouble the heat; since all fat bodies are less sensible of cold than lean ones.

BLUE-BELL, a wild flower found chiefly in woods. (*See also* HYACINTH.)

BLUE-BIRD, also known as Blue Robin, Blue Redbreast, Blue Warbler (*Sylvia sialis*).—An American bird, closely resembling in its habits the English robin. (*See* SYLVIADÆ.)

BLUEBOTTLE-FLY. (*See* FLESH-FLY.)

BLUE-BREAST (*Motacilla suecica*), one of the English names of a pretty bird which forms the link between the redstart and the lapwing. It resembles both birds closely, and is sometimes called the blue-throated robin, and sometimes the blue-throated redstart. The blue-breast is found in the same countries where the red-breast is found, and particularly on the borders of forests. It is very rare in this country. The song of the blue-breast is very agreeable: it resembles two voices—one deep like the humming of a violin string, and the other soft, like the sound of a flute. The blue-breast builds its nest in the bushes and in the holes of trees, and lives upon flies, worms, and the larvæ of insects. It is also said to feed upon elder-berries. It lays six eggs, which are of a greenish-blue colour.

BLUE CARDINAL. (*See* LOBELIA.)

BLUE COPPER, a fine blue mineral, consisting of sulphide of copper. It is also known as indigo-copper.

BLUE COPPERAS, sulphate of copper, so called to distinguish it from green copperas, which is sulphate of iron. (*See* COPPER, SULPHATE OF.) It is also called blue vitriol and blue stone.

BLUE EYE (*Entomyza cyanotis*), a beautiful little bird found in New South Wales, a species of the *Honey Sucker*, and sometimes called the Blue Cheeked Honey Eater. It also feeds on insects and berries.

BLUE JOHN, a name given by miners to the blue variety of Derbyshire or fluor spar. It occurs in cubical crystals or in granular crystalline masses, and is much used for making vases, cups, and other ornaments. It is found principally at the Blue John mine at Castleton, in Derbyshire, and in the lead mines of Alston Moor, in Cumberland. (*See* FLUOR SPAR.) This material is daily becoming scarcer. It requires great skill in working, owing to its brittleness.

BLUE TITS. (*See* TITS.)

BLUE THROAT (*Sylvia Suecica*), also called Blue-Breast, Blue-Throated Warbler, Blue-Throated Robin-becfin, and Beccafico. A summer bird of passage, well-known in many parts of Europe, but rare in Britain. It much resembles our Robin, but has a blue, instead of a red breast. (*See* also SYLVIADÆ.)

BLUE WING, an American bird somewhat resembling our wild duck, highly esteemed for the table. As its name implies, the principal colour of its plumage is blue, except the back which is brown mixed with green. The lower parts are reddish-orange, spotted with black. It is very common in the marshes of the Southern States.

BLUSHING, *blush'-ing* (Dan., *blussen*, to blaze or glisten), is a sudden reddening of the face, excited by a sense of shame, confusion, or surprise. It is produced by an increased flow of blood into the capillary vessels of the face and neck; and besides reddening, it creates a sensation of heat in those parts. It is occasioned by the mental shock acting upon the brain, and, withdrawing the nervous energy which ordinarily contracts the muscular coats of the bloodvessels of these parts, whence the blood is permitted to flow with greater violence through the vessels.

BO TREE, *Ficus Religiosa*, a common name given in Ceylon to the *Peepul* (q.v.), a sacred tree to the Buddhists, planted close to the temples. The Bo Tree near the city Anarajapoora is reported to be the oldest in the world. It was planted 288 B.C., and is now, therefore (1882), 2170 years old. It is supposed to have sprung from a branch of the identical fig-tree under which Gotama Buddha reclined at Uruwelaya when he underwent his apotheosis. Sir James Emerson Tennent, in his work on Ceylon, describes this particular tree, and gives conclusive reasons for believing in its great age. He finds it mentioned in historic documents of centuries ago.

BOA, a name popularly applied to all large serpents which kill their prey by twining round and crushing it, but restricted by zoologists to that section of them which have plates under the tail singly. They are all found in the Western Hemisphere, those in Asia, Africa, &c., being known as pythons (which *see*). These have the plates on the under surface of the tail double. The boas feed chiefly on small quadrupeds in search of which they often ascend trees and suspend themselves from the branches by the tail, and thus hanging motionless they await the coming of their victim. The prehensile power of the tail is also supplemented by two spine-like hooks occurring on the lower part of the body, which they fasten at will on the boughs of trees. These claws are connected with the bones of the main skeleton, and form a characteristic of the *Boidæ* or boa family.

Boa Constrictor.—This name is popularly applied indiscriminately to any huge serpent, but particularly it designates an enormous reptile found in the interminable marshes of New Guinea, and other hot portions of the American continent. The branches of the upper and lower jaw of this creature, as well as the bones of the palate, are armed with recurved and pointed teeth, forming four rows above and two below. The pedicle of the lower jaw is movable, which itself is almost wholly suspended to another bone, analogous to the mastoid, attached to the skull by muscles and ligaments. The branches of the lower jaw are not united, and those of the upper jaw are attached to the intermaxillary bone only by ligaments, so that these animals can expand the mouth sufficiently to swallow bodies much larger than themselves. The ground-colour of the boa is most frequently a yellowish-grey; and disposed along the entire length of the back is a series of chain-like reddish-brown variegations, leaving large open oval spaces of the ground-colour at regular intervals. The boa constrictor is, however, not the largest of the species, being seldom more than 12 feet long. The number of species, their habits, &c., are not yet well ascertained. Boas have been reported, by credible authorites, as reaching the enormous length of thirty feet; and it is no uncommon thing to read of their reaching *sixty* feet in length. Indeed, if we go back to the period when Rome was a great city, we shall read of one that had its lair on the shores of the Bagradas, and that measured a *hundred and twenty* feet in length. All the weapons the army of Regulus was able to bring against the monster were of no avail, and it was not slain till it had destroyed several battalions, and the siege-engines, loaded with ponderous stones, were levelled against it. It is certain, however, that this boa, if not a pure invention, has been lengthened outrageously. Actually, boas possess enormous strength, appetite, swallow, and powers of digestion. They have been known to swallow whole goats and pigs, beginning the prey at the muzzle and gradually sucking it down. A boa constrictor, confined in the Jardin des Plantes, swallowed the blanket provided for its warmth, and, after retaining the indigestible meal for four weeks, disgorged it: it died shortly afterwards.

Water Boa or Anaconda (*Ennecteus murinus*) is the largest serpent in the world, attaining, it is said, a length of 40 feet. Its habitat is the marsh country of Brazil and also Guiana. It is exceedingly voracious, feeding on fishes and animals that come to the water to drink. It also attacks young cattle, and, when hard pushed, either by hunger or fear of capture, will face man. The spotted boa (*Boa scytale*) of South America, the ringed boa (*Boa cenchria*) of the same country, the embroidered boa (*Boa Phrygia*), the canine boa (*Boa canina*), and the garden boa (*Boa hortulana*) are all members of the same family. The embroidered boa is supposed to be the most splendid of the tribe; it is about four feet long, the ground-colour is white, the back tinged with golden brown, while along the whole of the upper part is a series of black variegations bearing a striking resemblance to embroidery.

BOAR, *bore*, the male of swine. All the varieties of the useful genus *Sus* that are now seen in civilized countries, owe their origin to the wild boar, which is a native of nearly all the temperate parts of Europe and Asia. It was formerly a beast of chase in the woods of this country, and, at the present day, it is hunted in India and in many parts of Europe. It is generally more gaunt and bony than the common hog, and its muscular strength is greater. When about a year or two old, the hide has a yellowish-brown hue; but, in time, this changes to a dark-brindled grey. There is a fine soft hair, of a woolly nature, next the skin, between the bristles. The snout of the wild boar is rather longer than that of the common hog; but the chief difference lies in the savage disposition of the former and the extraordinary length of his tusks. The females are mild, except when their young are attacked. The tusks of the wild boar are long, curved, and sharp, and are capable of inflicting severe and fatal wounds. After they are five years old, however, these tusks begin to turn up, and are not such formidable weapons. Buffon says of wild boars: "These animals, when they have young, form a kind of flock, and it is upon this alone that their safety depends; when attacked, the largest and strongest front the enemy, and by pressing all round against the weaker, force them into the centre." On account of the excitement and danger connected with wild-boar hunting, it has been at all times a very favourite sport. The ancient Romans used to hunt them on foot with large spears. In later times, William the Conqueror punished, with the loss of their eyes, all persons convicted of killing the wild boar, the stag, or the roebuck. (*See* HOG, SUS.)

BOAR-FISH (*Capros*), a fish of the Dory family which takes its name from the resemblance borne by its mouth to the snout of the hog. Its fins are covered with rough scales, and it has no spines along the dorsal or anal fins. The eyes are very large, and placed far forward. It is of a carmine colour, lighter below, and with seven transverse orange bands on the back. It is a well-known inhabitant of the Mediterranean, and is very rarely seen on the British coast. Its flesh is of poor quality.

BOATBILL, *bote'-bill*, (*Cancroma cancrophaga*), a bird about the size of the domestic hen, an inhabitant of Cayenne, Guiana, and brazil. Its beak resembles a boat reversed, having a strong keel-like ridge down the middle of the upper mandible. The food and general habits of this bird place it among the herons. It chiefly lives by the sides of rivers.

BOAT FLY (*Notonecta*), an aquatic insect of the family *Hydrocorisæ* or Water bugs. Its form is somewhat like that of a boat, and is eminently adapted for progression on the water. It swims on its back and also floats and rests on the water in this position. There are not many known varieties, the commonest in Britain being *N. Glauca*, the *Water-Boatman*. It is about half-an-inch long, and varies greatly in colour; but, as a rule, exhibits a tinge of green. Their food consists principally of insects like themselves, and indeed they often devour their own species. They have a hollow between their folded wings, which they can store with air for their respiration when they descend below water.

BOBOLINK, *bob'-o-link*, (*Dolichonyx oryzivorus*), otherwise named the Reed-bird or Rice-bird, an American bird, nearly allied to sparrows and buntings. The plumage of the males in summer is very handsome, consisting of black, yellow, and white; and their song is very musical and voluble, on which account they are in great demand as cage-birds. The bobolink is a bird of passage, going southward even as far as the West Indies in winter. The flesh of the bird is considered a delicacy.

BODE'S LAW, *bodes'-law*, an arithmetical formula which approximately expresses the distances of the planets from the sun. Kepler led the way to its discovery in an attempt to find a general law by which the distances of the planets from the sun were governed, by showing that there was an undue space between the orbits of Mars and Jupiter, in comparison with the relative distances of the planets from the sun. This caused him to conjecture that a planet hitherto unobserved really existed, having its orbit between those of Mars and Jupiter; and in 1772, this formula (since known as Bode's law) was enunciated by Johann Elert Bode, a German astronomer, who boldly declared that Kepler's idea would be found to be an actual fact. The law itself is as follows:—Supposing 4 to represent the distance of Mercury from the sun, the distance of the other planets is obtained by adding to this number a geometrical series, of which 3 is the first term, increasing by the ratio 2. Thus, the distances of the planets from the sun are respectively represented as follows:

NAME OF PLANET.	Distance according to Bode's Law.
Mercury	$4 = 4$
Venus	$4 + 3 = 7$
The Earth	$4 + (3 \times 2) = 10$
Mars	$4 + (3 \times 4) = 16$
Supposed Planet (asteroids)	$4 + (3 \times 8) = 28$
Jupiter	$4 + (3 \times 16) = 52$
Saturn	$4 + (3 \times 32) = 100$
Uranus	$4 + (3 \times 64) = 196$
Neptune	$4 + (3 \times 128) = 388$

These theoretical distances very closely approximate to the real distances. That there must be some truth in the system above given, is proved by the discovery of the sixty-nine asteroids (*see* ASTEROIDS) since 1800, which fill the place that Kepler supposed to be occupied by a planet. There is no very great deviation from the numbers arbitrarily laid down, except in the case of Neptune. The satellites which revolve round Jupiter and Saturn follow a similar law in their respective distances from their planets.

BODY, *bod'-e*, a term very variously used. In Physics it denotes a solid, extended, palpable substance of three kinds; as a soft body—one which, yielding to a blow, undergoes a change; a hard body—one which remains unaltered after being struck; an elastic body—one whose form changes upon being struck, but recovers again when the impelling force is removed. With respect to animals, body signifies the frame, the material substance, in contradistinction to the living principle in beasts and the soul in man; in other words, matter as opposed to spirit.

Bodies, Regular, in Geometry, a term applied to five solids; as the icosahedron, with twenty regular pentagonal faces; the dodecahedron, with twelve triangular faces; the octahedron, with eight triangular faces; the cube, or hexahedron, with six square faces; and the pyramid, or tetrahedron, with four triangular faces.

BŒHMERIA, *be(r)-meer'-i-a*, a genus of plants belonging to the natural order *Urticaceæ*. From several species valuable fibres are obtained. *B. frutescens*, or *puya*, a plant growing wild in Nepaul and Sikkim, is the source of the celebrated Pooah fibre, which rivals the best European flax for tenacity. This species attains the height of six or eight feet; but the stem is usually very slender. It is cut down for use when the seed is formed; the bark is then peeled off, dried, boiled with wood ashes, and beaten with mallets, to separate its component fibres. *B. speciosa*, the wild rhea, also yields a very strong fibre, which is much used in the East. *B. nivea*, the Tchou Ma of the Chinese, is now known to yield the fibre used in the manufacture of the beautiful fabric called Chinese grass-cloth. The species constituting this genus were formerly regarded as species of *Urtica*, the nettle.

BOERHAAVIA, *be(r)-ha'-vi-a* (so named after Boerhaave, the celebrated physician), a genus of plants belonging to the natural order *Nyctaginaceæ*. The species are employed medicinally, both in Peru and the East Indies, having emetic and purgative properties. *B. tuberosa*, a native of Peru, is employed as a culinary vegetable.

BOG, *bog* (Celtic, soft), the name commonly given to a wet spongy morass, composed, for the most part, of decayed vegetable matter. The Bog of Allen is the most extensive of the numerous bogs found in the British isles. Chatmoss, in Lancashire, is another celebrated bog, being twelve square miles in extent. The origin and composition of bogs will be found to be fully treated of under the head PEAT.

Bog-bean. (*See* MENYANTHES.)

Bog-butter, a mineral substance found in some of the bogs of Ireland. It is evidently of vegetable origin, and produced by the decomposition of peat. It resembles, in some respects, bitumen and asphalt. It becomes liquid at 124° Fah., and is soluble in alcohol.

Bog-head Mineral, also known as the Torbane-head mineral (which *see*).

Bog Iron-ore, a ferruginous deposit found at the bottom of bogs. It consists mainly of peroxide of iron, and is formed by the subsidence of the iron oxides and carbonates held in solution by the bog water. It occurs in some parts of America in such large quantities as to be commercially valuable. When smelted, it yields good iron. It is of a reddish-brown colour, and has been occasionally used as a pigment. Some varieties of bog iron-ore contain phosphates. Ehrenberg came to the conclusion that the mineral is formed of the shields of animalculi.

Bog-oak, Bog-wood, a name applied to the trunks and large branches of oaks, firs, and other trees found in the Irish and Scotch bogs. It derives its intense black colour from being impregnated with iron. It is very hard, and is capable of receiving a high polish. It is much used in Ireland, in combination with gold and silver, for articles of jewellery.

BOHEMIAN WAXWING, *wax'-wing* (*Bombycivora garrula*), a bird about the size of the starling, more distinguished for its pretty plumage and graceful form than for sweet song. It only visits Britain in the winter. The country in which the young are reared is not known with certainty. M. Temminck states that the European waxwing breeds in the eastern part of the north of Europe, and lives in the northern parts of Asia.

BOIL, *boil* (Latin, *Bulla*, a bubble), called also *furunculus*, from the Latin *furo*, I rage, on account of the violent heat and inflammation attending it, is a hard painful tumour of the skin and the subjacent cellular tissue. It makes its appearance as a small, hard, inflamed spot, and gradually enlarges into a painful tumour, having a white conical centre, surrounded by a hard inflamed base, and varying in size from the bulk of a pea to that of a pigeon's egg. It proceeds to suppuration, and discharges a few drops of purulent matter commonly mixed with blood, and a central mass called the *core*. This last often lies deep, and causes considerable pain before coming away; but, without its removal, the abscess will not heal. Boils, though generally very troublesome, are not attended with danger. They take their rise in some disordered state of the digestive organs; and hence it is necessary that the bowels be kept open, but not purged, and tonics are given to improve the digestive powers. The diet should be plain and simple, and stimulants ought to be avoided. In dealing with the boil itself, suppuration is to be hastened and perfected by means of linseed-meal or bread poultices; and as soon as the prominent part of the swelling becomes soft, a free opening should be made into it with a lancet, and as much matter as can be pressed out of it by tolerably firm pressure should be removed, together with the core; or the poultices should be continued until the core is drawn out, when the wound will speedily heal. *Old People's Boil* usually occurs on the back of the neck in elderly people after some disorder of the stomach. *Night boils* (*epinyctes*), attack some persons for a length of time. They are troublesome little pustules which arise during the night and accompanied by languor and nausea. Slightly laxative medicine, &c., as mentioned above, will usually rid the system of these unpleasant affections.

BOILING-POINTS, *boil'-ing points*. A liquid is said to boil when, by means of heat, it is made to assume a constant state of ebullition by the formation of bubbles of its vapour. The boiling-points of liquids differ according to their chemical constitution; in many instances, in direct ratio to the differences in their composition. The boiling-point of the same liquid may vary under different circumstances; such as the pressure on its surface, the amount of attraction exerted by the vessel containing it, or by salts held by it in solution. Boiling, or the emission of steam in bubbles, consists in the formation of a vapour of equal elasticity to that of the atmosphere, which exerts its pressure on the surface of the liquid. It therefore follows that any lessening or increasing of the pressure of the air is accompanied by a corresponding depression or elevation of the boiling-point. This fact is made evident by the familiar experiment of placing warm water under the receiver of an air-pump, when, on exhausting the air, ebullition takes place from the diminished pressure. Liquids, in general, boil from 60° to 140° lower than their ordinary boiling-point when heated *in vacuo*. This property is made use of in the manufacture of certain medicinal preparations, the properties of which would be destroyed by exposure to a temperature of 212°. Advantage has been taken of this property of fluids in the measurement of heights. M. Saussure found that on the summit of Mont Blanc, which is nearly three miles above the level of the sea, water boiled at 185° Fah.; and M. Wisse observed the boiling-point of water to be 185° Fah. on Mount Pechiacha, while the barometer stood at 17 inches. From these facts it has been calculated that for every difference in height of 596 feet, a variation of 1° Fah. in the boiling-point is produced. It has also been ascertained that a variation of one-tenth of an inch in the barometer produces a difference of more than a twentieth of a degree Fah. in the boiling-point. The contrary property of increase of pressure causing elevation of the boiling-point, is evident from the above considerations. Papin's digester is an example of this. By confining water in an air-tight vessel, it may be heated to a temperature only limited by the strength of the vessel. This property is taken advantage of in the preparation of gelatine from bones, which are heated to a temperature much higher than 212° Fah. By this means the gelatine is easily

separated from the earthy matter, although the bones might be boiled for hours at 212° Fah. without any such effect taking place. The attraction of a fluid for the surface of the vessel in which it is boiled has a great influence on the boiling-point. Water boils at 212° in a metallic vessel, in a glass vessel at 214°, while in a vessel varnished inside with shell-lac the heat may be raised to 220° without ebullition taking place. Also when water contains salt, sugar, or other substances in solution, it requires a higher temperature. From the experiments of Kopp and others, it has been discovered that an exact ratio exists between the chemical constitution of certain liquids and their boiling-points at the same pressure. Thus methylic, ethylic, propylic, and butylic alcohols differ from each other by an increment of C_2H_2, and their boiling-points differ by an increment of 31·4° Fah. Another example of this is shown in the hydrocarbons benzole, toluole, xylole, and cumole, the difference in their composition being C_2H_2, while the difference of their boiling-points is 41° Fah. The same relation runs through the acids, ethers, aldehyds, and salts of these bodies. (*See* also EBULLITION.)

BOILING SPRINGS. (*See* GEYSER.)

BOKHARA CLOVER. (*See* MELILOT.)

BOLDERBERG BEDS, *bol'-der-bairg*, a typical group of tertiary sands and gravels occurring in the Bolderberg hill, about 40 miles from Brussels.

BOLE, a term applied to friable clayey shale or earth, containing silica and alumina, and coloured red or brown by peroxide of iron.

Bole, Armenian, *bole* (Swed., *bol*), a dark-red earthy mineral consisting of hydrated silicate of alumina, mixed with peroxide of iron in large quantities. It also contains traces of lime and magnesia. It is occasionally used for coarse paint and for stage purposes; also for colouring tooth powders, false anchovies, &c. When the amount of magnesia is such as to cause it to feel greasy, it is termed *mountain soap*, or *fett-bol*.

BOLETUS, *bo-le'-tus*, a genus of *fungi*, division *Hymenomycetes*, sub-division *Polyporei*, which may be distinguished from *Agaricus* by the absence of gills, the under-side of the cap or pileus being covered by a porous layer composed of innumerable short tubes united together. Some of the species are edible, though they are all set down as mere toadstools by the mushroom-gatherers of this country. *B. edulis*, the *Ceps ordinaire* of the French markets, is much used throughout the European continent. It grows in woody situations and attains a considerable size, the cap being usually six or seven inches across. In moist, warm summers, it usually grows in considerable quantities, but in Britain this species is seldom seen. The colour of the cap ranges from light brown to brownish-black, while that of the layer of tubes beneath is at first white, then yellow, and finally yellowish-green. The stem is thick, solid, and beautifully reticulated. To prepare the fungus for the table, the layer of tubes, the skin, and the stem, must be thrown away, for nothing but the firm and delicate flesh of the cap is to be eaten. This may be either eaten raw with salt and pepper, or cooked like a common mushroom. Many other species are usually found exposed for sale in the French markets.

BOLOGNA PHOSPHORUS, OR STONE, *bo-lone'-ya*. Heavy spar, or sulphate of baryta, on being ignited with a small portion of carbon, and exposed to the sun's rays, acquires phosphorescent properties, and is called Bologna phosphorus, from having been first discovered in that city. The name is also applied to the same mineral when calcined, powdered, and made into little lumps with gum-water, for after being exposed to strong sunshine it likewise exhibits phosphorescent properties.

BOMBACEÆ, *bom-bai'se-e*. (*See* STERCULIACEÆ.)

BOMBARDIER BEETLE, a name applied to many coleopterous insects of the tribe *Carabidæ*. They are divided into two genera—the *Brachinus* and the *Aptinus*; the latter has no membranous wings under the wing-sheath. Those found near the tropics are large and brilliantly coloured, but those found in this country are generally small. They are called bombardier beetles on account of a remarkable property they possess of violently expelling a pungent acrid fluid, which, if the species be large, has the power of producing discolouration of the skin, similar to that produced by nitric acid. It also changes blue vegetable colours to red, and then to yellow. The most common English species is little less than half an inch long; if irritated, it will make more than twelve rapid and noisy discharges. The bombardier beetle is generally found under stones, and occurs plentifully in chalky districts.

BOMBAY DUCK, *saurus ophiadon*, the name given to a marine fish found on the coasts of India, and highly esteemed as an article of food because of its rich flavour. When salted and dried it is largely exported inland. It is of elongated form, with large fins and immense mouth, armed with long and barbed teeth. *Bummaloti* is a name by which it is also known.

BOMBAX, *bom-bax'*, a genus of plants, the type of the tribe *Bombaceæ*, natives of South America and India, and commonly known as silk-cotton trees, owing to their seeds being covered with long silky hairs. These hairs cannot be spun into thread, like those of ordinary cotton; but they are sometimes used for stuffing beds and cushions. The American tree *B. Ceiba*, and the Indian tree *B. Pentandrum*, are remarkable for their prodigious height. The bark of the latter is said to be emetic.

BOMBYX (*See* SILKWORM.)

BONASIA, *bon-a'-shi-a*, a genus of birds of the grouse family (*Tetraonidæ*), characterized by having the lower part of the shank destitute of feathers, also by the elongated feathers of the upper part of the head. To this genus belongs the Hasel Grouse, found in nearly all parts of the Continent of Europe, a bird about the size of a partridge, mottled with grey and reddish-brown plumage, and with a black near the extremity of the tail feathers. The Ruffled Grouse of America, a large bird, known in some parts of the United States indifferently as pheasant or partridge, belongs to this genus.

BONASSUS, *bo-nas'-sus*. (*See* BISON.)

BONE, *bone*, is a hard complex structure forming the framework or skeleton of the body in man and the higher animals. It is confined to vertebrate animals; and even in the lowest order of this class, the cartilaginous fishes, it is entirely wanting. The bones form a framework for the moulding and adequate support of the soft parts of the body; cavities for the lodgment and protection of delicate organs; joints for locomotion, and levers for the action of the muscles. They are always in the interior of the body, and even when they approach the surface are covered by some soft membrane, muscle, skin, &c. The first development of bone is commonly—though not always, as in the bones of the head—preceded by the formation of a cartilaginous structure, occupying the place which the bone is afterwards to take. It is supposed that the bone is formed by the ossification of the cartilage; but some physiologists have doubted whether this is the case. The process of bone-formation always commences in the immediate neighbourhood of blood-vessels, which pass down into canals excavated in the substance of the cartilage, and lined by a continuation of its investing membrane. Hence the spots where these vascular canals are especially developed are termed centres of ossification. One of these is usually found in the centre of the shaft of a bone, and one at each end, with an additional one for any considerable projection or process. In the flat bones there is generally one in the middle of the surface, and one in each of the principal processes. Until the bone attains its full dimensions, the parts which contain distinct centres are not connected by osseous union, but only by cartilage, so as to allow an increase in the size of the bone by the growth of cartilage between its detached portions, which gives place to bony structure, when there is no further need of increase. There exists a close correspondence between the number of ossific centres in the early condition of the skeleton of all vertebrated animals. The growth of bone is effected by the addition of new tissue in three different modes:—1, By the development of new bone in the cartilage between the parts yet remaining separated; 2, by the development of new bone in the membrane covering the surface; and 3, by the interstitial formation of new layers within the canals of the osseous fabric already developed. The perfect reparation of bone after severe injuries, effected by the development of new osseous tissue in the substance of membrane or cartilage formed in the seat of injury, is one of the most remarkable features of its character. Bones are so constituted that a constant process of deposition and absorption is carried on in them, as in the softer tissues, modelling the shaft into its requisite proportions during the successive stages of growth. It is much more actively carried on in youth than in middle life, and is greater in the vigour of manhood than in old age. Bones increase in length not so much by interstitial deposit, as by addition to their ends; that is, by progressive ossification of the layers of cartilage which intervene between the ends of the shaft and the epiphyses. Bones are largely supplied with blood-vessels. The solid osseous texture which forms the cylindrical shafts of the long bones and the thick external plates of the denser flat bones is penetrated by a series of canals, termed Haversian (after their discoverer, Clopton Havers, an old English anatomist), which form a network in its interior, and serve for the transmission of blood-vessels into the interior. These canals, in the long bones, run for the most part in a direction parallel to the central cavity, and communicate with this, with the external surface, and with each other, by frequent transverse branches. They vary in diameter from $\frac{1}{200}$ to $\frac{1}{2500}$ of an inch, averaging about $\frac{1}{500}$; and are smallest near the outer surface, where the bone is most compact; but become gradually larger towards the interior. In the long bones of man and of most mammalia there is a central cavity, which is filled with the fatty substance known as marrow; and the space in which the marrow lies is called the medullary canal. This cavity does not exist in the bone in its early state, but is formed by the removal of the cancellated osseous tissue first developed in its interior. Among birds, however, the central cavity, instead of being occupied by marrow, is filled with air, and communicates with the lungs; so that the membrane lining it becomes an auxiliary organ of respiration; whilst the lightening of the bones thus produced diminishes their specific gravity. Bones are covered externally by a strong fibrous membrane termed the periosteum, which serves to protect the blood-vessels entering them. The medullary canal is also lined by an extremely delicate membrane, termed the medullary membrane, which supports the marrow, and provides a stratum for the subdivisions of the medullary artery before they penetrate the contiguous osseous substance. The Haversian canals are also lined by a similar membrane. Though bones possess little sensibility in health, yet, when diseased, they become highly sensitive, a manifest indication that they are supplied with nerves. These may, indeed, be traced into some of the minute foramina on the shaft of a long bone, but more easily into the articular ends. A nerve also enters the medullary canal with the nutrient artery of the medulla, and divides, like the artery, into an ascending and descending branch. Bone is composed of a basis of animal matter, impregnated with "bone-earth," or phosphate of lime. The first ingredient makes it tenacious and elastic; the second gives it the requisite hardness. These may be separated from each other: the latter may be entirely dissolved away, by soaking the bone in dilute muriatic or nitric acid, when a substance of cartilaginous appearance is left; the former, by subjecting the bone to a heat sufficient to decompose the animal matter, when we obtain the whole calcareous substance *in situ*. The animal portion of a bone forms about one third, the earthy about two thirds; and the relative proportion of the two elements is said to differ little in different classes of animals. It is not yet a settled point whether the proportions vary at different periods of life; bnt the general opinion is that they do, the animal element predominating in early life, the earthy in old age. The bony framework of the higher classes of vertebrate animals presents very nearly the same chemical characteristics in most individuals. Bones, when dried at 212° until they cease to lose weight, consist of one third ossein, or organic matter, and two thirds of phosphate and carbonate of lime and phosphate of magnesia. Ossein, when boiled in water, gradually dissolves, leaving a small quantity of fatty and vascular matter floating on the solution, which, on cooling, gelatinizes, forming a weak glue or size, consisting of nearly pure gelatine. The earthy matter may be separated from the ossein, either by means of an acid, or else by boiling in water in a Papin's digester, at a temperature over 300°, the gelatine being only dissolved at that heat. The mineral constituents of bone are used as manure and in the manufacture of cupels. When bones are distilled in close vessels, at a gradually increasing temperature, oily matters, mixed with carbonate of ammonia, pass over, leaving behind bone-black, or animal charcoal.

BONGAR, *bon'-gar*, a genus of venomous serpents, natives of the East Indies, where they are known as Rock Snakes. One species, *B. annularis*, attains a length of six feet, and is surrounded with black and yellow rings. The head is broad and depressed.

BONGARDIA, *bon-gar'-di-a*, a genus of herbaceous plants of the natural order *Berberideæa*, natives of the East. The tubers of one species are eaten, either boiled or roasted, in Persia, and the leaves of another species, having a slightly acid taste, are eaten as salad.

BONITO, *bon'-e-to* a name applied to several fishes belonging to the mackerel family, or *Scomberidæ*. There are three varieties—the *Thynnus pelamys*, the *Pelamys sarda*, or Belted Bonito, and the *Auxis vulgaris*, or Plain Bonito. The *T. pelamys* resembles the tunny, and is not unlike a large mackerel. In tropical climates it is found in large numbers, and is well known to sailors as one of the fishes constantly seen in pursuit of the flying-fish. It is a very pretty fish, of a rich blue colour, with four dark lines stretching from the pectorals to the tail, on either side of the belly. Its average length is about two feet, and it is generally caught with an imitation flying-fish as a bait. The belted bonito is common in the Mediterranean and Black Sea. The plain bonito is also found in the Mediterranean, where its flesh is salted or pickled, and used for food. It is occasionally taken off the English coast.

BONY PIKE, *pike* (*Lepidosteus osseus*), an elongated pike-like fish, one of the few living representatives of the fossil Ganoid fishes inhabiting the warmer lakes of America. The jaws of this fish are usually produced into a long narrow snout, presenting considerable resemblance to that of the Gangetic crocodile. The vertebral column presents a structure such as is met with in no other fishes, being regularly articulated, and the head is capable of a remarkable degree of motion. The body is covered with bony square scales. The flesh of the bony pike is considered a delicacy.

BOOBY, *boo'-be* (*Sula fusca*), a name given to a large bird, a species of gannet. It is not quite so large as a solan goose, and it inhabits the desolate islands and unfrequented coasts of most warm climates. It has received its name in consequence of its apparent stupidity, in sitting quietly and allowing itself to be knocked on the head, or be taken away by any one attempting it. It is very powerful on the wing, and feeds on fishes, which it watches while flying close to the surface of the water, and then catches by suddenly diving down upon them. Its colour is dark brown, rather white underneath. Its bill is much longer than its head, and its gullet is so expansible that it is able to swallow fishes of large size. The male and female resemble each other closely in appearance, and the latter only lays one egg. It is found in almost all tropical and sub-tropical shores, and sometimes at a considerable distance from land. The flesh of the booby, like that of all birds that live on fish, is not agreeable when cooked. (*See* GANNET.)

BORACIC ACID, *bo-ras'-ik* (from Arab., *baurac*, a species of nitre) (BO_3).—This acid, which may be regarded as a teroxide of boron (*see* BORON), is the only known compound of oxygen and boron. It occurs in nature in certain volcanic districts, where it issues from the earth in jets mixed with steam. In Northen Italy, these jets, or *fumerolles* as they are called, are conducted into artificial basins or small ponds. One of the chief places where the jets occur is Monte Cerboli, described in local legends as the entrance to the infernal regions. The boracic acid remains dissolved in the water, which is periodically removed, and evaporated in shallow leaden pans, which are heated by other *fumerolles* in the neighbourhood. During the evaporation, great quantities of sulphate of lime are deposited, which require removal from time to time. About 1,200 tons of crude boracic acid are annually exported from this district. The crude acid is contaminated with 25 per cent. of sulphate of ammonia and alumina, and other saline impurities. Boracic acid is used principally for making borax, or biborate of soda. (*See* BORAX.) Boracic is formed in the laboratory by dissolving purified borax in four parts of boiling water, and adding to the hot solution a quantity of sulphuric acid, equal to one-fourth the borax used. On cooling, boracic acid crystallizes out in white, feathery, crystals, containing three equivalents of water. When a solution of boracic acid is evaporated, a certain quantity of the acid rises with the steam; and this is the cause of the *fumerolles* described above. Boracic acid is used as an ingredient in the preparation of glaze for pottery, as a flux, and in the manufacture of wicks for stearine and composite candles.

BORACITE, *bor'-a-site*, an anhydrous borate of magnesia, found at Luneberg, in Lower Saxony, and one or two other localities in that neighbourhood. It occurs in cubical crystals, and, when heated, possesses electric properties, the opposite angles of the tube being found to develop opposite forms of electricity.

BORAGE, *borage*. (*See* BORAGO.)

BORAGINACEÆ, *bo-raj'-i-nai'-se-e*, the Borage family, a natural order of dicotyledonous plants in the sub-class *Corolifloræ*, characterized by an ovary deeply divided into four lobes, from the middle of which a single style arises. The species are herbs or shrubs, with alternate leaves, usually rough with hairs. The flowers are regular and symmetrical; the calyx is persistent, and divided into either four or five segments; the corolla has the same number of lobes, and usually scales in the throat; the stamens rise from the corolla, are equal in number to its lobes, and alternate with them. The fruit consists of two or four distinct achænia placed at the bottom of the persistent calyx. There are 54 genera, which include nearly 700 species, chiefly natives of the temperate regions in the northern hemisphere. Among them we find many well-known plants, such as the Forget-me-not, Borage, Comfrew, and Alkanet. (*See* ANCHUS, BORAGO, MYOSOTIS, SYMPHYTUM.) The various species are remarkable for their mucilaginous properties; some have roots which are valuable dyeing agents.

BORAGO, *bo-ra'-go* (*bor*, for Lat., *cor*, the heart, *ago*, I cheer; because it was believed to exhilarate the heart), a genus of plants forming the type of the natural order, *Boraginaceæ*. The species *B. officinalis*, commonly known as Borage, is now naturalized in England and most of the countries of Europe, but was at a remote period confined to Asia Minor. It is characterised by a wheel-shaped corolla with a very short tube, the mouth of which is closed by scales: by five stamens with forked filaments, the inner arms of which support the anthers; and by these anthers being connivent around the style, in the form of a cone. The entire plant is rough with hairs, and has rather a coarse appearance; but its flowers are very beautiful, being of a fine blue colour. The young leaves are added to a *cool tankard*, or draught made of wine or cider, with water, lemon, and sugar. The flowers are used on the Continent to ornament salads, and the tender tops are sometimes boiled in soups.

BORASSUS, *bo-ras'-sus* (Gr., *borassos*, the skin of the date), a genus of Palms, consisting of but one species, which is found in every part of India. This has been named *B. flabelliformis*, and is commonly known to the European inhabitants as the Palmyra. Its stem attains a height of from 25 to 40 feet, and bears upon its summit a magnificent coronal of fan-shaped leaves. The fruit is about the size of a child's head, and, when very young, contains a sweet pulp, which may be eaten. From the juice obtained from this plant, large quantities of an intoxicating drink are prepared by the natives. The fibres of the leaves are used for cordage, and the outer wood of the stem for bows.

BORAX, *bor'-ax* (Arab., *baurac*, a species of nitre), a compound containing boracic acid (which *see*) and soda, found in nature as a saline incrustation on the shores of lakes in Persia and Tibet. It is said to have been known to the ancients as *chrysocolla*, and to have been used in soldering, brazing, and casting metals. It was formerly imported from the East in the crude state, under the name of *tincal*, which contained borax in combination with various substances of a saponaceous nature. It was purified by being heated with lime or soda until the whole of the soapy matter and other impurities were separated. Borax is now mostly prepared by fusing two parts of boracic acid, obtained from the Italian lagoons (*see* BORACIC ACID), with one part of soda-ash. The mixture is thrown on the floor of a reverberatory furnace, and heated until all effervescence has ceased. The fused mass is lixiviated and boiled until the impurities are precipitated: it is then decanted, and set aside to crystallize slowly. It crystallizes in rectangular hexagonal prisms, containing 10 equivalents of water. A new source of borax has lately been discovered in a deposit of borate of lime, occurring in the interior of Peru. Great pains are taken to crystallize the solution in regular crystals of a large size, as such only are marketable.

BORER, *bor'-er*, a name given to many very small coleopterous insects of the genus *Ptinus*. Their name is derived from the fact that their larvæ, small white maggots, eat their way into old wood, &c., by means of strong cutting jaws, called *maxillæ*. These holes, which they are constantly making in old furniture, have all the appearance of having been produced by a fine gimlet or drill. After working its way into the wood, the borer fills up the drill-hole in its passage with a fine powder, and forms a cocoon, from which it afterwards emerges in the form of a small winged beetle. The *Anobium tesselatum*, one of the same genus, is remarkable for a loud ticking noise which it makes at night, and which has gained for it the title of the Death-watch. The *Anobium striatum* is also remarkable for the persistent way in which it simulates death.

BORON, *bor'-on*, a combustible element, closely allied in its properties to carbon and silicon. In nature it occurs in combination with oxygen, in the form of boracic acid, in a few localities. It was first obtained by Davy in 1808, by submitting moistened boracic acid, inclosed between platinum plates, to the action of the voltaic current. A brownish substance appeared at the negative pole, which, conceiving to be a metal, he termed *boracium*. By further experi ment he proved it to be a non-metallic body, resembling carbon in its properties, and altered its name to *boron*. It was, however, but imperfectly known until Thenard and Gay-Lussac obtained it more readily by heating boracic acid with potassium. The metal combined with the oxygen of the acid to form potash, which was washed away with water, leaving the boron behind. More recently MM. Deville and Wöhler have obtained it in garnet-red transparent crystals, by fusing boracic acid with 80 per cent. of metallic aluminium in a powerful furnace. The crystals are extremely hard, scratching sapphire and corundum, and yielding only to the diamond, which is generally injured by the operation. Crystallized boron has never been fused, and resists the action of oxygen at very high temperatures. Boron is obtained in a graphitic form when borofluoride of potassium is decomposed by aluminium. It bears a close relation to the graphitic form of carbon, or ordinary graphite. Boron combines with several elements, forming borides with the metals. The close relation always supposed to exist between boron and carbon has been curiously confirmed by the fact of both of these elements being capable of assuming the amorphous, crystalline, and graphitic forms. The only important compound of boron is boracic acid.

BOS. (*See* BOVIDÆ.)

BOSWELLIA, *bos-wel'-li-a*, a genus of plants belonging to the natural order *Amyridaceæ*. The most important species is *B. thurifera*, or *serrata*, a tree which grows to a large size, in hilly situations, from the Coromandel coast to the central parts of India. This plant is the source of the valuable gum-resin known as Indian olibanum, and generally believed to have been the frankincense of the ancients. (*See* OLIBANUM.) *B. papyrifera*, a native of Abyssinia, also yields a fragrant gum-resin, and is further remarkable on account of its inner bark, which peels off in thin white layers like paper.

BOTANY, *bot'-a-ne* (Gr., *botane*, an herb), that part of natural history which relates to the vegetable kingdom. In its widest sense, botany comprehends all that is known of plants, and, therefore, forms a boundless field of inquiry. The student has to consider the external configuration of plants—their structure, the functions which they perform, the relations which they bear to each other, and the uses to which they are subservient. The practical bearings of botany are most important. All the principal plants affording food, timber, medicine, fibres, dye-stuffs, and other useful products, are noticed in this work under the names of the genera which include them. Many arts and sciences closely connected with botany are explained in separate articles. (*See* MATERIA MEDICA, AGRICULTURE, HORTICULTURE, ARBORICULTURE, GARDENING, PHYSICAL GEO-

GRAPHY.) Two primary divisions of the whole subject are adopted as facilitating the study of the science:—I. STRUCTURAL, or BIOLOGICAL BOTANY, which includes the investigation of the organic structure, life-growth, action and propagation of plants. II. SYSTEMATIC BOTANY, relating to plants as consisting of various kinds, enumerated and classified.

I. *Structural Botany.*—That branch of structural botany which has reference to the elementary tissues is sometimes distinguished as *Vegetable Histology.* The microscope has shown that the various tissues are composed of little membranous sacs or vesicles, varying in form and size, and united in different ways. (*See* CELL.) Some plants consist of single cells only, which continue throughout life to produce new cells, and to perform all the vital functions. A flowering plant, however, although originally cellular, produces organs composed of cells and vessels, variously modified and arranged, and covered by an epidermis. These compound organs may be divided into *nutritive*, or those concerned in the nourishment of the plant, and *reproductive*, or those which are employed in the production of new individuals. The former are the *stem*, *root*, and *leaf;* the latter, the *flowers* and *fruit.* Leaves occupy various positions on the stem and branches, and their arrangement forms a subject for special study. (*See* PHYLLOTAXIS.) The arrangement of flowers on the floral axis and its ramifications, has also to be considered. (*See* INFLORESCENCE.) The term *Morphology* has been applied to that part of structural botany which treats of the transmutation of leaves into other forms and their resulting adaptations to new uses. The researches which have been made in this department, have confirmed the doctrine first advanced by the German poet Goethe, that all those parts familiarly known as leaves, flowers, and fruit, are constructed on a simple uniform plan, out of one kind of organ in different states of modification and combination. *Biological*, or *Physiological Botany* treats of plants in a living or active state, and of the manner in which their functions are performed; it explains how they are influenced by the several agencies of light, heat, air, and moisture; and it describes their various secretions and the nutriment afforded by the soil. Plants, not being endowed with voluntary motion, derive their food either from the soil in which they are fixed, or from the atmosphere by which they are surrounded. The nutriment, consisting of water, generally holding salts in solution, is absorbed, by the aid of endosmose, by the extremities of the roots. It then passes from cell to cell, and ascends the stem, dissolving, in its course, some of the organic matter stored up in the vegetable tissue. Arrived at the green shoots and surfaces of the leaves, which are covered with minute openings, or *stomata*, the sap is exposed to the influence of light, heat, and air. About two-thirds of the moisture taken up is now evaporated and exhaled; the remainder, which, of course, becomes thickened, undergoes certain chemical changes, and then begins to descend by the under-surface of the leaf, and along the bark. It takes either a direct or a circuitous course downwards, communicating with the centre of the stem by the medullary rays, depositing various secretions, more especially in the bark, and giving origin to substances which are destined to nourish and form new tissues. Finally it reaches the extremity of the root, where absorption had commenced: a small portion is there excreted, while the remainder mixes with the newly-absorbed fluids, and again circulates in the sap. (*See* ENDOSMOSE, SAP, SECRETIONS.) The circulation of the sap has been adduced as an example of the vital processes elucidated by physiology, because it is due to the combined action of all the organs of nutrition, and may therefore serve instead of several illustrations. The study of the special functions of the various organs necessarily precedes that of the general physiological phenomena, such as circulation, assimilation, respiration, fertilization, and germination. Under the names of the different organs of nutrition and reproduction, the reader of this work will find full particulars respecting their functions. The physiology of reproduction is treated of at length under the heads POLLEN and EMBRYO.

II. *Systematic Botany.*—This department of the science is sometimes named Taxological Botany (Gr., *taxis*, and *logos*, a discourse), or, less accurately, Taxology or Taxonomy. It includes the principles of classification, which are based on the observations which have been made on the structure and physiology of plants; and the study of it should be preceded by a study of structural botany. The object of systematic botany is to name, describe, and arrange plants in such a manner that the botanist may readily ascertain the name of any specimen, and, at the same time, get an insight into its true nature and general properties. When it is considered that there are some 120,000 known species of plants, it is obvious that there must be a definite nomenclature and classification, were it only to facilitate reference and communication. Before plants can be classified, their peculiarities of structure must be clearly defined: hence the necessity of the technical language which is employed in descriptive botany. Botanists are blamed for using so many hard words (Hood humorously remarked that if gardeners really loved the flowers they would not call them such hard names), but it should be remembered that they have to explain very minute points of structure, and must employ a language more rigorously defined than that of ordinary conversation. That part of systematic botany which relates to the technical language of the science is sometimes called *Glossology.* The principles of classification constitute what is properly called *taxological botany*, though this term is often applied to the whole department. There have been two great plans proposed for the classification of plants, one denominated *artificial*, and the other *natural.* The first is founded on characters taken from certain parts of plants only, without reference to others; while the second takes into account all the parts of plants, and involves the idea of *affinity* in essential organs. In both artificial and natural systems, the lower divisions—namely, the genera and species—are the same, the great difference between them consisting in the manner in which the genera are grouped into orders, and the orders into classes. (*See* SPECIES, GENUS, ORDER, CLASS.) The plants in one of the higher divisions of an artificial system, such as that of Linnæus, have no necessary affinity, and are connected only by certain characters, more or less superficial, which have been selected as the signs of that division. Such a system may therefore be compared to a dictionary, in which words are arranged for convenience of reference, in alphabetical order, adjacent words not necessarily agreeing with each other, further than in commencing with the same letter. In a natural order, on the contrary, all the genera will be found to have a true family likeness; for their association is the result of a careful consideration of the structure of every organ. The classes in the natural system have been formed upon the same principle, by uniting orders which possess many important characters in common. The natural system of classification is based upon the real affinities of plants, and necessarily takes into account all the organs. Though it cannot be perfect until all the plants of the globe have been examined, it has already reached a very high point of development, and a great number of the orders which have been determined are quite as natural as the orders in the animal kingdom. A knowledge of one species is to a great extent the knowledge of many; for an individual, if well selected, will exhibit the most important characters of all the other plants in the same natural group. Thus, by studying the common radish (*see* RAPHANUS), or the mustard (*see* SINAPIS), the botanist may obtain a general knowledge of about 1,600 species which constitute the order *Cruciferæ*, and which are all formed, as it were, on the same ype. The properties of plants accord in a very remarkable manner with their structure; and, as a general rule, the position of a plant in the natural arrangement indicates its properties. For example, if a botanist, on examining a plant, finds all the structural peculiarities of the order just mentioned, he may feel confident that it is not poisonous, but most likely antiscorbutic or pungent. If, however, he should meet with one of the *Atropaceæ*, he might safely set it down as a plant possessing poisonous narcotic properties. Enough has been said to prove that the natural system is much more than a mere index to the names of plants. It reveals to a certain extent the plan of creation, and is at once an aid to research and a record of discovery. Several schemes based upon the natural affinities of plants have been devised. These may be regarded as so many versions of the one true system; for, though they have been worked out by different methods, they agree in nearly all their grand divisions. The characters by which the primary groups have been determined are furnished by the elementary tissues, and the most important organs of vegetation and reproduction. Regarding only the elementary structure, plants may be arranged under the heads of *Cellular* and *Vascular*, according to the absence or presence of regular vessels. (*See* TISSUE, CELL, VESSEL.) A more satisfactory arrangement results from a consideration of the different modes by which plants are propagated. Some spring from true *seeds*, containing the rudimentary organs called cotyledons; while others are developed from *spores*, in which no distinct organs can be traced. The former are said to be *cotyledonous*, and the latter *acotyledonous* (without cotyledons). As the number of cotyledons forms a natural distinctive character, the first group of plants is subdivided into *monocotyledonous*, having one cotyledon, and *dicotyledonous*, having two cotyledons. The mode in which the root is produced affords characters which confirm this arrangement. The young root of an acotyledon is *heterorhizal*, that of a monocotyledon is *endorhizal*, and that of a dicotyledon *exorhizal*. (*See* EMBRYO.) The three groups are further characterized by the stems; those of the first being *acrogenous*, those of the second *endogenous*, and those of the third *exogenous*. (*See* STEM.) Stemless plants are said to be *thallogenous*, and form a distinct section of the acotyledonous group. The venation of the leaves establishes the same great natural divisions; and similar results are obtained from a consideration of the flowers; monocotyledons and dicotyledons being flowering, and acotyledons flowerless The arrangement adhered to in this work is that adopted by Professor Bentley in his excellent "Manual of Botany." It is founded upon the schemes of Jussieu, De Candolle, and Lindley.

Divisions of the Vegetable Kingdom.—The vegetable kingdom is divided into two sub-kingdoms—Phanero gamia, flowering or cotyledonous plants; and Crypto gamia, flowerless, or acotyledonous plants.

PHANEROGAMIA.—Plants which have evident flowers and which are propagated by seeds containing coty ledons.

Class I.—*Dicotyledones.*—In this class there are two great divisions:—Division 1. *Angiospermia.*—Ovules inclosed in an ovary, and fertilized indirectly by the action of the pollen on the stigma. In this division there are four sub-classes:—1. *Thalamifloræ*, or plants with flowers usually furnished with both calyx and corolla, the latter composed of distinct petals inserted on the thalamus; stamens hypogynous, or adherent to the sides of the ovary. 2. *Calycifloræ*, with flowers having usually calyx and corolla, the latter mostly with distinct petals and inserted on the calyx; stamens either perygynous or epigynous. This sub-class is divided into—1. *Perigynæ*, in which the calyx is free, or nearly so; the stamens usually perigenous, and the ovary superior. 2. *Epygenæ*, in which the calyx is more or less adherent, and the ovary inferior. 3. *Corollifloræ*, flowers having both calyx and corolla, the latter with united petals; stamens inserted on the corolla or ovary, or free and arising from the thalamus. Sub-divisions:—1. *Epigynæ*, in which the calyx is adherent, and the ovary consequently inferior. 2. *Hypostaminæ*, in which the stamens are inserted into the thalamus, and do not adhere to the corolla; ovary superior. 3. *Epipetalæ*, or *Epicorollæ*, in which the corolla arises from the thalamus, and has the stamens attached to it; ovary superior. 4.—*Monochlamydeæ* or *Apetalæ*, flowers having either a calyx only, or without both calyx and corolla. Division 2. *Gymnospermia*—Ovules naked, or not inclosed in an ovary, being fertilized directly by the action of the pollen.

Class II.—*Monocotyledones.* In this class there are three sub-classes:—1. *Dictyogenæ*—Leaves with a reticulated venation, deciduous; rhizome and root with the wood arranged in a concentric manner; floral envelopes verticillate. 2. *Petaloidæ* or *Floridæ*—Leaves with a parallel venation, permanent; floral envelopes (perianth) verticillate, and usually coloured, rarely scaly, sometimes absent. Sub-divisions:—1. *Epigynæ*, in which the flowers are usually hermaphrodite; perianth adherent; ovary inferior. 2. *Hypogynæ*, with flowers usually hermaphrodite; perianth free; ovary superior. 3. *Diclines*, in which the flowers are usually unisexual; perianth, either absent or consisting of a few scales. 4. *Glumaceæ*—Leaves parallel-veined, permanent; flowers glumaceous, that is, having no proper perianth, but consisting of imbricated bracts.

CRYPTOGAMIA.—Plants which have no flowers, and which are propagated by spores. This sub-kingdom constitutes a class by itself—viz., Class III.—*Acotyledones.* Other characters besides those which define the sub-kingdom may be enumerated. The germination is indefinite or obscure; the stem is sometimes present and sometimes absent—in the former case, when woody, it is acrogenous; the leaves, when they exist, have forked veins; no true flowers are produced. There are two sub-classes:—1. *Acrogenæ*—Plants with stems and leaves distinguishable, and possessing stomata. 2. *Thallogenæ*—Plants with no distinct stems or leaves; stomata absent.

Various Systems of Botany.—The Linnæan system leads to little more than a knowledge of names, and can only be looked upon as an index to the genera. Though superior to every artificial scheme previously promulgated, its day has gone by, and the more philosophical system has taken its place. Linnæus himself never intended it to be anything more than a provisional arrangement, and distinctly stated that a natural method was the great object of scientific inquiry. The general principles of the Linnæan, or Sexual system, may be explained in a few words. Twenty-four classes are founded on the number, position, relative lengths and connection of the stamens; while the orders in these classes depend on the number of styles, the nature of the fruit, the number of the stamens in the classes where this character is not used used for distinguishing them, and the perfection of the flowers. The twenty-fourth class includes plants having inconspicuous flowers, and in it the orders are formed according to natural affinities. Under these classes and orders, all the known genera and species are arranged. Even as an artificial method for discovering the names of plants, the Linnæan system has many imperfections. Being based upon the more obvious characters of the reproductive organs, it cannot be of the least use when the plants are not in full flower, with all the stamens and styles perfect. The different flowers on the same plant often vary as regards the number of the stamens. Again, if the classification were carried out rigidly, it would separate, in many instances, the species of the same genus; but so sensible was Linnæus of the importance of maintaining the natural character of his genera, that he sacrificed the symmetry of his scheme for the sake of keeping all the species together. The scheme devised by Professor Lindley is more symmetrical, and in many respects more philosophical, than any other; but the names given to the different groups have not been as yet generally adopted by botanical writers. The seven classes of this beautiful arrangement are distinguised by the following characters:—1. *Thallogens*—A sexual or flowerless plants, without proper stems or leaves. 2. *Acrogens*—A sexual or flowerless plants, with stems and leaves. 3, *Rhizogens*—Sexual or flowering plants, with acotyledonous embryos and fructification springing from a thallus. 4. *Endogens*—Monocotyledonous flowering plants, with endogenous stems, parallel venation, and ternary symmetry. 5. *Dictyogens*—Monocotyledonous plants, with reticulated venation. 6. *Gymnogens*—Polycotyledonous exogens, with naked seeds. 7. *Exogens*—Dicotyledonous plants, with seeds in a seed-vessel. These are arranged in four subclasses. Under the above heads Lindley places all the natural orders, which he arranges in groups termed Alliances.

History of Botanical Investigation.—The earliest work on the subject of which we have any knowledge, is the production of Theophrastus, a pupil of Aristotle. More than 600 plants were described by Dioscorides, who lived in Asia Minor in the first century of the Christian era, and his work was for a long period considered as a great authority; but very inferior to that of Pliny the elder, who described more than 1,000 species. One of the earliest methodical arrangements was that of Cæsalpinus, a Roman physician attached to the court of Pope Sixtus V., in the 16th century; and other students of the subject about the same period were German, the Otto Brunsfels, Bock, Fuchs; Dodœns and De L'Obel, Hollanders; Gesner, a Swiss; Moulins, L'Ecluse, and other French writers. These authorities were ultimately displaced by the attractive scheme of Linnæus, who must be looked upon as the great promulgator of the artificial method of classification. Turner, who lived in the early part of the 17th century, has been styled "the father of English botany," and he was followed by Robert Morison, who became professor of botany at Oxford. The first attempt at arranging plants according to their natural affinities was made by our great countryman John Ray, in the year 1682. His scheme was necessarily very imperfect, for the number of plants then known was comparatively small; still it was in its leading features correct, and has really formed the foundation of every later system. About the middle of the 17th century, the invention of the microscope afforded invaluable aid to the botanist, and investigations were eagerly made by Henshaw, Hook, and Grew, in this country, and by Malpighi, in Italy. About the same time Tournefort, a Frenchman, and Rivinus, a German, achieved great results. Jussieu developed Ray's views of the natural affinities in the vegetable kingdom. Jussieu's method was first made known in the year 1789, just eleven years after the death of Linnæus. Von Haller, a German, almost rivalled Linnæus in eminence. The natural method has been since advanced by the labours of De Candolle, Brown, Endlicher, Lindley, and many others.

Geographical Botany treats of the manner in which plants are affected by climate and station, and endeavours to determine the conditions under which particular families or species of plants are confined to certain zones of latitude and altitude. It is a study of great interest, and one which cannot be successfully prosecuted without an intimate acquaintance with most of the sciences. Of course, so long as there are vast tracts of continents unexplored by botanical travellers, the knowledge upon which this department is founded must be imperfect. (*See* DISTRIBUTION OF PLANTS.)

Palæontological, or Fossil Botany investigates the nature of the plants found in a fossil state in the various geological formations. It is therefore at once a branch of botany and of geology. (*See* PALÆONTOLOGY.)

BOTANY BAY KINO. (*See* EUCALYPTUS.)

BOT-FLY, *bot'-fli* (*Œstridæ*). This name, or that of Gad-fly, is commonly given to insects, which, although most of them are incapable of taking nourishment when in their perfect condition, from the obsolete nature of their mouths, are nevertheless to be regarded as among the greatest pests that afflict cattle. During their larva state (when they are known as *bots*) they are all parasitic upon the various herbivorous animals, some of them harbouring in the skin, and others in the internal cavities of their bodies. In horses these pests are called *bots;* in sheep, *maggots;* and in oxen, *wornibs.* Of the internal parasites, some live in the frontal sinuses of sheep and deer, the parent laying her eggs in the nostrils of the animal, whence the larva creeps up to its destined abode; whilst others (the bots) make their way to the very core of the animal's intestines. The eggs of the latter are laid upon the skin of the horse in such positions as are easily reached with the tongue. This selection of situation, however, is not invariable, nor does it appear to be necessary, to insure the bot's purpose. After the eggs have remained among the hair of the horse's hide four or five days, they arrive so near maturity that the least additional heat is sufficient to hatch them. This additional heat is supplied by the application of the friendly horse's lips and tongue; the larvæ are liberated, and, adhering readily to the moist surface of the horse's mouth, are conveyed straight into his intestines. It is satisfactory to learn that opinion is at least divided as to whether the bot-fly in the horse's stomach is hurtful. The horse has an instinctive horror of this insect, and, as soon as it flies near him, he gallops round the field or inclosure until he is in a profuse perspiration, and then comes to a sudden stop, in a state of tremor. The fly makes a most delicate poise on the wing, and then suddenly darts at the horse and deposits an egg. This is repeated until several hundreds are affixed to the hairs, generally of the leg. When the larvæ become perfect, they pass from the body of the animal with the dung, in which they remain until they are matured into a fly. They frequently attach themselves, by a hook-like process, near the anus of horned cattle, and drop with the dung. The ox-bot (*Hypoderma bovis*) is more troublesome than any species of the insect which attacks the horse. Each species is about half an inch long. The sheep-bot (*Cephalemgia ovis*) is somewhat smaller, is a greater pest even than the others. The eggs are deposited in the nostrils of the sheep, and, when hatched, drive the sheep almost mad. Goats, deer, and other quadrupeds are subject to the attacks of the bot-fly. In the summer months oxen frequently stand in a pond or pool for a considerable time, their instinct leading them to this course in order that they may effectually get rid of their future enemy.

BOTHRODENDRON, *both'-ro-den'-dron* (Gr., *bothros*, pit, *dendron*, tree), fossil stems, with dotted surfaces, occurring in the coal-measures, and distinguished from *Sigillaria* and *Stigmaria* by two opposite rows of deep oval pits, which appear to be the scars left by large cones or seed-bracts.

BOTHRIOCEPHALUS, *both-rio-sef'-a-lus* (Gr., *bothrion*, a small cavity, and *cephale*, a head), a genus of intestinal worms, belonging to the order Cestode Worms. It differs from the true tapeworm, in having two longtitudinal hollows, which serve for the purpose of adhesion, in place of the four sucking disks of the tapeworm. These worms are very abundant in some kinds of fish, and in fish-eating birds. It very frequently appears in the stickleback, but remains undeveloped until the fish is eaten by a bird, when it acquires its mature form and remains in the bird's intestines. It exudes an oleaginous matter, which is probably the cause of the injurious effects produced on the animals infested by the worm. Only one species, *B. latus*, is found in human beings, and is sometimes known as the Broad Tapeworm. Each of the segments contain organs of reproduction. It sometimes attains a length of fifteen feet, and sometimes several of them will be expelled by one patient. It is very rare in this country, but more frequent in marshy districts of the Continent.

BOTRYCHIUM, *bo-trik'-i-um* (Gr., *botrus*, a bunch of grapes), a genus of ferns of the division *Ophioglosseæ*. The only British species is *B. lunaria*, commonly called Moonwort, a little fern common on mountain pastures. *B. Virginicum* is found in many parts of America, Asia, and Africa; but in Europe it is strangely confined to Norway. Its fronds, which are large and succulent, are boiled and eaten in the Himalaya, New Zealand, and a few other parts. It is, in America, frequently known as the Rattlesnake fern, being found in places where rattlesnakes abound.

BOTRYOIDAL, *bot'-ri-oi-dal*, a term applied to masses occurring in a concretionary form resembling bunches of grapes. Certain limestones and hæmatites are found in this form.

BOTRYOLITE, *bot'-ri-o-lite*, datholite, or boro-silicate of lime, occurring in a *botryoidal* form at Arendahl, in Norway. It is also found near Lake Superior in such large quantities, that it has been used as a flux for copper, and as a source of boracic acid.

BOTRYTIS, *bot'-ri-tis*, a genus of fungi, comprising many of those microscopic plants which, in their fully-developed condition, form the different kinds of mould found on bread, cheese, preserves, fruits, paper, and other substances. Many of the species are peculiarly destructive to living animals and plants: thus the disease in the silkworm known by the name of *muscardine*, is produced by one or more; a disease to which turnips are particularly liable is connected with the growth of the species *B. parasitica;* and the much-dreaded potato disease is confidently ascribed by many observers to *B. infestans*. (*See* POTATO DISEASE.)

BOTTLE-FISH (*Saccopharynx ampullaceus*), a very singular fish, belonging to the genus *Saccopharynx*. Very few specimens of the genus have been taken, and, with the exception of size, they realize many of the fabulous accounts of the sea-serpent. The length is from four to six feet. The most singular fact connected with the bottle-fish is, that its body is capable of being inflated like a leathern bottle, and it has a long slender tail like a whiplash. It has a pointed snout, and its mouth is furnished with long sharp teeth. Under the small pectorals the three branchials can be seen through the irregularly-shaped gill-openings; and the extensibility of the jaws is greater than that of the serpent tribe. It has a slightly granular, but soft, loose, and slimy skin, and is very voracious; one of the examples found was discovered to have swallowed a fish longer than its own body, and the other a sea-perch thicker than itself.

BOTTLE-GOURD, *goord*, a genus of plants known as *Lagenaria* (from Lat., *lagena*, a bottle), belonging to the natural order *Cucurbitaceæ*, and nearly allied to the true gourd, but differing from it in having white flowers and the disposition of the seeds. The common bottle-gourd, sometimes known as the False Calabash, is a native of India, but is now cultivated in warm climates in other parts of the world. It is a climbing, musky-scented annual, with clustering flowers, and the fruit, varying from one foot to five, or even six feet in length, is shaped like a bottle. The rind, when dried, is used for holding water (*see* BOTTLE), and is generally known as a Calabash. In the wild state this plant is bitter and poisonous, and when cultivated has generally strong purgative properties. Some varieties, however, have an edible pulp of refreshing qualities. In warm countries, especially Arabia, it is cooked with vinegar, or boiled with rice and meat.

BOTTLE-HEAD, known also as the Bottle-nosed or Bottle-headed Whale, and the Beaked Whale, a cetaceous animal, generally described as belonging to the Dolphin family, but appearing to be a connecting link between them and the whale. The average length is about 25 feet; the skin is smooth and glossy, black on the back, yellow on the sides, and nearly white on the belly. The snout is lengthened into a beak-form, and the forehead rises suddenly from the beak, and is unusually elevated, owing to the large bony crests above the upper jaw. The animal is very rarely met with in European waters, but occasionally enters harbours or the mouths of rivers; and about 1786 one was captured in the Thames, above London Bridge, and its skeleton may be seen in the Museum of the Royal College of Surgeons, Lincoln's Inn Field.

Bottle-Nosed Whale. The name is also sometimes given to a species of dolphin, *Delphinus Tursio*, occasionally found in British waters.

BOTTOM-BEDS, in Geology, the name sometimes given to some partially or doubtfully fossiliferous strata which immediately underlie the Silurian system in Wales.

BOULDER CLAY. (*See* DRIFT.)

BOULDERS, *bole'-ders* (Sax.), in Geology, any rounded or waterworn blocks of stone too large to be included under the heads of "pebbles" and "gravel." The term *erratic boulders* is generally applied to the detached masses of rock which are found lying upon the surface, and which have been washed out of the clays of the Glacial epoch, or brought separately from their original sites by icebergs. They are often found resting on hill-tops, which during the Glacial period were banks and shallows in the sea, and so arrested the laden icebergs in their course. The largest boulder known in the British islands is near the head of the Devil's Glen in county Wicklow. It is 27 feet long by 18 wide, and 15 high. It is of granite, resting on Cambrian grits and slates, six or eight miles from the nearest granite *in situ*, with a wide shallow valley between the hill on which it now stands and the granite district. Very large erratic blocks of Scandinavian rocks are scattered over the plains of Denmark, Prussia, and northern Germany. The monolithic pedestal of the statue of Peter the Great at St. Petersburg was hewn out of a boulder weighing 1,500 tons, that lay on a plain not far from the city. (*See* DRIFT, GLACIER, PLEISTOCENE.)

BOULIMUS, *boo'-li-mus* (Gr., *bou*, great, and *limos*, hunger), is a word used in medicine to denote a morbidly voracious appetite.

BOUQUETIN, *boo'-ke-tang*, or Ibex of the Alps, (*Capra Ibex*) a species of goat, now almost extinct, inhabiting the higher regions of the Alps; between Valais and Piedmont, it is larger and more powerful than the ordinary goat, having a small head and great horns. It feeds on shrubs, lichens, and the scanty herbage growing on high mountains. The horns of the male are some times 20 inches long, and curve backwards, the horns of the female are only about 6 inches. It has no beard, only a few hairs in winter. Formerly it was found on all the Alpine mountains and is regarded as the true ibex of the ancients. When taken young, it can easily be tamed and will breed well with the common goat. It has a most extraordinary power of leaping great heights and distances, and also of ascending or descending steep precipices. It is often found at greater heights even than the chamois. Among the inhabitants of German Switzerland, it is known as the *Steinbock*. (*See* IBEX and STEINBOCK.)

BOURBON TEA, *boor'-bawhn*. (*See* ANGRÆCUM.)

BOURNONITE, *boor'-no-nite*, a mineral found at Endellion, in Cornwall, in steel-grey tabular crystals, or massive granular aggregations. It is a mixed sulphide of antimony (26 per cent.), copper (12·8 per cent.), and lead (41·8 per cent.); sulphur (19·4 per cent.). It is often found in masses resembling a cogged wheel, and is thence called *wheel-ore*. It is also known as *Endellionite*.

BOUVARDIA, *bov-var'-di-a*. (*See* CINCHONACEÆ.)

BOVEY COAL, a species of lignite or wood-coal found at Bovey in Devonshire, from which place it takes its name.

BOVIDÆ, *bo'-vi-de* (Lat., *bos*, *bovis*, an ox), the hollow-horned ruminating animals belonging to the class *Mammalia*, order *Ruminantia*. The species belonging to this family are hoofed, and their stomachs are adapted for chewing the cud. Their frontal bones are usually provided with hollow horns. They have also twelve grinders or molar teeth on each jaw. In this family are included—*Bovina*, the oxen; *Giraffina*, the giraffes; *Cervina*, the deer; *Moschina*, the musk-deer; and *Camelina*, the camels. The exact number of species has not yet been accurately ascertained. (*See* also ARNEE, BANTERING, BISON, BUFFALO, URUS, YAK, &c.)

BOWDICHIA, *bo-dik'-i-a*, a genus of plants belonging to the natural order *Leguminosæ*, sub order *Papilionaceæ*. The only species requiring notice is *B. virgilioides*, the bark of which, with that of one or more species of *Byrsonima*, forms the American alcornoco bark of commerce. (*See* BYRSONIMA.)

BOWERBANKIA, a genus of Zoophytes, of the class *Polyzoa*, order *Infundibulata*, growing on seaweeds, stones, and corallines, and forming branching tufts sometimes nearly two inches in height. One species, B. *imbricata*, is very abundant on the British coasts. The branches are filled with cells, in each of which is a polype, connected with the common life of the polypidon. Each polype has ten finely cilicated tentacula, which, being kept in active motion, bring animalculæ or organic particles into the mouth.

BOWER-BIRD, *bauw'er-bird*, an Australian bird, belonging to the *Sturnidæ* or Starling family, remarkable for making extraordinary bower-like structures of sticks and twigs so interwoven that the tops turn in and form a covering. These bowers are decorated with all kinds of brilliant and striking objects, such as gaudy-coloured rags, parrot feathers, shells, bleached bones, &c. Like the magpie of the British isles, the bower-bird will often take away spoons and cups, so that if the natives or settlers lose any of their scanty possessions it is quite probable they may be found in the bowers of the bower-bird. Mr. Gould, in his "Birds of Australia" says that these bowers are not used as nests, but probably as assembly rooms, where the bower-birds of both sexes sport in the most playful manner; they are probably also used as places of rendezvous during pairing time, and for the elegancies and amusements, rather than the necessities, of bird life. The *satin bower-bird* is about the size of a jackdaw or small crow. In the adult male the plumage is a deep satiny blue-black. This species is the *cowry* of the natives. There are other species—the green satin bower-bird, spotted bower-bird, and the great bower-bird. The latter is about 15 inches long, and is found in North-Western Australia, and makes highly ornamented bowers, which are always adorned with sea-shells.

BOW-STRING HEMP, a silky, white and elastic fibre used to make bow-strings, produced from the large leaves of the *Sanseviera Feylanica*, a plant found in the East Indies. The Hindoo name is *moorva*. It does not rot in water so quickly as hemp. A species of the *Sanseviera* is found on the west coast of Africa, from which fine fibre, called African bow-string hemp, has been obtained.

BOX, a genus of evergreens, shrubs, or small trees. (*See* BUXUS.)

BOX TORTOISE, OR LOCK TORTOISE, popular names of a species of tortoise found in America, and characterized by a cross-wise division of the plastron which enables the animal to shut himself up entirely in his shell. Box tortoises are very timid and gentle; their legs are larger and their speed greater than the ordinary tortoise.

BOX THORN (*Lycium*), a genus of plants not known in England, of the natural order *solanaceæ*, having numerous species found in all quarters of the world. Some grow to the height of 30 or 40 feet.

BOYLE'S LAW, ALSO CALLED MARRIOTTI'S LAW, is the law that the volume of a gas is inversely as the pressure—*i.e.*, if we double the pressure upon a gas its bulk is reduced half the size, if we triple the pressure its bulk becomes one-third the size.

BRACHIAL ARTERY, *brak'-i-al*, the downward extension of the axillary artery, or, in other words, the principal artery between the armpit and the elbow. It is situated in the inner side of the arm along the inner edge of the biceps muscle, and behind the great median nerve; in cases of bleeding from the arm, it may be pressed against the bone. It gives out four smaller branches; first, the superior profunda; second, a small artery to supply the medullary membrane of the arm bone; third, the inferior profunda; and fourth, the anastomotica magna, which is again divided into numerous branches around the elbow. Below the bend of the arm it divides into two branches, the cubitalis and radialis.

Brachial Muscle, or *brachialis internus*, is situated on the fore part of the os humeri. It rises fleshy from the middle of the os humeri at each side of the insertion of the deltoid muscle, covering the inferior and forepart of this bone, and is inserted by a strong short tendon into the cornoid process of the ulna. Its use is to bend the fore-arm.

BRACHINUS. (*See* BOMBARDIER BEETLE.)

BRACHIOPODA, *bra-ki-op'-o-da* (Gr., *brachion*, an arm, *pous*, a foot).—A term applied to certain molluscous animals having bivalve shells. They derive their name from the remarkable organs by which they procure their food. From the sides of the mouth project two long arms, disposed wholly or partly in spiral curves when not used for seizing the prey. These organs are not only used for obtaining food, but also in maintaining the necessary current for respiration. They are usually furnished with a number of vibratory filaments. The *Brachiopoda* or *Palliobranchiata*, differ from the great majority of recent molluscs with bivalve shells, both internally and externally. The species now existing are very widely diffused, and are all marine; one of them, the *Crania personata*, has been brought up from a depth of 500 yards. The *terebratulæ*, or Lamp shells, are most numerous.

BRACHIUM, *brai'-ki-um* (Gr., *brachion*, the arm), the name given to the arm, or that part of the upper extremity which extends from the shoulder to the wrist.

BRACHYPTERÆ, OR BRACHYPTERES, (from the Greek signifying short-winged), web-footed birds with short wings, as auks, ducks, grebes, puffins, penguins, &c. They are all aquatic in their habits.

BRACHYSTOCHRONE, *brai'-kis-to-krone* (Gr., *brachus*, short; *stoicheion*, a line), a term employed to designate the curve described most rapidly, between two points in its course, by a falling body. The term was first used by John Bernouilli, professor of mathematics at Groningen, in 1696, who first drew the attention of philosophers to it. The curve is commonly called "the line of swiftest descent."

BRACKLESHAM BEDS, *brak'-el-sham*, the lower tertiary sands and clays immediately overlying the London clay, so called from being well exposed at Bracklesham Bay, near Chichester. These beds are included in the Bagshot series.

BRACT, BRACTEA, OR FLORAL LEAF, *brakt* (Gr., *bracho*, I crepitate), a modified leaf from the axil of which a flower-bud, instead of an ordinary leaf-bud, arises. Strictly speaking, the term bract should only be applied to the leaf from which the primary floral axis, whether simple or branched, springs; while the leaves which are produced on the axis between the bract and the outer envelope of the flower should be distinguished as *bractlets* or *bracteoles*. In ordinary descriptions, however, the term bract is used to indicate either kind of floral leaf. Bracts are sometimes large, and similar to the ordinary leaves of the plants upon which they are placed, as in the white dead-nettle. Such bracts are termed *leafy*, and can only be distinguished from the true leaves by their position with regard to the flower-stalk or flower. In general, however, bracts differ greatly from ordinary leaves. Though the bract is generally a small and inconspicuous organ, it occasionally acquires a considerable size, and may actually surround all the flowers of a plant so as to completely inclose them when in a young state. A sheathing bract of this description is called a *spathe*; it is very remarkable in the common arum. From the word bract several adjectives are formed; namely, *bractiscent*, assuming the appearance of a bract; *bractical*, furnished with bracts; *bractiolate*, having little bracts.

BRADFORD CLAY, *brad'-ford*, a blue unctuous clay occuring at Bradford, near Bath, and extending for a few miles around that town. It is a member of the Oolitic system; nowhere more than sixty feet in thickness, and is full of the fossils called *Apiocrinites*. The clay rests on calcareous rock, and is supposed once to have been a sea or lake in which these animals lived. When, however, the once clear water became charged with mud, and gradually or suddenly filled up, their bodies became dismembered and distributed through the clay. The surface of rock consists for the most part of their bases now turned to stone. (*See* FOSSIL and ZOOPHYTE.)

BRAHMIN BULL (*Bos indicus*). (*See* ZEBU.)

BRADYPUS. (*See* SLOTH.)

BRAIN, *brain*, is the name given to a soft pulpy substance, which in man and the higher orders of animals constitutes one of the great central masses of the nervous system (which *see*). It is the upper end of the cerebro-spinal tube, and expands into three primary cerebral vesicles, named anterior, middle, and posterior. As might be expected, it is found most perfectly developed in man, in whom, with its membranes, vessels, and nerves, it constitutes the whole of the matter enclosed within the bones of the skull, and is, hence, termed the *encephalon*. The brain is divided by anatomists into the cerebrum, or brain proper; the cerebellum, or little brain; the pons Varolii, and the medulla oblongata. The *cerebrum* occupies the whole of the superior portion of the cavity of the cranium, or skull, and is by much the largest portion of the brain. The *cerebellum* occupies the lower and back part of the cranium, and is next in size to the cerebrum. The *pons Varolii* and *medulla oblongata* occupy the base of the brain. The former occupies a central position on the under surface of the brain, and is connected with the cerebrum by two cords or peduncles, termed *crura cerebri*, with the cerebellum with two similar cords, termed *crura cerebelli*, and is also in contact with the medulla oblongata. This last is that portion of the encephalon which connects it with the spinal cord. It is of a pyramidal form, having its broad extremity turned upwards, and connected with the pons Varolii, while its under portion is united with the spinal cord. The brain is covered by three membranes, two of which, the outer and inner, are termed *matres* (mothers) from the old notion that they gave rise to the other membranes of the body. The outermost of these membranes, from being of a firmer texture than the others, is termed the *dura* (hard) *mater*, and incloses the brain with its appendages, lining also the whole internal surface of the cranium. Its outer surface, which adheres to the bones of the cranium, as the periosteum does to the other bones, appears to be rather rough and irregular; but the inner surface is smooth and shining, and is lubricated by a fluid which is secreted by it. This membrane is the densest and strongest of the whole body, its component fibres interlacing each other in all directions. It sends off several folds or processes, which descend between certain portions of the brain. The second, or middle, of the three membranes, is an extremely thin and delicate substance, and from its fancied resemblance to a spider's web, it receives the name of *arachnoid*. It is transparent and colourless, and is spread uniformly over the surface of the brain. The third investing membrane, the *pia* (soft) *mater*, is also very delicate and tender, but differs from the arachnoid in its abounding in blood-vessels, whereas no blood-vessels have yet been discovered in the latter. The blood-vessels with which every part of this delicate membrane is covered are the nutrient arteries of the brain. They subdivide and ramify to an extreme degree upon the surface of this membrane, so that the blood may enter the substance of the brain only in very minute quantities. As the pia mater contains and supports the nutrient vessels of the brain, it is not only, like the others, spread over its entire surface, but it also penetrates between all its convolutions, and lines every cavity which it contains. The nervous matter of the brain is composed of two distinct substances, differing from each other both in colour and consistence. One of these is the *grey* or *cineritious substance*, termed also, where it forms the outer covering, as in the cerebrum and cerebellum, the *cortical* substance, from its surrounding the inner part like the bark of a tree. The cineritious substance is of a softer consistence than the other, and is composed almost entirely of blood-vessels, connected and sustained by exceedingly fine cellular membrane. It forms an outer covering to the entire surface of the cerebrum of generally about one-tenth of an inch in thickness. The *white* or *medullary substance*, which constitutes the internal portion of the cerebrum and cerebellum, is of firmer consistence, and is composed of microscopic fibres arranged into laminæ and bundles, between which intervening vessels ramify. In the cerebrum these fibres run, in general, in such a direction as to converge towards the base of the brain. The *cerebrum* is of an ovoid shape, but irregularly flattened on its under side. It is divided into two lateral halves, termed hemispheres, separated from each other through a great portion of their extent by the great longitudinal fissure, into which is inserted the *falx cerebri*. This fissure, both before and behind, passes quite through to the base of the cerebrum; but in the middle it is interrupted by a transverse portion of white substance termed the *corpus callosum*, which connects together the two hemispheres. Each hemisphere is subdivided into an anterior, middle, and posterior lobe, but it is only on the under surface of the brain that these lobes are properly marked off. The surface of the cerebral hemi spheres is not plain and uniform, but presents numerous tortuous eminences, named convolutions or *gyri*, which are separated from each other by deep grooves or furrows, termed *sulci*. These are generally about an inch in depth, but they vary considerably in different brains, and even in different parts of the same brain; and, indeed, those of one side frequently differ from those of the other. The convolutions are more marked as the brain is better developed, and are more numerous and manifest in man than in the lower animals. As the cortical substance of the brain is continuous over the whole surface of the hemispheres, in the fissures as well as upon the convolutions, it follows that the greater the number and depth of these, the greater is the superficial extent of the grey matter which is generally regarded as the seat of all the nervous manifestations, as sensation, volition, &c. On slicing away the substance of the hemispheres to a level with the *corpus callosum*, it will be seen to be formed by the converging fibres of the two hemispheres, whence it has been termed the *commissura magna*, or the great commissure of the brain. Under the corpus callosum are the two great cavities termed the *lateral ventricles*, distinguished into right and left. They are very irregular in shape, and are described as each consisting of a body and three horns, or *cornua*—the anterior, posterior, and middle. They are separated from each other by the septum lucidum, which descends from the lower surface of the corpus callosum, and consists of two laminæ, between which is the very small cavity of the septum lucidum. It rests upon the *fornix*, a triangular medullary body, having its apex directed forwards and its base backwards. Posteriorly it is connected with the corpus callosum, and it divides laterally into a posterior cornu on each side, which terminates in, or rather is continuous with, the *tænia hippocampi*, and the *hippocampus major* and *minor*. The third ventricle is a small narrow cavity lying between the *optic thalami*. These last are two large firm oblong bodies nearly an inch and a half long by three-fourths of an inch wide and deep. The *corpora striata* are two grey pear-shaped bodies, but internally they are streaked with white matter—whence their name. In front they are obtuse, and approach each other; but they separate and narrow as they proceed backwards. The *Pineal gland* is a small portion of grey matter about the size of a small pea. It was supposed by Descartes to be the seat of the soul. The *cerebellum*, or little brain, consists of a body and three pairs of crura or peduncles, by which it is connected with the rest of the encephalon; and it is not covered with convolutions like the cerebrum, but appears to be formed of a number of lamellæ, or plates, with sulci between them. The *pons Varolii*, or annular protuberance, is a comparatively small portion of the brain, and occupies a central position on its under surface, above and in front of the medulla oblongata, with which it is continuous. It consists of transverse and longitudinal white fibres, interspersed with a quantity of diffused grey matter. The transverse fibres, with few exceptions, communicate with the cerebellum by means of the middle crura; while the longtitudinal fibres are those which ascend from the medulla oblongata into the crura cerebri. The *medulla oblongata* is that part of the encephalon which is immediately connected with the upper end of the spinal cord, and has an inclination obliquely downwards and backwards towards the foramen magnum. From the under-part of the brain issue a number of nerves, known as the cranial, and pass through foramina in the base of the skull. They are usually reckoned as forming nine pairs. (*See* NERVES.)

Weight and Size of the Brain. In males, the average weight of the full-grown human brain is about 49 or 50 ozs.; in females, 44; but, as the female body is lighter than the male, there is no inferiority in the *relative* size of the brain. It varies, however, considerably in different individuals. Some brains of men have been known to weigh as much as 64 ounces, and of women, 56. Great weight and size do not always go together. Byron had a small head, but his brain was of far more than average weight. In fact, the brain may be compressed into a small compass, or it may be less compact, and therefore occupy greater space, without increasing in value. In fact, sensation and thought depend upon the amount of the grey matter; a small brain may be more active than a larger one; and in this, as in other matters, quantity and quality must be considered together, and temperament (which *see*) must be taken into account as a qualifying element. Anatomists differ as to the size or weight of the brain at different periods of life. In general, the weight of the brain increases rapidly up to the seventh year, then more slowly to between sixteen and twenty, and then more slowly to between thirty-one and forty, at which time it reaches its maximum point. Beyond that period there appears a slow, but progressive, diminution in weight of about 1 ounce during each subsequent decennial period. Generally speaking, as compared to the weight of his body, the brain of man is heavier than that of the lower animals; but there are some slight exceptions to this rule, as in the case of certain species of small birds and in the smaller apes. Huxley says that an average European child of four years old has a brain twice as large as an adult gorilla, whose weight is, perhaps, four times as great. The proportionate weight of the human brain to the body is greatest at birth, being about 1 to 5·85 in the male, and 1 to 6·5 in the female. At the tenth year, it is about 1 to 14; at the twentieth, about 1 to 30; and after that age it averages about 1 to 36·5, with a trifling decrease in advanced life.

Chemical Composition of the Brain. Brain matter (grey and white together) averages in 100 parts.

Water, ...	$75\frac{1}{2}$
Albuminous matter, ...	7
Fat (colourless and red), ...	$11\frac{1}{2}$
Salts (including about $1\frac{1}{2}$ of phosphates),	6

There is most water in the grey, cineritious matter; and most colourless fat in the white matter. It is a noticeable fact that the amount of salts in the healthy brain is about twice that in the brain affected by insanity.

Functions of the Brain. That the brain is the organ of sensation and volition is an established proposition of physiology. In what method the mind acts through it is not so easily determined—anatomists can only arrive at results, metaphysicians can only guess at principles. Some consideration will be given to this subject under the heading MENTAL PHILOSOPHY AND PHRENOLOGY. It is certain that injury to the brain produces abnormal effects; that wasting of the brain is exhibited in imbecility; and that acute disease produces insanity. That temporary inflammation or overstimulation by alcohol induces mental delusions, or loss of power; and that during sleep the mental operations, of which the brain is somehow the medium, are among the most familiar of facts. (*See* IMBECILITY AND INSANITY.)

Brain of the Lower Animals. The only animals that possess absolutely a larger brain than man are the elephant and whale. In the former the brain weighs from 8 pounds to 10 pounds, and in the case of a large whale, about 5 pounds; but we must take into account the proportion of the brain to the size of the body, and the smaller amount of cineritious, or sensitive matter, owing to the comparative absence of convolutions. In the dog the brain bears an average proportion to the body of about 1 to 120; in the horse, 1 to 450; in the sheep, 1 to 750; and in the ox, 1 to 800. The convolutions, too, which are so marked on the human brain, are few, or altogether wanting, on the brains of animals. The nerves of sense, too, in animals are usually much more largely developed than in man. In man the olfactory nerve is not one-fourth the size of that of the horse, though the brain is so much larger. In the smaller quadrupeds the comparative size of the brain approaches nearer to that of the human, being in the mouse about a forty-third part of the weight of the animal; but it is composed almost entirely of medullary matter. In birds, the brain is in general a much less complex organ than in mammals, presenting no convolutions on its surface and having only a very small quantity of cineritious matter. Though its bulk is in general proportionally much smaller than the human brain, yet in some of the smaller birds, as the chaffinch and the redbreast, it approaches, and indeed exceeds, the proportion observed in the human being. In fishes the brain is yet more diminished; in the chub being only 1 to 842, and in the lamprey 1 to 1,425. It consists merely of two pairs of ganglia and a single one. The two anterior ganglia or lobes are the olfactory lobes, immediately behind which are two others, generally of larger size, called the optic lobes; while behind these is a single ganglion, or lobe, situated in the median line, and termed the cerebellum.

Brain, Diseases of the.—Inflammation is one of the most common diseases to which the brain is subject, and may result from a number of causes—from external injuries, as blows or falls, the symptoms of which may not manifest themselves for many days; from the improper use of narcotics or stimulants, exposure to the cold or the action of the sun's rays, protracted study, excessive joy, or other mental emotion; as well as less directly from diseases of the digestive or other organs of the body. It is characterized by more or less violent pain of the head, with suffusion or prominence of the eyes, the countenance generally tumid or flushed, and delirium or stupor. In the treatment of this disease, general and local bleeding are usually had recourse to; the latter by means of leeches applied about the head, or by cupping. The head is also usually shaved, and kept cool by cloths wet with cold or iced water. Frequently, in children, inflammation leads to a form of disease known as water in the head, or hydrocephalus (which *see*). Softening of the brain is caused by the want of a proper supply of nourishment to the cerebral substance, and may arise from various causes. It is characterized by lowness of spirits, headaches, giddiness, the loss of memory, and at length imbecility and paralysis. Unfortunately, this is a disease which little can be done to remedy, especially when it results from a disordered state of the nutrient organs themselves, as from disease or obstruction in the arteries which convey the blood to the cerebral substance. Frequently it is occasioned by over-anxiety or excessive study; in which case everything is to be done to get rid of the predisposing cause. Every thought, every mental effort, destroys a certain portion of the cerebral matter; and hence, if destruction takes place more rapidly than renewal, a wasting or softening of the brain is the result. The blood-vessels, particularly in the aged, are also liable to be ruptured. (*See* APHASIA, APOPLEXY, CONVULSIONS, INSANITY, DELIRIUM TREMENS, PARALYSIS.)

BRAINSTONE CORAL, the common name of certain kinds of Madrepores, or corals of slow growth, formerly included in the Linnæan genus, Madrepora, but now composing the more restricted genus, *Meandrina*. They are found chiefly in the Indian Ocean, but also in the South Atlantic, and some have been seen in the Red Sea. They derive their popular name from their general resemblance to the brain of man. When broken, the coral presents a beautiful appearance, and the markings may be traced inwards through all its substance, even to the central nucleus.

BRAKE, OR BRACKEN, a genus of common ferns, growing luxuriantly on heaths and uncultivated ground in Britain and on the Continent. (*See* PTERI.)

BRAMA *bra'ma*, a genus of fishes, of the family *Chatodontidæ*, of which the body is very deep and compressed, and about two feet in length; tail forked, and with extremely divergent points, and head obtuse; they are most common in the Mediterranean, though occasionally found in British waters. They are sometimes called *Sea-bream* and *gilt head*, though these names are also applied to fishes of other families but of similar characteristics.

BRAMBLE. (*See* RUBUS.)

BRAMBLING, *bramb'-ling* (*Fringilla*), *montifringilla*), also called mountain-finch. This bird is rather larger than the chaffinch, with which it is closely allied. The tail is forked, and its prevailing colour black, white, and yellow. It only visits Britain in winter and breeds in the northern parts of Scandinavia.

BRANCH, *bransh* (Fr., *branche*), that part of a plant which does not rise direct from the root, but originates from a lateral leaf-bud on the primary axis or stem. It is looked upon as part of the stem, and not as a distinct organ. A branch generally produces secondary branches, and these give rise to minor ramifications, called *branchlets* or *twigs*. The different modes in which branches spring from the stem give rise to the various forms of trees; such as pyramidal, spreading, and weeping. The comparative length of the upper and under branches also gives rise to great differences in the contour of trees, as seen in the conical form of the spruce, and in the umbrella-like shape of the Italian pine. (*See* BUD and STEM.)

BRANCHIÆ. (*See* GILLS.)

BRANCHIOPODA, *bran-ki-op'-o-da* (Gr., *branchia*, gills, *pous*, a foot), an order of small crustacea, belonging to the division *Entomostraca*, which usually abound in still fresh waters. These animals have thin mouths, furnished with jaws fitted to masticate their food, and their name is derived from the peculiarity which they possess in having the *branchia* or gills, which are numerous, attached to the feet. Some are popularly known as water fleas and some as brine shrimps. (*See* BRINE SHRIMP.) They swim freely, but their feet are not generally adapted for locomotion. The antennæ, in some cases, serve as organs of motion. While swimming, they keep their feet constantly moving, and thus prevent the water from becoming stagnant.

BRANDLING, *brand'-ling*. (*See* PAR and SALMON.)

BRASH. (*See* RUBBLE.)

BRASSICA, *bras'-si-ka* (from *bresic*, the Celtic name of the cabbage), a genus of plants belonging to the natural order *Cruciferæ*, and containing several species, which are commonly cultivated as food for man and cattle. *B. rapa* is the common turnip. The species *B. campestris* is regarded by some as the source of the Swedish turnip: but others consider this vegetable to be a hybrid between *B. campestris* and *B. rapa*, or *napus*. The species *B. oleracea* is supposed to be the common origin of all the different kinds of cabbage, cauliflower, brocoli, and kohl-rabi, the different varieties having been produced by the art of the gardener. Brocoli and cauliflowers are deformed inflorescences; the kohl-rabi is produced by the stem enlarging above the ground into a fleshy knob, resembling a turnip. On comparing the original plant, as found on our shores, with wavy green leaves, no appearance of head, and flowering like wild mustard or charlock, say with the red cabbage or the cauliflower, the difference is astonishing. *B. napus* yields the rape, cole, or colza seeds, from which a large quantity of bland fixed oil, much used for burning and other purposes, is expressed. The cake left after the expression of the oil constitutes the well-known oil-cake used for feeding cattle. The seeds of *B. Sinensis* yield Shanghai oil.

BRAUNITE, *brown'-ite*, a protoxide of manganese, occurring in Piedmont and Thuringia, in dark-brown square octahedrons. It contains 79 per cent. of manganese.

BRAXY, *brax'-e*, a disease of sheep, the word being variously applied to continuous diarrhœa, and to a blood disease which causes plethora. The too sudden change from poor to very rich pasture will often occasion diseases of this character.

BRAYERA, *brai-e'-ra*, a genus of plants belonging to the natural order *Rosaceæ*, sub-order *Roseæ*. The only interesting species is *B. anthelmintica*, a native of Abyssinia, the flowers of which constitute the drug known as Koussoo, or Cusso, which has been employed in both France and England with considerable success for expelling tapeworm. The flowers are apetalous and diœcious, and are imported in a dried state. The mode of administering the Koussoo is peculiar. About half-an-ounce is infused in a glass of warm water, and taken thus, flowers and water together, on an empty stomach. The flowers contain a considerable quantity of tannin, and an odorous principle to which the anthelmintic property is probably owing.

BRAZIL NUT. (*See* BERTHOLLETIA.)

BRAZIL AND BRAZILETTO WOODS. (*See* CÆSALPINIA.)

BREAD-FRUIT. (*See* ARTOCARPUS.)

BREAD-NUT. (*See* ARTOCARPACEÆ.)

BREAD-ROOT. (*See* PSORATEA.)

BREAD-TREE. (*See* CAFFER BREAD.)

BREAKERS, *brai'-kers* (Sax., *bræcan*, to break), a term applied to a peculiar kind of billows that may be easily distinguished by the white foam with which they cover the surface of the sea, and the terrible roaring noise which they produce. Breakers are generally found in shallow parts of the ocean, where rocks lie hidden below the surface, over which they break with great violence; and when once a ship is driven amongst them, it is almost impossible to save her, as every billow that heaves her up serves to dash her down again with additional force, when it breaks over the rocks or sands beneath.

BREAM, *breem* (Fr., *brème*) (*Abramis Brama*), a fish of the carp family, found in deep and still parts of rivers. In proportion to the length of the body, this fish is extremely deep and thin. In length, it is about two feet. Its flesh is not in very high repute. The Sea-Breams belong mostly to the family of the Sparidæ, and are nearly allied to the Gilt-head. (*See* GILTHEAD.)

BREAST, *brest* (Saxon, *breost*), is a term applied to the whole of the anterior part of the thorax. In a more restricted sense it is applied to the two globular fleshy protuberances adhering to the anterior and lateral regions of the thorax of females, and containing the mammary or lacteal glands. On the middle of each breast is a projecting portion termed the *papilla* or nipple, in which the excretory ducts of the glands terminate, and round which is a coloured orb or disc called the *aureola*. The use of the breasts is to secrete milk for the nourishment of newly-born infants. They are composed of common integuments and adipose tissue, in which are lodged numerous ducts radiating from the nipple, and afterwards dividing and subdividing into branches and twigs until they terminate in very minute vessels. The enlargement of the breasts is one of the signs of womanhood. Their fullest development commences in the earlier stages of pregnancy, and they continue to increase in size until about the time of delivery, when they are filled with the lacteal fluid, which passes readily on suction into the mouth of the child. The breasts of females are subject to a variety of disorders, one of the most common of which is inflammation. It may be produced by various causes, as a blow, exposure to cold or wet, great mental excitement, excessive accumulation of milk, or undue pressure on the parts. It occurs most frequently within the first three months after parturition, and is characterized by great heat, pain, redness, and swelling of the breasts. The pain is intense, and of a throbbing nature, and often extends to the axillary glands. The breasts become tense, heavy, and painful to the touch; and there is high inflammatory fever. The treatment consists in the application of warm fomentations to the part, and the administration of purgatives. If the inflammation do not subside in a few days, suppuration may be expected. In general the abscess may be left to nature; but when it occasions much pain it is advisable to get rid of it by a free incision. Chronic inflammation sometimes seats in the breasts, in which case stimulant applications will be found useful. Where this is attended with abscess, it should be opened, so as to give free exit to the pus, and pressure applied to the part. The breast is also subject to various kinds of tumours, some of which may be got rid of by simple pressure, and attendance to the general health. Sometimes some of the lactiferous ducts are blocked up, producing an enlargement termed lacteal tumour. It is to be remedied by puncturing the duct, and keeping it open for some time. Occasionally great pain and uneasiness is felt in the breast from sympathy with other parts of the system. There is no inflammation, swelling, or external alteration of the mamma, and yet the pain is excessive, usually intermittent. In this case the general health is chiefly to be looked after. Women are frequently subject to *sore nipples* after childbirth, occasioning great pain. In such cases care is to be taken to keep the nipples as dry as possible; and an application of glycerine is generally found useful. Nipple-shields of ivory or glass, with India-rubber teats, should also be used when the nipples are too tender to bear the application of the child's mouth. The most terrible disease to which the breast is subject is cancer. (*See* CANCER.)

BREATH, *breth* (Sax., *brath*), is the air which is inhaled and expelled in respiration. (*See* RESPIRATION.) Much can be gathered by the skilful physician as to the condition of the internal organs from the manner of breathing—if it be short and rapid, slow and laboured, painful, &c. *Fetid*, or *offensive breath*, to which some people are subject, may arise from a variety of causes, and is to be treated in as many different ways. Sometimes it is owing to a deranged state of the digestive organs, and in this case purgatives and tonics are to be administered. Occassionally it arises from a diseased condition of parts about the mouth or nose, as decayed teeth or morbid secretions about the tonsils. In such cases, the teeth should be frequently cleaned, and the mouth should be washed with a weak solution of chloride of lime or soda. Inhalation of steam from hot water, into which some creosote has been dropped, is recommended in cases in which the cause resides in the nose and respiratory passages. The injection of a lotion of sulphate of zinc or copper, by means of a syringe, into the nostrils will frequently be of use when the disorder has its seat there. Fetid breath may also arise from a diseased state of the lungs. Where it cannot be remedied, it will be well for the patient to chew a little cinnamon occasionally, or to take some of the aromatic pills prepared for the purpose.

BRECCIA, *brech'-cha* (Ital., a crumb or fragment), a rock consisting of angular fragments bound or cemented together by calcareous, ferruginous, or silicious matter. Such a rock differs from a *conglomerate*, or *puddingstone*, in having its component fragments irregular and sharp, whereas the pebbles of the latter are rounded and water-worn. (*See* CONGLOMERATE.)

BREEZE (It., *brezzia*), a shifting wind that blows during certain hours of the day and night, from sea and land alternately, and is only sensibly felt near the coast. The sea-breeze generally rises about 9 in the morning, proceeding slowly, in a fine curl on the water, towards the shore, gradually increasing until 12, and dies away about 5, when it is succeeded by the land-breeze, which also continues increasing until midnight, and is again followed, in the morning, by the sea-breeze. Breezes differ from *etesiæ*, or trade-winds, inasmuch as the former have their periods daily and nightly, and are only found near the coast, while the latter are annual and blow at a distance from land. (*See also* WIND.)

BREEZE-FLY. (*See* BOT-FLY.)

BRENT GOOSE. (*See* GOOSE.)

BREVIPENNES, *brev'-i-pen-nes* (Lat., short-winged).—A term applied to several birds of the order *Cursoria*. (*See* BIRDS.) Their wings are too short to enable them to fly, but are useful as an assistance in running. Their bodies are massive, and the muscles of the thighs and limbs are enormously thick, and they are generally able to run with great rapidity. The ostrich, emu, and cassowary belong to the brevipennes; and the gigantic *Dinornis*, and other fossil birds, belonged to the same class. All the brevipennes shun the presence of man, and generally inhabit desolate and solitary localities. Many of them, such as the emu and cassowary, are becoming very rare. The extinct Dodo belonged to the same order. The extinct and gigantic birds, whose footsteps are found on sandstones in Connecticut valley, appear also to have belonged to this tribe.

BRIGHT'S DISEASE, or GRANULAR DISEASE OF THE KIDNEYS, *brites*, is a particular disease of the kidneys, named after the late Dr. Bright, who first pointed out its nature and character. It consists in a degeneration of the tissues of the kidneys into fat, by which their secreting powers are impaired, and the urea is not sufficiently separated from the blood. The distinguishing characteristic of this disease is the existence of albumen in the urine, which, though not invariably, is almost always present, and is readily detected by its coagulating on the application of heat. Healthy urine contains no albumen, which is the great agent in nutrition. It is obtained here at the expense of the serum of the blood, and no disease so closely approaches hæmorrhage in its power of impoverishing the blood and exhausting its red particles. Hence arises that waxy and leucophlegmatic aspect which so strongly characterizes this complaint. Patients labouring under this disease are liable to inflammatory and congestive states of other important organs; and hence coma, convulsions, and apoplexy may occur during its progress. The heart, too, may become implicated, and dropsy almost always occurs, sooner or later. This disease may be occasioned by severe cold, repressed perspiration, or immoderate use of ardent spirits, and it not uncommonly follows scarlet fever. In the treatment, the secretions of the skin are to be encouraged by the use of warm baths and diaphoretics, and the dropsical tendency is to be counteracted, as far as possible, by purgatives and diuretics. Local bleeding is frequently beneficial, but general bleeding is to be avoided, from the exhausting tendency of the disease. The disease is, in some medical works, named Nephria.

BRILL, *bril* (*Rhombus vulgaris*), a fish resembling the turbot in shape, but inferior to it both as regards size and quality. The London market is chiefly supplied from the southern coast of England, where the brill is very plentiful. The brill is distinguished from the turbot by the perfect smoothness of its skin, which is covered with small scales, and marked with yellowish or rufous spots. As is the case with the turbot, the lateral line first describes an arc over the pectoral fins, and then runs straight to the tail. The brill very seldom attains an equal weight with the turbot, rarely going beyond 7 lb. It is found both in deep water, as well as in sandy bays.

BRIMSTONE, *brim'-stone* (Sax., *brenne stone*, a stone that burns.) (*See* SULPHUR.)

BRINE, *brine* (Sax., *bryne*), water saturated or highly impregnated with common salt. Brine is either natural, as when it flows from brine-springs, or artificial, when it is formed by dissolving salt in water. Brine-springs are fountains which flow with salt water instead of fresh. (*See* SALT and SPRINGS.)

BRINE SHRIMP (*Artemia salina*), a small crustacean of the order *Branchipoda*, found in salt water. It is about half-an-inch long, almost transparent and very lively in its movements.

BRINJAREE DOG, *brin-ja-re'*, a long-haired variety of greyhound, used in India for hunting, larger and stronger than the Persian greyhound, but inferior to the British greyhound in swiftness. It is generally of a yellowish or tan colour.

BRISTOL DIAMONDS, *bris'-tol*, small brilliant hexagonal crystals of white quartz, found in the limestone at Clifton, near Bristol.

BRITTLENESS, *brit'-tl-ness* (Ang.-Sax.), a property possessed by some bodies, which, although solid, have their component particles so arranged that the cohesive force which holds them together is overcome by comparatively small mechanical force. They can easily be reduced to powder. Brittleness is the reverse of malleability: as an instance, lead is malleable and glass is brittle.

BRITTLEWORTS. (*See* DIATOMACEÆ.)

BRIZA, *bri'-za* (Gr., *brizo*, I nod, on account of the quaking character of the spikelets), a genus of grasses, commonly known as Quaking-grass, or Maiden-hair. Two species are natives of Britain, the *B. major* and *minor*. Their dense clusters of flowers hang upon the ends of very delicate filamentous peduncles, forming elegant panicles, which shake with the slightest breath of air.

BROAD BILL. (*See* SHEVELLER.)

BROCCOLI, *brok'-o-le* (Ital., sprouts), the name given to one of the many cultivated varieties of the *Brassica oleracea*. It is a common garden vegetable, and differs from the cauliflower only in having coloured instead of white heads. (*See* BRASSICA.)

BROKEN KNEES, the abrasion or more serious injury sustained by a horse from stumbling. The value of a horse which has suffered from broken knees is deteriorated, as it is presumed to be unsafe.

BROKEN-WIND, a disease or unsoundness in horses, caused by a morbid secretion from the mucous membrane lining the larynx and the windpipe, with its many ramifications. The nature of the disease is not well understood, and the present mode of treating it is very unsatisfactory. Broken-wind is in reality incurable; and all that a veterinary surgeon can do is to mitigate the disease. Low-bred horses, which do not thrive, are most liable to broken-wind. While the horse is being exercised, the symptoms can be best observed. The eyes becomes suffused with blood, which is mostly impure, the nostrils are distended, and the breathing becomes very laboured. A broken-winded horse has always a hollow cough, and, if watched while at work, the ribs are noticed to be actively moved, and after the air is expelled from the lungs they are depressed with a sudden jerk, produced by the abdominal muscles. When employed on hard work, broken-winded horses often drop down and die from exhaustion or from suffocation, internal hemorrhage, or congestion of the lungs.

BROME-GRASS. (*See* BROMUS.)

BROMELIA, *bro-me'-li-a* (named after Bromel, a Swedish botanist), the typical genus of the natural order *Bromeliaceæ*. The green fruit of *B. pinguin* is used to destroy worms, and as a diuretic in the West Indies: the prickly leaves yield strong fibres, which are twisted into ropes, and woven into coarse cloth.

BROMELIACEÆ, *bro-me-li-ai'-se-e*, the

Bromelia, or the Pine-apple family, a natural order of monocotyledonous plants, sub-class *Petaloideæ*. Leaves persistent, crowded, channelled, rigid, sheathing at base, and frequently scurfy and with spiny margins; flowers showy; perianth superior, or nearly or quite inferior, arranged in two whorls, the outer of which has its parts commonly united into a tube, while the inner has its parts distinct, imbricated, and of a different colour; stamens 6; anthers introrse; ovary 3-celled, with a single style; fruit capsular or indehiscent, and 3-celled; embryo minute, in the base of mealy albumen, with the radicle next the hilum. There are 28 genera and about 175 species, which are distr buted through the tropical regions of America, West Africa, and the East Indies. They are chiefly important for yielding edible fruits and useful fibres. Some have worm-destroying properties, and others contain colouring matters. (*See* ANANASSA, BROMELIA, BILLBERGIA, TILLANDSIA.)

BROMUS, *bro'-mus* (Gr., *bromos*, wild oat), Brome-grass, a genus of plants belonging to the natural order, *Graminaceæ*. Many of the species are very common British grasses, especially the soft Brome-grass, which has soft downy leaves and is much liked by cattle. It is supposed but not sufficiently established that the seeds of Brome-grass are poisonous. Field Brome-grass and tall Brome-grass are very common.

BRONCHI, *bron'-ke* (Gr., *bronchos*, the windpipe), is the name given to the subdivisions of the trachea, or windpipe, which proceed to the lungs. The trachea divides into the two bronchi opposite the third dorsal vertebra. The right bronchus is larger than the left, and is shorter, reaching the lung on a line with the fourth dorsal vertebra. The left bronchus passes under the arch of the aorta. The structure of the bronchi is similar to that of the trachea, being round and cartilaginous in front, and flat, with muscular and fibrous tissue, behind. On entering the substance of a lung, the bronchi divide and subdivide into numerous branches, till they terminate in very minute air-cells.

BRONCHITIS, *bron-ki'-tis*, or inflammation of the lining membrane of the bronchial tubes. The great exciting cause is cold, especially when combined with moisture; but whatever tends to diminish the general vigour of the system, and excesses of every kind, predispose to it. Any sudden change of temperature is apt to produce it. It is especially prevalent during the spring months. Its first symptoms are generally those of a common cold, accompanied with an occasional cough and a sense of weariness and headache. The cough increases, and there is a feeling of oppression in the chest, and the breathing produces a kind of wheezing noise. The pulse is rapid and weak, and there is extreme lassitude, with pain in the limbs, mental heaviness, &c. If the feverish symptoms increase, the breathing becomes difficult from the clogging of the tubes with mucus, which is, to some extent, expectorated during the cough. In severe cases, the symptoms become more and more alarming; the breathing becomes so embarrassed that the patient can no longer lie down, but requires to maintain an upright posture and use all his muscles in respiration. At last, he is so exhausted that he ceases to expectorate, and dies of suffocation from the accumulated mucus, usually in from five to seven days. Even in less severe cases, the delicate respiratory tubes are frequently permanently injured; so that the proper aëration of the blood is interfered with. The treatment of this disease will vary, according to its nature and the constitution of the patient; and the necessity of always having recourse to a medical man cannot be too strongly insisted upon. The great object of the treatment is to reduce and remove the inflammatory condition of the organs: hence, a mustard-poultice should be applied to the chest, the feet bathed in hot water, and warm diluent drinks, as barley-water or linseed tea, given. It is frequently necessary to have recourse to emetics, in order to remove the accumulations of mucus. The bowels should be kept moderately open during the whole course of the disease. (*See* CATARRH, COUGH.)

BRONCHOCELE. (*See* GOITRE.)

BRONCHOTOMY. (*See* TRACHEOTOMY.)

BRONZITE, *bron'-zite*, a variety of diallage (*see* DIALLAGE) occurring in serpentine and greenstone. It is found in dark green foliated masses, with a pearly metallic lustre resembling bronze; whence its name. Chemically it is a silicate of magnesia, containing small portions of lime, protoxide of iron, manganese, alumina, and water.

BRONZE-WING, a name given to some species of pigeons in Australia, on account of the beautiful bronze colour of their wings. The best known species are the *Columba chalcoptera*, or ground dove; the *C. elegans*, the Brush Bronze-wing, and the *C. histrionica*, or pale green Bronze-wing.

BROOKITE, *brook'-ite*, oxide of titanium, crystallizing in thin masses; found on Snowdon and in Dauphiny.

BROOM. (*See* CYTISUS.)

BROOM-RAPE. (*See* OROBANCHACEÆ.)

BRORA BEDS; *bro'-ra*, a series of strata, containing coal seams of good quality, occurring at Brora, a village in Sutherlandshire. They are of the same age as the inferior oolite of Yorkshire.

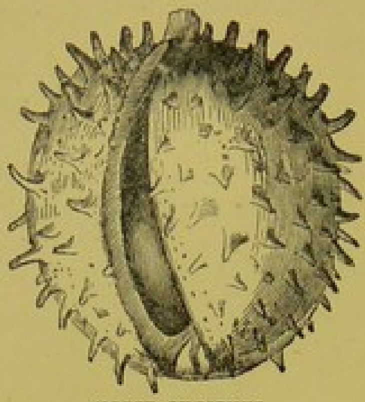
BROSIMUM, *bro'-si-mum* (Gr., *brosimos*, eatable), a genus of plants belonging to the natural order *Artocarpaceæ*, or Bread-fruit family. The species *B. utile*, sometimes called *Galactodendron utile*, is the celebrated palo de vaca, or cow-tree, of South America. It yields a milky juice, said to be almost as nutritious as milk from the cow. From the bark of *B. namagua* strong fibres are obtained, which are much used in Panama for making sail-cloth and ropes.

BROUSSONETIA, *broo-so-ne'-ti-a* (in honour of M. Broussonet, a French naturalist and traveller), in Botany, a genus of plants belonging to the natural order *Moraceæ*. There is but one species, *B. papyrifera*, the paper mulberry, the bark of which is used in China and Japan as paper material, and in the South Sea Islands for making a kind of cloth. The plant forms a small tree, with soft, brittle, woolly branches, and large, hairy, rough leaves, either heart-shaped and undivided, or cut into deep irregular lobes.

BROWN COAL, *broun kole*, a name used for lignite, in contradistinction to fine coal, which is black. (*See* LIGNITE.)

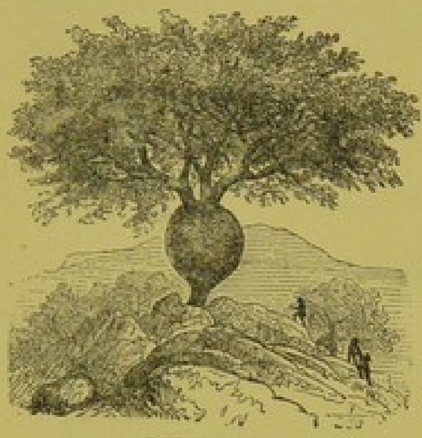
BROWN SPAR. (*See* DOLOMITE.)

CHAFFINCH.

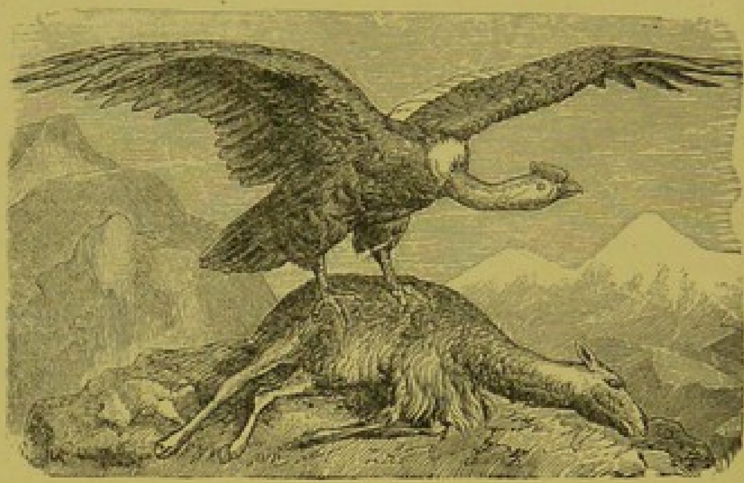


HORSE CHESTNUT.

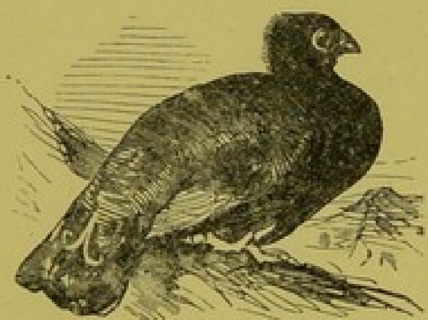
CURASSOW.



BOTTLE-TREE.



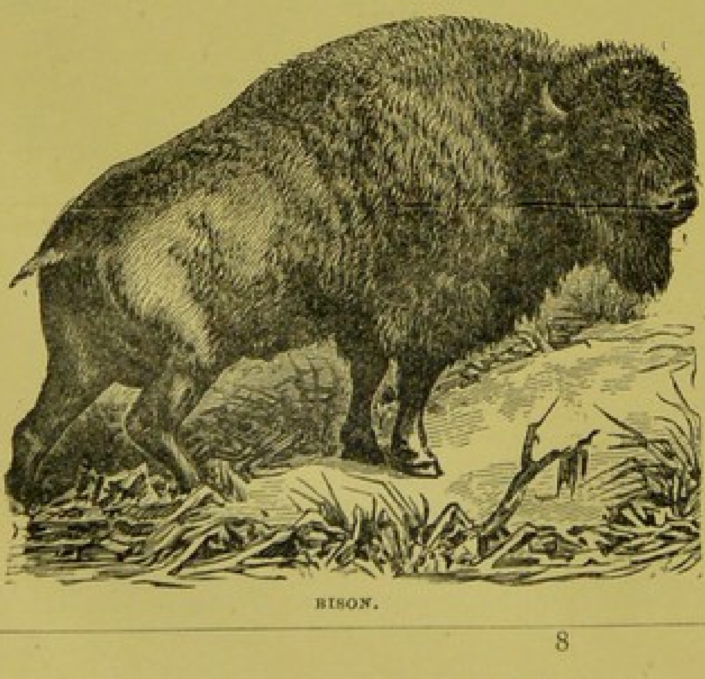
CONDOR.



CAPERCAILZIE.

WILD BOAR.

BLACKBIRD.



BISON.

BIRCH.

BRUCEA, *bru'-se-a*, a genus of shrubs, natives of Abyssinia, the Indian archepelago, and China, the leaves of which are tonic and astringent. The name is taken from James Bruce, the traveller in Abyssinia.

BRUCINE, *bru'-sine*, an alkaloid occurring in large quantities in conjunction with strychnia in the *strychnos nux vomica*. It is less marked in its properties than strychnia, which it closely resembles. It crystallizes in colourless transparant rhombic prisms, which are insoluble in ether. Its poisonous properties are less active than those of strychnia. (*See* STRYCHNIA.)

BRUCITE, *bru'-site*, a fibrous hydrate of magnesia, occurring in silky greyish or bluish-white masses. A name given to chondrodite or chrysolite.

BRUNIACEÆ, *bru-ne-ai'-se-e*, the *Brunia* family, a natural order of dicotyledonous plants in the sub-class *Calyciflorœ*. They are small heath-like shrubs, found at the Cape of Good Hope and in Madagascar. Their properties and uses are unknown.

BRUNONIAN SYSTEM OF MEDICINE, *bru-no'-ni-an*, was founded by Dr. John Brown, a Scottish physician, who flourished towards the end of last century. His system is explained at large in his "Elementa Medicinæ," published in 1780. It found numerous supporters, and gave rise to much opposition. According to him, all diseases are of two kinds—*asthenic*, or diseases of weakness, or debility; and *sthenic*, or diseases of excess of strength. His mode of treating diseases, therefore, had for its object merely the increasing or diminishing of excitement, without regard to their particular symptoms. The doctrine, in its original form, may be considered as exploded; but more recently a sect has arisen, principally in Italy, who profess a modification of the Brunonian system, and who are known as Modern Brunonians. They advocate what is known as the *contra-stimulant* mode of treatment of disease.

BRUSH-TURKEY (*Talegalla Lathami*). This bird, called also the Wattled Tallegalla, inhabits New South Wales. It is about the size of a common turkey three parts grown. The whole of the upper surface is of a blackish-brown, the feathers of the chest edged with silvery grey. The skin of the head and neck is of a deep red, and the neck is ornamented with a bright yellow wattle. The most curious circumstance connected with the brush-turkey is, that it does not, like other birds, hatch its eggs by sitting on them, but collects together an immense heap of decaying vegetable matter as a depository for its eggs, and trusts to the heat evolved during the process of decomposition for the development of its young. This heap is gradually collected by the bird for several weeks previous to the period of laying, and is sometimes so large as to contain two or three cartloads.

BRUSSELS SPROUTS, a cultivated variety of *Brassica oleracea*, producing in the axis of the leaves small clusters of leaves which form miniature cabbages, they make a delicate table vegetable; chiefly in winter and spring. The seed is sown in February or March.

BRYACEÆ, *bry-ai'-se-e* (Gr., *bruo*, I sprout), Urn-mosses, a sub-order of the Moss family. (*See* MUSCI.)

BRYGMUS, *brig'-mus* (Gr., *brucho*, I grind my teeth), grinding of the teeth, or the gnashing and chattering of the teeth which takes place in epilepsy and other convulsive disorders.

BRYONIA, *bri-o'-ne-a* (Gr., *bruo*, I sprout), in Botany, a genus of plants belonging to the natural order *Cucurbitaceœ*. The most interesting species is *B. dioica*, the red-berried bryony, or wild vine, an indigenous perennial, growing in hedges and thickets, and blossoming during the month of May. The flowers are yellowish-white, with green streaks, and are diœcious; that is, the male and female flowers are borne by distinct plants. The stems are put forth annually, and climb by means of tendrils. The root is large, white, and is sold by herbalists under the names of white bryony and mandrake-root. (For the true mandrake, *see* MANDRAGORA.) The root contains a peculiar bitter principle, termed *Bryonin*. It is a violent emetic and purgative, and is highly poisonous, giving rise to symptoms much resembling those of cholera. It is stated to be frequently used by quack doctors in the country, and is employed as a topical application to bruises. *B. alba*, *Americana*, and *Africana*, have similar properties.

BRYUM, *bri'-um*, a genus of Mosses in the sub-order *Bryaceœ*. The species are very numerous, and many of them are natives of Britain. Their stems are short, and their leaves form tiny rosettes, from the centre of which the fruit-stalks spring.

BUAZE, *bu'-aize*, a South-African plant, found growing in the Maravi country by Dr. Livingstone. It affords a remarkably strong fibre, which is used by the natives for stringing beads upon. The botanical characters and relations of the plant have not yet been ascertained.

BUBALUS, OR BUBALIS, *bu'-ba-lus*, an antelope of Northern Africa, about the size of a large stag, with head and muzzle very like those of an ox, and two curved horns with the points directed backwards. The general colour is reddish brown, and the tail has a black tuft. It is easily domesticated.

BUBBLE, *bub'-bl* (Du., *bobble*), a small vesicle or bladder of water, or any other fluid inflated with air or gas.

BUBO, *bew'-bo* (Gr., *boubon*, the groin), a swelling of a lymphatic gland, particularly those of the groin or armpit. It may arise from mere irritation or some local disorder, in which case the bubo is termed sympathetic; or it may arise from the absorption of some irritating matter, or from constitutional causes.

Bubo. (*See* OWL.)

BUBONOCELE, a term applied to inguinal hernia. (*See* HERNIA.)

BUCCAL, *buk'-kal* (Lat., *bucca*, the cheek), denotes of or belonging to the cheek; as, the *buccal artery*, which is a branch of the internal maxillary; the *buccal glandules*, small mucous glands, or follicles, situated within the cheek, under its lining membrane.

BUCCINATOR, *buk-si-nai'-tor* (Lat., *buccina*, a trumpet), a muscle of the cheek, so called from being brought much into play by trumpeters.

BUCCINUM. (*See* WHELK.)

BUCEROS, *bu'-se-ros.* (*See* HORNBILL.)

BUCHU LEAVES. (*See* BAROSMA.)

BUCK, *buk* (Saxon, *bucca*), the male of the fallow deer. A buck is called a fawn in his first year; a pricket in his second; a sorel in his third; a sore in his fourth; a buck of the first head in his fifth; and a great buck in his sixth. The female of the buck is termed a doe. The male of the red deer is termed a stag, or hart, and never called a buck. (*See* DEER, STAG.)

BUCKBEAN, OR MARSH TREFOIL, *buk'-been,* a very beautiful plant (*Menyanthes trifoliata*) of the natural order, *Gentianeæ*, the only known species of its genus. It is common in Britain and in cold regions, grows in marshy places, and has long and closely matted roots which often make boggy ground firm. The stalk is long, and bears from ten to twenty white flowers, tipped with red. The leaves are very bitter, and a valuable medicine in cases of dyspepsia and disorders of the bowels is obtained from them. In Germany the plant is sometimes used as a substitute for hops.

BUCKEYE. (*See* HORSE CHESTNUT.)

BUCKHOUND, *buk'-hound,* a kind of dog formerly very common in England, but comparatively rare now. It was used exclusively for buck-hunting, and closely resembles the staghound but is smaller. Many varieties of hounds, beside the buckhound, are now used for deer-hunting.

BUCKLANDIA, *buk-lan'-de-a,* a magnificent evergreen tree of the natural order, *Hamamelideæ*, growing on the Himalaya Mountains. It grows unbranched to the height of 40 feet, and is not unfrequently seven feet in girth, with thick, bright, and glossy foliage.

BUCKTHORN. (*See* RHAMNUS.)

BUCKU, *buck'-u,* a name given to several small shrubs of the genus Barosma, natives of South Africa. They are used in medicine on account of their powerful action on the urinary organs.

BUCKWHEAT. (*See* FAGOPYRUM.)

BUD, *bud* (Du., *bot.*), the organized rudiment of a branch or flower. Buds which produce leaves, and have the power of extending into branches, are called *leaf-buds;* while those which produce flowers only, and are ordinarily destitute of this power of extension, receive the distinctive appellation of *flower-buds.* Theoretically considered, however, a flower-bud is merely a modified leaf-bud; for all the different parts of a flower may be regarded as altered leaves. A leaf-bud usually originates in the axil of a previously-formed leaf, the terminal bud of a branch being no exception to this rule. Every leaf has one or more of these organs in its axil, either in a rudimentary or perfect state. Whether lateral or terminal, each bud consists at first of a minute conical cellular mass, which communicates with the cellular tissue of the stem or branch. Around this, spiral and other vessels and wood-cells are soon developed, and these are also connected with similar parts of the wood. Outside all, in a cellular substance, which ultimately becomes the bark, the rudimentary leaves are developed. By the growth of these parts, a little conical body is produced, which, under favourable circumstances, develops into a branch resembling in every respect the parent axis. In temperate and cold climates, the buds, which remain dormant during the winter, are generally covered with modified leaves, called *scales.* These protective organs are usually of a hardened texture; sometimes they are covered with a resinous secretion, as in the horse-chestnut and several species of poplar; and sometimes they have a dense coating of soft hairs, or down, as in some of the willows. Buds thus protected are said to be *scaly.* In the buds of tropical regions, and those of herbaceous plants which are never exposed to the cold of winter, such protective organs would be useless, and are accordingly absent. These buds are distinguished as *naked.* In a few instances, even buds of perennial plants growing in cold climates are naked, like those of tropical plants: such is the case with the alder, and with the buckthorn. Within the leaf-bud the future leaves are often very curiously folded, or rolled up, and the different positions which they assume are highly characteristic of different kinds of plants. Leaf-buds are sometimes *extra-axillary;* that is to say, they are occasionally developed in other positions besides the axil of leaves. Such buds are termed *adventitious* or *abnormal.* The woody nodules, called *embryo-buds*, seen in the bark of the beech, elm, and other trees, are looked upon as partially-developed abnormal buds, in which the woody matter has been hardened by the pressure of the surrounding tissue. The nodules sometimes form knots on the surface of the stem; at other times they appear as large excrescences; and in some cases twigs and leaves are produced by them. Adventitious buds are produced naturally on the edges of certain leaves, and on the surfaces of others. These are capable of forming independent plants. Similar buds may be made to appear on the leaves of *Gesnera*, *Gloxinia*, and *Achimenes*, by wounding various parts of them, and placing them in moist soil: this is the method often pursued by gardeners in their propagation. Flower-buds, like leaf-buds, are ordinarily axillary, being produced in the axil of floral leaves or bracts. They cannot be used for budding, for they always die when removed from the parent stem. (*See* LEAF, FLOWER, BULB.)

BUDDLEA, *bud-le'-a* (after Adam Buddle, an English botanist of the 17th century), a genus of plants belonging to the natural order, *Scrophulariaceæ*. The species are shrubs, natives of the warmer regions of the world, and are remarkable for their gay and sweet-scented orange-coloured flowers. *B. neemda* is said to be one of the most beautiful plants of India. *B. globosa*, a native of Chili, is hardy enough to endure the climate of most parts of England, and has become a common ornament of our gardens.

BUFFALO, *buf'-fa-lo,* (Ital. and Span., *bufalo.*) This animal (*Bos Bubalus*) differs from the bison in having no hump on the back, and only a small dewlap on the breast. Besides this, it carries no shock of hair about its neck and shoulders. Buffaloes generally live in flocks of about a hundred, and affect marshy regions, both on account of the coarse but luxuriant vegetation there to be found, as well as the opportunity for a "mud" bath, of which the buffalo is remarkably fond. The way he indulges this predilection is singular: throwing himself flat upon his side in the mire, he shuffles round and round, the soil yielding to his immense weight the exudation of any moisture it may contain, till he manufactures for himself a delicious basin of mortar covering him to his very eyes. When he emerges and has basked awhile in the sun, he looks like some hideous slack-baked clay image. This manœuvre, however, is not without purpose. Among the rank vegetation, and in the air, swarm millions of stinging flies, and until the buffalo's mud coat peels off through long wear, he is as impregnable to their attacks as the clay image he represents. The buffalo is one among the very few animals who manifest no fear at the approach of the tiger; indeed, sportsmen concur that unless a tiger be full-grown, and in possession of all his strength, he will not venture to attack the bull buffalo. Should the tiger, made desperate by hunger, attack a herd of buffaloes, his fate is certain. The whole herd will band against the common foe, and, assailing him with hoofs and horns, trample him maimed and crushed into the mire. In India, Egypt, and the south of Europe, the buffalo is employed as a beast of burden. It is larger than the ox, and more powerful, but generally very docile. The Cape Buffalo (*Bos Caffer*) is generally regarded as a distinct species. It has immense horns spreading in a dense mass over the top of the head. It has never been domesticated; and is regarded by hunters as the most formidable beast of South Africa. The Kaffirs make shields of its impenetrable hide.

BUG, *bug* (probably Welsh *bwg*), a name given, especially in America, to a large family of insects, *Cimicidæ* of the order *Herupitera*. In England the name is commonly limited to the too familiar and abominable bed-bug (*Cimes lectutarius*), which differs from other members of the family in having no wings, which is the only point in their favour, for if they could fly, life, where they abound, would be unendurable. It is commonly asserted, though with what degree of truth it is hard to say, that before the year 1670 the insect in question was unknown in England, and that it was imported from America with the timber that country furnished for the rebuilding of London after its destruction by the great fire. The female bug deposits her eggs at the beginning of summer: they are small, white, and of an oval shape, each being fixed to a hair-like glutinous stalk, ready to adhere to anything it touches. Some members of the bug family suck the blood of birds and small animals; but many live on the juices of vegetables, some of the winged bugs of tropical climates are as large as cockchafers. They suck blood and emit a most revolting odour.

BUGLE, in Botany. (*See* AJUGA.)

BUGLOSS. (*See* ANCHUSA.)

BUHR-STONE, *boor*, a name given to certain quartzose rocks the worked surfaces of which possess the property of cutting or grinding. They are used principally as millstones. The best kinds are creamy white, with a granular and somewhat cellular texture, and are obtained in the tertiary formation of the Paris basin and the surrounding district. They are cut into wedge-shaped parallelopipeds called *panes*, which are bound together with iron hoops to form large millstones.

BUKKUM-WOOD. (*See* CÆSALPINIA.)

BULB, *bulb* (Lat., *bulbus*), a shortened stem or branch, usually subterranean, bearing on its surface a number of fleshy scales, which are modified leaves. It is only found in monocotyledonous plants, and is seen in the hyacinth, lily, and onion. The bulb may be looked upon as a subterranean leaf-bud, arising from a shortened axis. From its centre an herbaceous stem arises, and from the subterranean axis new bulbs, or *cloves*, as they are called, are produced. Every new bulb is formed in the axil of a scale, like a bud (which *see*); sometimes it remains attached to the parent bulb, and sends up an axis and leaves; at other times, it is detached in the course of growth, and forms an independent plant. The new bulbs feed on the parent one, and ultimately cause its complete absorption. The scales are generally thickened by the decomposition of nutritive matters, intended for the future use of the plant. In the onion, squill, and leek, these scales are covered externally by thin membranous coats or tunics: hence the bulbs are said to be *tunicated*. When the membranous coats are absent, the bulb is said to be *naked* or scaly, as in the white lily. The solid rounded underground stem, called by botanists a *corm*, is commonly regarded as a bulb. (*See* CORM.)

BULBILS, OR BULBLETS, *bul'-bils*, small conical or rounded bodies produced in the axil of the leaves of some monocotyledonous plants, and which are of the nature of bulbs. They can be readily distinguished from ordinary leaf-buds by their fleshy character. They are easily detached from the parent stem, and, when placed in favourable circumstances, they produce new individuals. They may be seen in *Lilium bulbiferum*, *Dentaria bulbifera* (coral-wort), and *Ranunculus ficaria* (pilewort).

BULIMIA, *bul-i'-mi-a* (Gr., *bous*, an ox, and *limos*, hunger), denotes an insatiable craving for food. The real nature of this disease is very imperfectly known. In some cases, the health appears to be otherwise good; but usually bulimia is a concomitant of other diseases. Its consequences are leanness, pulmonary fevers, consumption, or dropsy.

BULL, (Dutch, *bulle*), the male of the *bos* or bovine genus of quadrupeds, of which the cow is the female.

BULLA, a genus of molluscous animals with univalve shells, whose general characteristics are,—that the shell is sub-oval, that the aperture is oblong and smooth, and that one end is a little convoluted. The animal breathes by gills, but has no respiratory tube, and consequently the margin of the aperture of the shell is entire. Most of this genus, especially of the larger sizes, are furnished with an organ exactly resembling the gizzard of a fowl, and which they appear to use for the purpose of masticating their food. All the species are marine, and some are found on the British coasts.

BULLACE, *bul'-laise*, the English name of a kind of plum, the *Prunus insititia*. (*See* PRUNUS.)

BULL-DOG, *bull'-dog* (*Canis molossus*), a variety of the dog, remarkable for its broad, short muzzle. It is generally looked upon as an essentially English dog; but there is a doubt as to whether it has not existed as a definite race since the time of the Romans, or whether it is not a recently-formed variety of mastiff. It is smaller than the mastiff, and has a massive head;

the forehead sinks between the eyes, and the nose-line rises again at a considerable angle; the lower jaw projects in a remarkable manner beyond the upper, continually showing the teeth; the lips are thick and pendulous, the neck strong and thick, and the legs short. The projection of the under-jaw and the livid redness of its eyes give the bull-dog a fierce and forbidding aspect, often heightened by a designing leer, which seems natural to the animal. The strength and courage of bull-dogs are proverbial. They will attack any animal, utterly regardless of its strength and size. They were formerly much used for bull-baiting; since the abolition of which sport, the breed has decreased in numbers. One of these dogs will seize an ox by the nose, and, with apparent ease, hold him still, or throw him on his side, as he is ordered by his master. When trained for the purpose, they fight very savagely with one another; and in certain of the mining and manufacturing districts of England this sport is still carried on. On growing old, the bull-dog becomes very vicious and dangerous, often inflicting severe bites on the slightest provocation. The bull-terrier is a cross between the bull-dog and the terrier. It is more pugnacious even, if less doggedly ferocious, than the bull-dog itself; but possesses also more amiable qualities and exhibits great affection towards its friends.

BULLET-TREE, OR BULLY-TREE, a tree supposed to belong to the genus *Mimusops*, in the natural order *Sapotaceæ*. It is a native of Guiana, and much valued for its timber, which is hard and durable. It yields a delicious fruit about the size of a cherry.

BULLFINCH, *bull'-finsh* (Ang.-Sax.), a song-bird, *Pyrrhula vulgaris* of the family of *Fringillidæ*, common to all parts of England and Europe generally, and throughout Asia. It is about the size of the common hedge-sparrow, but of bulkier build, the bill is short, strong, and of a blue-black colour. On the upper part of the head, round the base of the beak, and forming a chin-shaped patch beneath, jet black predominates; the back is ash-grey; breast and belly dusky read; wings and tail black; upper tail-coverts white; legs dark brown. The female resembles the male, except that her colours are less distinctly marked, and her under-parts are rather russet than red. The bullfinch has acquired considerable celebrity from the facility with which it learns to whistle airs. Training bullfinches to "pipe" is a mode of making money frequently practised in Germany: considerable pains are requisite, the time required frequently extending to nine months. The bullfinch is very easily domesticated and becomes very fond of those who feed and notice it.

BULL-FROG (*Rana pipiens*), the largest of the species *Rana*, or Frogs. It is generally six to eight inches long, exclusive of the feet, and four inches broad. It is an inhabitant of North America, particularly of the southern states. At a distance, its voice resembles the lowing of a bull; hence its name. The fore feet of the bull-frog are unwebbed, and have only four toes; but the hind feet, which are long, are webbed very widely. Its colour is a dull olive, marked irregularly with dark stains; the belly, however, is of a pale green colour, thickly spotted. The bull-frog frequents springs only where the constant running of water has made a deep pool. Scarcely a spring of this description is without a pair of these frogs. They prey on young ducks and geese, which they swallow whole; it is also believed that they keep the springs in which they reside wholesome. The hind legs are eaten, and are said to be of good flavour.

BULLHEAD OR MILLER'S-THUMB, *bull'-hed* (*Cottus Gobio*), a small fish, common to brooks and rivers. It is about four inches long, with a large roundish head, and a capacious mouth, formidably filled with teeth. It is generally found under loose stones at the bed of the stream, and is seemingly so insensible to danger, that, should half-a-dozen of them be lying together, the juvenile angler may capture the whole by continuing to drop in his bait till they are all hooked. A seafish of a nearly allied genus, *Aspidophorus*, is sometimes called the Armed Bullhead.

BULL-TROUT, *bull'-trout* (*Salmo Eriox*, or *Salmo griseus*). This fish, which is often called the Grey Trout in England, and the Sewen in Wales, is nearly allied to the salmon. It generally lives in the sea, but deposits its spawn in rivers. Its form is not so elegant as that of the salmon; its head and neck are thicker, and its tail more bulky in proportion. The colour of the male is reddish brown, and that of the female dark grey; their scales are smaller than those of a salmon of equal size. Anglers look upon the bull-trout as ranking next to the salmon as regards sport. It is usually under 15 lbs. weight, but some attain a weight of 20 lbs. The flesh, which is lighter coloured than that of the salmon, is coarser, and has not so delicate a flavour. The name has also been given to the salmon of the Danube (*Salmo Hucho*) a very much larger fish.

BULLRUSH, *bull'-rush*, the popular English name for any large rush-like plant growing in marshes. (*See* TYPHA, SCIRPUS.)

BUMASTUS, *bu-mas'-tus*, a genus of Silurian trilobites, remarkable for their oblong-oval or grape-like form. They occur in large numbers in the limestone of Barr, in Staffordshire, and on this account are commonly called the "Barr trilobites."

BUMMALOTI, *bum-ma-lo'-ti* (*Saurus ophiodon*), a fish taken off the coasts of India, commonly known as the "Bombay duck." The flesh, salted and dried, is highly esteemed as a relish. It is a long fish, with a large mouth, and is extremely voracious. Some naturalists class it with the Salmonidæ.

BUNIAS, *bu'-ni-as*, a genus of plants of the natural order *Cruciferæ*, natives of the Levant. One of the species *B. Orientalis*, is cultivated in France and some other countries, the leaves being used as food for cattle. In this country it is sometimes known as Hill Mustard.

BUNION, *bun'-yun* (Gr., *bounos*, an eminence), a painful inflammatory swelling of the foot, most commonly about the root of the great toe. It is caused by a gradual displacement of the bones. The pressure of tight shoes is usually the exciting cause; and, in order to remedy it, all such pressure upon the part should be avoided. Warm fomentations, or poultices, should be resorted to, in order to remove the inflammation; but surgical operation is sometimes necessary.

BUNIUM, *bu'-ni-um*, in Botany, a genus of plants belonging to the natural order *Umbelliferæ*. The species are perennial herbs, with usually tuberose and globose roots, square stems, compound leaves, and white flowers. *B. flexuosum* and *bulbocastanum*, both growing wild in this country, have edible tubers, which are commonly known as earth-nuts or pig-nuts. *B. ferulaceum*, a native of Greece, has also edible tubers, which are termed topana.

BUNT, *bunt*, a disease of wheat and other grains, caused by a parasitic fungus. It is also known as Pepper Brand and Smut Ball.

BUNTER, *bun'-ter* (Ger., variegated), the term applied by the Germans to the new red sandstone of English geologists, in allusion to its variegated colours. (*See* TRIASSIC SYSTEM.)

BUNTING (*Emberiza*), an interesting group of passerine birds, whose chief characteristic is a bill very strong, short, conical, and compressed laterally, but without any tooth or notch; the upper mandible is narrow, turned in at the edges, and with a bony knot at the palatal end, forming, as a whole, an instrument admirably adapted for breaking the rinds or shells of seeds, and ejecting them without losing any of the kernel. The Common, the Yellow, the Cirl, the Ortolan, the Snow, the Reed, and the Lapland, are the various distinguishing names of the British members of this family. Besides these there are the Black-throated bunting of the south-western and middle states of North America; the Painted bunting of South America, and the Yellow-shouldered bunting of the Cape. When the female of this last-mentioned species loses, through age, the faculty of propagating her kind, she throws off her comparatively modest attire, and appears for the rest of her life, as splendidly plumed as her mate; and so exactly like, that it is simply impossible to tell one from the other without the minutest examination.

BUPHAGA AFRICANA, *bu-fai'-ga*. (*See* BEEFEATER.

BUPRESTIDÆ, *bu-pres'-ti-de* (Gr.), a genus of hard-shelled beetles, generally very beautiful in appearance. Green would seem to be their most ordinary colour, but many are of the richest azure, spangled with gold-colour; some are vivid red, and others of a glowing copper hue. They are found on the trunks and branches of trees, and, when disturbed, will fall to the ground seemingly without life, and by this means frequently escape. There exist nearly five hundred of this genus, but not more than twenty are commonly met with in this country. One of the largest species, *B. gigores*, a native of Cayenne, is about two inches long. Some of the species are known as Golden Beetles, or, in America, Golden Bug.

BUR, BURR, OR BARB, *ber*, a very small ridge raised on the edges of lines that have been cut on a plate of metal by the action of the graving-tool or dry-point. It is generally removed by a tool called a scraper, as it gives a somewhat smeared appearance to impressions taken from the plate if it be allowed to remain. In plates engraved by Rembrandt the bur was not removed, and he managed to take advantage of it to give additional effect to his etchings.

BURATITE, *bu'-ra-tite*, a hydrated carbonate of copper, containing also zinc and lime, occurring in the radiating needles at Chesey in France, and in the Altai Mountains.

BURBOT, *ber'-bot* (*Lota vulgaris*), a fish of the same genus as the Ling, the only British fresh water fish of the family *Gadidæ*, found in many northern English lakes and rivers, and in many parts of the north of Europe and Asia. The ordinary weight is two or three pounds; but frequently that weight is greatly exceeded. It is of a yellowish brown colour, spotted with darker brown on the upper parts. The whole body is covered with a mucous secretion. The flesh is white, firm, and of good flavour.

BURITI PALM. (*See* MAURITIA.)

BURMANNIACEÆ, *bur-man'-ni-ai'-se-e*, the *Burmannia* family, a natural order of monocotyledonous plants in the sub-class *Petaloideæ*. This order is said to include 10 known genera and 38 species, natives of the tropical parts of Asia, Africa, and America. They are herbaceous plants, without true leaves, or with tufted radicle ones.

BURNET, *bur'-net*, the English name of two genera of plants belonging to the natural order *Sanguisorbeæ* (*see*). The Great Burnet (*Sanguisorba officinalis*) is a common meadow plant of Europe, and cattle are very fond of it. It is nearly two feet high and has flowers with dark red spikes. The Common Burnet (*Poterium Sanguisorba*) is rather smaller, and the flowers are of a dull purplish colour. It is common in England in the chalk districts, especially on the South Down and Salisbury Plain.

BURNING, *burn'-ing* (Sax., *byrnan*, to burn), the action of fire or heat upon any combustible matter, by means of which the constituent particles of the substance acted upon are rapidly oxidized and converted into vapour and ashes, or into calx.

BURNS AND SCALDS, *burns, skawlds*, are injuries done to the body through excessive heat; burns being produced by fire or heated solids, scalds by heated fluids. Scalds seldom penetrate deeper than the cutis; burns, on the contrary, may penetrate to any depth. Burns are more fatal in the young and old than in those of middle life, and are more dangerous on the head or trunk than on the extremities. A burn affecting an extensive surface is more to be dreaded than one which penetrates deeper without extending over much surface. Where the skin is blistered, cold evaporating lotions should be applied; as, camphorated spirits of wine, sugar-of-lead lotion, or cold water, so as to prevent the blisters from bursting, and to lessen the inflammation. The blisters may be pricked with a fine needle, in order to allow the serum to escape; but care is to be taken not to admit the air, and on no account is the raised cuticle to be removed. When the cuticle is destroyed, and the inflamed cutis exposed, spirit of turpentine is the best application that can be used in the first instance. A mixture of lime-water and milk, or of lime-water and olive-oil, will also be found useful. In more serious cases of burning, arising from clothes taking fire, the explosion of gunpowder, &c., the patient frequently, immediately after the accident, falls into a state of collapse, occasioned by the shock. Stimulants, as brandy, are to be freely administered, to prevent the patient from dying from the shock; and warm lime-warm and oil or milk, or spirits of turpentine, are to be applied to the parts. In the antiphlogistic treatment now adopted, much care has to be observed, as it is necessary to keep up the patient's strength. Poultices may be applied to the deeply-burnt parts, in order to expedite suppuration and the separation of the sloughs. When the sloughs have separated, and suppuration is established, cicatrization commences. The poultices are now to be laid aside, and moderately stimulating ointments to be applied. Extensive burns may prove fatal in any stage and the patient, especially if young, or advanced in years, can seldom be pronounced free from danger until cicatrization has been completed. In removing the clothes from the burnt parts great care is to be taken not to break any blisters that may be raised, as a great object is to exclude the air from raw or inflamed surfaces.

BURSÆ MUCOSÆ, *bir'-se mu-co'-se* (Lat., mucus-bags), small membranous sacs, situated about the joints of the bones, and containing a kind of mucous fat, which serves to lubricate the joints, in order to render their motion easy. They are of different sizes and firmness. *Bursalogy* is the name given to a description of the *bursæ mucosæ*.

BURSERA, *bir'-se-ra* (so named in honour of Burser, the naturalist), a genus of plants belonging to the natural order *Amyridaceæ*. The species *B. gummifera* and *acuminata* yield fragrant resinous substances, that from the former being termed Chibou, or Cachibou resin, and that from the latter, resin of Carana.

BURYING-BEETLE (*Necrophorus*), a genus of *Coleoptera*, found in Europe and North America. They have received their name from a remarkable habit they have of burying the bodies of dead birds, mice, moles, and other small animals, in which they deposit their eggs. One of the species is a native of Britain, the *Necrophorus vespillo*. It is a black-beetle about an inch in length, and has two bright orange bands across the back. It has an intensely fœtid odour, and the hands smell for hours after touching it. In this country they feed upon putrefying dead bodies and the garbage that is thrown out near towns, as soon as it begins to smell. They hunt in couples, and as soon as they find a dead bird or mouse, they alight upon it, and, after feeding, the male commences his work of interment. This is done by digging with his head alone a trench round the dead object; a second trench is then dug within the first, and then another, until the earth is entirely excavated. The dead bird or mouse then falls into the hole thus formed. As soon as the corpse is fairly dragged to the bottom of its grave, the beetle quickly throws back the removed earth, and both insects bury themselves in the body. After the female has deposited her eggs, the pair work their way out. The larvæ are whitish, with six feet and a brownish head.

BUSH ANTELOPE, OR BUSH GOAT, are names given to several species of antelopes, natives of the southern and western parts of Africa. (*See* ANTELOPE.) They are not so light and graceful as the typical antelopes.

BUSSU PALM. (*See* MANICARIA.)

BUSTARD, *bus'-tard* (Fr., *bistarde*), the largest of European land birds. When full grown, the Great Bustard (*Otis tarda*) weighs from twenty-five to thirty pounds. It is about four feet long, and across its extended wings measures three yards. The head and neck are ash-coloured, and there is a tuft of feathers about five inches long on each side of the lower mandible. The bustards generally live in open countries dotted with low bushes, a locality which gives them the advantage of a broad look-out and secures them from surprises by enemies. They are said seldom to use their wings for aërial locomotion, but as adjuncts to their long legs in running. The speed they make this way is considerable, and may be sustained a very long time. The bird is still found in parts of France and Germany, and is common in Russia and on the extensive plains of Tartary. In this country, however, it has long been rare, indeed, may be almost considered as extinct. Yet that they were sometimes common is certain, so common as to be a looked-for dish at feasts and banquets. One of the bustard's chief peculiarities is a singular pouch, shaped like a modern soda-water bottle, and hanging immediately beneath the base of the lower mandible. The real use of this pouch has not been ascertained. The Little Bustard (*Otis Tetrao*), though common in France, Sardinia, and Italy, is very rarely seen here: it is also found in North Africa, Turkey, and Greece. It is about eighteen inches in length. It is a very shy bird, and when disturbed, escapes by alternately running and flying. The Kori Bustard (*O. Kori*) of South Africa, and the Australian bustard (commonly known as the wild turkey), are very large and handsome birds; the former, indeed, approaches the ostrich in size.

BUTCHER-BIRD (*Lanius excurbitor*). The sanguinary title of this member of the Shrike family, received from Gesner two hundred and fifty years ago, arises not only from its savage and cruel disposition, which seems to lead it to kill for the pleasure of killing, but also from its singular habit of impaling its victims on thorns and twigs, and in that position tearing and devouring their carcasses to piecemeal. It is about the size of a common thrush. Its bill is black, and furnished with bristles at the base; the upper parts of its plumage pale blue, and its under-parts white. It is common all the year in France, but in this country is only a rare winter visitant. When confined in a cage, the same love of fixing its food before it tears it to pieces is discovered, and for this purpose the bird usually avails itself of the wires of its prison, to which it hangs its dead captive. Another of these shrikes (*Lanius collaris*), a native of Southern Africa, exhibits this carcass-suspending propensity in as marked a manner as the above. The Hottentots assured Le Vaillant that this bird does not prefer fresh food, and that its motive for hanging its carcasses was much the same as prompts some of us to hang venison and game. A curious result sometimes follows this habit of the African shrike. Beneath the scorching sun of that region the process of decomposition does not always take place, from the rapid exhalation of the animal moisture; consequently, the trees and shrubs are sometimes found bearing amongst their fragrant buds and blossoms many ready-dried specimens of the small birds of the country.

BUTEA, *bu-te'-a* (named after, John, earl of Bute, a great patron of botanists), a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Papilionaceæ*. The most important species is *B. frondosa*, a native of India. This tree yields an astringent gum called *butea gum*, which resembles kino in its properties, and is sometimes forwarded to this country under that name. It is used medicinally in India in diarrhœas and similar diseases; also for tanning.

The dried flowers of this species and those of *B. superba* are known as Tisso and Kessaree flowers, and are extensively used by the Indians in the production of beautiful yellow and orange dyes. The fibres of the inner bark of *B. frondosa* (the Dhak tree) are known under the name of *Pulas cordage*.

BUTOMUS, *bu-to'-mus* (Gr., *bous*, an ox; *temno*, I cut), the typical genus of the natural order *Butomaceæ*. *B. umbellatus*, the common flowering rush, is frequent in ditches and ponds in England and Ireland, but is very rare in Scotland. The leaves, which spring from the crown of the root, are from two to three feet long and of a triangular shape. The scape or flowering stem is longer than the leaves, and terminates in a large umbel of rose-coloured flowers. The plant possesses acrid and bitter properties, and was at one time used in medicine. The roasted rhizome is edible. The sharp leaves of the *Butomus* were believed to cut the mouths of the cattle that cropped it—whence the name.

BUTTERCUP. (*See* RANUNCULUS.)

BUTTERFISH. (*See* GUNNET.)

BUTTERFLY, *but'-ter-fly* (so named from the colour of the yellow species) (Sax., *buterflege*), the name of an extensive group of the order *Lepidoptera* which fly by day. They are distinguished from other insects by these generic characters: The antennæ are terminated by a knob, or at least are somewhat suddenly thicker at the extremity; by the beauty as well of the under as of the upper side of their wings, which are usually erect when the animal is in a state of repose. They possess four wings, covered with minute scales, which to the naked eye appear like powder. Butterflies are the only lepidopterous insects which have no spines, bristles, or hooks on the margins of their wings, by which the second wing on each side can be attached to the first. The number of British *Papilionidæ* is not more than seventy; and it singularly happens that some of these affect particular localities, sometimes of an area of but a few acres, and are never elsewhere seen. Even on such favourable spots their appearance is limited to a few days in a certain season of the year. Another peculiar circumstance is, that several species appear in certain localities, at intervals of several years, when they will literally swarm; come the next season, and not a solitary one will reward the most diligent searcher. This might be attributed to the variable character of our climate, but it is well known that in tropical countries the same irregularities occur. Butterflies are found in all parts of the world; in tropical regions flying together in an apparantly compact mass, one or even two miles in extent. They vary in size from one inch to ten or eleven inches across the expanded wings, the largest species being tropical, and the colours displayed by some are remarkably rich and varied. The caterpillars have always sixteen feet. The external form of the chrysalids varies according to the species of butterfly that inhabits them; in all, however, there are apertures opposite to the thorax, by which respiration is carried on during the whole period of their inactive state. When the entombed creature has acquired sufficient vigour, and the down already grown upon it has separated it on all sides from the shell, the latter is broken through by the insect's head, and it emerges a butterfly. At first, however, the wings are closely folded to its body; but they soon expand of themselves, and are sufficiently hardened by the air to endure the effort of flying. It is not, however, every chrysalis that becomes a butterfly, probably not a thousandth part of their number do. Both in a caterpillar and in a perfect state they are surrounded by ever-hungering enemies. Many species of the Ichneumonidæ perforate the body of the caterpillar and there deposit their eggs; and although the caterpillar continues to live, and is transformed into a chrysalid, no butterfly is produced from it, those internal parts which were essential to its perfection being consumed. Sparrows and other birds are mortal foes to butterflies, and a single pair will easily dispose of between three and four hundred in the course of a single week.

BUTTERFLY FISH. (*See* BLENNY.)

BUTTERFLY WEED, sometimes known as Pleurisy Root (*Asclepias tuberosa*). (*See* ASCLEPIAS.)

BUTTERWORT. (*See* PINGUICULA.)

BUTUA ROOT, *bu'-twa*. (*See* CISSAMPELOS.)

BUTYL, *bu'-tile*, an organic radicle, discovered by Kolbe amongst the products obtained by electrolysis from valerate of potash. It may also be prepared by the action of sodium on iodine of butyl, in a vessel so arranged that the volatilized products may return into it as fast as they are volatilized and condensed. When the reaction has terminated, the butyl may be distilled off at a temperature not exceeding 300° Fah. When pure, it is a limpid oil, with an agreeable ethereal odour. It boils at 226° Fah., and may be distilled without alteration. It is one of the lightest known fluids, its specific gravity being only 0·694. It is the radicle of a great number of very interesting organic compounds. It has been called valyl by certain chemists, from being formed from valeric acid, and by others tetryl.

Butylic Ether, or Oxide of Butyl, *bu-til'-ik* was first described by Kolbe as a product of the voltaic decomposition of valerate of potash. It is at present but little known. *Butylic alcohol*, or hydrated oxide of butyl was discovered by Wurtz in beetroot molasses. It is a colourless highly refractive liquid, boiling at 228°, and has a slightly vinous odour, somewhat resembling that of amylic alcohol. Its specific gravity is 0·803. It is quite similar in properties to the other alcohols of the same group.

Butyline, *bu'-ti-line* (C_8H_8), butyl less one equivalent of hydrogen. This compound was discovered by Faraday amongst the products of distillation of oil, and is frequently called oil-gas. It is a colourless gas, burning with a white luminous flame. It is one of the principal products of the distillation of India-rubber. It was afterwards obtained by Kolbe from valerate of potash, and by Wurtz by acting on butylic alcohol with chloride of zinc. It is similar in its properties to ethyline (C_4H_4), or olefiant gas, the corresponding product of ethyl.

BUXBAUMIA, *bux-bau'-me-a*, a genus of mosses. Only one species is known, *B. aphylla*, a very rare British plant. It appears to consist of a little conical bulb, with minute scales, which are really leaves.

BUXUS, *bux'-sus* (supposed to be from Gr., *puknos*, dense, in reference to the wood), the Box, a genus of plants belonging to the natural order *Euphorbiaceæ*, and consisting of evergreen shrubs or small trees with opposite leaves, entire at the margins, and easily split into two plates. The flowers, which are very small, grow in little axillary clusters, the male and female flowers being distinct, but borne on the same plant. There are only two species known: namely, *B. sempervirens* and *B. balearica*. The former, which is the common box, is remarkable, botanically, for being the most northern arborescent species of *Euphorbiaceæ*. In Britain, it seldom attains a height of more than twelve or fourteen feet; but, in the south of Europe, it is often twice that height. It grows wild in this country only on the dry chalky hills of the south. Many varieties are known in gardens, the most remarkable of which is the dwarf-box, so much used for the edgings of walks. The wood of the arborescent *B. sempervirens* is heavier than that of any other European tree, and will sink when placed in water. It is of a beautiful pale-yellow colour, and of a fine regular and compact texture. It is preferred to every other kind of wood for the manufacture of flutes, flageolets, and other wind instruments; of rules and mathematical instruments; and of the handles to most small tools. For the purposes of the turner, the wood-carver, and especially of the wood-engraver, boxwood is invaluable on account of the closeness of grain. *B. balearica*, the Turkey, Minorca, or Balearic box, forms a larger tree than the other species, and has leaves three times as large. It is much more impatient of cold, but is occasionally seen in shrubberies in the south of England. The wood is of a bright yellow, and much inferior to the true boxwood, for which it is often substituted.

BUZZARD, *buz'-zard* (Dutch, *buzaard; Buteo vulgaris*), a predacious and carrion-feeding bird, common to the whole of Europe. It is a sluggish bird, and its courage is not nearly commensurate with its size; for, while it measures nearly two feet in length, and its extended wings cover a breadth of nearly five feet, it will flee from the attack of a magpie or jackdaw. Like the kite, the raven, and all birds that feed much on carrion, the buzzard has a lofty flight when in search of food. In colour it is reddish-brown above, and white or cream-colour beneath; the tail is barred with black and ash-colour, and has a white tip. The bird's beak is comparatively small and feeble. It breeds in extensive woods, builds a ragged nest, and lays two or three eggs, which are either wholly white or white blurred with yellow. If during the period of incubation the hen should be killed, the male bird will take upon himself the business of hatching and rearing the brood. The honey-buzzard, or pern (*Pernis apivorus*, Cuvier), is a little longer than the common buzzard, and not so bulky. The crown of the head is of a pure bluish ash-colour; the upper surface deep brown, inclining to greyish, and the under parts dingy white, barred with deep brown. It is said to derive its name from the partiality it shows for bees, wasps, and their larvæ as food. The honey-buzzard inhabits Russia, Sweden, and Norway, and is found generally in the south of Europe. It is rare in this country, though it has been known to breed here.

BYRRHUS, *bir'-rus*, a genus of the order *Coleoptera*. This insect is about the size of the lady-bird, is of a deep brown colour, with its wing-shells marked by black lines. It is commonly found in gardens.

BYRSONIMA, *bir-so-ni'-ma*, a genus of plants belonging to the natural order *Malpighiaceæ*, consisting of tropical trees, all remarkable for their astringency. Thus the bark of *B. crassifolia* is used internally as an antidote to the bite of the rattlesnake, and for other purposes where an astringent medicine is desirable. The barks of other species are much employed in Brazil for tanning. Several species have edible fruits. The fruit of *B. spicata* is used medicinally in the treatment of dysentery.

BYSSOLITE, *bis'-so-lite* (Gr., *bussos*, fine flax, *klados*, a branch), a name applied to fibrous varieties of amianthus, tremolite, actinolite, and other minerals of a filamentous nature.

BYSSUS, *bis'-sus* (Gr., *bussos*), the silky filament by which molluscs with bivalve shells attach themselves to rocks or other fixed substances.

In Botany, a name given to some of the lowest and most obscure forms of vegetation, sometimes ranked among *algæ*, sometimes among *fungi*.

BYTTNERIACEÆ, *bit'-ne-ri-ai'-se-e* (in honour of A. S. Buttner, a professor at Gottingen), the Chocolate family, a natural order of dicotyledonous plants in the sub-class *Thalamifloræ*—trees, shrubs, or undershrubs, sometimes climbing. There are 45 genera and 400 species, mostly tropical plants. In their properties they closely resemble the *Malvaceæ* and *Sterculiaceæ*; thus, many are mucilaginous, as the *Waltheria douradinha*, the species of *Pterospermums*, and the bark of *Guazuma ulmifolia*, *Abroma angustum*, and *Donbeya spectabilis*. The fruit of *Guazuma ulmifolia* contains a sweetish pulp, which is eaten in Brazil. The most important plant of the order is *Theobroma Cacao*, the cacao or cocoa-tree, from the seeds of which cocoa and chocolate are prepared. (*See* THEOBROMA.) The typical genus *Byttneria* does not include any plants remarkable for useful products.

C.

CAAING WHALE, *ka'-ing* (*Globicephalus deductor*), known also as the Black Whale, the Howling Whale, the Social Whale, and the Pilot Fish, a species of whale found in the northern seas between the Orkney Islands and Iceland, and also on the Scandinavian coasts. By some naturalists it was formerly included in the genus *Delphinus*, with dolphins and porpoises, but it is now regarded as a distinct genus, characterized by the rounded top of the head and rounded muzzle. In appearance it is not unlike a common porpoise, but it is far larger, being from 16 to 25 feet in length. The body is thick, sometimes 11 feet, and tapers to the tail, which is deeply forked. The breast-fins, or arms, are long and narrow, sometimes reaching as long as 6 feet, and in this peculiarity the Caaing differs from every other whale. The skin is black in colour and is beautifully smooth and shiny. The under part has a white strength running throughout its full length. Its food consists of large fish such as cod and ling, but it also feeds on mollusca, and particularly on the cuttle fish. It is very gregarious, and immense shoals are seen in the northern seas.

CABBAGE, *kab'-baj*. (*See* BRASSICA.)

Cabbage Bark. (*See* ANDIRA.)

Cabbage Butterfly, a common name for several species of butterfly, the larvæ of which devour the leaves of plants of the cabbage tribe, and are popularly known as cabbage-worms or kale-worms. The well-known white garden butterflies are of this kind. The excessive multiplication of these insects is generally prevented by small birds, which devour them and the caterpillars.

Cabbage Moth (*Noctica brassicæ*), a species of moth, the caterpillar of which (greenish-brown in colour) is sometimes very destructive. The perfect insect is very handsome, of a rich brown colour, the upper wings waved with darker brown and with pale and white spots. The fringe of the wings is dotted with black and ochre.

Cabbage-Fly (*Anthomyia Brassicæ*), an insect of the same genus as the house-fly, beet-fly, and turnip-fly. Its larvæ feed upon the roots of cabbage, and often do great injury. It is about a quarter of an inch long, and the expanse of its wings is about half-an-inch. The colour of the male and female is dark grey. The larvæ, which are yellowish-white in colour, closely resemble those of the common flesh-fly.

CABBAGE PALM, OR CABBAGE TREE, a name commonly given to various palms in various countries having a tender terminal bud, which is boiled and eaten as a vegetable, thus the Cabbage Palm of the West Indies is *Areca oleracea*, and of the southern states of America the Palmetto. (*See* ARECA, CHAMÆROPS, EUTERPE, PALMETTO.)

CABOMBACEÆ, *kai-bom-bai'-se-e*, the Water-shield family, a natural order of plants in the class *Dicotyledones*, sub-class *Thalamifloræ*—aquatic plants with floating peltate leaves. There are only two genera belonging to the order: namely, *Cabomba* and *Hydropeltis*. The species occur in America, Australia, and India; they have no important properties. *Hydropeltis purpurea* is said to be nutritious.

CACAO, OR COCOA. (*See* THEOBROMA.)

CACHALONG, OR CACHOLONG, *kash'-a-long*, a fine variety of opal, found on the borders of the river Cach, in Bucharia. (*See* OPAL.) A specimen from the Faroe Islands consisted of silica 95·32, water 3·47, and traces of iron, potash, soda, lime, and magnesia. It is sometimes called Pearl Opal.

CACHALOT. (*See* SPERM WHALE.)

CACHEXIA, *kak-ex'-i-a* (Gr., *kakos*, bad, *hexis*, habit), a term used in Medicine to denote a group of diseases, and also the bad condition of body accompanying any particular disease: thus, cancerous cachexia and gouty cachexia express the peculiar state of body when cancer or gout is developed, as opposed to a mere local attack. It is employed by Cullen to denote a particular class of diseases in which the general habit is affected; and a change of complexion, with emaciation or morbid enlargement, are characteristic symptoms; as, jaundice, dropsy, &c.

CACTACEÆ, OR CACTEÆ, *kak-tai'-se-e*, the Cactus or Indian Fig family, a natural order of plants belonging to the class *Dicotyledones* and the sub-class *Calycifloræ*. The *Cactaceæ* are remarkable for their succulence, for the great development of their cellular tissue, and the anomalous forms of their stems, which are globular, columnar, flattened, or angular. Most of the species are leafless, having tufts of hairs or spines instead of leaves. The flowers are sessile, sometimes very showy; the sepals and petals are usually numerous, and scarcely distinguishable from each other. The stamens originate in the orifice of the tube formed by the combination of the petals and sepals, are very numerous, and consist of delicate thread-like filaments terminated by small roundish anthers. The ovary, which, in consequence of its adhesion to the sepals, seems to occupy the place of the flower-stalk, consists of a single cell lined with parietal placentas, covered over with minute ovules; its style is slender, with stigmas equal in number to the placentas. The fruit is succulent, and contains a great number of seeds, which are without albumen. These plants are, without exception, natives of the tropical regions of America. There are 18 genera and about 800 supposed species. Many yield edible fruit, useful in febrile complaints. Some grow on high mountains reaching even to the snow line, and some thrive well on old lavas, splitting them by their penetrating roots, and thus preparing the soil for other plants. Their organisation well adapts them for the endurance of great heat and long droughts; their tough skin enables them to resist the action of a dry atmosphere and scorching sunshine, while their method of growing is to thrive vigorously for a few months, and then rest for the remainder of the year, having stored up sufficient moisture in their succulent stems. They are a great boon to the districts in which they abound, in consequence of thus containing a store of wholesome juice. Cattle feed on the succulent stems of some species during the dry season in certain districts of South America. One plant belonging to the order is largely cultivated in Mexico for the nourishment of the cochineal insect; and numerous species are grown in European conservatories on account of their splendid flowers, or their singular forms. Most of them are easily propagated by taking off branches, drying them a little, and then planting them; but the horticulturist must follow the normal conditions of their growth by watering freely for a few months, and then almost entirely withholding moisture for the remainder of the year. The most interesting species are described under the names of the genera to which they belong. (*See* CEREUS, ECHINOCACTUS, MELOCACTUS, OPUNTIA, PERESKIA.)

CACTUS, *kak'-tus* (Gr., *kaktos*, a prickly plant), the name under which Linnæus included the *Cactaceæ*, believing that they formed a single genus. The name still continues in popular use, being applied to any plant in the order. (*See* CACTACEÆ.) The term appears to have been adopted from Theophrastus, who used it to describe a spiny plant.

CADDICE WORM, OR CADDICE FLY, *kad'-dis*, the common name of the species of *Phryganea*, the larvæ of which, the well-known Cad-bait or Caddice worms of anglers, reside in the water in cases, which they form of various substances, such as bits of stick, grains of seed, small stones, &c., held together by a silken thread, secreted in their bodies in the same manner as in the silkworm. The perfect insect, the caddice-fly (*Phryganea grandis*), has a body of a leathery consistence, and thickly clothed with hair; head small, with semi-globular eyes; antennæ as long as the body; anterior wings elongated lanceolate in the females, but rather more obtuse in the males. They are very active, moving with a gliding motion; but their flight is awkward. They frequent damp and marshy situations. When handled, they emit a very unpleasant odour. Their colours are ordinarily brown or grey.

Nearly 200 species have been described in Britain alone.

CADELLE, *ka-del'* (*Trogosita Mauritanica* or *Caraboides*), an insect of the family *Xylophagi*, order *Coleoptera*, section *Tetramera*. It is sometimes found in granaries in Britain, but apparently imported from southern continental countries where its larvæ commit great ravages on stored corn, bread, almonds, &c. The larvæ are about ¾-inch long, flat, fleshy, rough, and white. The perfect insect is a glossy, chestnut-coloured beetle.

CADMIA, *kad'-me-a*, a term applied to the incrustation found in zinc furnaces and so called because it contains about 15 or 20 per cent. of the metallic element cadmium.

CADMIUM, *kad'-me-um* (symbol Cd, atomic weight 56, specific gravity 8·6). A soft white metal, with a slightly bluish tinge found usually in combination with zinc and discovered independently by Stromoyer and Hermann, in 1817. It was first found in small quantities in certain zinc ores, in consequence of the behaviour of their solutions with sulphuretted hydrogen. It is occasionally found in nature as a sulphide in zinc ores, and is obtained as an accidental product during the extraction of that metal. Being much more volatile than zinc, the first portions of the distilled metal contain a large proportion of cadmium. It is separated from the zinc by means of sulphuretted hydrogen. It much resembles tin in its physical properties, being soft, malleable, and ductile, and when bent emits a creaking sound, like tin. It is easily fused, and distils at a high temperature. When heated in air, it oxidizes more readily than zinc, burning with a luminous flame, and producing a reddish-brown oxide. It fuses at 442° Fah., and rises in vapour at 600°; by slow cooling it may be obtained in beautiful octahedral crystals. When heated in dilute hydrochloric or sulphuric acid, it evolves hydrogen. The protoxide is one of the principal compounds. In the former state it is obtained when cadmium is ignited or heated in air. It is yellow, brown, or black, according to the temperature to which it has been exposed. It is infusible, does not volatilize, and forms well-marked salts with the acids. In the latter state it is a white precipitate obtained by adding an alkali to a solution of a cadmium salt. The *chloride* is formed by dissolving the metal in hydrochloric acid. It crystallizes in four-sided prisms. The *sulphide* occurs in nature as the mineral greenockite, and may be artificially obtained by heating a mixture of oxide of cadmium and sulphur, is much used as a pigment under the name of cadmium yellow. It is of a bright yellow colour, but becomes temporarily red on being heated. The iodide of cadmium has of late received an important application in photography. Being a very stable salt, it is not decomposed when added to collodion. For this reason, collodion iodized with it preserves its sensitiveness undiminished during many months.

CADUCOUS, *ka-du'-kus* (probably from *caduc*, fleeting, frail), falling early or soon after development. Thus, a calyx is said to be *caducous* when it falls off before the flower expands, as in the poppy.

CÆCILIA, *se-sil'-ia* (Latin, *cæcus*, blind), a genus of reptiles with very small, imperfect or blind eyes, hence the name. They inhabit warm countries and marshy places. Formerly they were placed among the serpents, on account of their shape, but by reason of their anatomical structure (the vertebræ being articulated as in fishes), and of the fact that they are found to breathe by gills when young, and afterwards undergo metamorphosis, they are now classed with the *Batrachia*. The body is worm-like, the head small, the skin viscous, smooth, and annularly wrinkled, apparently uncovered, but upon dissection minute scales are discovered on some species, if not all, between the wrinkles. The genus has been sub-divided, and now forms the family *Cæciliadæ*.

CÆCUM, *se'-kum* (Latin, *cæcus*, blind), a sac or tube having a closed end connected with the intestines of any animal. In man there is but one, and is apparently of but little use, if any. It is situated at the end of the small intestine, and terminating at the commencement of the large intestine. (*See* INTESTINES.) In many of the mammalia, however, it is large, and secretes an acid juice to aid perfect digestion. Birds have two cæca.

CAEN STONE, *kan(g)*, an oolitic limestone, so termed from its being extensively quarried in the neighbourhood of Caen, in Normandy. It is the French representative of our *Great* or *Bath oolite*. It forms an admirable building-stone; for though it is soft in the quarry, it hardens on exposure, and is found to be exceedingly durable.

CÆSALPINIA, *se-zal-pin'-i-a* (so named in honour of Cæsalpinius, a Romish physician of the 16th century), a genus of plants belonging to the natural order *Leguminosæ*, being the type of the sub-order *Cæsalpineæ*. The species are trees or shrubs, natives of the warm parts of America and Asia, having pinnate or bipinnate leaves, showy yellow flowers, and stems which are usually more or less prickly. The useful products of the genus, especially dye stuffs, are very numerous. The twisted ligumes of *C. coriaria* are powerfully astringent, and are extensively used in tanning. In commerce they are known as Divi-divi, or Libi-dibi pods. The legumes of *C. Papai*, the Pi-pi of commerce, are employed for similar purposes, but they are very inferior to them.

CÆSALPINIEÆ, *se-zal-pin'-e-e*, a sub-order of the *Leguminosæ*, or Bean family, characterized by irregular flowers, which are not papilionaceous, and by the petals being imbricated in the bud, with the upper or odd petal inside the lateral ones. The genera belong to the warm regions of the globe, and some of the species—the locust-trees, for example—grow to a prodigious size.

CÆSIUM, *sees'-i-um* (Latin, bluish), a rare alkaline metal, found in some mineral waters by Bunsen, in 1861, by means of the spectrum analysis.

CAFFEINE, OR THEINE, *kaf-feen'*, a white crystalline alkaloid found in tea, coffee, Paraguay tea, and in *guarana*, a species of chocolate prepared from the fruit of the *Paullinia sorbites*. Tea contains from 2 to 6 per cent. of caffeine, coffee but 1 per cent. It is easily obtained from tea by making a strong infusion of the leaves, mixing it with subacetate of lead, which precipitates the tannin, and transmitting a current of sulphuretted hydrogen through the liquid to precipitate the excess of lead. On evaporating the solution, and allowing it to cool, the caffeine crystallizes out in long silky needles. It has a weak, bitter taste, and fuses at 352° Fah. and sublimes without decomposition at a higher temperature, cold water and alcohol dissolve but a small quantity; but it is very soluble in boiling water and ether.

CAFFRES, OR KAFFIRS. (*See* ETHNOLOGY.)

CAFFRE-BREAD. (*See* ENCEPHALARTOS.)

CAINOZOIC, *kain-o-zo'-ik* (Gr., *kainos*, recent, *zoe*, life), a term applied to the upper stratified systems holding recent forms of life, as distinguished from *Mesozoic* (holding intermediate), and *Paleozoic* (holding ancient and extinct forms). The cainozoic period embraces the tertiary and post-tertiary systems of British geologists. (*See* GEOLOGY.)

CAIRNGORM, OR CAIRNGORUM, *kairn'-gorm*, a smoky-tinted variety of quartz, often of a fine brown or amber colour. It receives its name from the mountain Cairngorm in Aberdeenshire, on the sides of which it is found in great perfection. It is sometimes so dark as to be nearly black. It is much used for seals, brooches, and the larger forms of jewellery; and one Edinburgh lapidary is said to have cut nearly £400 worth from a single crystal. The brown coloured is frequently called smoky quartz, and the amber variety, which is sometimes nearly yellow, is spoken of as topaz.

CAITHNESS FLAGS, *kaith-ness'*, a series of dark-coloured flaggy beds, belonging to the middle portion of the Old Red Sandstone, as developed in Scotland. These beds are rich in fossil fishes. The stone is of great toughness and durability, and is largely employed for paving.

CAJANUS, *kaj'-a-nus* (from the Malay name *Catjang*), a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Papilionaceæ*. The species yield a kind of pulse, known as pigeon-peas, much used for food by the poor of the West Indies. In Jamaica, pigeons are usually fed with these seeds; hence their English name.

CAJEPUT. (*See* MELALEUCA.)

CALABAR BEAN, *kal'-a-bar*, the seed of *Physostigma venenosum*, a twining plant of the natural order *Leguminosæ*, somewhat similar to the kidney bean. It is a very powerful poison, but very small doses of the powder or extract are found to be valuable in teranus, paralysis, and other diseases of the nervous system. When placed on the eyeball, a remarkable effect of contraction is produced, of which eye-doctors avail themselves.

CALABASH TREE. (*See* CRESCENTIA.)

CALABASH NUTMEG. (*See* MONODORA.)

CALADIUM, *kal-ai'-di-um*, a genus of plants belonging to the natural order *Araceæ*. The species are mostly natives of South America and the West Indies, and are frequently cultivated as stove-plants in this country for the sake of their elegant spotted stems and neat leaves. They have the same general appearance as the species of *Arum*, and resemble them in being all more or less acrid. The species *C. seguinum* is highly poisonous, and when any part is chewed, the tongue swells so much that the power of speech is lost. On this account, it has received the popular name of dumb-cane. *C. sagittifolium*, the Brazil cabbage, is cultivated in many parts of the world for its leaves and root-stock, which, when boiled, are edible. The leaves are preferred, and are said to form a most nutritious and delicate vegetable. The corms of many other species, when cooked, are edible.

CALAMANDER-WOOD. (*See* DIOSPYROS.)

CALAMARY, *kal'-a-ma-re*, squid, or sleeve fish, a genus of cephalopodous mollusks, the various species of which are distributed all over the world. The body contains an internal shell shaped like a pen, and the mouth is furnished with eight arms. Like the cuttle fish, they have the power of diffusing a dark-coloured liquid around them in the water. The common calmary, popularly known as the squid, grows to nearly $1\frac{1}{2}$ feet in length, and is of a bluish colour speckled with purple. (*See* also CEPHALOPODA.)

CALAMINE, *kal'-a-mine*, a carbonate of zinc, found in various parts of America in rhombic prisms and in massive incrusted aggregations. It is an important ore of zinc. (*See* ZINC.)

CALAMINTHA, *kal-a-min'-tha* (Gr., *kalos*, beautiful, *mintha*, mint), a genus of plants belonging to the natural order *Labiatæ*. Four species are natives of Britain, and are known respectively by the names of mountain-balm, cat-mint, basil-balm, and wild basil. The first, which is also termed the common calamint (*C. officinalis*), has aromatic leaves, which are frequently employed by country peoply to make herb-tea, and as a pectoral medicine.

CALAMITES, *kal'-a-mites* (Lat., *calamus*, a reed), fossil stems occurring abundantly in the coal-measures, where about 40 species have already been discovered. They are hollow-jointed cylinders, with longitudinal furrows, and their flattened condition proves that they must have been so soft as to offer little resistance to pressure. Hooker supposes them to be allied to Ferns or Club-mosses.

CALAMUS, *kal'-a-mus* (Lat., from Gr., *kalamos*, a stalk, stem, or reed), a pen made from a reed, probably the stem of *Arundo Donax*, used by the ancients. The best were obtained from Egypt. The stem was softened, dried, and then cut as quill pens are now cut. The reed-pen, called *Kalâm* by the Arabs, is still commonly employed in Oriental countries.

CALAMUS, a genus of palms consisting of numerous species, all having very slender stems, which are found climbing over the trees in the forests of the hotter parts of the East Indies. Some of the best descriptions of walking-canes are obtained from the plants of this genus. The Malacca cane is the produce of *C. Zalacca*; Rattan cane, of *C. scipionum* and *rudentum*; and Partridge cane, of an undetermined species. The fruit of *C. Draco* is the chief source of the astringent resinous substance known in commerce as dragon's blood. This completely covers the fruit, and is melted or scraped off, and then formed into small cakes.

CALAMUS AROMATICUS, *a-ro-mat'-i-kus*, a name given by the ancients to a plant to which special medicinal virtues were ascribed, perhaps the lemon-grass of India. "Sweet calamus" is mentioned in the book of Exodus.

CALAMUS SCRIPTORIUS, *scrip-to'-ri-us* (Lat., a writing-pen), in Anatomy, is a groove or canal with a pen-like termination at the bottom of the fourth ventricle of the brain.

CALANDRA, *kal-an'-dra*, a genus of coleopterous insects closely allied to the *Circulionidæ*. The corn-weevil (*C. granaria*) is included in this genus. In its perfect form this little beetle is of a reddish-brown colour, about an eighth of an inch long; has a slender snout slightly bent downwards, a closely-punctured and very long thorax, and furrowed wing-covers, that do not entirely cover the tip of the abdomen. It bores a hole into the grain with its proboscis, in which an egg is deposited. It will afford some idea of the formidable character of these tiny beetles, to state as an ascertained fact that one female is capable of producing six thousand of her kind in a single year.

CALAPPA, OR BOX-CRAB, *kai-lap'-pa*, a genus of *Crustacea* inhabiting the seas of the Indian Archipelago, the Pacific and Atlantic oceans, and the seas of South America. One of this family (*Calappa granulata*) is an inhabitant of the Mediterranean, and found frequently in the fissures of rocks, at a depth sometimes of a thousand feet. Their general colour is pale rose, with whitish feet and brown nails.

CALASAYA BARK. (*See* CINCHONA.)

CALATHUS, *kal'-a-thus*, a genus of coleopterous insects belonging to the *Geodephaga* section. Upwards of twenty of this species of ground-beetle are found in Europe.

CALCAIRE-GROSSIER, *kal-kaire gros'-se-ai* (Fr., coarse limestone), an important member of the Eocene group of beds in the Paris basin, usually co-ordinated with the Barton, Bagshot, and Bracklesham beds of England. The fossils found in it are very abundant, and at one spot at least 400 different species have been discovered. They consist of fresh water and marine mollusca. *Calcaire-Silicieux*, *sil-e-se-u(r)* (Fr., flinty limestone), a compact silicious limestone, which sometimes takes the place of the *Calcairegrossier* in the Paris basin.

CALCAREOUS, *kal'-ka-re-us*, a term applied to any substance containing much lime.

Calcareous Spar. (*See* CALCITE.)

Calcareous Tufa, *kal-kai'-ri-us tu'-fa*. —Calcareous tufa is formed in volcanic districts by the deposition of calcareous matter in a more or less compact form.

Calcareous Waters.—Waters which hold in solution much carbonate or sulphate of lime or both. They are frequently known as hard waters, and when heated in a bottle, or other vessel, deposit some of their lime in white masses around its sides. In the high temperature the carbonic acid escapes, leaving behind a crystalline deposit of carbonate of lime. In nature enormous crystalline concretions are formed by water charged with carbonic acid percolating through calcareous strata. The stalactite caverns of Derbyshire are instances of this. (*See* STALACTITES, STALAGMITES.)

CALCEDONY, OR CHALCEDONY, *kal-sed'-o-ne* (from Calcedon, in Bithynia), a translucent massive variety of quartz, closely allied to opal and agate and often found associated with them. It often occurs in cavities in amygdaloid and other rocks in the form of "icicles," or stalactites. The colours vary from white to yellowish-brown, pale grey, bluish grey, and light brown.

CALCEOLA, *kal-se-o'-la* (Latin, a little shoe), a fossil brachiopod, so called from its under valve, which is shaped like the point of a shoe, and fitted with a lid-like upper valve. It is characteristic of the middle Devonian period.

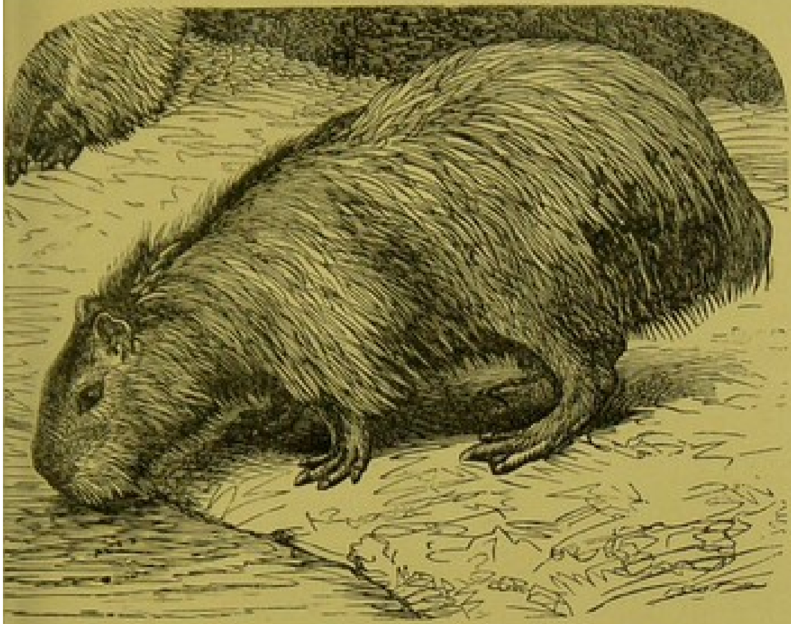
CALCEOLARIA, *kal-se-o-lai'-re-a* (Latin, *calceola*, a little shoe), a genus of herbaceous or shrubby plants belonging to the natural order *Scrophulariaceæ*. The species are natives of South America and the Falkland Islands. In Chili and Peru they occur in such abundance as to give a peculiar aspect to the landscape. Most of them have corymbs of showy flowers, generally yellow, but sometimes purple. Calceolarias are extensively cultivated in Europe as greenhouse plants, and by crossing the species some beautiful hybrids have been produced. Some of the species are used in South America for dyeing.

CALCINE, *kal-sine'* (Latin, *calx*, lime), a chemical term, signifying the separation of the more volatile portions of a solid body by means of heat. Thus lime is formed of chalk or limestone by calcination. The older chemists applied the term to the oxidation of metals by heat, thinking it was an analogous process to that just mentioned; they therefore called all oxides produced by heat, calx, or calces of the metal; thus, calyx of tin is what is now called oxide of tin.

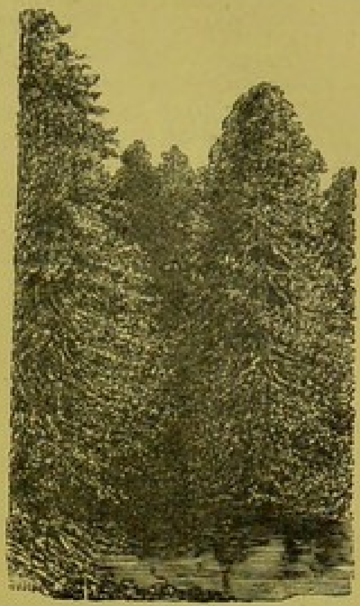
CALCINITES, *kal'-sin-ites*, compact calcareous incrustations formed in the open air. A section shows layers and lines of varying colour and hardness, which mark the gradual progress of the deposit.

CALCITE, CALCAREOUS SPAR, OR CARBONATE OF LIME, *kal-site'*, native crystallized carbonate of lime, occurring under nearly 600 different crystalline forms, all derived from the fundamental rhombohedron. It is one of the most abundant of all minerals, and occurs in all geological formations. The purest crystals are transparent and colourless; other varieties are semi-transparent and opaque, often coloured with grey, red, yellow, rose, and violet. When crystallised in hexagonal and square prisms, it is known as arrogonite. One transparent form occurring in rhombohedral crystals possesses the property of double refraction—*i.e.*, objects seen through it appear double. From having been found in Iceland, it is called Iceland Spar (which *see*).

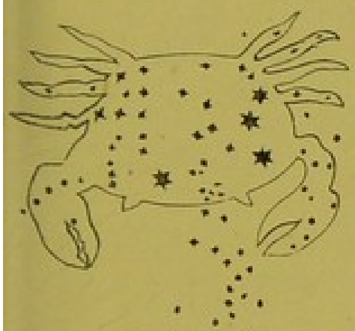
CALCIUM, *kal'-se-um*, the metallic base of the alkaline earth lime. Calcium belongs to the second group of metals, and is one of the most abundant substances in nature, forming a very large portion of the crust of the earth. It occurs in nature in combination with fluorine as fluor spar, with oxygen and carbonic acid as chalk, limestone, and marble, and with oxygen and sulphuric acid as gypsum, which is hydrated sulphate of lime. Calcium was first obtained by Sir Humphrey Davy by electrolysis, in 1808; but little was known of its properties until Dr. Matthiessen formed it by the electrolytic decomposition of a mixture of the chlorides of calcium and strontium. It is a light-yellow metal of the colour of gold when alloyed with silver, and as hard as gold, very ductile and malleable. It rapidly decomposes water, tarnishes in a day or two even in dry air, and in moister air it becomes slowly oxidized. It burns with a brilliant flash when heated in air, chlorine, or the vapours of iodine, bromine, and sulphur, and rapidly decomposes even at ordinary temperatures. It has also been obtained by acting on iodide of calcium with



CAPYBARA.

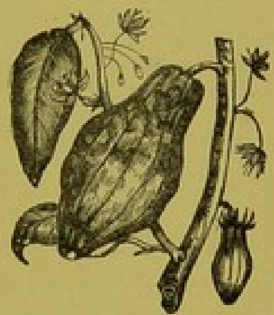


CEDAR.

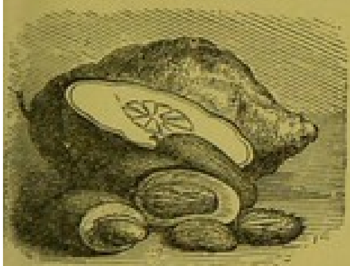


CANCER (ZODIAC).

CRANE.

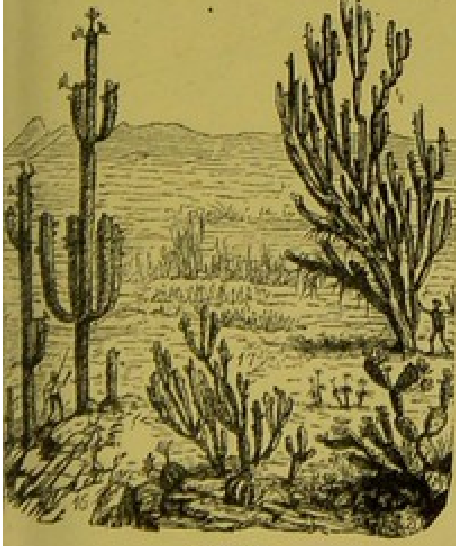


COCOA-BEAN.



CITRON.

COFFEE.



CACTUS.

CARACAL.

sodium. The best-known compound of calcium is its oxide or lime (Ca_2O). (*See* LIME.)

Chloride of.—Chloride of calcium may be obtained from the residue remaining in the retort after the preparation of ammonia, by adding to it a slight excess of hydrochloric acid and evaporating. On cooling, the solution deposits crystals containing six atoms of water of crystallization. These crystals, which are six-sided prisms, are highly deliquescent. By fusing at a heat not exceeding 302° Fah., four equivalents of water are expelled, and the remaining white porous mass is extremely useful in the laboratory for drying gases.

Fluoride of.—Fluoride of calcium occurs somewhat abundantly in the mineral kingdom as fluor spar, which is generally associated with the ores of tin, lead, copper, and zinc. It is found in crystals, the primitive form of which is the cube. They are generally yellow or purple, and sometimes pale green, or even colourless. On being heated, they decussitate violently, and emit a peculiar bluish-green phosphorescent light, which is probably due to electricity. Fluoride of calcium is principally used in the laboratory for this latter purpose. It is also employed as a flux in copper-smelting.

Phosphide of.—Phosphorus and calcium unite to form this compound, which is interesting as the source of the phosphides of hydrogen. It is prepared by distilling phosphorus over lime heated to low redness, a mixture of phosphide of lime and phosphate of calcium being the result. Phosphide of calcium is a dull red substance, hard enough to strike fire with steel. When powdered and exposed to the air, it slacks, emitting phosphuretted hydrogen.

Sulphides of.—There are several compounds of calcium with sulphur, the principal of which are the protosulphide, which is known by the name of Canton's phosphorus, and the pentasulphide.

Teroxide of.—This compound was procured by Thénard in brilliant crystalline plates, by adding lime-water to peroxide of hydrogen.

CALCULUS, *kal-ku-lus* (Lat., dim. from *calx*, a limestone), a hard inorganic concretion formed in various parts of the animal body, and bearing a general resemblance in form or composition to stone. It receives various names, from the parts in which it exists; as, *salivary* in the salivary glands and ducts, *pulmonary* in the lungs, *intestinal* in the stomach or intestinal canal, *biliary* in the gall-bladder, *urinary* in the kidneys or bladder, *gouty* in the joints of gouty persons. The most familiar instance of the formation of calculus is the tartar which is deposited from the saliva and mucus of the mouth upon the teeth. The term calculus is, however, most frequently applied to those concretions which are formed in the gall-bladder or biliary ducts, and those formed in the kidneys or bladder. *Biliary calculi*, or *gall-stones*, are composed almost entirely of cholesterine, with some colouring matter. They vary greatly in size and number, amounting sometimes to hundreds, and even, it is said, to thousands; but so long as they remain in the bladder they do not usually cause much uneasiness. It is when they pass into the canal by which the bile is conveyed to the duodenum, that they occasion great pain and derangement of the system. The pain occurs in paroxysms, and is generally attended with shivering and vomiting. If the bile be wholly obstructed, jaundice comes on, and rapid emaciation succeeds. The disorder sometimes proves fatal, but generally the stones find their way, sooner or later, into the intestines and the disturbance subsides. Hot applications over the seat of pain, or a warm bath, may be applied with advantage. *Urinary calculi, gravel, or stone in the bladder*, are concretions formed and existing in the urinary passages. They generally originate in the kidneys, and afterwards pass down into the bladder, where they frequently attain a very large size: some have been found to attain a weight of 14 to 16 oz., and even more. While in the kidneys they are termed *renal calculi*, and they sometimes remain there permanently, and may even attain a considerable size without causing much inconvenience; but they may also produce inflammation and abscess, and ultimately cause death. Generally, however, while yet of small size, they pass down the ureters into the bladder. Sometimes the passing is attended with symptoms similar to those occasioned by the passing of a gall-stone, and similar remedies are to be had recourse to. The calculus having passed into the bladder, is then termed a *vesical calculus*. At first, it is attended with comparatively little pain; but unless removed or evacuated, it is sure to enlarge, and to give rise to one of the most dreadful diseases that can afflict humanity. In the earlier stages much may be done to check the progress of this dangerous malady; but when the calculus is once formed, the only means by which it can be got rid of is an operation. The stone must either be withdrawn through the urethra by an instrument, or it must be broken into fragments small enough to be voided with the urine, or it must be extracted by an incision. (*See* LITHOTRITY, LITHOTOMY.) Many of the calculi, and, indeed, most of them, are not of one uniform composition, but consist of strata of two or three varieties, one forming a nucleus for the other deposits, and culculi thus formed receiving the name of *alternating*. Uric acid is more common as a nucleus than any other substance. Urinary calculus is more frequent in some districts than others, and locality likewise influences the species of the stone. It is much more common among males than females. The predisposing causes of it, however, are still very imperfectly understood.

CALCULUS, is a term generally applied to signify any branch of mathematics which may lead to or involve calculation—in fact, to all except pure geometry. There is the common *arithmetical* caiculus, and there is the *algebraic* calculus. The invention of the *infinitesimal* calculus (sometimes called the transcendental analysis), which involves the *differential* calculus and the *integral* calculus is claimed for Leibnitz; they are identical with the *fluxionary* calculus invented by Newton. The calculus of *partial differences* is a branch of the differential and integral calculus; and the calculus of *variations* is another portion of the same theory. That part of Algebra which relates to exponents and logarithms is sometimes called the *exponential* calculus.

CALEDONITE, *kal-e'-do-nite* (from Caledonia, Scotland), a compound of sulphate of lead with the carbonates of copper and lead, found in long prismatic crystals, of a deep bluish-green colour, at the Leadhills mine, in Scotland.

CALENDULA, *kal-en'-du-la*, the Marigold, a genus of plants belonging to the natural order *Compositæ*, sub-order *Tubilifloræ*. The species *C. officinalis* is the common marigold of English gardens, the gold-blume of the Germans, the *souci du jardin* of the French, and the furrancio of the Italians. Formerly, many medicinal virtues were ascribed to this plant, and its flowers were usually added to soups to colour them, and also to act as "comforters of the heart and spirits." Saffron is frequently adulterated with the yellow florets of the marigold. The name is stated to be derived from *calendulæ*, the Latin for the first day of the month, there being flowers almost any month in the year.

CALENTURE, *kal'-en-ture* (Lat., *caleo*, I make hot), is a term derived from the Spanish, and applied to a violent ardent fever common among sailors in very hot climates. It is so called either as being accompanied by a burning heat, or as resulting from the great heat of the climate.

CALIGO, *kal'-e-go* (Lat., darkness), dimness or obscurity of vision; it forms part of the name of various diseases of the eye attended with dimness or loss of sight; as *caligo corneæ, lentis, humorum*, &c. (*See* BLINDNESS, EYE.)

CALITRICHACEÆ, *kal-it-ri-kai'-se-e* (Gr., *kalos*, beautiful, *thrix*, hair), the Starwort family, a natural order of dicotyledonous plants, in the sub-class *Monochlamydeæ*. The species are small aquatic herbs. *Calitriche* is the only genus, and includes six species, natives of fresh-water pools in Europe and North America. Their uses are unknown.

CALLA, *kal'-la* (from Gr., *kallos*, beauty), a genus of plants belonging to the natural order *Orontiaceæ*. The most interesting species is *C. palustris*, from the acrid rhizomes of which the Laplanders prepare a kind of bread, by a tedious process, which includes drying, washing (to remove the acrid juices), grinding, and baking.

CALLICHTHYS, *kal-lik'-this*, (Gr., *kalos*, beautiful, *ichthys*, a fish), a genus of fishes of the family *Siluridæ*, natives of South America and other warm climates. They are entirely covered by rows of narrow scaly plates, and the head is protected by a sort of helmet. When the streams or pools in which they dwell dry up, they make their way across the land, for considerable distances, to other pieces of water. They deposit their eggs in nests made of leaves.

CALLIDIUM, *kal-lid'-i-um* (Gr., *kallos*, beauty, *eidos*, form), small beetles, infesting houses, and very destructive to woodwork, especially of spruce and fir. One of this family (*Callidium bajulus*), a flattish, rusty-black insect, will, according to Messrs. Kirby and Spence, not only eat their way through the rafters of a house, but even bore through sheet-lead: fragments of lead having been found in their stomachs.

CALLIGONUM, *kal-ig'-o-num* (Gr., *kalos*, beauty, *gonia*, angle), a genus of plants belonging to the natural order *Polygonaceæ*, characterised by a quadrangular fruit, winged at the angles. The species *C. Pallasia*, which is found on the sandy steppes near the Caspian sea, is valued by the wandering Kalmucks for the acid juice of its fruit and shoots, which often serves to allay their thirst; and also for the nutritious gum which may be obtained from its root.

CALLITRIS, *kal'-e-tris*, a genus of coniferous plants, *C. quadrivalvis*, the arar-tree, yields the resin called sandarach, juniper resin, or gum-juniper, which is imported in large quantities from Mogadore. It is much employed in the preparation of varnishes. When powdered, it is called pounce. The timber furnished by this tree is very durable, and is used by the Turks for the floors and ceilings of their mosques.

CALLOSITY, *kal-os'-i-te* (Lat., *callositas*), is an induration or hardness of the skin; as that of the hands through hard labour. (*See* CORNS.)

CALLUNA, *kal-lu'-na*, (*See* HEATH.)

CALLUS, *kal'-us*, the bony matter which is deposited between the fractured ends of broken bones. It is an osseous substance, formed by a process of nature for the re-uniting of broken bones.

CALM, *kahm*, the name given to that state of complete rest in the air when there is no wind stirring. The regions in the immediate vicinity of the equator are the parts of the ocean where the mariner is overtaken by the most frequent and most durable calms. In the Atlantic Ocean the region of calms has a breadth of six degrees. The Pacific Ocean derives its name from being characterized by an equatorial belt of calm region averaging five degrees in breadth, and lying between the south-eastern and north-eastern trade-winds. (*See* TRADE-WINDS.) The calm latitudes of the Atlantic Ocean are situate between the tropic of Cancer to very nearly lat. 29° N. When a calm occurs unexpectedly, it is likely to be followed by a violent storm.

CALOMEL, *kal'-o-mel* (Gr., *kalos*, good, *melas*, black, from the qualities and colour of the Ethiop's mineral to which the name was originally applied), sub-chloride of mercury. (*See* MERCURY, CHLORIDE OF.)

CALOPHYLLUM, *kal-o-fil'-um* (Gr., *kalos*, beautiful, *phullon*, leaf), a genus of plants belonging to the natural order *Guttiferæ*, including many valuable timber trees. *C. angustifolium*, the piney-tree of Penang and the islands to the eastward of the Bay of Bengal, furnishes fine straight spars. *C. calaba* and *C. inophyllum*, besides yielding timber, produce seeds from which good burning oil is obtained. The fragrant resinous substance known as East-Indian tacamahaca is a product of the species of this genus.

CALOR MORDICANS, *kal'-or mor'-de-kans* (Lat., biting heat), is applied to a particular kind of heat that sometimes attends typhus and other fevers, and is considered a dangerous symptom. It is biting and pungent, rather than burning, and leaves a smarting sensation on the fingers for several minutes after touching it.

CALORIC. (*See* HEAT.)

CALOTROPIS, *ka-lot'-ro-pis* (Gr., *kalos*, beautiful, *tropis*, keel, in allusion to the keel of the flower), a genus of tropical plants belonging to the natural order *Asclepiadaceæ*. The species *C. gigantea* or *procera* yields the medicinal bark known as Mudar bark, which has been much employed in India for the treatment of cutaneous affections, and occasionally as a substitute for ipecacuanha. It contains a peculiar principle, called *mudarine*. The fibres of the bark are known under the names of *Ak* and *Mudar fibres*. The bark of the root of *C. Hamiltonii* has similar properties.

CALTHA, *kal'-tha* (Gr., *kalathos*, a goblet), a genus of plants belonging to the natural order *Ranunculaceæ*, tribe *Helleboreæ*. The species *C. palustris*, commonly known as the Marsh Marigold, grows wild in marshy places, and has showy bright yellow flowers.

CALUMBA, OR COLUMBO, *ka-lum'-ba*, the name given to a root very extensively used in medicine as a stomachic and mild tonic. It takes its name from Colombo, in Ceylon, whence it was first brought; but it is now obtained chiefly from the Mozambique. (*See* JATEORHIZA.)

CALX. (*See* LIME.)

CALYCANTHACEÆ, *kal-e-kan-thai'-se-e*, the *Calycanthus* family, a natural order of dicotyledonous plants in the sub-class *Calyciflorœ*. These are shrubby plants, greatly resembling the *Rosaceæ*, but they differ in having opposite leaves, and some other particulars. There are but two genera, *Calycanthus* and *Chimonanthus*, the species of which are natives of Japan and North America. The flowers have a peculiar aromatic fragrance. The bark of *C. Floridus*, the Carolina allspice, is sometimes used in the United States as a substitute for cinnamon-bark.

CALYCERACEÆ, *kal-e-se-rai'-se-e*, the *Calycera* family, a natural order of dicotyledonous plants in the sub-class *Corolliflorœ*. They are exclusively natives of South America, and hold an intermediate position between *Dipsaceœ* and *Compositœ*.

CALYCIFLORÆ, *kal-e-se-flor'-e*, a sub-class of *Dicotyledones*, comprising plants with flowers having the following general characters:—Calyx and corolla usually present, the petals of the latter being generally distinct, but sometimes slightly connected; stamens borne on the calyx, but free from the ovary, or else apparently seated on the ovary. The *Calyciflorœ* are subdivided into *Perigynœ* and *Epigynœ*. Fifty-one calyciforal orders are described by botanists.

CALYMENE, *kal-e-me'-ne* (Gr., *kekalumene*, concealed), a genus of trilobites, so named from the obscurity which long hung over the real nature of these fossil crustaceans. They belong to the Silurian system, and are particularly well represented in the Ludlow rocks. The most abundant species is *C. Blumenbachii*, which has long been known as the Dudley locust. (*See* TRILOBITE.)

CALYPTRÆA, *ka-lip-tre'-a* (Gr., *kalyptra*, a head-dress), a genus of gasteropodus mollusks, of the order *Pectini branchiata*, the shell is limpet-shaped, but the apex is more or less spiral. They are generally natives of warm climates, but two species are British. There are considerable varieties of shape as expressed in the common names given—cup and saucer limpets, bonnet limpets, slipper limpets, and chambered limpets.

CALYX, *kai'-liks* (Gr.), the external envelope of the flower. It is composed of modified leaves, called *sepals*, which are usually green. Within the whorl of sepals there is generally another whorl of leaves, called the corolla (which *see*), but sometimes the calyx is the only envelope of the parts of fructification. The calyx may either consist of a number of separate sepals, as in the poppy, buttercup, and wallflower, or these parts may be more or less united, as in the fuchsia, melon, and tobacco. In the former case, the calyx is termed *polysepalous* or *polyphyllous*; in the latter, *monosepalous* or *monophyllous*, or, more correctly, *gamosepalous* or *gamophllous*. Whatever be its colour, the external envelope must be considered as the calyx. The tube of the calyx sometimes adheres, more or less, to the ovary, as in the iris, gooseberry, currant, and in all plants of the Composite order. When such adhesion takes place, the calyx is said to be *adherent* or *superior*, because it appears to arise from the summit of the ovary. When there is no such adhesion, the ovary being quite distinct, as in the wallflower and buttercup, the calyx is described as *free*, *non-adherent*, or *inferior*.

CAMARA NUTMEG, *ka-ma'-ra*, a false or wild nutmeg, obtained from the *Acrodiclidium Camara*, a plant of the Laurel order, growing in Guiana. It is also known as the Ackawa nutmeg by the natives.

CAMASSIA, *ka-mas'-se-a* (from *quamash*, its native name), a genus of plants belonging to the native order *Liliàceœ*. The species *C. esculenta*, a native of North America, has edible roots. They are also known as biscuit-roots.

CAMBERWELL BEAUTY, the name given to a large and beautiful butterfly (*Vanessia Antiopa*), common in central and southern Europe, but rare in England. The wings are of a rich brown colour, of velvety appearance, with external bands of black and pale yellow, with large blue spots. The caterpillar feeds on the willow.

CAMBIUM, *kam'-be-um* (Latin, *cambio*, to change), a layer of vitally active cells placed on the outside of each annual zone of wood in an exogenous stem. It is from this that the new layers of wood are formed. The cambium-layer is dormant during the winter, at which time the bark is firmly attached to the wood beneath; but in spring it is in full activity, being charged with the elaborated sap of the plant; and then the bark may be separated from the wood beneath.

CAMBOGE. (*See* GAMBOGE.)

CAMBRIAN ROCKS, *kam'-bre-an*, a term applied by Professor Sedgwick to the lowest fossiliferous rocks, on account of their extensive development in North Wales, anciently called Cambria. The term is usually limited to a series of sandstones, gritstones, and slates, which underlie the Silurian Lingula strata. (*See* SILURIAN SYSTEM.)

CAMEL, *kam'-el* (Lat., *camelus*).—Of this genus of mammiferous ruminants there are two species—1, the common camel (*Camelus bactrianus*); 2, the Arabian camel or Dromedary (*Camelus Dromedarius*). The first is principally distinguished by its humps being two in number, whilst the dromedary has but a single hump. The latter species is distributed over an immense extent of country, being found in Arabia, Persia, Southern Tartary, Egypt, India, and the Canary Islands. The common camel is not nearly so abundant, and its geographical range much more limited. It is principally found north of the Taurus and the Himalaya Mountains. The camel is distinguished from all other ruminants, except the llama, by having incisor teeth. The upper jaw contains sixteen teeth—two incisors, two canines, and twelve molars; the lower jaw, six incisors, two canines, and ten molars—eighteen in all. The upper lip is swollen and divided, the nostrils slit obliquely, the neck elongated, the head long, the eyes very prominent, and the ears somewhat small. The legs of the camel are long, weak-looking members, terminating with two hoofs or toes, padded with soft cushions underneath, which enable the animal to walk securely on the soft sands of the desert. The stomach of the camel is a curious construction, and enables it to carry a supply of water wherewith it may refresh itself on its terribly long and tiresome journeys. The hump is composed of gelatinous fat, which, by re-absorption, furnishes the animal with sustenance when the nature of the country, or any other unfortunate contingency, deprives it of a supply of food. So well is the nature of the hump understood in the East, that the condition of the animal is judged of, and its improvement after a long journey measured by it. It is not uncommon to see camels come in after long and painful journeys with almost straight backs, the hump having almost entirely disappeared. Ordinarily a patient and rather stupid animal, the camel is sometimes very vicious and dangerous. The services of the camel to the wandering tribes of Arabs, and other inhabitants of the East, cannot be too highly appreciated, or, indeed, understood, by the people of civilized nations. The usual load of a caravan-camel (the Bactrian) is about five hundredweight; but, on extraordinary occasions, a strong camel will carry a thousand pounds! It will travel, so loaded, at the rate of nearly three miles an hour. The usual travelling speed of a caravan is eighteen miles a day. A dromedary will carry a rider a hundred miles in a day. Usually the camel produces only one young at a time, the average of the life of the animal is about thirty-five years. The flesh and milk of the camel are used as food by the Arabs. The only part of Europe in which this animal is found is at Pisa, in Tuscany. The date of the introduction of the camel into Europe is unknown. The usefulness of the camel as a beast of burden was not unknown to the ancients. In the Scriptures we frequently find allusions to the camel; the three thousand of these animals belonging to Job forming a considerable portion of his property. In the book of Genesis there are several notices of the camel, which would at least prove that this animal was a domesticated and useful servant of man four or five thousand years ago. The names of the camel in different countries are all very similar. The Hebrew name is gamal; it is the djemal of the Arabs; camelo of the Italians; in France, chameau; in Germany, kamel.

CAMELINA, *ka-me-li'-na*, the Gold-of-pleasure, a genus of cruciferous plants. *C. fœtida* is sometimes found growing in fields of corn and flax in Britain. *C. sativa*, which is a common field-plant in France, has seeds containing much fixed oil.

CAMELLIA, *ka-mel'-li-a* (in honour of George Joseph Camellus, a traveller in Asia), a genus of plants belonging to the natural order *Terustrœmiaceæ*, natives of China, Japan, and the north of India, and extensively cultivated as greenhouse-shrubs throughout Europe and the States of America. The species *C. Japonica*, which, as its name indicates, is a native of Japan, has received great attention from the florists of that country and of China from time immemorial. It has shining leaves, flowers without stalks, generally solitary, large, and rose-like. In its wild state the flowers are red; and the red single camellia is much prized by gardeners as a stock on which to graft the fine double varieties which have been developed by cultivation. Some of these varieties are of Chinese or Japanese origin; others have been raised in Britain, continental Europe, and America. Their colours are various, and the varieties differ much in the form and position of the petals. Camellias flower in the autumn, winter, and spring. They are propagated by cuttings and by layers, or, when the finest varieties are dealt with, by grafting and inarching. The single camellia is often propagated by seed, and in this way the finest stocks for grafting are produced. Of the other species cultivated, the most hardy, and one of the most beautiful, is *C. reticulata*. From this and *C. japonica* many splendid hybrids have been produced. The seeds of *C. oleifera*, which is extensively cultivated in China, yield by expression an excellent kind of salad-oil. *C. sasanqua* has fragrant flowers, which are said to be used in some parts of China for flavouring teas.

CAMELLIACEÆ. (*See* TERUSTRŒMIACEÆ.)

CAMELOPARD, *kam-el'-o-pard* (Lat., *camelus*, camel, *pardalis*, panther. (*See* GIRAFFE.)

CAMEL'S THORN. (*See* ALHAGI.)

CAMOMILE, OR CHAMOMILE. (*See* ANTHEMIS.)

CAMPANULA, *kam-pan'-u-la* (Lat., a little bell), the Bell-flower, a genus of plants forming the type of the natural order *Campanulaceæ*. It includes several British species, which are known to all lovers of wild flowers; thus, *C. rotundifolia* is the hare-bell; *C. glomerata*, the clustered bell-flower; and *C. Rapunculus*, the rampion. The roots of the latter species are eaten in some parts.

CAMPANULACEÆ, *kam-pan-u-lai'-se-e*, a natural order of dicotyledonous plants in the sub-class *Corolliflorœ*, consisting of herbs or undershrubs. There are 29 genera and 500 species, chiefly natives of the temperate parts of the northern hemisphere.

CAMPANULARIA, CAMPANULARIDÆ, *kam-pan-u-lai'-ri-a*, a genus and family of zoophytes. (*See* ZOOPHYTES.)

CAMPHOR, *kam'-for* (Gr., *kamphogen;* Arab., *kaphoor*), a solid crystalline substance found in many plants, though only obtained in large quantities from two: namely, *Camphora officinarum* and *Dryobalanops aromatica*. The former, an evergreen tree growing in China, Formosa, and Japan, yields almost all the camphor of European commerce. The camphor, which may be regarded as a solid volatile oil, is diffused through the entire plant, and is separated from the root, trunk, and branches. These parts are cut into chips, and boiled in water till the camphor begins to adhere to the stirring-rod, when the liquid is strained and allowed to stand until the camphor concretes. It is then sublimed into inverted straw cones contained within the earthen capitals of the stills. Vast quantities of this *crude camphor* are procured from the province of Fokien, in China, and the opposite island of Formosa; but some of good quality is exported from Japan. It is generally in small greyish, slightly sparkling grains, which, by aggregation, form crumbling cakes. Refined camphor is prepared by mixing the crude product with lime, and subliming it into thin glass vessels of a peculiar shape, which are afterwards cracked so as to obtain the camphor in concavo-convex cakes, each about three inches thick, with a hole in the middle. Camphor is colourless and translucent, and has a strong, penetrating, aromatic odour, and a bitter, rather pungent, taste, though leaving a sensation of coolness in the mouth. Its specific gravity is from ·98 to ·99; so that it floats upon water, and, evaporating while doing so, undergoes a curious rotatory movement. It volatilizes slowly at ordinary temperatures, melts at 288° Fah., boils at 400°, and burns with a bright flame. It is soluble in alcohol, ether, oils, and dilute acids; also to a certain extent in water. The Sumatra, or Borneo, camphor is the produce of *Dryobalanops aromatica*. It greatly resembles the ordinary camphor, but is never seen in European commerce, because the Chinese give a price for it eighty or a hundred times greater than that at which they sell their own camphor. The same tree which affords this rare substance yields also a pale yellowish limpid fluid, called *liquid camphor*, or *camphor oil*. Camphor is used in medicine, both internally and externally, as a temporary stimulant, and in some cases as a remedy for gout and rheumatism. In moderate doses, it will allay nervous irritation and produce quietude and placidity of feeling. The alcoholic solution of camphor and liniments, of which it is the principal ingredient, are much used for external application in sprains and bruises, chilblains, and chronic rheumatism. Insects are kept from attacking specimens of natural history by placing pieces of camphor in the cases in which such specimens are preserved. Chemically considered, camphor is a compound of carbon, hydrogen, and oxygen, in the proportions expressed by the formula $C_{10}H_8O$.

CAMPHORA, *kam-fo'-ra*, in Botany, a genus of plants belonging to the natural order *Lauraceæ*. The most interesting species is *C. officinarum*, the camphor-tree, a native of China, Formosa, and Japan, where it grows to a considerable size. It is an evergreen, and all parts emit a camphoraceous odour when bruised. The wood is white, light, and durable, and is much used in China for carpenter's work. From the roots, trunk, and branches of this plant, the *common*, or *officinal, camphor* is obtained. (*See* CAMPHOR.)

CAMPION. (*See* LYCHNIS and SILENE.)

CAMPYLOSPERMÆ, *kam-pi-los-per'-me* (Gr., *kampulos*, a curve; *sperma*, seed), a sub-order of the *Umbelliferæ*, characterized by the albumen of the seed being rolled inwards at the edges, so as to present a vertical furrow on its face.

CAMWOOD. (*See* BAPHIA.)

CANADA BALSAM. (*See* BALSAM.)

CANAL, OR CANALIS, *ka'-nal* (Lat., *canna*, a reed), is applied to many small passages or channels of the human body.

CANARIUM, *ka-nai'-ri-um*, a genus of trees belonging to the natural order *Amyridaceæ*, natives of the Spice Islands and parts of Asia. *C. commune* is cultivated for the sake of the kernels of its fruit, and for the fragrant resinous substance which exudes from its bark, which probably constitutes the manilla elemi of commerce. This tree is about 50 feet high. *C. microcarpum* yields an oil very like copaiva, known in ship-building yards as Damar. Other species produce edible fruits, useful oils, and resins.

CANARY, OR CANARY-BIRD, *ka-nai'-re* (*Carduelis canaria*). This popular and pretty singing-bird is a native of the Canary Islands; it is also found in Madeira and the Cape Verd Islands. It belongs to the numerous family of finches (*Fringillidæ*) being the *Fringilla Canaria* of Linnæus; by some ornithologists, however, it is placed in the genus *Carduelis*, and by others in the *Linota*, while there are others who make of it a genus by itself, *Canaria*. Its introduction into Europe was somewhat singular. According to some authorities, at the end of the 14th century, and to others, at the beginning of the 16th century, a vessel containing, among other merchandise, a number of canary-birds, and which was bound for Leghorn, was wrecked on the coast of Italy. The birds, being set at liberty, took refuge in the adjacent island of Elba, and the climate being congenial to their habits, they increased considerably. The islanders, finding such an elegant songster suddenly settling in their country, were anxious to become possessors of them, and quickly the whole colony of canaries were taken prisoners. From Italy they were brought to other countries, and became highly valued as singing-birds. The wild bird of the Canary Islands and the domesticated bird so familiar in this country are quite at variance in personal appearance. The colour of the wild canary is a dusky grey; whereas, in the domesticated canary, we have a great variety of colours —green, yellow, white, brown, grey, &c. This is, of course, owing to the numerous cross-breedings to which it has been subjected. It breeds freely with several other species; the goldfinch, the bullfinch, the siskin, the green-bird, and the linnet, among the number. Altogether, it is reckoned that there are no less than thirty varieties of the canary. The canary that is most admired amongst us now is one with the body whitish yellow; the head (particularly if crested), wings, and tail, yellowish-dun. The second in degree is of a golden yellow, with the head, wings, and tail black, or, at least, dusky grey. In Germany and the Tyrol the breeding of this bird is carried on on an extensive scale, and it is principally from these places that the rest of Europe is supplied. In its native home, the canary builds its nest in thick, bushy, high shrubs and trees, with roots, moss, feathers, hair, &c.; pairs in February, lays from four to six pale-blue eggs, and hatches five and often six times in the season.

CANARY-GRASS. (*See* PHALARIS.)

CANCELLARIA, *kan-sel-la'-ri-a*, a genus of mollusks with univalve shells, now usually placed among the *Buccinidæ* or Whelks. The recent species are natives of tropical seas, and are found chiefly on sandy bottoms. The fossil species appear in the newer strata. (*See* WHELK.)

CANCELLI, *kan-sel'-li* (Lat., lattice-work), the spongy or reticular substance of the bones (*See* BONE.)

CANCER, *kan'-ser* (Lat., *cancer*, a crab), a group of stars forming the fourth of the twelve constellations of the Zodiac, although it is many centuries since the constellation and the sign occupied the same position. The zodiacal division so called occupies the thirty degrees of the ecliptic between 90° and 120° from the first point of lines, or the vernal equinox. The sun enters this sign about the 21st June, and leaves it about the 22nd July. It contains 83 stars, of which the most conspicuous is *Acubens*, a star of the third magnitude.

CANCER (so called from the large blue veins which appear, in cancer, to resemble crab's claws), a disease of a very malignant character, and one of the class of new growths. It differs from all other tumours, being an infiltration amongst the natural tissues of the body. Its peculiar construction can only be discerned by the microscope.

Any part of the body may be the seat of this disease, though the glands are most liable to its attack. The female breast, the tongue, or lips, are among the parts most subject to it. There are several forms of cancer, *scirrhous*, *medullary*, *melanic*, *epithelial*, *osteoid*, *colloid*, and *villous*. The most frequent form is the scirrhous. Its first appearance is that of a small stony-hard tumour, which is due to the abundance of fibrous tissue. There is at first little or no discolouration of the surrounding skin. It remains in this state for a longer or shorter period, sometimes for years, but at length it passes into a more active condition:—the tumour increases in size, the skin changes to a livid or red appearance, and pain begins to be felt in it. The pain, which is of a shooting or lancinating nature, is at first slight, and occurs at considerable intervals; but it increases by degrees, and the intervals diminish until it becomes almost constant. The cutaneous veins become turgid, and the surface of the tumour presents to the feel a knotty, uneven surface. Sometimes the skin never actually breaks, but usually, after a longer or shorter period, the tumour ulcerates and becomes an open sore. The disease pursues its onward course; sometimes it seems as if it had exhausted itself, and was allowing nature to work a cure by the formation of new flesh; but this is merely a delusion, for it soon recommences its destructive course, and at length, it may be after years, it seizes upon some vital organ, or the patient sinks exhausted by the pain and continued drain upon his system. Of the cause, nature, or treatment of this terrible disease little is, unfortunately, known. By some it is regarded as constitutional, by others as local; some maintain that it is hereditary, others that it may be transmitted by inoculation. Though all ages and both sexes are liable to this disease, the young are less frequently attacked by it than the old, and females are more subject to it than males. The only hope of a cure in cancer is by extirpating the tumour in its earliest stages; and even this, after all, frequently affords but a temporary relief. Sometimes, in place of the knife, escharotics, as chloride of zinc, are had recourse to, but with no better success. Among the lower animals this disease is not of unfrequent occurrence, the animals most liable to its attack being the dog and cat.

CANCER, a genus of short-tailed *Crustacea*, or crabs, now generally restricted to the common crab. (*See* CRAB.)

CANCER-ROOT. (*See* EPIPHEGUS.)

CANCRUM ORIS, *kan'-crum o'-ris*, canker of the mouth, an ulcerative affection of the gums and cheeks seldom observed in adults, and occurring principally among young children. It is occasioned by poor feeding, and residence in a state of dirt and squalor. A more severe form attacks children when just recovered from measles, when many patients are crowded together. Deep foul ulcers appear, the gums become gangrenous, and there is a fœtid discharge from the mouth. Strong beef-tea and plenty of nourishing food and flesh are required, while the local treatment demands energy and skill. The mouth should be frequently washed with weak solution of carbolic acid.

CANDLE-TREE. (*See* CRESCENTIACIACEÆ.)

CANDLEBERRY, known also as Candleberry Myrtle, Bayberry, Tallow Tree, Wax Tree, or Wax Myrtle. (*Myrica cerifera*), a low spreading shrub or tree found in America, bearing berries, about the size of pepper corns, which, when ripe, are covered with a whitish green wax. The berries are boiled, and the wax, which rises to the top, is then skimmed off, and afterwards melted and refined and made into candles. They burn with a feeble light but give an agreeable balsamic odour. A bush of berries yields from four to five pounds of wax. A pleasantly scented soap is also made from the wax.

CANDLE FISH, OR EULACHON, a remarkable fish (*Thaleichthys Pacefecus*) of the family *Salmonidæ*. It is a sea fish, but approaches the coasts to spawn. It is found in the Pacific Ocean, near the north western shores of America, is of a greenish-olive colour on the back, with white sides and belly, and a few yellow spots, and is about seven inches long. It is a remarkable oily fish, and the Indians pass a strip of rush or bark through it for a wick and use it as a candle, whence the popular name. The flesh is dried for food and oil is obtained from the fish by the Indians.

CANDLE NUT, a heart-shaped nut, about the size of the walnut, the fruit of the tree *Aleurites triloba*, sometimes known as the candle nut tree. It is a member of the order *Euphorbiaceæ*, and is found in the South Sea Islands, Madagascar, Malacca, Java, &c., a gummy substance exudes from it, which some of the natives chew. The nut has a hard shell which yields a lamp black used in tattooing, and the kernel is fit for food when roasted. In the raw state it usually causes purging and colic. A bland oil is expressed from it which is used for food and also for lamp-oil. After being slightly boiled, holes are bored in the kernels and they are strung on a rush to be burned as a torch. This is done by wrapping four or five strings together in a leaf of the screw-pine (*Pandaum*), when they burn with so much brilliancy that they are used for fishing by night.

CANDYTUFT (*Iberis*), a genus of plants of the natural order *Cruciferæ*. The genus is divided into several species, one of which is a doubtful native of Britain (*I. amara*), and is very bitter; another comes from Candia (hence the name), and another from Spain-Iberia, hence the Latin designation. Some are annuals, some herbaceous perennials. The most familiar are the annual White and Purple (*I. umbellata*), the Sweet-scented (*I odorata*), and two slightly shrubby species (*I semper virens* and *I semper florens*). The latter, as its name implies, will blossom throughout the year in favourable situations.

CANE, *kain* (Lat., *canna*), a term commonly applied to any small smooth stick of the thickness of an ordinary walking stick or even less, but more correctly limited to the stem of small palms or large grasses. Thus we speak of sugar cane, bamboo cane, &c. The name is particularly applied to the species of the genus *Calamus*, known as rattan, and it is also to this genus belong the cane largely imported from the eastern tropics for making the bottoms of chairs, couches, &c. (*See* CALAMUS, BAMBUSA.)

CANE-BRAKE (*Arundinaria macrosperma*), a large reed or grass allied to the bamboo, found in marshy situations of the warmer parts of North America.

CANE SUGAR. (*See* SUGAR.)

CANELLA, *ka-nel'-la*, often called Wild Cinnamon, the typical genus of the natural order *Canellaceæ*. The inner bark of *C. alba* forms the Canella of the apothecaries. The tree is common in many parts of South America and in the West India islands; in commerce, white wood bark and white cinnamon. The bark is removed and dried in the shade. It is seen in flat or quilled pieces, of a light buff-colour, and from having been confounded with Winter's bark (*see* DRIMYS), it is sometimes called spurious Winter's bark. Being aromatic, stimulant, and tonic, it is used in medicine, and sometimes as a spice. Distilled with water, it yields an essential oil, which is often mixed with, and sometimes sold for, oil of cloves.

CANELLACEÆ, *ka-nel-lai'-se-e*, the Canella family, a natural order of dicotyledonous plants, in the sub-class *Thalamifloræ*. There are but two genera known—*Canella* and *Cinnamodendron*, which consist of evergreen shrubs possessing aromatic properties.

CANES VENATICI, *ka'-nez ven-a-ti'-ci* (Lat., hunting dogs), a constellation of the northern hemisphere. Within the limits of this constellation are several very remarkable nebulæ.

CANINA, CANIDÆ, *kan-i'-na* (Lat., *canis*, a dog), the dog tribe, which includes dogs, foxes, wolves, and jackals, all of which have a similar dentition. (*See* VARIOUS HEADINGS.)

CANIS MAJOR, *kai'-nis mai'-jor* (Lat., *canis*, dog; *major*, greater), a constellation of the southern hemisphere containing Sirius (*see* SIRIUS), which is the brightest star that appears in the heavens. It is situated below Orion, and a line drawn through the stars composing Orion's belt will pass through Sirius if prolonged. Besides this brilliant star, the constellation contains one of the second magnitude and many of the third and forth; 31 in all.

Canis Minor, a constellation of the southern hemisphere between Gemini and Canis Major. It contains one of the first magnitude called Procyon, which lies in a direct line between Sirius and Pollox. It contains 14 stars.

CANKER, *kank'-er* (Lat., *cancer*), a kind of gangrene which attacks young shoots and branches, and then the trunks of trees. If not cured or its progress prevented by cutting back the tree, that it may throw out new branches, it will gradually destroy it in the course of a few years. It is produced by accidental injury to the branches, or by superabundant moisture about the roots, that a stiff subsoil will not allow to drain away. Canker is also a name vaguely given to various diseases, attacking human beings and some of the lower animals, especially dogs and horses, characterised by the ulceration of the parts affected and the growth of a fungoid excrescence.

CANNA, *kan'-na*, a genus of plants belonging to the natural order *Marantaceæ*, or Arrow-root family.

CANNABINACEÆ, *kan-na-bi-nai'-se-e*, the Hemp family, a natural order of plants of the class *Dicotyledones*, sub-class *Monochlamydeæ*; consisting of rough herbs with a watery juice. There are only two genera—*Cannabis* and *Humulus*, the Hemp and the Hop, and each consists of but one species. (*See* HEMP and HOP.) They are natives of the temperate parts of Europe and Asia.

CANNABIS, *kan'-a-bis* (Lat.), the Hemp, a genus of plants representing the natural order, *Cannabinaceæ*.—*Cannabis sativa*, the only species, yields the valuable fibre called hemp, known from time immemorial as a material for cordage, sacking, and cloth. (*See* HEMP.)

CANNEL COAL, *kan'-nel kole*, a brittle, compact variety of coal having a waxy lustre and a conchoidal fracture. It burns with a bright flame, emitting large quantities of gas, which renders it particularly valuable for gas-making. Cannel coal is a corruption of candle coal, a name given to it from the candle-like brilliancy of its flame. The Scotch miners call it *parrot coal*, from the chattering noise it makes when thrown into the fire. Some of the harder varieties are used for working into ornaments like jet.

CANNON-BALL TREE, *Couronpita Guianensis*, a large tree, native of Guiana of the natural order *Lecythidaceæ*. It bears fruit resembling large cannon balls, the hard woody shells of which are often used for drinking vessels.

CANOPUS, *ka-no'-pus*, a very bright star of the first magnitude in Argo, a constellation of the southern hemisphere. The origin of the name is uncertain; but it was probably derived from the ancient Egyptian city Canopus, or Canobus, which was situated on one of the mouths of the Nile called the Canopic mouth, about three miles distant from the modern Aboukir.

CANTERBURY BELLS. (*See* CAMPANULA.)

CANTHARADIN, *kan-tha'-ra-din*, the crystalline blistering principle contained in the *Cantharis vesicatoria*, or Spanish blister-fly. To procure it the flies are digested in alcohol. The alcoholic solution is afterwards evaporated to dryness, and washed with cold ether, which dissolves out the cantharadin. When pure, it is insoluble in water, but very soluble in boiling alcohol. Lard containing one five-hundredth of cantharadin will produce a very powerful blistering effect when applied to the human skin.

CANTHARIDÆ, *kan-thar'-e-de* (Gr., *kantharos*, a beetle), the name given to a family of coleopterous insects, very numerous, much variegated in colours, of moderate size, and generally living on vegetable substances. They are distinguished by the head being dilated behind the eyes, and then suddenly narrowed into a short neck. When alarmed, they counterfeit death; and some varieties at the same time emit a thick yellowish fluid, with a disagreeable smell, from the articulatories of the legs, &c. Many species are employed externally in medicine to produce blisters, as they possess strong vesicating powers. Many species of the genus *Cantharis* which possess this property are natives of Europe, India, and America. The *Cantharis vesicatoria* is the common blister-fly. (*See* BLISTER-FLY.) The stripped cantharis is a native of North America, where it is called the Potato-fly. The genus *Mylabris* contains several species, which have properties similar to those possessed by the Cantharis; and the genus *Meloe* has also various species which have all the properties of the blister-fly.

CAOUTCHOUC MINERAL, *ka-oot'-chook*, an elastic bituminous mineral, resembling caoutchouc in its physical properties. A few specimens of this substance have been found in a lead mine in Derbyshire, in a coal mine at Moxbrelais, and in bituminous limestone at Woodbury, in Connecticut.

CAPACITY, SPECIFIC INDUCTIVE, *ka-pas'-i-te*, a term applied by Faraday to indicate a difference in the powers or capacities which various dielectrics (materials between the plates of an electric battery) possess for transmitting statical inductive influence across them. Numbers expressing the difference with reference to some common standard are named the *specific inductive capacities* of the substances. Thus, air being taken as unity, the following numbers represent the capacities of various substances: spermaceti, 1·45; resin, 1·7; pitch, 1·80; wax, 1·86; glass, 1·90; shellac, 2; sulphur, 2·24. The specific inductive capacity of all gases is the same.

CAPELLA, *ka-pel'-la* (Lat., *capella*, a she-goat), a brilliant star of the first magnitude in the constellation Auriga.

CAPERCAILZIE, OR CAPERCAILIE, *ka-per-kail'-ze* (*Tetrao urogallus*), a bird of the Grouse species, whose appellation is of Gallic origin, and means "horse of the wood;" it is also called the Cock of the wood. It is the largest of the gallinaceous birds of Europe, and was formerly common in the Highlands of Scotland, but became extinct. It has, however, recently been re-introduced. It prefers the pine forests of Norway and Scandinavia, in which regions it is found in abundance. The food of the capercailie consists of the leaves of the Scotch fir, also various berries found in the North. The young have a more luxurious diet, feeding on ants, worms, and other insects. The size of this species varies considerably; in some cases a full-grown male (which is one-third larger than its mate) will scarcely weigh ten pounds; whereas it will sometimes exceed sixteen pounds. The capercailie may lay claim to considerable beauty. Its plumage is beautifully glossy, mottled with grey and brownish-black, the neck and breast black, tinged with a rich green. The female's attire, unlike its more resplendent mate, is humble, and is variegated with yellowish-brown, white, and brownish-black. It is much esteemed for the table.

CAPERS. (*See* CAPPARIS.)

CAPILLARIES, *kap-il'-la-rees* (Lat., *capillus* a hair), the minute blood-vessels of the body, which form the connection between the extremities of the arteries and the veins. It is in the capillaries that nearly all the changes in the blood take place.

CAPILLARY ATTRACTION, OR ACTION, a term applied to the phenomena produced when solid bodies are brought into contact with liquids. These phenomena are best observed in small tubes, about the diameter of a hair—hence the name. In all cases, although the phenomena are very varied in their nature, the result may be attributed to the mutual attraction of the liquid molecules for each other, and to the attraction between these molecules and solid substances. When a solid substance is immersed in a liquid which wets it, as, for instance, a glass rod in water, the liquid becomes curved upwards towards the side of the solid, making its surface slightly concave, instead of being horizontal. If, however, the liquid does not wet the solid, as, for instance, a glass rod dipped into mercury, the liquid is depressed against the sides of the solid and assumes a convex shape. The surface of the liquid against the sides of the vessel which contains it is also concave or convex, according to whether the liquid does or does not wet it. If a small tube, instead of a glass rod is employed, these phenomena become much more apparent. The liquid ascends, or is depressed, according to whether the tubes are moistened by the liquids or not. The amount of ascent or depression is proportionately greater according to the diameter of the tube. Analogous capillary phenomena occur when two bodies of any given shape are immersed in water, provided they are sufficiently near. If two parallel plates of glass are immersed in water at a short distance from one another, the water will rise between them in the inverse ratio of the separating distance. If the plates are immersed in mercury instead of water, a corresponding depression is the result. If two glass plates, inclined to one another at a small angle, be so immersed in a liquid which wets them that the line of contact between the two plates is vertical, the liquid will rise towards the summit of the angle of the two plates. The theory of capillary attraction is one of the most difficult in physics, and can only be completely treated by mathematical analysis. The effects of capillary attraction are to be observed in many operations in nature. By it the blood circulates in the porous tissues of animals, water is supplied to the roots of growing plants, and moisture is raised to the surface for the maintenance of vegetable life in seasons of drought. Insects can often move on the surface of water, because their feet are not wetted by the fluid, and a depression is caused which buoys them up. A polished sewing-needle will float on the surface of water. Oil ascends in the wicks of lamps by capillary attraction, and water rises in wood, sponge, bibulous paper, and other substances, by the same force.

CAPITULUM, *ka-pit'-u-lum*, a kind of inflorescence, consisting of a close terminal collection of flowers surrounded by an involucre. It constitutes the *compound flower* of Linnæus, and is also known under the names *anthodium* and *head*.

CAPNOMOR, OR KAPNOMOR, *kap'-no-mor* (Gr., *kapnos*, smoke, and *moira*, a part), a colourless oil of peculiar odour, resembling that of ginger, discovered by Reichenbach, amongst other products, in heavy oil of tar. It is limpid and volatile, insoluble in water and solution of potash, but dissolving readily in alcohol, ether, and the essential and fixed oils. Its specific gravity is slightly below that of water. It boils at 345° Fah. and distils unaltered. It is obtained by distilling a solution of crude creosote in potash and with water. With sulphuric acid it forms a purple-red solution.

CAPPARIS, *kap'-par-is*, the Caper-bush, the typical genus of the sub-order *Cappareæ*, of the natural order *Capparidaceæ*. The pickled flower-buds of various species are used under the name of capers. Those eaten in Europe are the produce of *C. Spinosa*, a trailing shrub which grows in rocky places in the south of Europe. It is the only species of the order found on the north of the Mediterranean. The seeds of the caper of Mount Sinai (*C. Sinaica*) are pickled and used instead of pepper. The capers used in Barbary are obtained from *C. Fontanesii*, and those used in Egypt from *C. Ægyptiaca.* It has been suggested that the latter species is the hyssop of Scripture. (*See* HYSSOP.)

CAPPARIDACEÆ, *kap-par-i-dai'-se-e* (from the Arab., *kapar*, capers), the Caper family, a natural order of dicotyledonous plants in the sub-class *Thalamifloræ*, including 28 genera and about 340 species—herbs, shrubs, and a few trees, mostly natives of tropical and sub-tropical regions. The two kinds of fruit, one dry and pod-like, the other a berry, have led to a division of the order into two sub-orders—viz., *Cleomeæ*, characterised by a capsular fruit, and *Cappareæ*, by a baccate fruit or berry. In their properties the *Capparidaceæ* greatly resemble the *Cruciferæ*, being generally pungent, stimulant, and antiscorbutic. Some are aperient, diuretic, and anthelmintic.

CAPRA, the Goat. (*See* GOAT.)

CAPRICORNUS, *kap-re-kor'-nus* (Lat., *capricornus*, a goat), a constellation in the southern hemisphere, from which the tenth sign of the zodiac, between 270° and 300° of longitude from the first point of Aries, originally derived its name. The sun enters the winter solstice in this sign which is usually represented as having the forepart of a goat and the hind part of a fish.

CAPRIDÆ, *kap'-ri-de*, a family of ruminant quadrupeds, constituting the sheep and goat family, in which some naturalists include antelopes.

CAPRIFOLIACEÆ, *kap-ri-fo-li-ai'-se-e* (Lat., *caper*, goat; *folium*, leaf, in reference to the climbing habit of the plant), the Honeysuckle family a natural order of dicotyledonous plants in the sub-class *corollifloræ*. There are 16 genera and about 220 species, chiefly natives of the northern parts of Europe, Asia, and America. They often have showy flowers, which are commonly sweet-scented. Many are cultivated in our gardens and shrubberies; as Honeysuckles, which are species of the genera *Caprifolium* and *Lonicera*; Guelder-roses, species of *Viburnum*; the Laurustinus (*Viburnum Tinus*); the Snowberry (*Symphoricarpus racemosus*); and the common Elder (*Sambucus nigra*). Some of the plants are emetics and mild purgatives; others are astringent; others sudorific and diuretic; and a few are acrid.

CAPRIMULGIDÆ, *kap-ri-mul'-ji-de*, a family of birds of the order *Insessores* and tribe *Fissirostres*, nearly allied to the swallow tribe. They are insectivorous, have long wings, short legs, and toes united at the base by a membrane. The family includes the goat-sucker, the whip-poor-will, and the American night-hawk.

CAPSICINE, *kap'-si-sene* (from *capsicum*, derived from Gr., *kapto*, I bite, in allusion to its pungency), an alkaloid found in the capsules of the various species of capsicum used in the manufacture of cayenne pepper. It has a burning taste; is insoluble in water and ether, but soluble in alcohol, and may, when quite pure, be crystallized. It forms salts with nitric, sulphuric, and acetic acids.

CAPSICUM (from Gr., *kapto*, I bite), a genus of plants belonging to the natural order, *Solanaceæ*, consisting of numerous species. Though now extensively cultivated in many parts of the Old World, the various species are supposed to be natives of South America. The officinal capsicum, the *C. annuum* of Linnæus, or the *C. fastigiatum* of Blume, has oblong cylindrical fruits, not an inch long in the most valuable varieties, but two or three inches long in others. These fruits are commonly sold as *Chillies*, and are used to make a hot pickle, and the liquid known as *Chili vinegar.* Cayenne pepper consists of the powdered fruits of several species of capsicum, found in the West Indies and South America. In medicine, the fruit of the capsicum is used as a counter-irritant: with salt as a stimulant in scarlatina; as a gargle in relaxed sore-throat; and in the form of Cayenne lozenges.

CAPSULE, *kap'-sule* (Latin, *capsa*, a chest), a one or more-celled, many-seeded, dry, dehiscent fruit. It is *syncarpous*, that is, formed of several carpels united together. The dehiscence or opening of the capsule may either take place by valves, as in the foxglove, primrose, and rhododendron, or by pores near the summit, as in the poppy and snapdragon. The distinctive name of *Pyxis* or *Pyxidium* has been given to a beautiful kind of capsule, which opens as if cut around near the summit, and presents the appearance of a cup with a lid. Examples of the latter may be seen in the pimpernel and henbane. The capsule is one-celled in the mignonette, heart's-ease, and gentian; two or more celled in the scrophularia, colchicum, iris, and datura. It is a very common form of fruit.

In Anatomy, a membranous production, inclosing any part like a bag; as the capsular ligaments inclosing the synovia of the joints, the capsule of the crystalline lens of the eye.

CAPUCHIN MONKEY, a name given to some South American monkeys, of the genus *Cebus*, which has the head covered with short hair, so disposed as to resemble the cowl of a Capuchin monk. The name Capuchin Sapajou is sometimes used.

CAPUT, *kai'-put* (Lat., the head), that portion of the human body which comprises the skull and face. The skull is distinguished into the following parts:—the *vertex*, or crown; the *sinciput*, or fore part of the skull; the *occiput*, or hind part; the *tempora*, or temples. The parts of the *facies*, or face, are the forehead, eyes, nose, &c. (*See* FACE.) The term *caput* is also applied to—1, the upper extremity of a long bone, as the humerus; 2, the origin of a muscle; 3, a protuberance resembling a head, as the *caput Galli-naginis*, a small eminence in the urethra; 4, the beginning of a part; as *caput coli*, the head of the colon.

Caput Obstifrum (Lat., stiff head), denotes wry-neck, an involuntary and fixed inclination of the head towards one of the shoulders.

CAPYBARA (*Hydrochærus capybara*), *kap-i'-ba-ra.* A rodent animal found in South America, in general appearance greatly resembling a small pig, and sometimes called the Water Hog; or, in Demerara, the Water Horse, a corruption of the Danish Water Haas, water hare. The dentition shows a link of connection between the rodents and the pacherdymata. It feeds on vegetables, and is especially fond of the sugar cane. The flesh of the young animal is eaten.

CARABIDÆ, *ka-rab'-i-de* (Gr., *karabos*, a beetle), a family of coleopterous insects, comprising several species. In general, the members of this family prey upon insects; and the construction of their bodies is eminently adapted for this purpose, being very firmly encased in a stout covering, enabling them to search among the stones, crawling over and under them for their prey without fear of hurt; at the same time they can suffer but little from the attacks of other insects. The Bombardier Beetle (which *see*) belongs to this family, and a very large and singular insect of the tribe is the *Mormolyce phyllodes*, a native of Japan, which has an extremely flattened body. Some species of the Carabidæ are, it has been ascertained, herbivorous, finding their food principally in the cornfields.

CARACAL, *ka-ra-kal'* (*Felis Caracal*), sometimes called the Persian lynx, is found in both the continents of Asia and Africa. This animal is the lynx of the ancients. It is about three feet in length, of a pale reddish-brown above, and whitish beneath. It has a small head, although somewhat elongated, and ears with tufts of long black hair. In disposition it is fierce and savage, and it possesses great strength. It can, however, be tamed, and is used as an animal of chase.

CARACARA, *ka-rak'-a-ra* (*Polyborus*), a genus of birds of prey, regarded as a connecting link between eagles and vultures. They are peculiar to the American continent, and the name is derived from the harsh cry of a common Brazilian species (*P. Braziliensis*). This bird has very fine plumage, and measures from tip to tip of the wings, when expanded, about 50 inches. The hooked bill and claws resemble those of the eagle; but the naked face and the liking for carrion give a resemblance to the vulture.

CARADOC SANDSTONE, *kar'-a-dok.* (*See* BALA LIMESTONE.)

CARAMBOLE. (*See* AVERRHOA.)

CARAPA, *ka-rai'-pa* (from *caraipe*, its African name), a genus of tropical plants belonging to the natural order *Meliaceæ*. *C. Guineensis*, an African species, yields a fatty oil called kundah or tallicoonali, which is purgative and anthelmintic. Besides being valuable in medicine, it is well adapted for burning in lamps. It is expressed from the seeds. The bark of the tree has febrifugal properties. *C. Guineensis*, a native of Guiana, South America, and the adjacent countries, furnishes similar products; indeed, it is somewhat doubtful whether the species are essentially distinct.

CARAPACE, *kar'-a-pace*, the strong shell or shield covering the backs of tortoises, turtles, crabs, lobsters, &c.

CARAWAY. (*See* CARUM.)

CARBAMIC ACID, *kar-bam'-ik.* When dry carbonic acid and dry ammoniacal gas are mixed, a white substance results, which was formerly supposed to be anhydrous carbonate of ammonia. Later investigations proved that it was a compound, containing ammonia combined with carbonic acid. Carbamic acid forms salts with numerous other bases, which are interesting only in a theoretical point of view.

CARBAMIDE, *kar'-bam-ide*, a peculiar compound, formed by the action of ammonia on chloro-carbonic acid. It is said to be identical with urea. (*See* UREA.) Carbamide may be regarded as carbonic acid with an equivalent of oxygen, replaced by an equivalent of amidogen.

CARBAZOTIC ACID, OR PICRIC ACID, *kar'-bai-zot'-ik*, a complex acid, produced by the action of nitric acid on a number of organic substances, such as phenic acid, salicin, phloridzin, silk, indigo, and a number of the resins. Carbazotic acid is soluble in 80 or 90 parts of cold water, forming a liquid of a bright yellow colour. It has an intensely bitter taste, and has been used as a fraudulent substitute for hops in making bitter ale. It has been employed in dyeing silk and wool, to which, in conjunction with cream of tartar or alum as a mordant, it gives a fine yellow colour. Carbazotic acid is sometimes employed as a test for potash, with which it forms a bright yellow crystalline precipitate, even in dilute solutions.

CARBON, *kar'-bon* (Lat., *carbo*, a coal)—symbol C, equivalent 6, specific gravity as diamond 3·55, as graphite 1·9 to 2·3—an elementary non-metallic solid body, very widely diffused through nature. Its purest and rarest form is that of the diamond (*see* DIAMOND), but in the forms of graphite and mineral charcoal it occurs very abundantly in nearly every part of the world. It also occurs, in combination with oxygen, as carbonic acid, in small quantities in the air, and in the waters of most springs. In combination, as carbonic acid, with lime and magnesia, it occurs, in enormous quantities, as lime-stone, marble, chalk, dolomite, &c.; whilst, combined with hydrogen, it enters largely into coal, peat, and lignite. From its invariable presence in all organic matter, it has been called the organic element. From entering thus directly into the vegetable and animal creation, carbon may be considered as the most important element; and the pouring out of carbonic acid by animals, to serve for the food of vegetables, is one of the many silent chemical operations constantly going on around us. The wonderful provision of Nature by which the carbonic acid cast out by animals as a poisonous product is converted into food for the support of plants, by the action of the sun's rays, has been the admiration of all philosophers and chemists from the days of Lavoisier to the present time. Carbon, as it exists in the form of the diamond is fully described under that head.

CARBONIC ACID, *kar-bon'-ik*, is the product of the combustion of all substances containing carbon. It exists in the atmosphere to the extent of one volume to 2,500 of air, occurs in combination with metallic oxides in the mineral kingdom, also dissolved in mineral springs. It issues from the earth in volcanic districts, and forms the deadly choke-damp of the coal-mines. It is also a product of respiration, fermentation, and putrefaction, which is nothing more than slow combustion. It is easily prepared by acting on a carbonate, such as chalk or marble, with nitric, sulphuric, or hydrochloric acid, in a gas-generating apparatus. The carbonate of lime is converted into chloride of calcium, and the carbonic acid escapes as gas. Carbonic acid is known in the solid, liquid, and gaseous states. By a pressure of thirty atmospheres, at 32° Fah., it is liquefied, the pressure requires decreasing as the temperature gets lower. Liquid carbonic acid is colourless, insoluble in water and fatty oils, but mixing in all proportions with ether, alcohol, bisulphide of carbon, naptha, and turpentine. At—94° Fah. it solidifies into a vitreous transparent mass. Solid carbonic acid is best prepared by generating carbonic acid in a condenser until it is liquid, and then allowing it to escape through a stop-cock into the air. The liquid gas evaporates with such rapidity that intense cold is produced, and the remainder is converted into snow. It is a bad conductor of heat, and may be handled with impunity, a film of gaseous carbonic acid always protecting the hand from injury. If pressed upon the skin, a blister is produced similar to that caused by a burn. It is used, in conjunction with ether and bisulphide of carbon, for producing intense cold. Gaseous carbonic acid is colourless, possessing a slightly acid smell and taste. At ordinary temperatures it dissolves in water in the proportion of bulk for bulk. By pressure water may be made to take up great quantities of the gas, the same *volume* being always absorbed, no matter how great the pressure may be. Upon the removal of the pressure, the gas escapes in bubbles. A familiar instance of this occurs in the effervescence of bottled beer or aërated waters. When inhaled, carbonic acid produces death, even when much diluted. A lighted candle is generally used to test an atmosphere suspected to contain carbonic acid; but it is found that air that will support combustion will contain sufficient of this gas to cause insensibility and dangerous illness. It is the deadly poison of the Upas valley of Java, of the Grotto del Cane, near Naples, and of the Laach lake in Rhenish Prussia. Carbonic acid produced during respiration may be shown by breathing through a tube into lime-water, which is at once rendered cloudy by the formation of carbonate of lime. The ill effects of crowded rooms are owing to the systemic depression produced by small quantities of carbonic acid. Carbonic acid was formerly called *fixed air*, from the fact of its having been discovered as a solid or fixed constituent in limestone by Dr. Black, in 1757. Though a feeble acid, and easily separable from its combinations, carbonic acid unites with the metallic oxides, forming a very numerous and important class of salts, the carbonates, descriptions of which will be found under the headings of their bases. The carbonates of the alkalies are soluble in water, the carbonates of the other metallic bases being for the most part insoluble, except the water is highly charged with carbonic acid. Hard water contains carbonate of lime or magnesia, held in solution by the carbonate acid contained in the water: hence, when the gas is dissipated by boiling, the carbonate of lime is precipitated, incrusting the vessel in which it has been boiled. Carbonic acid contains one equivalent of carbon, united with two of oxygen. Its true composition was discovered by Lavoisier, who bestowed on it the name it bears.

CARBONIFEROUS SYSTEM, *kar-bon-if'-e-rus*, in Geology, the name given to the great assemblage of fossiliferous strata resting upon the old Red sandstone, and capped by the Permian series. To this system the great coal-fields of the world belong. It consists of alternations of sandstones, shales, clays, limestones, coals, and ironstones, in every degree of admixture and purity, and of every condition of formation—terrestrial, fresh-water, estuary, and marine. In the strata there have been discovered fossils representing all the great forms of life, with the exception, perhaps, of true dicotyledonous plants in the vegetable kingdom, and of birds and mammals in the animal kingdom. The most striking peculiarity in the system is the profusion of fossil vegetation which marks almost every stratum, and which, in numerous instances, forms thick seams of solid coal. Although this *coaly* or *carbonaceous* aspect prevails throughout the whole, it has been found convenient to arrange the system into three groups—The lower coal-measures or carboniferous slates, the mountain or carboniferous limestone, and the upper or true coal-measures; or more minutely, according to the views of most British geologists, into the following series:—1, upper coal-measures; 2, millstone grit; 3, mountain limestone; and 4, lower coal-measures. Other sub-divisions have been attempted, according to the local peculiarities of different coal-fields; but it is enough for the purposes of the general reader to know, that all these minor arrangements can be readily co-ordinated with one or other of the above four series.

CARBUNCLE, *kar bun'-kl* (Lat., *carbunculus*, a little coal), is a broad, flat, firm, burning tumour, usually of considerable size. It begins with a hard, painful swelling, of a livid colour, which rapidly enlarges. The pain is severe, and is much increased by pressure; the patient is much depressed, and a general derangement of the system takes place. Vesicles form on the part, which soon open, and discharge a thin viscid fluid, with occasionally slaughed portions of disintegrated tissue. Sometimes these apertures run into each other, and form large openings. The predisposing cause of this disease is a derangement of some of the secretions of the human body, which is to be remedied by purgative and other medicines suited for each particular case; the system being at the same time supported by tonics and a nourishing diet. This, however, is not enough—an early and free application of the knife is necessary to the part itself. An incision, usually in the crucial form, throughout the whole extent of the diseased massevacuates the purulent formation, and affords an exit for the sloughs when loose. Poultices are also applied with advantage.

CARBUNCLE, the beautiful mineral pyrope (which *see*), and the name is also given to a garnet, cut on the under side, and concave on the upper. The light is generally reflected in a flame-like form: hence the name. The clear deep-red garnets from Pegu are most highly valued. (*See* GARNET.)

CARBURETS, *kar'-bu-rets.*—Carburets are now called carbides, the word being more analogous to chloride, iodide, &c.

CARBURETTED HYDROGEN. (*See* HYDROGEN.)

CARBYLE, SULPHATE OF, *kar'-bile*, ethronic anhydrine, so called by its discoverer Magnus. It is a combination of four equivalents of sulphuric acid with one of olefiant gas. (*See* ETHIONIC ACID.)

CARCERULE, *kar'-se-rule* (Lat., *carcer*, a prison), many-celled fruit, each cell being dry, indehiscent, and one or few-seeded, and all more or less cohering by their united styles to a central axis. The fruit of the common mallow is a good example.

CARDAMINE, *kar-de-mine* (from Gr., *kardia*, heart or courage, on account of its strengthening properties), a genus of plants belonging to the natural order *Cruciferæ*. *C. pratensis*, the cuckoo-flower, or lady's-smock, is an indigenous perennial met with in meadows and moist pastures, blossoming in the months of

April and May, when its flowers, which are flesh-coloured, white, or light purple, present a very pleasing appearance. Formerly the flowers were used medicinally, as a remedy in epilepsy. The leaves are antiscorbutic, and are sometimes eaten as watercress.

CARDAMOMS. (*See* ELETTARIA and AMOMUM.)

CARDIA, *kar'-di-a* (Gr., the heart), the superior opening of the stomach, on account of its being situated near the heart.

CARDIACEÆ, *kar-di'-ai-se-e* (Gr., *kardia*, the heart), a family of bivalve *Mollusca*. They have a thick, closed, equivalve shell, with the umbones usually bent round, so that the shell, when seen from either extremity, presents a more or less cordate appearance. The hinge-teeth are strong, from one to three in each valve, and there are usually one or two smaller teeth on each side of the hinge. The animal possesses two adductor muscles. The species of this family are very numerous, and greatly vary in size, some of their shells being remarkable for the smallness and delicacy of their construction. The type of this family is the Cockle. (*See* COCKLE.)

CARDIALGIA, *kar-di-al'-jia*, pain of the heart or stomach. (*See* HEARTBURN, INDIGESTION.)

CARDINAL BIRD. (*See* GROSBEAK.)

CARDINIA, *kar-din'-i-a*, a genus of fossil conchiferæ, with oval or oblong shells. They extend from the Silurian to the inferior oolite, and abound in the "mussel-bands" of clay ironstone. In Derbyshire, vases and other ornaments are turned from these fossils.

CARDIOSPERMUM, *kar-di-os-per'-mum* (Gr., *kardia*, heart, *sperma*, seed, in reference to the shape of the seeds), a genus of plants belonging to the natural order *Sapindaceæ*. The root of the species *C. halicacabum* is diuretic, diaphoretic, and aperient. The leaves are boiled and eaten as a table vegetable in the Moluccas.

CARDITIS, *kar-di'-tis* (Gr., *kardia*, the heart, terminal *itis*), inflammation of the heart. It is characterized by pain in the region of the heart, great anxiety, fever, difficulty of breathing, palpitation, cough, irregular pulse, and fainting. It is applied properly to inflammation of the muscular tissue of the heart itself; but this is a form of disease that rarely occurs alone, being usually accompanied by *pericarditis*, or inflammation of the pericardium, or by *endocarditis*, or inflammation of the lining membrane of the heart. The symptoms and treatment in each case are similar. (*See* HEART, DISEASES OF.)

CARDIUM, *kar'-di-um*. (*See* COCKLE.)

CARDOON, *kar-doon'* (Sp., *cardon*), a garden vegetable, introduced into this country about the middle of the 17th century from the south of Europe. It bears a great resemblance to the artichoke, and belongs to the same botanical genus. (*See* CYNARA.) The tender stalks of the inner leaves, rendered white and crisp by earthing up, are used for stewing, and for soups and salads during the winter. With the florets of the cardoon, called *cardo do coalho*, the Portuguese formerly coagulated milk for cheese-making.

CARDUELIS, *kar'-du-e'-lis* (from Lat., *carduus*, a thistle, on account of their love for the seeds of the thistle), a genus of birds of the Finch tribe. (*See* CANARY, GOLDFINCH, &c.)

CARDUUS, *kar'-du-us*. *See* THISTLE.)

CAREX, *kai'-reks* (Lat., *careo*, I want, the upper spikes being without seeds), a genus of plants belonging to the natural order *Cyperaceæ*, or sedge family, consisting of upwards of 450 species, more than sixty of which are British. The creeping stems of *C. arenaria* and other species help to bind the sands of seashores, and the plants are sometimes carefully cultivated for this purpose on the dykes of Holland. These stems, improperly called roots, have been used medicinally as substitutes for sarsaparilla, under the name of German sarsaparilla.

CARIACOO, *kar'-i-a-koo*, or Virginian deer (*Cervus Virginianus*), a species found in all parts of North America. It is small and of elegant shape, and the colour is variable, being light reddish brown in spring, slaty blue in autumn, and dull brown in winter. The belly, throat, chin, and inner parts of the limbs are white. The horns of the adult male are bent backwards and then suddenly forward, so as to bring the tips nearly above the nose.

ÇARIAMA, *sa-ri-a'-ma*, a bird (*Microdactylus cristatus*) of the order *Grallæ*, nearly allied to the cranes, a native of South America. It is larger than the common heron, and feeds chiefly on serpents, lizards, and insects. The plumage is brown, but whitish on the lower parts.

CARIBOU, *kar-i-boo'*, the American reindeer (*Rangifer caribou*). There are two well-marked permanent varieties inhabiting the fur-countries, one limited to the woody and more southern districts, and the other, known as the barren-ground caribou (*R. Grœnlandicus*), retiring to the woods only in the winter, and passing the summer on the coast of the Arctic ocean. There is a large variety in Newfoundland, Nova Scotia, and New Brunswick, having very large and heavy horns. The colour of the caribou is in the summer a rich, glossy reddish brown, becoming more grizzly, especially about the head, neck, and belly, during the winter. The tail is short, like that of a rabbit, and the hoofs have an immense spread, which gives the animal, when running over soft snow, or a crusted surface, a support almost equal to that of a snow-shoe. The average length of the animal is about six feet, and the height at shoulder three and a half feet. The flesh is said to equal the finest English venison, and the skin is made into clothing, which is almost impervious to cold.

CARICA, *kai'-re-ka* (from being erroneously supposed to be a native of Caria), a genus of plants belonging to the natural order *Papayaceæ*. The species are natives of South America and the tropical regions of the old world. The acrid milky juice of *C. digitata* is said to be a deadly poison. The juice of the unripe fruit, and the powdered seeds of *C. papaya*, are powerful anthelmintics; but the fruit, when cooked, is edible. It is stated that newly-killed meat hung among the leaves soon becomes soft and delicate, and that the flesh of old hogs and old poultry fed on its fruit or leaves is remarkably tender. The leaves are used in some districts as a substitute for soap. The juice is said to be a highly animalized product, resembling animal albumen in its characters and reactions.

CARIES, *kai'-reez* (Lat., rottenness), a disease of the bones analogous to ulceration of the soft parts. Caries most frequently attacks the bones of the spine; but it may affect any of the bones, especially such as are of a spongy texture, as the carpal or tarsal bones, or the heads of the long bones, where they form articulations. The young, or those of a scrofulous habit of body, are most subject to this disease. It sometimes appears spontaneously; at others, as the result of an injury, as a blow or fall. It begins with inflammation, usually attended with a dull, heavy pain and weakness in the part affected. In course of time an abscess forms, which, if not arrested, at length bursts and discharges a thin fluid containing particles of the bone. In caries of the vertebræ, curvature of the spine takes place, more or less, according to the number of vertebræ affected, and paralysis generally sets in. At the articulation of the bones, the part enlarges, the cartilages become affected, and amputation or excision of the joint is often necessary, in order to save the patient's life. Much may be done in arresting the progress of this disease, at least in its earlier stages. For this purpose, the patient should be strengthened by good air and nourishing diet, at the same time that rest is enjoined: the state of the stomach and bowels should also be attended to. In the local treatment of the disease, blisters, leeches, and issues, are to be employed. The abscesses are best left to nature, unless they are productive of much uneasiness. When they have burst, the exfoliation of the diseased part should be expedited as much as possible, so that the healthy portions of the bone may granulate and heal. Caries of the teeth is the cause of that most painful affliction, toothache.

CARISSA, *kar-is'-sa*, a genus of plants belonging to the natural order *Apocynaceæ*. The species *C. Carandas* bears an edible fruit about the size of a small plum, which is eaten in the East Indies, either alone or with meat, as a substitute for red-currant jelly. The fruits of *C. edulis* and *tomentosa* are also eaten in Abyssinia.

CARLINA, *kar-li'-na* (after the emperor Charlemagne, whose army was cured of the plague by it), a genus of plants belonging to the natural order *Compositæ*, and closely allied to the Thistles. *C. acaulis*, the Carline thistle, grows on hills and mountains, especially in calcareous soils, in the middle latitudes of Europe. It was formerly in high repute for the medicinal virtues of its root, which, in large dozes, acts as a drastic purgative; but its use is now confined to veterinary practice. The *C. vulgaris* is the only British species.

CARLUDOVICA, *kar-lu-dov'-e-ka* (in honour of Charles IV. and Louisa of Spain), a genus of plants of the natural order *Pandanaceæ*. The unexpanded leaves of *C. palmata* furnish the material employed in the manufacture of Panama hats.

CARMINATIVES, *kar-min -a-tivs*, certain substances which have the power of dispelling flatulence, or relieving pain in the stomach and bowels. They belong chiefly to the vegetable kingdom; as, cardamoms, peppermint, ginger, and other aromatic stimulants.

CARNATION, a beautiful cultivated flower, a variety of the clove pink. (*See* DIANTHUS.)

CARNATRUBA, OR CARANAIBA, PALM, *kar-na-tru'-ba, ka-ra-nai'-ba* a beautiful species of palm (*Copernicia cerifera*) abounding in the northern parts of Brazil. It is not very tall, averaging about 30 feet, and has a black fruit about the size of an aloe. The leaves have scales of wax on the under part, which is collected and often used to adulterate bees' wax. It is also used in the manufacture of candles, the timber is valuable, and is used for veneer.

CARNELIAN, *kar-ne'-li-an* (Fr., *cornaline*), a term originally applied to a flesh-coloured calcedony, but now applied to blood-red, yellow, white, brown, and nearly black varieties of this mineral. They consist principally of silica coloured by oxide of iron. Bright red carnelians are the most highly valued, but larges tones equal in colour throughout are rare. This word is frequently written and pronounced *cornelian*. The finest carnelians are found in Arabia, India, Surinam, and Siberia. They are sometimes known as Cambay stones, being abundant in the Cambay district of India, where they are worked up into necklaces, bracelets, armlets, seals, chessmen, rings, and other ornamental articles.

CARNIVORA, *kar-niv'-o-ra* (Lat., *caro*, flesh; *voro*, I devour), a term applied to all creatures which feed upon flesh. It is definitely applied to that order of the mammalia which preys upon other animals.

CAROB. (*See* CERATONIA.)

CAROLINA PINK. (*See* SPIGELIA.)

CAROTID ARTERY, *kar-ot'-id* (Lat., *arteria carotidea*). A large artery on each side of the neck. It is so called from the Greek verb *karoo*, I cause to sleep, because, if tied or compressed, the person becomes comatose. The researches of Dr. A. Fleming prove conclusively that there is some connection between deep sleep and the compression of this artery. The right carotid arises from the arteria innominata, the left from the aorta. The left is thus rather longer than the right, and is in general somewhat smaller. They ascend backwards and outwards into the neck, and, when opposite the os hyoides, each of them divides into the external and internal carotid arteries; the former proceeding to the face and parts without the cranium, the latter to those within. The external carotid afterwards divides into ten branches—viz., the superior thyroid, lingual, lateral, occipital, muscular, pharyngea ascendens, posterior auris, transverse facial, temporal, and internal maxillary. The internal carotid enters the cranium by a somewhat tortuous course, and afterwards separates into four branches—the ophthalmic artery, and the anterior, posterior, and central arteries of the brain. A wound of the carotid is generally fatal, although instances have occurred, when by prompt and skilful treatment the artery has been tied and life saved. Sir Astley Cooper first tied the carotid for spontaneous aneurism.

CARP, *karp* (Fr., *carpe*) (*Cyprinus carpio*). This fish is found in most of the lakes and rivers of Europe, and in many places it is cultivated in ponds with great care. It is said to have been introduced into England about the beginning of the 16th century, and it has always been greatly esteemed as a delicate article of food. The carp usually feeds on worms and various insects; this diet, however, in places where this fish is bred, is intermixed with grain, &c. The length of a carp's life is amazing. A century would seem to be about the average; but a healthy fish will occasionally live to the age of 200 years, or thereabouts, its scales becoming white with age. When it is considered that it is an extraordinarily prolific fish, and that its roe has been known to turn the scale against the remainder of the carp out of which it has been taken, and that about 700,000 eggs have been taken from the ovaries of a moderate sized fish, it is, perhaps, fortunate that it is so generally popular as a diet. The carp usually measures about fifteen inches in length; in warm climates, however, it sometimes nearly reaches three feet. The general colour is yellowish-olive; the head is large, and the mouth is provided with two beards, one shorter than the other; the scales are large and very distinct. Its average weight in England seems to be three pounds; but thirty pounds is not unusual in Germany, and one weighing 70 has been taken. The gold fish is a near relation of the carp.

CARPEL, *kar'-pel* (Gr., *karpos*, fruit), a modified leaf, forming the whole or part of the pistil. When several carpels are present, they may be either distinct from each other, as in the columbine, or combined so as to form one body, as in the poppy. The carpels, taken collectively, constitute the *Gynœcium*, or female system of flowering plants. (*See* PISTIL.)

CARPENTER BEE, *kar'-pen-ter* (*Xylocopa*). This species belongs to the *Apidæ*, or true bees. Its name is derived from the singular manner in which its nest is built. This is generally found in soft decaying wood, and is lined with leaves of a semicircular form cut from plants. It is also known as the leaf-cutting bee and upholsterer bee. It is found in all parts of the world.

CARPINUS, *kar-pi'-nus* (Celtic *car*, wood, *pinda*, head, the wood being used for the yokes of cattle), a genus of plants belonging to the natural order *Corylaceæ*, which also includes the oaks, the hazels, the beeches, and the chestnuts. *C. Betulus*, the hornbeam, and *C. Americanus*, yield excellent timber, largely employed for agricultural implements and the cogs of mill-wheels.

CARPOLITES, *kar'-po-lites*, fossil fruits, which cannot be referred precisely to their proper place in the vegetable world. There are about 100 species now known.

CARPUS, *kar'-pus* (Gr., *karpos*), the wrist, or that part of the upper extremity between the forearm and the hand. The carpal bones, or bones of the wrist, are eight in number, and are arranged in two rows—a superior and inferior, each containing four bones.

CARRAGEEN, *kar'-ra-geen*, known also as Irish Moss, a generic term for several species of sea-weed, of the natural order *Algæ*, sub-order *Ceramiaceæ*, of late years it has been recommended for medicinal and dietetic purposes, principally by reason of the notice called to it by Mr. Todhunter of Dublin. The name is Irish, and doubtless the various species have been used by the Irish peasantry for many years. Several varieties are found on the coasts of Ireland, and also on the rocky shores of most parts of Europe and east coasts of N. America. The species principally used is the *Chondrus crispus*, of which there are several varieties. They all contain a large quantity of vegetable jelly, and when soaked in water and then boiled ($\frac{1}{2}$ oz. weed to 3 pints water) and strained, a pleasant drink is obtained. If boiled for a longer time a mucilage is produced which is sometimes used instead of size for house-painting, and which, when cooled, forms a stiff jelly, much valued on account of its demulcent properties. If boiled in a similar way with milk, spices, and sugar, a kind of *blancmange* is obtained which forms a nutritious, pleasant, and digestible food, recommended in cases of pulmonary consumption, and also in cases where iodine would be of value.

CARRARA MARBLE, *kar-ra'-ra*, a beautiful saccharine limestone of great beauty and fine texture, belonging to the Oolitic period. It is obtained from the famous quarries of Carrara (a town in North Italy) which have been worked for more than 2,000 years.

CARRIER PIGEON. (*See* PIGEON.)

CARRION CROW, *kar'-ri-on*, also called *Black Vulture*, a large carniverous bird found in America; a member of the Vulture family, and not a species of Crow as its name might indicate. (*See* CROW and VULTURE.) In this country a crow is commonly spoken of as a carrion crow.

CARRION FLOWERS, the common name given to many species of the genus *Stapelia* natural order *Asclepiadeæ*, because of their remarkably unpleasant smell, which resembles putrid meat. They are natives of Southern Africa, and in appearance are similar to the Cactos family, having thick fleshy stems, very small leaves, and large beautiful flowers.

CARROT. (*See* DAUCUS.)

CARTHAGENA BARK. (*See* CINCHONA.)

CARTHAMIN, *kar'-tha-min*, a red dye obtained from the safflower, or *Carthamus tinctorius*, by digesting it first in weak acetic acid and then in a solution of carbonate of soda, a skein of cotton is placed in the liquid, and lemon-juice or citric acid is added. The colouring matter is removed by the cotton, from which it is washed, redissolved in carbonate of soda, and reprecipitated with citric acid. When dry, carthamin is a red substance, metallic-green when viewed in the mass, but purplish-red when seen in thin layers. Safflower was formerly much used as a dye, particularly in the form of pink saucers, for dying silk stockings; but its fugitiveness is a great objection to its use. Safflower is largely used in the manufacture of rouge for the toilet.

CARTHAMUS, *kar'-tha-mus* (from the Arab., *quortom*, to paint), a genus of plants belonging to the natural order *Compositæ*. The most important species is *C. tinctorius*, the safflower, or bastard saffron. The florets of this yield a beautiful pink dye, and are sometimes used to adulterate hay saffron. The substance called cake saffron consists of safflower and mucilage. The fruits commonly called seeds yield, by expression, a useful oil, which is known in India as Koosum oil.

CARTILAGE, *kar'-ti-lej* (Lat., *cartilago*), is a white, firm, elastic substance, intermediate between bone and ligament, and commonly known by the name of *gristle*. In early life, cartilage in various parts occupies the place of bone, and becomes afterwards ossified. The physical properties of cartilage—its firmness, elasticity, and powers of resistance—render it specially fitted for the purposes which it serves, facilitating the motions of bones or connecting them together.

CARTILAGINOUS FISHES, *kar-ti-laj'-i-nus*, are fishes the skeletons of which are destitute of bony fibre. In some cases, they would almost appear to form the connecting link between the vetebrate and invertebrate animals. The centre of the backbone of the sturgeon is a column of cartilage, and the vertebræ of sharks consist of hollow cones, which have their cups filled up with the remains of a gelatinous cord. In many of the more highly organized cartilaginous fishes, several vetebræ are joined together in one piece, and the skull is formed without sutures, although the shape corresponds with that of other fishes.

CARUM, *kai'-rum* (from Caria, in Asia, it being originally found there), a genus of plants belonging to the natural order *Umbelliferæ*. The species *C. Carui* is the common caraway, a native of most parts of Europe. It is largely cultivated in Essex for its fruits commonly called seeds, which have a pleasant odour and a warm aromatic taste, owing to the presence of about five per cent. of volatile oil. They are much used in confectionery and for flavouring cakes. The oil, obtained by distilling the fruits with water, is used as a corrective adjunct in medicine.

CARUNCLE, *kar'-un-kl* (Latin, *caruncula*, diminutive of *caro*, flesh), a small piece of flesh, or a little fleshy excrescence; hence the *caruncula lachrymalis*, a small fleshy glandiform body, situated on the inner angle of each eye.

CARYA, *kai'-ri-a* (Gr., *karuon*, a nut), a genus of plants belonging to the natural order *Juglandaceæ*. The species are chiefly natives of North America. *C. alba*, the common hickory, is valuable for its timber, and also for its edible seeds, which are commonly known as hickory nuts. *C. olivæformis* yields an olive-shaped or elliptical nut, which resembles the walnut in flavour, and is known as the peccan nut. *C. porcina* yields an edible nut called the hog-nut.

CARYOCAR, *kar-ri-o'-kar* (Gr., *karuon*, nut), a genus of plants belonging to the natural order *Rhizobolaceæ*. The species are large trees, natives of the hottest parts of South America, and sometimes known as Pekea trees. *C. butyrosum* is much esteemed for its timber, which is used in ship-building and for other purposes. The separated portions of the fruit constitute the Souari or Suwarrow nuts of commerce, the kernels of which are delicious. An excellent oil may be extracted from them.

CARYOPHYLLACEÆ, *kai-ri-o-fil-lai'-se-e* (Gr., *karuon*, nut; *phullon*, leaf), the Pink or Clovewort family, a natural order of dicotyledonous plants in the sub-class *Thalamifloræ*. They are mostly herbaceous plants, with stems swollen at the joinings, and opposite, entire, and exstipulate leaves. The flowers are usually hermaphrodite, and the sepals, petals, and stamens exhibit a quaternary or quinary arrangement. The stamens are hypogynous, the anthers innate. The ovary is commonly one-celled, with from two to five styles. The fruit is a one-celled capsule, or rarely two—five-celled, generally with central placents, to which the seeds are attached. The plants of this order are natives chiefly of temperate and cold regions. When found in the tropics, they are generally on the slopes and summits of mountains, often reaching the limits of eternal snow. Lindley gives 59 genera, and 1,055 species. They possess no important properties. Some of the wild species are eaten as food by small animals, and some, particularly the *Vaccarria vulgaris*, are thought to increase the secretion of milk in cows fed upon them. Some of the plants have showy flowers, as the species of *Dianthus*, *Silene*, and *Lychnis*. From plants of the first of these genera are derived all the beautiful cultivated varieties of the sweet-william, pink, and carnation.

CARYOPHYLLUS, *kai-ri-o-fil'-us*, a genus of plants belonging to the natural order *Myrtaceæ*. The most important species is *C. aromaticus*, the clove-tree. (*See* CLOVE.)

CARYOPSIS, *kai-ri-op'-sis*, a one-celled, one-seeded indehiscent fruit, with a thin, dry, membranous pericarp, completely and inseparably united with the seed. The grains or fruits of the grasses, as wheat, barley, rye, and maize, are examples.

CARYOTO, *ka-re-o'-ta* (Gr.), a genus of palms, natives of the East Indies. From the species *C. urens*, sugar, or *jaggery*, is procured, and its juice, when fermented, forms a kind of toddy or palm-wine. The tree grows to a height of about 60 feet, and has a fine appearance. From the trunks of the old trees a kind of sago is obtained, and this is much used as food in Assam.

CASEINE, *kai'-se-een* (Lat., *caseus*, cheese), is the nitrogenous principle of milk, which form, a large portion of the curd. Caseine, in the soluble form, appears to be preserved in solution by a small quantity of alkali contained in the milk. In the coagulated form it is readily obtained by adding dilute sulphuric acid to the milk, which precipitates in the form of a curd. The curd is well washed and dissolved in carbonate of soda, and allowed to stand for twenty-four hours, to let the oil rise to the surface. This is skimmed off and the caseine precipitated by an acid. The process is repeated a second time, and the coagulum digested with alcohol and ether, and dried. With all these precautions the caseine still contains some saline matter, which cannot be removed. It is also obtained by coagulating the milk with hydrochloric acid. Caseine also unites with earthy carbonates and forms insoluble compounds. The efficacy of milk as an antidote in cases of poisoning by acetate of lead, nitrate of silver, and corrosive sublimate, is due to the caseine, which forms insoluble precipitates with those poisonous salts, and so neutralises the poison. The most remarkable form of coagulation is that produced by the action of the secretion from the mucous membrane of the stomach. This substance is called rennet, and consists of the inner membrane of the fourth stomach of the calf, salted and dried. When a solution of rennet is mixed with milk, a dense coagulum is formed, leaving the whey behind, as a thin, clear, straw-coloured liquid. A form of caseine, known as legumin, is obtained from peas, beans, and other leguminous plants, and it resembles the caseine of milk so nearly that the one can scarcely be distinguished from the other, and in China cheese is made from vegetable caseine.

CASHEW NUT. (*See* ANACARDIUM.)

CASHMERE GOAT, *kash-meer'*, a native chiefly of Tibet, in Central Asia, but taking its name from Cashmere, where the well-known and beautiful shawls are manufactured from the fine and silky hair of the goat. The hair is straight and about eighteen inches long, and so fine and light that the fleeces of ten goats are required for the manufacture of a shawl a yard and a-half square. The male animal has very large, flattened, wavy horns. By crossing the breed with the Angora goat (which *see*) a more abundant fleece is obtained.

CASIA, *kai'-se-a*, a shrub (*Osyris alba*) of the natural order *Santalaceæ*. It is above three feet in height, with white flowers and long supple branches. It is very beautiful in appearance, and from the references to it in literature it is known as the "poets' Casia."

CASSAVA. (*See* MANIOC.)

CASSIA, *kash'-e-a* (from Arab., *katsa*, to tear off, the bark being stripped from the tree), a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Cæsalpiniæ*. The leaflets of several species furnish the important drug senna. Some uncertainty prevails as to the species yielding some of the commercial varieties. That kind commonly known as Alexandrian senna is generally supposed to be derived from *C. officinalis*, variety *lanceolota*, and *C. obovata*. This is the kind most esteemed in Britain; but it is frequently adulterated with the leaves of other plants. The common East-Indian, Mecca, or Bombay senna, is by the produce of *C. officinalis*, variety *acutifolia*; Tinnevelly senna, a very fine kind, is furnished by *C. officinalis*, variety. *elongata*. Other commercial varieties are, Tripoli senna, from *C. æthiopica*; Aleppo senna, from *C. obovata*; and American senna, from *C. marilandica*. Another drug, called cassia pulp, or purging cassia, is obtained from a species of this genus; namely, *C. fistula*. The pulp is contained in the pods. It is of a reddish-black colour, with a sweetish taste, and possesses laxative and purgative properties. The pods of *C. Braziliana* are used in veterinary medicine under the name of horse-cassia. The bark of *C. auriculata* is employed for tanning, and the flowers are said to be used for dyeing yellow. The seeds of *C. Absus*, under the names of Chichou and Cismatan, are used in Egypt as a remedy in ophthalmia.

CASSIA-BARK, AND CASSIA-BUDS. (*See* CINNAMOMUM.)

CASSICAN, *kas'-si-kan*, a genus of birds (*cassicus*), allied to starlings. They are natives of America, of gregarious habits, and remarkable for the ingenuity displayed in constructing their nests, by knitting together shreds of bark. The nest is sometimes a yard long and about ten inches wide, and is suspended from the branch of a tree. (*See* ORIOLE.)

CASSIOPEIA, *kas-se-o-pe'-e-a*, a constellation in the northern hemisphere, midway between the constellations Auriga and Cygnus. It is not far from the north pole, and may be distinguished by five stars disposed somewhat in the form of the letter M. It contains only one star above the third magnitude, and that is not so brilliant as stars of the second. It is figured on the celestial globe as a female figure sitting in a chair with its feet towards the pole. The name is said to be derived from Cassiopeia, the mother of Andromeda, who was made a constellation and placed in this position for having boasted that she was prettier than the daughters of Nereus. Tycho Brahe observed a star of great brilliancy in this constellation in 1572, which disappeared in 1574. It is said to have appeared there in 945 and 1264, but this is doubtful.

CASSOWARY, *kas'-so-wa-re* (*Casuarius*), a genus of large and powerful birds closely allied to the Ostrich. The cassowary is an inhabitant of Java and the adjacent Indian archipelago, and is generally called the helmeted cassowary, on account of an osseous crest or horny helmet which surmounts its head. The skin of the head and the upper part of the neck are without feathers, and of an intense blue and deep red colour. There are also two pendent wattles, partly red and partly blue, on the front of the neck. On the breast is a bare place, on which the bird rests when lying on the ground. In height it is less than the ostrich, standing little more than five feet when erect. It is, however, robustly built, and very strong. It is rather timorous and shy, but when attacked defends itself by kicking backwards with its feet, and striking with its short and otherwise useless wings. Its whole plumage is very poorly supplied with feathers, and, at a short distance, it presents the appearance of a rough coat of coarse hair. It feeds upon eggs, fruit, and succulent herbage. The eggs of the cassowary are greenish in colour, and have a much thinner shell than those of the ostrich.

CASSYTHACEÆ, *kas'-se-thai'-se-e*, the Dodder-Laurel family, a small natural order of plants of which there is only one genus—*Cassytha*, which includes nine species, natives of tropical regions, and distinguished from the species of *Lauraceæ* by their parasitical habit, by their scaly modified leaves, and by the fruit being inclosed in a succulent calyx.

CASTANEA, *kas-tai'-ne-a*, a genus of plants belonging to the natural order *Corylaceæ*. The species are familiarly known as chestnut-trees. (*See* CHESTNUT.)

CASTOR. (*See* BEAVER.)

CASTOR OIL. (*See* RICINUS.)

CASTOR AND POLLUX. (*See* GEMINI.)

CASUARINACEÆ, *kas-u-ar-in-ai'-se-e*, the Beefwood family, a natural order of dicotyledonous plants in the sub-class *Monochlamydeæ*. There is but one genus—*Casuarina*, which includes about thirty-two species, principally natives of Australia. They are very peculiar trees, with slender, wiry, drooping, jointed branches, which have no evident leaves. The name Beefwood was suggested by the colour of the timber resembling that of raw beef. The wood is also known under the names of Botany-bay oak, forest oak, he oak, and she oak. It is imported in considerable quantities, and used for inlaying and marqueterie.

CAT, *kat* (*Felis*).—It is not a little singular that the origin of the most important member of this family, the domestic cat (*Felis domesticus*), should be involved in such obscurity. By the older naturalists it was supposed that it might be considered to be descended from the wild cat (*Felis catus-ferus*); but modern naturalists have generally arrived at a different conclusion. It is well known that the ancient Egyptians possessed a domestic animal, which, judging from representations of it on the monuments of Thebes and elsewhere, bore a resemblance to our domestic cat. Moreover, in the British Museum there is a copy of an Egyptian painting, which is supposed to represent the cat of that country catching birds; and it is conjectured that it was trained for that purpose. This same animal has been referred to as being not unlikely the progenitor of the domestic cat; and the probability of this theory has been augmented by the discovery of a species (*Felis maniculatā* by Rüppel in Nubia. This animal is said to be about the size of the domestic cat, and one-third smaller than the wild cat. Rüppel gave his opinion that it must be a descendant of the domestic cat of the Egyptians, and that, at some remote period, it was transferred to the Europeans by the contemporary Egyptians. This opinion, however, has been strongly opposed. The wild cat is found in all the wooded districts of Europe—in Germany, Russia, and Hungary: it is also found in the north of Asia and Nepaul. In Great Britain it was at one time abundant, and met with in all the woods and forests. From a charter granted to the abbot of Peterborough, in the reign of Richard II., we learn that the wild cat was one of the animals hunted in those days. Its hide was probably not very highly valued; Archbishop Corbyl's canons (1127) ordained that the nuns and abbesses should not wear a more expensive apparel than that made of wild cats' or lambs' skins. At the present time, the number of wild cats inhabiting Britain is not very large, and they are principally found in the northern counties, in the mountainous parts of Wales, in Ireland, and more particularly in the north of Scotland. It is the only fierce beast of prey remaining in the British islands. The length of the wild cat frequently exceeds two feet, exclusive of the tail. The fur is soft, long, and thick, and the colour generally grey, with blackish stripes. The domestic cat is so well known that any description of it would be unnecessary. It is of many colours and sizes: there is the black cat, the tabby, the tortoiseshell, the white, the slate-coloured, the blue or Chartreuse, the dun-coloured cat, and a few others, the most beautiful of which, perhaps, is that known as the Angora cat, with its long silky hair. A breed of cats peculiar to the Isle of Man has only a stump of a tail. As a domestic animal the cat is greatly prized, and its services are extremely valuable. It is more attached to locality than to its owner; and there are numerous instances on record of its deserting a family with whom it has been living for years, on their removal from a residence in which it has been brought up, and to which it will return, even though it be under the rule of strangers. Perhaps one of the most admirable qualities of the cat is its extreme devotion to its young; for their sake it will brave the greatest danger, and its uneasiness at finding them removed, only for a few minutes, is familiar to all. The extraordinary artifices it will resort to to secure its young are astounding, and seem almost human in their character. The period of gestation is sixty-three days, the young remaining blind nine days after birth.

CATABROSA, *kat-a-bro'-sa* (Gr., *catabrosis*, a gnawing), a genus of grasses, the leaves of which appear as if they had been gnawed at the points. The *C. aquatica*, growing only in moist situations, is found both in the Old and New Worlds and is very common in Britain. It is a valuable grass, being much relished by cattle. Its leaves often float, and its stalks rise about a foot above the surface of the water. It is known as whorl, or as sweet water grass.

CATALEPSY, *kat-a-lep'-se* (Gr., *katalepsis*, from *kata*, down or into, and *lambano*, I seize), is a disease characterised by a sudden deprivation of sensation and voluntary motion. The attack usually comes on without any warning, and during the paroxysm the patient remains in precisely the same position as he was in at the moment of attack. The circulation and respiration are in most cases but little affected; but occasionally they are greatly depressed, and are sometimes even imperceptible. The attack may last only for a few minutes, or it may continue for hours, and even, it is said, for days; and consciousness generally returns with the same suddenness as it left, the patient having no recollection of anything that passed during the attack. This disease bears a great resemblance to the mesmeric state, and, indeed, is so often feigned that many have doubted whether it really had any existence. There can be little doubt, however, that it is sometimes, though not often, a real disease. The hysterical and melancholic are most predisposed to it; and the paroxysm is frequently induced by some strong mental emotion, or by some disorder of the digestive or secretive organs. The treatment will necessarily vary in each particular case, according to the general condition of the patient and the probable exciting cause. Generally, however, the system should be strengthened by nourishing diet, gentle exercise, sea-bathing, and tonics. During the attack the body should be kept warm and excited by gentle friction; mustard poultices should be applied to the soles of the feet, the palms of the hands, and the pit of the stomach; and strong ammonia applied to the nostrils.

CATALYSIS, *kat-al'-e-sis* (Gr., *kataluo*, I dissolve).—Catalysis, or power of presence, is a term applied to the chemical action that certain bodies exert upon others, without themselves taking part in the chemical changes resulting therefrom. Thus, yeast converts sugar into carbonic acid and alcohol, without itself entering into the composition of either of these bodies. Examples of this occur in many of the ordinary operations of the laboratory.

CATARACT. (*See* EYE, DISEASES OF THE.)

CATARRH, OR COLD, *ka-tar'* (Gr., *katarree*, I flow down), is one of the most common of all the disorders to which the human body is subject, more particularly in variable climates. There are two kinds of this disease—the one a common cold; the other influenza, or epidemic cold. (For an account of the latter, *see* INFLUENZA.) A common catarrh is an inflammatory state of the mucous membranes of the head or chest. In the former case it is called cold in the head, or *coryza*; in the latter, cold on the chest, or *bronchitis* (which *see*). The symptoms of a cold in the head are a sense of uneasiness, heat, and stuffing in the nostrils, diminution or loss of smell, dull, heavy pain in the forehead, inflamed and watery eyes, sneezing, and a slight impediment in breathing. Generally, it extends also to the throat and chest, occasioning hoarseness, cough, and difficulty of breathing. Frequently there is also a general derangement of the system, loss of appetite, lassitude, chilliness, succeeded by dry feverish heats and stiffness of the joints. The nostrils discharge a fluid at first thin and acrid, but which afterwards becomes thicker, and often purulent. The common cause of this disease is exposure to a cold or damp atmosphere, or to draughts, especially when the surface of the body is warm or perspiring. The treatment of a common cold is usually a simple matter. Confinement to the house for a day or two, a warm foot-bath, diluent drinks, abstinence from animal food and vinous or other fermented liquors, and a dose or two of some gentle laxative, are usually sufficient to remove the disease. There is also what is called the *dry* method of cure, which has the advantage of not requiring confinement to the house, though, otherwise, some might be inclined to regard the cure as worse than the disease. It consists simply in abstinence from every kind of drink, no liquor, or next to none, being allowed until the disease is gone.

CAT-BIRD (*Turdus felivox*) a species of American thrush, of the same group as the mocking-bird, which it closely resembles in its vocal powers and its courage in defence of its young. It feeds on fruit and berries of all kinds, worms and insects, and builds its nest in the most conspicuous manner, generally in the neighbourhood of human habitations. It derives its name from its peculiar mewing cry when disturbed in its nest.

CATECHU, *kat'-e-ku* (Jap., *kate*, a tree, *chu*, juice), called *kut* or *kutch* by the natives of India, is properly an extract prepared from the inner brown-coloured wood of the *Acacia Catechu;* but the term is now applied also to other extracts similar in appearance and properties. Some of the catechu of commerce is prepared from the kernels of *Areca Catechu*, and a kind called *Gambir*, or *Terra japonica*, from the leaves of *Uncaria Gambir*. The substance is largely employed in the arts of dyeing and tanning, and medicinally as an astringent. It is imported in roundish balls or square pieces, varying in colour from a pale whitish or light reddish-brown, to a very dark brown. The dark-coloured catechu from Pegu is said to be the most powerful of all vegetable astringents. Catechu contains a large proportion of *tannin*, very similar in properties to that of galls; also a peculiar principle called *catechine*. (*See* ACACIA, ARECA, UNCARIA.)

CATENARY, *kat'-te-na-re*, the curve formed by a flexible homogeneous cord hanging freely between two points of support, and acted on by no other force than gravity.

CATENIPORA, *kat-en-ip'-o-ra*, a genus of fossil corals, peculiar to Palæozoic strata, and in Britain found only in the Silurian measures. They are sometimes known as chain corals; the cells are terminal and oval, and are united together in the form of a hemispherical polypiderm, sometimes of considerable size.

CATERPILLAR, *kat'-er-pil-lar*, the common name given to the larvæ of the lepidopterous insects, butterflys and moths. There is as great a variety in the form of caterpillars as in the insects to which they change. Each family, genus, and species may be distinguished by its characteristics. The bodies of caterpillars are generally long, nearly cylindrical, and divided into thirteen segments, of which the anterior forms a horny head, furnished with jaws and antennæ, and usually with groups of simple eyes. On each side of the body are nine spiracles, or small openings for respiration. The mouth of the caterpillar is usually furnished with strong jaws, capable of tearing, cutting, and masticating the substances on which it feeds, which are very varied in their character, although they entirely differ from the substances eaten by the perfect insect. The first three segments of the body are each furnished with two feet, which represent the six feet of the insect into which they change. All the feet or legs are very short. When the caterpillar has arrived at the proper stage to undergo its metamorphosis, it seeks some secluded spot. Some species find a retreat in the hollows of the barks of trees, others in the walls or wooden palings of the garden, while a few species bury themselves in the earth. Fortunately for the agriculturist, a great quantity of the lepidoptera are destroyed by parasites, which lay their eggs in the larvæ. The caterpillar undergoes two changes, firstly to the pupa state, then to the perfect winged insect. (*See* BUTTERFLY.

CATHA, *katha*, a genus of plants belonging to the natural order *Celastraceæ*. The most important species are *C. edulis* and *spinosa*, two shrubs flourishing in Arabia. The young shoots, with the leaves attached, of these plants constitute the famous drug called *kât*, *khat*, or *kafta*, which is chewed by the Arabs, and is said to produce great hilarity of spirits and an agreeable state of wakefulness. A decoction is also made from it and used as a beverage, like our tea; its effects are described as somewhat similar to those produced by strong green tea.

CATHARTICS, *ka-thar'-tiks* (Gr., *kathairo*, I purify), a term applied to such substances as, taken internally, cause a special irritation of the intestinal canal, and increase the alvine evacuations; in other words, have a purgative effect. Cathartics act upon the system in various ways, and have been variously divided; as, into stimulating, as jalap, aloes, colocynth; refrigerating, as Glauber or Epsom salts; astringent, as rhubarb; emollient, as castor-oil; narcotic, as tobacco or henbane.

Cathartine, also known as "bitter of senna," is the essential principle in senna which possesses purgative properties.

CATKIN, *kat'-kin*, (*Amentum*), a spike of small unisexual flowers, without calyx and corolla, and furnished with scale-like bractæ instead, as in the willow, birch, hazel, alder, oak, and some other trees and shrubs.

CATMINT, *kat'-mint* a plant (*Nepeta Cataria*) of the natural order *Labiatæ*, common on chalky and gravelly soils. It has erect stems, more than two feet high, with whorls of whitish flowers, with pink spots, and velvety heart-shaped leaves. The name is taken from the strange liking cats exhibit for the plant.

CATOPTRICS, *ka-top'-triks* (Gr., *katoptron*, a mirror), that part of optics which treats of the reflection of light from the regularly-formed surfaces of such bodies as water, glass, and the metals. (*See* OPTICS.)

CAT'S EYE, a variety of quartz. It has a pearly appearance, and exhibits a fine play of light; is of various colours, is supposed to be silicified wood, and is obtained chiefly from Malabar and Ceylon.

CATTLE-PLAGUE, OR RINDERPEST, a contagious fever which attacks cattle, generally with a fatal result. It is prevalent on the plains of western Russia (from which it is known as the steppe murrain) whence it has spread, at various times, throughout Europe. Death usually occurs about seven days after the first symptoms appear. There have been many terrible outbreaks in this country, especially during 1865 and the two years following, when about 279,000 animals were attacked, and only 33,400 recovered.

CAUCASIAN VARIETY OF MANKIND. (*See* ETHNOLOGY.)

CAUDEX, OR STIPE, *kaw'-dex* (Lat., *cædo*, I cut, because, by cutting off the branches, what remains constitutes the trunk), in Botany, the acrogenous (summit-growing) stem of a tree-fern. The caudex often rises to the height of fifty or sixty feet, bearing on its summit a crown of foliage. It produces no lateral branches, but is covered with scars produced by the successive whorls of leaves or fronds which have fallen during the life of the plant. The stem is of uniform diameter from near the base to the top.

CAULESCENT, *kawl-es'-ent* (Lat., *caulis*, a stalk), a term applied to plants having evident stems.

CAULIFLOWER. (*See* BRASSICA.)

CAULIS, the term applied to the stem of an herbaceous plant which dies down annually to the surface of the ground.

CAULOPTERIS, *kawl-op'-ter-is*, a term applied to the stem of fossil tree-ferns, found in the Carboniferous and Triassic measures. Twelve species have been described.

CAUSTIC, *kaws'tik* (Gr., *kaustikos*, from *kaio*, I burn), such substances as burn or destroy the skin and flesh by acting chemically upon them. The caustics principally used in medical practice are the nitrate of silver, or lunar caustic, and potassa fusa, common caustic, or caustic potass.

CAUTERY, *kaw'-te-re*, a burning or searing of morbid flesh by a hot iron or by caustic medicines, the former mode being termed *actual cautery*, the latter *potential cautery*.

CAVALCADE, *kav-al-kaid'* (Fr.), a procession or march of persons on horseback; a formal, pompous march or procession of horsemen and equipages by way of ceremony, or as a means of gracing a triumph, or welcoming the public entry of a person of distinction, a victorious warrior, &c.

CAVES, OR CAVERNS, *kaivs, kav'-erns* (Lat., *cavus*, *caverna*, hollow), hollow places in the earth. They occur more or less along the rocky shores of all free-flowing seas, and are the results of abrasion by waves laden with fragments of stone, and acting upon pre-existing fissures or the softer portions of the exposed rocks. The most celebrated caverns, however, occur in limestone strata, and appear to be the results partly of fissuring by subterranean disturbance, and partly of waste by the percolation and passage of carbonated waters. Some are celebrated for their great extent, others for their gorgeous stalactites and stalagmites, and many for their treasures of sub-fossil bones. Among the most remarkable caverns may be mentioned the Mammoth Cave of Kentucky, and others scarcely less stupendous in other parts of America; the caves of Franconia in Germany; of Adelsburg, in Austria; one in the limestone rock at Kirkdale, Yorkshire; those found in the carboniferous limestone of Glamorganshire, in which remains of British pottery have been found, in addition to bones of birds and beasts. In the limestone strata of Derbyshire caverns are found lined with a calcareous deposit of brilliant whiteness, with pieces like icicles of great size hanging from the roof and rising from the floor. These pieces sometimes meet and form columns. Among the Derbyshire limestone caverns, Peake's Hole, near Castleton, Poole's Hole, and the Bagshaw Grottos, are the most remarkable.

CAVY. (*See* GUINEA-PIG.)

CAYENNE PEPPER. (*See* CAPSICUM.)

CAYMAN. (*See* CROCODILE.)

CEANOTHUS, *se-an-o'-thus* (a name given by Theophrastus to a spiny plant), a genus of plants belonging to the natural order *Rhamnaceæ*. The young shoots of *C. Americanus* are used as an astringent, and in New Jersey the leaves are employed as a substitute for tea: hence they are commonly known as New Jersey tea.

CEBIDÆ, *se-bi'-de* (Gr., *kebos*, a species of monkey), a term applicable to all the monkeys of the American continent.

CEBRIO, *seb'-re-o*, a family of coleopterous insects of peculiar structure. The body is of an oblong form, arched above and deflexed in front; the mandibles curved, and entire at the tip. The thorax is broadest behind, and the antennæ generally longer than the head and thorax.

CECIDOMYIA, *se-se-do-mi'-a* (Gr., *kekidion*, a gall-nut; *muia*, a fly), small two-winged flies, that deposit their eggs on the buds of growing plants. The best known is the wheat-fly (*Cecidomyia tritici*), that may be seen in immense masses flying about wheat-fields about June. It is said that they quit the wheatears at the beginning of August, and descend into the earth about half-an-inch below the surface, where they probably remain throughout the winter, making their appearance again in the shape of winged flies when the spring corn begins once more to show its head. There are about 30 British species, all of very small size.

CECROPIA, *se-kro'-pi-a* (after Cecrops, king of Athens, whose legs were fabled to be of snakes), a genus of plants belonging to the natural order *Artocarpaceæ*. *C. peltata*, a tree growing in the West Indies and South America, is remarkable for its stems being hollow except at the nodes. Owing to this peculiarity, the smaller branches are often used for making wind instruments.

CEDAR. (*See* CEDRUS.)

CEDAR-BIRD, *se'-dar* (*Ampelis cedrorum*), or Wax-wing, a native of America. The appellation of Cedar-bird is given to it on account of its partiality to the berries of the cedar. The cedar-bird is largely consumed as an article of food, and at the end of autumn is, owing to its voracity, in prime condition. At this season a great quantity are sent to the markets. The colour of this bird is, on the upper parts, of a fawn-colour; the chin is black, and the abdomen and breast yellow. The wings are slaty-blue; the tail feathers are rich yellow. Round the forehead there is a dark line, covering the eyes. It is about six inches and a half in length, and is rather a slim-built bird.

CEDRELA, *se'-dre-la* (from *cedrus*, the cedar-tree, its wood having an aromatic resinous scent like it), a genus of tropical trees, the type of the natural order *Cedrelaceæ* (the mahogany family) *C. febrifuga*, *C. Toona*, and other species have febrifugal and astringent barks, which have been used as substitutes for cinchona. *C. Toona* furnishes timber resembling mahogany, which is much used in the East Indies, and is occasionally imported into this country under the names Toon, Tunga, Poma, and Jeea-wood.

CEDRUS, *se'-drus* (Gr., *kedros*), the Cedar, a genus of trees belonging to the natural order *Pinaceæ*, sub-order *Abieteæ*. The cedar of Lebanon (*C. Libani*) has been celebrated from the earliest ages for its grave beauty, its longevity, and its magnitude; also for the excellence and durability of its timber. It is often alluded to in Scripture as an emblem of stability and prosperity. The grove of cedars on Mount Lebanon is about three-quarters of a mile in circumference; but of the four hundred trees now standing, there are but twelve of extraordinary age. One of these is 63 feet in circumference, and has possibly been in existence for some two thousand years. The cedar was introduced into England in the latter part of the 17th century. The Deodar, or Himalayan cedar (*C. deodara*), is also a magnificent tree, and is held in great veneration by the Hindoos. The turpentine obtained from this species is much used in India for medical purposes, and is known by the name of *Kelon-ke-tel*.

CELANDINE. (*See* CHELIDONIUM.)

CELASTRACEÆ, *se-las-trai'-se-e*, the Spindle-tree family, a natural order of dicotyledonous plants in the sub-class *Calyciflorœ*, consisting of 30 genera and about 260 species, chiefly natives of the warmer parts of Asia, North America, and Europe, though many are found at the Cape of Good Hope. They are shrubby plants, and are chiefly remarkable for the presence of an acrid principle. The seeds of some contain oil; those of *Celastrus paniculatus* yield an oil used as a medicine in India. Two other species of the typical genus, *C. scandens* and *senegalensis*, have purgative and emetic barks. (*See* CATHA, EUONYMUS.)

CELERY. (*See* APIUM.)

CELESTINE, *sel'-es-tine*, a mineral found in rhomboidal prismatic crystals, consisting of *sulphate of strontia*. It is the commonest mineral of strontia. It is frequently of a beautiful blue colour; but in some cases colourless, or of a red or yellow tinge.

CELLS, *sells* (Lat., *cella*, a cell), in Physiology, are closed vesicles, or minute bags, formed by a membrane in which no definite structure can be discerned, and having a cavity which may contain matters of variable consistence. These cells, remaining as separate corpuscles in the fluids, and grouped together in the solids, persisting, in some cases, with but little change, in others undergoing a partial or thorough transformation, produce the varieties of form and structure met with in the animal and vegetable textures. The embryo animal, as well as the embryo plant, is, in its early stages, entirely formed of cells of a simple and uniform character; and it is by a gradual transformation in the progress of development that some or these cells become converted into the diversified elements of a complex fabric. Every cell owes its origin, in some way, to a pre-existing cell. In plants, the most common mode of multiplication is the subdivision of the original cell into two halves. Sometimes the new cells originate in little bud-like prominences on the surface of the parent cell, which, after a time, become detached and form cells. Cells have ordinarily a spheroidal or rounded shape, but they assume various forms from coming in contact with other cells. Certain of the animal tissues, in their earlier conditions, appear in the form of a congeries of cells, almost entirely resembling the vegetable cells, and in their subsequent transformation pass through a series of changes resembling those that occur in vegetable development. In animals, as in plants, there are two principal ways in which cells may be developed—namely, within the cavity of a previously existing cell, in which case the process is said to be *endogenous*; or in the midst of a plastic fluid, or *blastema*, probably containing cell-germs, which has been prepared or elaborated by cells of a previous generation, but which has been set free by their rupture. The nucleus seems to perform a much more important part in animal than in plant cells, in which, indeed, as a rule, it is absent; and even in animal cells it is often wanting. It is a small round or oval body in the interior of the cell, sometimes lying free, but at other times attached to the cell-wall, and averaging in diameter, in the animal cells, from $\frac{1}{5000}$ to $\frac{1}{4000}$ of an inch. In the conversion of cells into the several tissues, there is in different instances a great difference, not only in the nature and extent of the change which the cells undergo, but also in the condition which these bodies have attained when the process of change commences. In some cases they have already acquired a distinct cell-wall and cavity; in others they never attain the condition of cells strictly so called, and the process of transformation begins while they may be said to be but in a nascent state. The following are the principal modes in which cells or their elements are metamorphosed:—1, Increase in size and change of figure; 2, alteration of substance and of contents; 3, division into fibrils; 4, changes in the relation of cells to each other: 5, formation of membranes and fibres from the blastema, without the intervention of actual cells; 6, changes in the nuclei of cells; and 7, ulterior changes in the blastema. Two or more of the processes here mentioned may occur in the same cell.

CELLULAR TISSUE, *sel'-u-lar*, in Anatomy, is the old name given to what is now commonly known as areolar, reticular, or connective tissue. It is composed of a large number of small transparent fibrils, each about $\frac{1}{25000}$ of an inch in diameter, crossing each other in all directions, and leaving small open spaces. or *areolæ*; whence its name of areolar tissue. This is one of the most extensively diffused of all the tissues of the human body, forming the connecting medium of all the others. It is very sparingly supplied with blood-vessels, and no nerves have been found distributed to it.

In Botany, any vegetable tissue formed of cohering cells alone, and in which there are no vessels. The cells vary much in form and size.

CELLULARES, *sel'-u-la-res*, plants composed of cellular tissue only, forming one of the

COCKATOO.

two great sub-kingdoms in De Candolle's system of classification.

CELLULOSE, *sel-lu-lose'*, the cartohydrates which form the mass of the cell-membranes of plants.

CELOSIA, *se-lo'-si-a*, in Botany, a genus of plants belonging to the natural order *Amaranthaceæ*. Several species have bright-coloured persistent flowers, and are cultivated in our gardens. The best-known is *C. cristata*, the cock's-comb.

CELTIS, *selt'-is*, a genus of trees belonging to the *Ulmaceæ*, or Elm order. The fruit of *C. occidentalis*, which is commonly known as the Sugar-berry or Nettle-tree, has a sweetish, astringent taste, and has been used with some success in dysentery. *C. orientalis* has aromatic properties.

CENTAUREA, *sen-tor'-re-a*, a genus of plants of the natural order *Compositæ*, containing many species, annual and perennial, chiefly natives of the temperate and cold regions of the eastern hemisphere. Some of the British species are weeds; others are ornamental flowers. The common bluebottle (*C. cyanus*), the large bluebottle (*C. montana*), and the star-thistle (*C. calcitrapa*) are familiar plants of this genus.

CENTAURUS, *sen-tor'-us*, a constellation in the southern hemisphere, between those of Lupus and Ara; it contains about thirty-five stars, one of which is of the first magnitude.

CENTAURY, *sen-tor'-e*, a genus of plants (*Erythræa*) of the natural order *Gentianæ*, pretty little annuals with pink and red flowers, natives of the temperate parts of Europe and Asia. A domestic tonic medicine is made from the flowers. The common centaury (*E. Centaurium*), about ten inches high, is most frequent in Britain.

CENTIPEDE, *sen'-te-pede* (Latin, *centum*, a hundred; *pedes*, feet) (*Scolopendra*), a genus of carnivorous *Annulosa*, distinguished by possessing antennæ of fourteen joints or upwards; a mouth composed of two mandibles, a quadrifid lip, two palpi or small feet, united at their base, and a second lip formed by a second pair of dilated feet joined at their origin, and terminated by a strong hook, having an opening beneath its point through which a strong poison is ejected. In the West-India islands and the hotter parts of America the centipede is regarded very seriously as a pest. It attains a length of five or six inches, and very frequently finds its way into beds. The common English centipede is a harmless thing, not exceeding an inch in length, and for the most part hiding under the decayed bark of trees and among old lumber.

CENTRAL FORCES are those forces which cause a body in motion to tend towards the centre of motion. The first law of motion is, that a body must continue for ever in a state of rest, or in a state of uniform and rectilineal motion, if it be not disturbed by the action of an external cause. Upon this law the doctrine of central forces is founded. It therefore considers the external forces which act upon a body in motion when there is an alteration either in its velocity or direction round a central point. It also considers the law of the force by which a body moves round another in a known curve, and solves various mathematical problems. Gravity, as exemplified in the force which acts on all bodies from the centre of the earth, is the simplest and most general example of a central force. Kepler and Newton gave much time and labour to the study of central forces.

Centre of Gravity, *sen'-ter*, a term employed to denote a certain point in the interior of a body, or system of bodies rigidly and invariably connected, so situated that any plane whatever which passes through it divides the body into two segments of equal weight.

Centre of Gyration is that point in a rotating body, or system of bodies, at which, if the whole mass were collected, a given force applied would produce the same angular velocity that it would have communicated to the system in its first condition.

Centre of Magnitude, or Figure, is that point in plane figures and curved surfaces where, supposing their areas had weight, they would balance themselves. Thus, the centre of magnitude of a circle would be its own centre. The same term is applied to any point which bisects all lines that pass through it, and are terminated by the circumference.

Centre of Oscillation is that point in a body oscillating about a fixed axis, into which, if the whole mass were collected, the body would vibrate through a given angle in the same time as in its first condition.

Centre of Percussion is that point in a solid body, or system of bodies, into which, if the whole mass were collected, the greatest possible effect could be produced by striking it against another body. It may also be defined as a point in the axis of a moving body at which, when striking an immovable obstacle, the body rests in equilibrio, without inclining to either side or acting on the centre or axis of suspension.

Centre of Pressure of a fluid pressing against a surface, is that point at which, if a force equal to the pressure were applied in an opposite direction, the surface would remain at rest.

CENTRIFUGAL FORCE, *sen-trif'-u-gal* (Gr., *kentron*, centre; Lat., *fugio*, I flee), is the force that urges a revolving body to fly off in a straight line instead of describing a curve. The moon is held in her orbit round the earth by the opposing *centripetal force* (which *see*), and a stone flies from a sling by centrifugal force.

CENTRIPETAL FORCE, *sen-trip'-e-tal* (Gr., *kentron*, centre; Lat., *peto*, I seek), is the force by which a body in motion is kept revolving round a central point, instead of flying off at a tangent to its orbit; the force opposed to centrifugal.

CEPHAËLIS, *sef-a-e'-lis* (from Gr., *kephale*, head), a genus of plants belonging to the natural order *Cinchonaceæ*. The annulated root of *C. ipecacuanha* is the officinal ipecacuanha of the British pharmacopœias. It is known as *true*, *annulated*, Brazilian, or Lisbon ipecacuanha, and is the only sort commonly met with in this country. It is collected in all seasons of the year, but chiefly from January to March, and is imported from Rio Janeiro, Bahia, and Pernambuco. When given in large doses, it acts as an emetic and as a purgative: in small doses it is expectorant and diaphoretic. Its peculiar properties are principally due to an alkaloid called *emetina*.

CEPHALASPIS, *sef-a-las'-pis* (Gr., *kephale*, head; *aspis*, shield), in Geology, the Buckler-head, a fish of the lower Old Red Sandstone or Devonian period, so called from having the bones of the head united into a single shield-like case. Six species have been described.

CEPHALITIS, *sef-a-li'-tis* (Gr., *kephale*, the head), inflammation of the brain.

CEPHALOPODA, *sef-a-lop'-o-da* (Gr., *kephale*, head; *pous*, foot), a class of molluscous animals, more highly organized than any other, presenting undoubted rudiments of an internal skeleton, and containing secretive, digestive, respiratory, and generative organs. They are also distinguished by the possession of locomotive organs around the head in the shape of prolonged tentacula, which project forward and more or less conceal the mouth. The nautilus, argonaut, cuttle-fish, and similar molluscs belong to this class, represented in fossils by the ammonites and belemnites.

CEPHALOPTERA, *sef-a-lop'-te-ra* (Gr., headwing), a genus of cartilaginous fishes of the ray family. The head is terminated in front by membranes (known as precephalic fins) which roll up and resemble in shape a pointed horn. Only one species of this "hornet ray," the *C. Giorna*, is found on the British coasts. In the Mediterranean, the fish is of great size, one having been known to weigh half-a-ton, and in tropical seas it is much larger.

CEPHEUS, *se'-fe-us*, a constellation of the northern hemisphere, midway between the Polar star and Cygnus, containing 35 stars. The principal star in this group, Alderamin, is of the third magnitude only.

CEPOLA, *sep-o'-la*. (*See* BANDFISH.)

CERAMBYCIDÆ, *se-ram-bi'-se-de* (Gr., *keras*, a horn; *ambyx*, a cup), a family of coleopterous insects, distinguished by the inordinate length of their antennæ. Generally they are of elegant form, and are found in forests and woods, on the trunks of trees, but rarely on flowers. Some of the exotic species are remarkable for emitting after death a scent resembling that of musk. The only scented Cerambycid known in England is the musk beetle (*Cerambyx moschatus*), the odour of which, however, is more like that of roses. It is about an inch long, and of a fine green colour. It is found on willows in the neighbourhood of London. The *C. heros* is one of the largest of European beetles.

CERAMIACEÆ, *se-ram-i-a'-se-a*, a suborder of *Algæ*, also known as Florideæ, seaweeds of a rose or purple colour, with fronds formed of cells arranged in rows. They are very beautiful, and abound in the northern temperate zone. Some of them are used for food, and are of agreeable flavour.

CERASTES, *se-ras'-tees* (Gr., *kerast*, horn), a snake distinguished by two horny protuberances on its head, and hence known as the horned viper. It is said to exist almost entirely without water. The best known species, *C. vulgaris*, is found in the north of Africa, but other species are met with on the western coast, and at the Cape of Good Hope.

CERASUS, *ser'-a-sus*. (*See* CHERRY.)

CERATITES, *se'-ra-tites*, a genus of fossil cephalopoda, found in the triassic strata.

CERATONIA, *ser-a-to'-ni-a*, a genus of leguminous plants of the sub-order *Cæsalpinieæ*. The most important species is *C. siliqua*, the ripe fruit of which is known under the names of carob, locust, St. John's bread, and Algaroba bean. Its pulp has a very sweet taste. The fruit is largely imported into this country for making cattle-food.

CERATOPHYLLACEÆ, *se-ra-to-fil-lai'-se-e*, the Hornwort family, a natural order of dicotyledonous plants in the sub-class *Monochlamydeæ*. There is but one genus, *Ceratophyllum*, the species of which are aquatic herbs, natives of the northern hemisphere.

CERCÉS, *ser'-ses*. (*See* JUDAS TREE.)

CERCOCEBUS, AND CERCOPITHECUS, *ser-ko-se'-bus*, *ser-ko-pith-e'-kus* (Gr., tail-ape). (*See* MONKEYS.)

CERDOCYON, *ser-do'-se-on* (Gr., cunning-dog), a genus of *Canidæ*, intermediate between dogs and foxes, sometimes known as Aguara foxes. They are natives of South America, and those of the coldest parts have a rich fur. They are very cunning, and exhibit a strange propensity to steal and secrete bright-coloured objects, having been known even to carry off gaudy pocket-handkerchiefs.

CEREALIA, *se-re-a'-le-a*, named from the Greek goddess Ceres, the plants which produce grain or corn. They belong to the great order of grasses. (*See* various headings.)

CEREBELLUM. (*See* BRAIN.)

CEREBRIC ACID, *ser'-e-brik* (Lat., *cerebrum*, brain), an acid of a peculiar character found in the brain of animals; also, in smaller quantities in the liver, blood, and nerves. It is composed chiefly of carbon, oxygen, and hydrogen, with small amounts of nitrogen and phosphorous, partly uncombined, and partly in the form of cerebrate of soda. It is a white solid, of a fatty nature, and may be obtained in crystalline grains, which are soluble in boiling alcohol and ether, but insoluble in cold ether. It is insoluble in water, but swells up when left in that liquid for several hours. This acid was formerly called Cerebrin.

CEREBRO-SPINAL FLUID, a fluid of a slightly albuminous character, containing about 1¼ per cent. of solid matters, occupying the space in the brain between the arachnoid and pia mater. (*See* BRAIN.) It affords protection to the nervous centres.

CEREBRUM. (*See* BRAIN.)

CEREOPSIS, *se-re-op'-sis* (Gr., wax-face), a genus of birds of the family *Anatidæ*. The best known species is the New Holland goose, found on the southern shores of Australia.

CERES, *se'-reez*, one of the asteroids that revolve between the orbits of Mars and Jupiter. It was first observed by Piazzi, an Italian astronomer, at the observatory at Palermo, in Sicily, January 1, 1801.

CEREUS, *se'-re-us*, a genus of plants of the order *Cactaceæ*, containing about 100 species, some of which have beautiful flowers. The *C. speciossimus*, with large scarlet flowers and delicious fruit, and the *C. grandiflorus*, with large and fragrant flowers, both American plants, are cultivated in greenhouses.

CERITHIUM, *se-rith'-i-um*, a genus of gasteropodus mollusc, a type of the family *Cerithradæ*. The species are numerous, mostly marine, but some are found in lakes and rivers. They abound chiefly in tropical climates, especially in mangrove swamps. The shell is spiral, elongated, and many-whorled, with an oval oblique aperture. There are many fossil species.

CERIUM, *se'-ri-um*, a very rare metal. It is only known as a grey powder, which becomes lustrous on being burnished. It forms two oxides —the *protoxide* and *peroxide*, which form a few salts of no importance or interest.

CERITE, or OCHROITE, *se'-rite, o'-kro-ite*, is the silicate of cerium, found as a mineral in gneiss.

CEROXYLON, *ser-ox'-e-lon*, or wax palm, a genus of palms. The species *C. audicola* yields wax, which is applied to many useful purposes. It is a native of South America.

CERUMEN, *se-ru'-men*, yellow waxy matter secreted by glands in the passage that leads from the external opening of the ear.

CERVIDÆ, *ser'-vi-de* (Lat., *cervus*, a deer). (*See* Deer.)

CESTOID WORMS, *ses'-toid* (Lat., *cestus*, a hand), a family of *Entozoa*, or intestinal worms, including tape-worms and others of a similar kind. (*See* Entozoa and Tape-worms.)

CESTRACION, *ses-tra'-shun*, a genus of sharks, interesting as the sole surviving relics of the once extensive family *Cestraciontidæ*, the remains of which first appear in the lowest Devonian rocks. They differ from the true sharks in having the mouth at the anterior extremity instead of under the head, and in having the mouth lined with solid bony plates for crushing their victims. The living species include the "nurse," or Port Jackson Shark (*C. Philippi*), and cat shark of the China Sea (*C. Zebra*).

CETACEA, *se-tai'-se-a* (Gr., *ketos*, Lat., *cetus*, a whale), an order of the mammalia, which differs from the rest of that class both in form and habit, and in ordinary language is generally classed with the fishes. All the cetacea have a fish-like form; but the tail fin is horizontal, and not vertical, as in fishes. It is moved by very powerful muscles, and is the great instrument of progression. There are no posterior limbs, and even the pelvis is only represented by two small rudimentary bones. The anterior limbs are in nearly all cases adapted for swimming. The bones, however, in the skeleton appear like those of a hand, but much abbreviated and solidified. The head is joined to the body without any apparent neck, and the upper parts of the vertebræ are consolidated. The skin is naked, and some of the species are conspicuously whiskered. The cetacea are viviparous, and suckle their young, towards which they show great affection. They are warm-blooded, and breathe by lungs, and inhale air at the surface of the water. Fossil cetacea have been found in the Tertiary formation. (*See* Zeuglodontidæ.) The name *Cetotolites* is given to fossil cetacean teeth and ear-bones found in the red crag of Suffolk. (*See* Whale, Dolphin, Porpoise.)

CETOTOLITES, *se-tot'-o-lites* (Gr., *ketos*, a whale, *otos*, an ear, and *lithos*, a stone), fossil cetacean teeth, and ear-bones, belonging to the pleiocene period and found in the red crags of Suffolk. They are valuable as a source of superphosphate manure.

CETRARIA, *set-rai'-re-a*, a genus of lichens which includes the well-known Iceland moss. This lichen, which has been named *C. islandica*, is employed both as a nutritious food and as a mild mucilaginous tonic in catarrh and consumption. Two kinds of starch are found in this lichen—one called *lichen starch*, and the other *inulin*; also a peculiar bitter principle, which has been named *cetrarin*. When used for food only, the plant should be deprived of its bitterness, either by heating it twice in water to near the boiling-point, or by digesting it in a weak alkaline solution, formed by adding half an ounce of carbonate of potash to about a gallon of cold water, and afterwards washing it with pure water. The species *C. nivalis* possesses somewhat similar properties.

CEVADILLA. (*See* Sabadilla.)

CEYLON MOSS. (*See* Gracilaria.)

CEYX. (*See* King Fisher.)

CHÆTODONTIDÆ, (Gr., *chætodon*, hair-tooth), a family of acanthopterous fishes, the typical genus of which, the chætodon, and those most nearly allied to it, have teeth, which resemble the hairs of brushes. Other species, however, have large teeth on the jaws, and palate. The most distinctive character of the family is that all the species have scaly fins. They are brightly coloured in stripes or bands; and most of the species are tropical, but one, *Brama Raii* is found near the rocky shores of the British seas. The flesh is generally of fine flavour.

CHAFER, *tchai'-fer*, a common name of those beetles or coleopterous insects, which, either in the perfect or larva state, are destructive to plants. The word is seldom used alone, but generally as part of a name, with some prefix, as cock-chafer, &c.

CHAFFINCH, *tchaf'-finch* (*Fringilla cœlebs*), one of the most popular of European song-birds. It is about six inches in length, including the tail, which is slightly forked; fore part of the head black; back part, and extending even to the nape of the neck, blue, shading off to an olive-tinted chestnut, and again to a grey-green to the stump of the tail. The tail itself is black and grey, and on each of the two outer feathers there is a peculiar wedge-shaped white spot. From the root of the lower half of the beak to the extremity of the under part of the body the colour is reddish-chestnut. The male may be distinguished from the circumstance of being smaller than its mate, and from the latter's under parts being dingier. The chaffinch lays four or five eggs, of pale purplish-buff colour, sparingly streaked and spotted with reddish-brown. Insects are its chief food, and in the summer season it effects incalculable good by destroying myriads of aphides and caterpillars. In Italy the chaffinch is killed for the table. It is very widely spread, being found in parts of Asia, in the north of Africa, and as far west as the Azores. It is migratory in the cold northern regions; but stationary further south. Linnæus gave the specific name *cœlebs* from observing that in winter, in Sweden, the flocks consisted mostly of males, the females having, as he supposed, sought a milder climate. In France the chaffinch is an especial favourite; and in Germany the "fancy" for the bird amounts almost to a mania. It is greatly sought after by English bird catchers, and caught by means of a decoy bird.

CHAILLETIACEÆ, *shail-le-ti-ai'-se-e*, the Chailletia family, a natural order of dicotyledonous plants in the sub-class *Monochlamydeæ*. The only remarkable member of this family is *Chailletia toxicaria*, a tree growing in Sierra Leone, producing fruit which is called ratsbane from its poisonous nature.

CHAIN RULE. (*See* EQUATIONS.)

CHAIN SNAKE, an American snake, known also as thunder snake and king snake, some specimens of which are four feet long. It is very handsomely marked, with about twenty white bars, so arranged that they have a chain-like appearance.

CHALCEDONY. (*See* CALCEDONY.)

CHALAZA, *tchal-a'-za*, a membrane which unites the nucleus and integuments at the base of an ovule of a plant. The term is also applied to the cords of viscid albumen which bind the yoke-bag of an egg to the lining membrane at the two ends of the shell, and keep it near the middle as it floats in the albumen.

CHALCIS, *tchal'-sis*, a genus of Saurian reptiles, the type of the family *Chalcidæ*, some of which are known as snake lizards, forming one of the transition links between the Saurian and ophidian reptiles they are found in hot climates in both hemispheres.

CHALK, *tshauk* (Lat., *calx*, lime), a variety of limestone, or carbonate of lime, of a soft, earthy nature, generally of a yellowish-white colour, and sometimes pure white. It often forms strata of great size. It has an earthy fracture, is easily broken, and is rough to the touch. Some varieties of chalk are so compact that they can be employed as building-stones when cut or sawn into shape. After being burnt into quicklime, chalk is converted into mortar, in which shape it is much used. Silica, alumina, and magnesia are often present in chalk, and when these are removed by pounding and diffusing in water, it becomes whiting. Chalk is also largely used in the manufacture of soda, for the purpose of decomposing the sulphate of soda in the "balling" process; and it is also used as a manure. (*See* LIME.) Perfectly purified chalk, when mixed with vegetable colouring matters, such as turmeric, litmus, and saffron, forms pastil colours. Vienna white is merely purified chalk. (*See* CRAYON.)

Black Chalk, is a name given to a mineral, which, however, has little resemblance to common chalk. It is of a slatey structure easily cut or broken, and, as it makes a black mark on paper, is used for drawing. It is essentially a kind of clay, and derives its colour from the carbon contained in it.

Red Chalk, is a mixture of clay and oxide of iron. The coarser varieties are used chiefly by carpenters for making marks on wood; the finer sorts are available as a pigment.

CHALK BEDS. (*See* GEOLOGY.)

CHALYBÆUS, *ka-li-be'-us* (Gr., *chalups*, steel), a genus of birds, of beautiful plumage, natives of New Guinea, closely allied to the Baritah (which *see*), but having a thicker bill. The name is taken from the metallic brilliancy of their tints, and the skins are sometimes sold as those of birds of Paradise.

CHALYBEATE SPRINGS, *kal-ib'-e-ait*, natural waters containing iron in solution. They are of two kinds, *carbonated* and *sulphated*. (*See* MINERAL WATERS.)

CHAMA, *ka'-ma*, a genus of molluscs with beautifully marked shells, generally of orbicular form, commonly known as *chams*. They are never found farther north than the Mediterranean. Thirty fossil species are known.

CHAMÆLAUCIACEÆ, *kam-e-law-se-ai'-se-e*, the Fringe-myrtle family, a natural order of dicotyledonous plants in the sub-class *Calyciflora*. This is a small group of shrubby plants only found in Australia, having evergreen dotted leaves. They are nearly allied to *Myrtaceæ*.

CHAMÆROPS, *kam'-e-rops*, a genus of Palms. *C. humilis* (sometimes known as the palmetto), is the only palm found wild in Europe. Fibres obtained from it have been used as a substitute for horse-hair, and in the manufacture of carpets and in Sicily the different parts of this plant are employed for making walking-canes, hats, baskets, and other useful articles. The materials from which the Brazilian chip or grass hats are manufactured are obtained from the species *C. argentea*.

CHAMELEON, *kam-e'-le-on*, a genus of Saurian reptiles constituting a distinct family, with several very peculiar characteristics. They are natives of the warm parts of Europe and Asia, and are very abundant in Africa. The neck is very short, and does not admit of the head being turned; but the eyes are very prominent and possess remarkable powers of motion. The skin is rough, like shagreen. The lungs are very large, and are connected with air-cells among the muscles and beneath the skin, so that the animal has a remarkable power of inflating itself with air. A very curious part of the animal is its tongue, which is composed of a hollow tube, which is terminated by a fleshy knob, and has a cup-like cavity in its anterior surface: this is covered with a glutinous secretion. By a wonderful provision the animal can dart its tongue with lightning-like swiftness and extraordinary sureness of aim at is prey. With regard to its colour-changing propensity of which so much has been said and written, the result of Mr. Milne Edward's investigation is, in substance, as follows:—Beneath the transparent epidermis of this reptile there is a great quantity of minute soft granules, which bear the different colours: these are more or less extended, according to the quantity of blood that reaches them, and the change of colour is thus effected. The changes it really will undergo under certain powerful excitements are from its natural colour, pale grey, through pale green to yellow and dingy red, and sometimes, but rarely, nearly to black. It is said that that lack of nervous co-ordination between the two sides which in most animals is only seen in diseased or defective organizations, is either normal to the chameleon, or easily produced in it. It is even asserted that one side of the reptile may be awake, while the other is asleep. The chameleon is a most sluggish animal, and will sit for hours on the branch of a tree, scarcely giving any token of its existence beyond an occasional roll of its singular eye, for while one eye is quite motionless, the other will protrude from the animal's head, and glare in a hideous fashion. Then, perhaps, suddenly it will dart out its tongue, oftentimes to twice the length of the whole animal, and whisk some unfortunate insect into its jaws. The period of time a chameleon will exist without food is astonishing. Hesselquist makes mention of one he kept for a month, which during the whole time, as far as he could ascertain, did not eat a single insect. Of this genus there are about eighteen species.

In Astronomy, a southern constellation containing nine stars within the antartic polar circle.

Chameleon Mineral.—Manganate of potash was so called from the changes of colour apparent in an alkaline solution of the salt. It is made by fusing binoxide of manganese with carbonate of potash in an open crucible.

CHAMOIS, *sham'-moi* (*Antilope rupicapra*), a species of antelope inhabiting the lofty mountain ranges of central and southern Europe. It is rather larger than the roebuck, and, when full grown, weighs from sixty to eighty pounds. Its colour changes with the seasons. In summer it is of a dusky yellowish brown, and in winter jet black, excepting the head and the hair of the forehead, the belly, and the tufts of hair that overhang the hoofs, which is tawny, and remains so always. The dark stripe, too, extending from the eyes to the mouth is permanent. It has been a disputed point whether the chamois should not be classed with the goat instead of the antelope. Examination, however, shows that there is but little affinity either in the structure of the animals or their habits. The frontal bone of the chamois just before the horns is concave; that of the goat is convex. The horns of the latter recede; those of the former advance, and are perfectly plain and smooth, while the goat's horns are wrinkled. More than all, the chamois is well known to avoid spots favoured by goats; and no instance has ever been shown where a female of either species has brought forth a cross-bred kid. The head of the chamois exhibits in its construction a wonderful blending of lightness and strength. The frontal bones are so fragile that a rap of a man's knuckles would suffice to shatter them—that is, if they were unsupported; but they are supported, and in a marvellous way. Over the first set of bones a second is thrown, and between the walls are arched cells and substantial girders of solid bone. The arched girders which occupy the space between the upper and lower surface rise, bridge-like, with a spiral twist, and here and there a flying buttress will give additional strength to the walls, or a lateral arch help to support the vault above. The horns of the chamois are very curiously constructed. Up to a certain point the horn is hollow, and thence to the point it is dense and solid. The hollow part fits over a bony protuberance growing out of the skull itself. The horns of a full-grown buck measure about seven inches in length, the points being extremely sharp, and hooked backwards. At first sight it would seem that as weapons of attack or defence, the chamois' horns, from their formation, would be next to useless. This, however, is far from the state of the case. When fighting, the chamois lowers his horns under the throat of his antagonist, or turns his head sideways, that the sharp point may come against the shoulder of the enemy, and then, drawing them back vigorously, inflicts a most formidable gash. The horns of the male chamois are thicker and altogether stronger looking than those of the female; they do not diverge from each other in so straight a line as do hers, but describe a slight curve as they rise upwards and apart from each other. The horns of the doe are not so abruptly hooked as those of her mate. Except when running, the gait of the chamois is extremely awkward. The cause is evident. In the first place, its hoofs, shaped like those of the sheep but longer and more pointed, are calculated for sliding rather than for stepping; and, in the second, its hinder legs have every appearance of being longer than the fore. Not only do the hind legs serve as springs, enabling the animal to perform flying leaps from crag to crag, clearing from 16 to 18 feet in a bound, but they break the concussion that would otherwise certainly occur in a leap from a great height, and enable the animal to alight with safety and freedom. A perpendicular wall of rock smooth as glass, and 12 to 15 feet in height, is no impediment to the upward flight of a chamois. He will leap against the slippery wall, and, striking it with its hind feet, obtain a renewed spring, rebound again in an opposite direction to some higher bank, and there find firm footing on a patch so small that a man's two hands could cover it. The food of the chamois consists of such herbs and lichens as grow on the mountains; when, however, the winter sets in so fiercely that every green thing perishes, the animals shift their quarters from the steeps to the woods that grow at their bases, and their subsist on grass and leaves. No animal possesses so tough a skin as the chamois. It will sometimes happen that the hunter's bullet will send one toppling over a precipice nearly a thousand feet deep; but though every bone in its body be smashed by the fall, the hide will remain intact. The skin is made into the famous "shammoy" leather. The hunting of the chamois is a favourite pursuit. The excitement more than counterbalancing the sense of the danger encountered. The flesh is considered a delicacy. The Persian chamois is a smaller variety.

CHAMOMILE. (*See* ANTHEMIS.)

CHAMPIGNON. (*See* AGARICUS.)

CHARACEÆ, *ka-rai'-se-e*, the Chara family, a natural order of acotyledonous plants, in the sub-class *Acrogenæ*—water-plants with distinct stems branching in a whorled manner, sometimes transparent and sometimes coated with carbonate of lime. They occur in stagnant, fresh, or salt water in all parts of the globe, but most abundantly in temperate climates. When in a state of decay, they give off a very fœtid odour, which is considered to be very injurious to animal life.

CHARADRIADÆ, *sha-rad-ri'-a-de*. (*See* PLOVER.)

CHARLES'S WAIN. (*See* URSA MAJOR.)

CHARR, *tsharr* (*Salmo umblas*), a fish of the Salmon family, inhabiting the lakes of Scotland, Wales, and the north of England. The body is longer and more slender than that of the trout; the weight averaging a little over a pound. The back is of an olive colour, speckled with white spots, and the belly red. Its flesh is held in high estimation.

CHAT, *tshat*, a genus of small birds of the order *Sylviadæ*. They are noticeable for their rapid movements in the air. Three specimens, the stonechat, winchat, and wheatear, are British. Chats are found all over the eastern world, and there is a larger bird in America, known as the yellow-breasted chat (*Icteria polyglotta*), but really belonging to the thrush family.

CHATI, *tcha'-te*, a leopard-like cat (*Felis mitis*), a native of South America. It is of small size, and of a yellowish white colour. It prowls about hen-roosts and is very destructive, and is nocturnal in its habits.

CHAVICA, *tshav'-e-ka*, a genus of plants belonging to the natural order *Piperaceæ*, the Pepper family. (*See* PEPPER.)

CHAY ROOT, or SAYAN, a perennial herbaceous plant (*Oldenlandia umbellata*) of the natural order *Cinchonaceæ*, a native both of India, and Mexico. A beautiful red dye is obtained from the bark.

CHEESE-HOPPER, *tshees*, known also as the Cheese-Jumper, or Cheese-Fly. A small black insect of the Beetle tribe, with whitish wings, margined with black. It is furnished with an admirable instrument for depositing its eggs in an ovipositor, which it can thrust out and extend to a great length, so that it can penetrate to a considerable depth into the cracks of cheese, where it lays its eggs, two hundred and fifty-six in number. The maggot is provided with a couple of horny, claw-shaped mandibles, which it makes use of, both for digging into the cheese and for moving itself, being destitute of feet. By bending itself into a circle it can leap to a considerable distance.

CHEETAH, *tchee'-ta*, the hunting leopard (*Feles jubata*), found in Africa, Persia, India, Sumatra, and other islands of the Indian archipelago. It is about equal in size to the leopard, but the body and limbs are longer. It is domesticated, and employed to hunt deer and antelopes.

CHEGOE, or CHIGOE, *tshey'-o* (*Pulex penetrans*), a small black flea, peculiar to South America and the West-India islands, burrows in and under the skin, and there deposits its eggs, the result being the most painful ulcers.

CHEIROLEPIS, *ki-rol'-e-pis*, a species of fossil fish, peculiar to the Devonian measures.

CHEIROMYS, *ki'-ro-mis*. (*See* AYE-AYE.)

CHEIROPTERA, *ki-rop'-te-ra*, (Gr., *cheir*, the hand, and *pteron*, wing), an animal whose anterior toes are connected by a membrane, and whose feet thus serve for wings, as is the case with the bat. (*See* BAT.)

CHEIROTHERIUM, *ki-ro-the'-re-um*. (*See* LABYRINTHODON.)

CHEIROSTEMON, *ki-ros-te'-mon* (Gr., *chier*, the hand; *stemon*, a stamen), in Botany, a genus of trees of the natural order, *Sterculiaceæ*. The species *C. platonoides* is the Hand-plant of Mexico, which derives its common name from the remarkable appearance of its flowers; the anthers and style being so arranged as to resemble a hand furnished with long claws.

CHELIDONIUM, *kel-i-do'-ni-um* (from Gr., *chelidon*, a swallow, the plant being said to flower at the coming, and dry up at the departure of the swallow), the Celandine, a genus of plants belonging to the natural order *Papaveraceæ*. The species *C. majus* is found in waste places and on old walls in this country, and may be recognized by its small yellow flowers, and the orange-coloured juice which exudes from its stem when plucked. This juice is poisonous, and is a popular application for the cure of warts. It has been used with success in the treatment of opacities of the cornea, and has been administered internally as a stimulant.

CHELIFER, *kel'-i-fer*, a genus of arachnida, bearing a close resemblance to scorpions, found in all parts of Europe. These remarkable animals are very small, and have the appearance of miniature tailless scorpions. They run fast, moving forwards, backwards, and even sideways, crab-fashion. They live under stones in crevices of rocks by the seaside. They also find a location in the barks of trees, and among papers and old furniture in houses. They feed upon insects, and are met with in all parts of Europe.

CHELONIA, *ke-lo'-ne-a* (Gr., *chelonia*, a tortoise), in the numerous order of reptiles in which are comprised the tortoises and the turtles. (*See* TORTOISE.)

CHEMISTRY, or CHYMISTRY, *kem'-ist-re* (Gr., *chemeia*).—This science has for its province "to ascertain the nature of the different substances of which the universe is composed, to trace their mutual reactions on each other, to effect new combinations of these components with each other, and to define the conditions on which the combinations existing around us are producible." Mr. Spencer, the author of a popular introduction to the science says, "Chemistry reveals to us the fact that we live in the midst of a vast laboratory, in which changes are perpetually in progress—in which compounds are continually being resolved into their constituent elements, which, in their turn, are destined to unite with other bodies, to form fresh combinations. These changes are not confined to the so-called organic world. It is not under the influence of vital energy alone that the material elements are compelled to combine, in order that they may be assimilated by and incorporated with the living tissue of the animal, or the plant, but we find that constant chemical action is, in like manner, going on in the air we breathe, and in the earth we tread on." The nature and properties of elementary substances, and the changes they undergo when in combination, are the subjects for the investigation of the student of chemistry; and his researches will be chiefly directed to the attainment of two results—the combination of two or more bodies, to form a third body, with properties unlike either of its components; and the separation for a compound substance of the more simple bodies present in it. At present chemists enumerate between 60 and 70 elements, or bodies which have hitherto resisted every attempt to resolve them into anything simpler, which cannot be separated into constituents, and which are consequently regarded as ultimate forms of matter. (*See* ELEMENTS, and the respective headings.) Many of these elements are of very rare occurrence and exist in very minute quantities. The combinations of these bodies are described under BASES, SALTS, ACIDS, RADICLES; while the general laws which regulate their composition will be found under ATOMIC NUMBERS, AFFINITY, SERIES, TYPES, ALLOTROPISM, ISOMORPHISM, ISOMERISM, POLYMORPHISM, &c. Inorganic chemistry treats of the nature and properties of elements and compounds of mineral origin, and organic chemistry of those belonging to bodies of a vegetable or animal nature. Chemistry may be considered under three leading aspects, as a theoretical or a practical, and as an applied science. I. *Pure theoretical, or philosophical chemistry*, is generally subdivided into *organic* and *inorganic* chemistry, although the advance of scientific research is gradually weakening, if not obliterating, the lines of demarcation between the two subjects. In books of instruction, organic chemistry is again divided into *animal* and *vegetable;* and inorganic chemistry into *agricultural*, *medical*, and *metallurgic*. II. *Practical chemistry*—for chemistry is an art as well is a science—which includes the application of theoretical principles to practical purposes—the formation of certain rules and mechanical methods. This, again, has subdivisions, *synthetical* chemistry, which treats of the union of bodies into well defined compounds; *analytical* chemistry, which detects the constituents of a component body, and estimates their quantities. (*See* ANALYSIS). III. *Applied chemistry*, is the application of chemical principles to the various substances used in ordinary life, such a *pharmaceutical* chemistry, which relates to the preparation of substances used in medicine, and *technical* chemistry, which relates to arts, manufactures, and agriculture.

Chemical Formulæ.—The alchemists, for the sake of mystery, employed the signs of the different planets to represent the various metals. Modern chemists, for the sake of convenience and brevity, have given to every element one or two letters called symbols, which are used, in conjunction with figures and algebraic signs, to express every known compound. The letters employed are in general the initials of the English or Latin names of the elements in question; thus, H stands for hydrogen, O for oxygen, K (Lat., *kalium*) for potassium. Two characteristic letters of the name are used when there are two or more elements with the same initial. Thus C stands for carbon, Cl for chlorine, and Co for cobalt. N denotes nitrogen, and Na (Lat., *natrium*) soda. Some familiar metals are marked by the initials or additional letters of the Latin names: thus, Au represents gold (*aurum*), Ag silver (*argentum*), Hg mercury (*hydrargyrus*), and Pb lead (*plumbum*). If a symbol be employed alone, it represents one equivalent in weight of hydrogen which is the unit. (*See* ATOMIC WEIGHT.) Thus, O signifies eight parts by weight of oxygen, that being the equivalent of one part of hydrogen, and C, six parts by weight. When two or more equivalents of one element unite with one or more equivalents of another element, the number of such equivalents is signified by a small figure being placed immediately after the symbol of the element so multiplied; thus MnO_2 (the symbol of black oxide of manganese) represents one equivalent of manganese with two of oxygen. In the formula of a compound substance, the symbol of the metal or its analogue is placed before the symbol of the oxygen, chlorine, or similar elements, as HgCl, the symbol of chloride of mercury. Two symbols, placed side by side, signify that they are in close chemical union: thus, AgO signifies a compound containing an atom of silver united to an atom of oxygen. A comma, separating two or more groups of symbols, must be taken to mean that they are not in such intimate chemical union that the groups cannot be separated without decomposition: thus AgO, NO_5 represents nitrate of silver, which, by certain treatment, can be separated into AgO, oxide of silver, and NO_5, nitric acid. The sign *plus* + signifies that the union is still weaker: thus, $AgO,NO_5 + HO$ means nitrate of silver united to an atom of water, HO. A number placed on the left of a group of symbols signifies that the whole group, as far as the next comma or *plus*, is to be multiplied by it: thus, $KO,2CrO_3$ signifies that one equivalent of potash is united with two of chromic acid. Sometimes the group to be multiplied is inclosed in a parenthesis: $3(HgCy) + 2(KO, SO_3)$ means that three equivalents of cyanide of mercury are united to two of sulphate of potash. Professor Frankland employs thick letters ("Egyptian") for the first symbol of a formula when the element so represented is directly united by points of attachment with the other elements or compound radicals following the first symbol. There are various slight modifications of formulæ which cannot be specified here. Formulæ may be *empirical* or *rational*—the former giving merely the constituents of a compound, the latter indicating the manner in which they are grouped. It is evident, therefore, that a compound can only have one empirical formula, while its rational formulæ are as numerous as the theories of its composition. Alcohol, for instance, is represented empirically by the formula $C_4H_6O_2$. Rationally, it may be represented as the ethylate of water, HO,C_4H_5O; the hydrated oxide of ethyl, C_4H_5O,HO; as a compound of olefiant gas and two equivalents of water, $2HO,C_4H_4$, and so on, *ad infinitum*. Braces are used to denote substitution compounds; that is compounds in which one element, or group of elements, has been substituted for another without materially affecting the character of the compound. Two changes have been lately introduced into chemical formulæ that it will be well to notice—one in which dashes or accents are used to denote the atomic power of the element; the other, a line through a symbol, to signify that its atomic number has been doubled. Bi''' means that bismuth has a triatomic power in the way of forming substitution compounds.

Chemical Nomenclature.—This is based on the great principle that the name of a compound should, as far as possible, express its composition and properties. The names of many of the simple elements we have received from the alchemists, and were formed on no definite plan. Those elements which have been lately discovered have been named either from some characteristic property possessed by them, or from some word indicating their source. Metals, as a rule, terminate in *ium*, as *potassium*, *thallium*, &c.; metalloids in *on*, as *boron*, *silicon*, &c.; gases in *ine* or *gen*, such as *chlorine* and *oxygen*. In several instances theory grounded on insufficient facts has been allowed to influence the name of an element; for example, oxygen was named from *oxus*, acid, and *gennao*, to generate; the theory of Lavoisier, who first adopted a systematic method of nomenclature, being that no acid could exist without oxygen. Subsequently, however, it was found that oxygen occurred in all bases, and that many acids existed that contained hydrogen in its stead. The Lavoisierian nomenclature is founded on the fact that when a compound of two elements is submitted to the action of the voltaic current, these elements separate, one (the electro-positive body) being attracted by the negative pole, and the other (electro-negative body) going to the positive pole. As a rule, it was found that the metalloids were electro-negative and the metals electro-positive. The simplest combinations of two elements are termed binary compounds, and fall naturally into two divisions—bases and acids. Bases always end in *ide*, and are compounds of different proportions of a metal with a metalloid. The proportion of the metalloid is indicated by the addition of a Greek or Latin numerical particle: thus we have the *protoxide*, *sesquioxide*, *binoxide*, and *teroxide* of various metals, indicating that these compounds contain one, one and a half, two, and three doses of oxygen to one of metal. When the metal is in excess, Greek prefixes are used: we have, for instance, the *dinoxide* or *trinoxide* of a metal, showing that the metal is in a double or triple dose. Generally the prefixes *sub* and *per* are used to indicate the excess of metal over metalloid, and *vice versâ*. The termination *uret* was formerly used in several cases, such as *sulphuret*, *phosphuret*, &c.; but it is now abandoned in favour of the termination *ide*. The compounds of the metalloids with each other are named on the same principle. When the proportion of oxygen is large, the compound is generally possessed of acid properties: thus we have Cr_2O_3, the sesquioxide of chromium, which is a base; but, by increasing the oxygen, we obtain CrO_3, which is an acid capable of forming salts with bases. The amount of oxygen contained in oxy-acids is indicated by the termination *ic* for the more highly oxidised, and *ous* for those containing less oxygen, or the prefixes *hypo*, under, or *hyper*, above. A few examples of bases and acids will illustrate this:—

Pb_2O .... Dinoxide or suboxide of lead.
CuO .... Protoxide or oxide of copper.
Fe_2O_3 .... Sesquioxide of iron.
MnO_2 .... Binoxide of Manganese.
AuO_3 .... Teroxide of gold.
PCl_5 .... Pentachloride of phosphorus.
PS_{12} .... Dodecasulphide of phosphorus.
ClO .... Hypochlorous acid.
NO_3 .... Nitrous acid.
ClO_4 .... Hypochloric acid.
NO_5 .... Nitric acid.

Certain metalloids, such as sulphur and hydrogen, combine with other metalloids to form acids: for instance, we have—

HCl .... Hydrochloric acid.
HBr .... Hydrobromic acid.
AsS_5 .... Sulpharsenic acid.
AsS_3 .... Sulpharsenous acid.

The compounds of acids with bases are always indicated by the termination or prefix of the word giving the name of the acid. Acids ending in *ous* and *ic* form salts ending in *ite* and *ate*, the prefix being, of course, preserved. A few samples of this will suffice:—

Sulphate of iron = sulphuric acid + oxide of iron.

Hypophosphate of lead = hypophosphoric acid + oxide of lead.

Sulphate of copper = sulphurous acid + oxide of copper.

Hyposulphate of cobalt = hyposulphurous acid + oxide of cobalt.

When the oxide with which the acid is united is a protoxide or peroxide, the prefixes *proto* and *per* are added; for instance, the pernitrate and protonitrate are the nitrates of the protoxide and peroxide of the metal. When the amount of acid is greater or less than the base, the prefixes *sub*, *sesqui*, *bi*, are used; as the *subcarbonate*, *bicarbonate*, and *sesquicarbonate of soda*. In double salts the name of the base only is repeated; as the *tartrate of potash and soda*. There are a few instances of acids and salts which have the same composition, but different properties. They are distinguished from the ordinary kind by the prefix *meta*; thus we have *phosphoric acid* and *metaphosphoric acid*. The prefix *pyro* signifies that the acid or salt has been obtained by heat; for instance, we have pyrogallic acid, produced in this way from gallic acid. In organic chemistry the nomenclature is in many cases somewhat confused. This is not owing to any want of proper principle in the formation of new words, but rather to the differences of opinion existing amongst chemists as to the composition of the substances indicated. Thus aniline is called *phenylamine phenylia*, and *benzidam*, by different chemists, who each have a theory touching its composition. Organic chemistry may be defined as the chemistry of organic radicles or compounds containing carbon, which act in every way as elements. Organic radicles generally terminate in *yl*, and mostly contain carbon, hydrogen, and oxygen. Thus we have *ethyl*, the radicle of ether, which forms oxides and salts in the same manner as iron, lead, or any of the purely elementary bodies. (*See* ORGANIC RADICLES.) There are also compounds corresponding to the electro-negative bodies *oxygen*, *hydrogen*, *nitrogen*, &c. We have, for instance, *cyanogen* and *amidogen*, which form *cyanides* and *amides*, similar in their properties to *chlorides* and *oxides*. The termination *ol* or *ole* is generally applied to neutral compounds of carbon and hydrogen, possessed of neither basic nor acid properties, and are mostly liquids; such as *benzol*, *pyrol*, *quinol*. The termination *in* is applied to other neutral substances, generally solid; such as *paraffin*, *naphthalin*, and *albumin*. Those ending in *ine* or *ia* are generally bodies allied to the alkalies in their properties. We have, for instance, *quinine* or *quinia*, *strychnine* or *strychnia*, *aniline*, &c., which form salts with acids. Many of those which end in *amine* resemble ammonia, and are considered substitution compounds of that body, in which one or more equivalents of hydrogen are replaced by an organic radicle. If two or three equivalents are replaced, the prefix *di* or *tri* is added to the word; for instance, we have *dimethylamine* and *tripropylamine*, the composition of which is plainly indicated by their names. When the hydrogen is replaced by different bodies, their names are prefixed. We have, for instance, *ethyl-methyl-amylamine*, which consists of one equivalent of nitrogen united to one each of the organic radicles ethyl, methyl, and amyl. There are also substitution acids as well as bases; such as *bromobenzoic acid* and *chloracetic acid*, in which *bromine* and *chlorine* are substituted for an equivalent of hydrogen. Thus, although these names appear unintelligible and unwieldy to the superficial observer, they are as easily understood by the chemical student as any term including several nouns and adjectives would be to an ordinary individual. Foreign chemists have adopted some variations from these general rules; but the representatives of the modern school, in order to obtain uniformity, generally act on the following rule respecting binary compounds, the names of which are formed from the English or Latin name of the positive constituent, with the terminal *ic* preceding that of the negative constituent, which ends in *ide*; thus argentic chloride (silver and chloride) has been substituted for chloride of silver, and plumbic iodide for the older iodite of lead.

Chemistry, History of.—Ancient Egypt was the foremost chemical nation of the East; the glass, pottery, colours, and method of embalming the dead, bearing strong testimony to the fact of the Egyptians being acquainted with chemical processes brought to a great state of perfection. The practical part of the science existed previous to the theoretical; but by degrees, as men began to think, they began also to observe and theorize. Paracelsus (who lived in the early part of the 16th century), though imbued with the fanciful doctrines of astrology and demonology, must be considered as the connecting link between the alchemists and the chemists. He was the first to offer a true chemical explanation of the action of mercury, iron, and lead in the human system. He distinguished alum from copperas, showing that the former contained an earth, the latter a metal. He admitted the existence of other elastic fluids besides air. He was aware that animals could not live, and inflammable matters could not burn, without air. To him succeeded Van Helmont, who was the first to distinguish between aërial fluids, or gases, as he called them. After Van Helmont came Boyle, the founder of the Royal Society, one of the most acute experimentalists that ever lived. His numerous experiments are marvels of accuracy, bearing even the test of our present knowledge. He and his contemporary Hook made great improvements in the air-pump, the invention of Otto Guericke, and paved the way to further discoveries. At the beginning of the 18th century come the names and discoveries of Bechar and Stahl, the founders of the phlogistic theory. They found that by heating charcoal with metallic oxides or calces, they were reduced to a metallic state. They further noticed, that when charcoal was burned it was entirely dissipated. Upon these facts they founded the theory that charcoal, or phlogiston, was a principle which united with the calx to form the metal. This theory, which was the first general principle applied to the whole range of chemical phenomena, maintained its ground for some time until the discoveries of Priestley tended to overthrow it, by proving that the calx, or oxide, of mercury, instead of gaining something by being heated, lost something, and that that something was oxygen. About this time Cavendish discovered hydrogen, and Rutherford nitrogen, experiment being heaped on experiment, and discovery on discovery, until the Stahlian theory gave way. It was succeeded by that of Lavoisier, the father of modern chemical science, who classified and arranged the known chemical facts into a system unparalleled for its precision, extent of view, and logical accuracy. His discoveries were few, but he reasoned on the discoveries of others with wonderful astuteness. From this moment chemistry marched onward with giant strides. Berthollet, Fourcray, Vanquetin, Klaproth, Richter, and other foreign chemists, greatly advanced the science; and the application of the Voltaic current to the decomposition of the alkalies, by Davy, resulted in the discovery of a dozen or more new metals. The atomic theory of Dalton threw great light upon the composition of salts and acids. The invention of the symbolic notation by Berzelius, and the determination of the elementary equivalents soon followed. In 1811, Davy overthrew the notion of Lavoisier, that acids could not exist without oxygen, by proving that hydrochloric acid consisted only of chlorine and hydrogen. In 1812, Courtois discovered iodine; Balard followed some time after with bromine. Element succeeded element until they reached the number of sixty. All this time organic chemistry was making great progress. The vegetable alkaloids began to attract great attention; their analyses were made, and new theories founded on them. The early labourers, Liebig and Berzelius, threw great light on this branch of the science, which is even to this day the most attractive to many famous chemists. Gay-Lussac and Thenard contributed greatly to the knowledge of organic substances, and the chemical nature of heat. The development of the theory of organic radicles has gone on increasing, fostered by the labours of Faraday, Laurent, Gerhardt, Hofmann, and a host of others, until it has assumed a mathematical precision unknown to any other branch of physical science. The investigations of organic compounds by these philosophers have resulted in a complete change, both in the notation and nomenclature of mineral substances. This theory, which was founded by Gerhardt, will be fully explained under GERHARDT'S THEORY. The last great discoveries have been spectral analysis, which has resulted in the addition of three new elements to our already bulky list—*cæsium* and *rubidium*, by Messrs. Bunsen and Kirchoff, of Heidelberg, and *thallium*, by Mr. Crookes, a distinguished English analytical chemist. The researches of Graham upon the diffusion of salts in solution and in dialysis, or the separation of crystallizable and non-crystallizable substances in solution by means of an intervening diaphragm, are amongst the most brilliant discoveries of the age. The researches of Schönbein, Schroetter, Brodie, and others, on the allotropic states of bodies, seem to point to the compound character of the present elementary bodies. In fact, chemistry at the present day is making such enormous strides, that its advance can only be properly studied in the current scientific journals.

Chemical Societies.—The Chemical Society of London was established in 1841; that of Paris in 1857; that of Germany at Berlin in 1867. The Institute of Chemistry of Great Britain was formed in 1877; and the Chemical-Industrial Society in 1881.

CHEMNITSIA, *kem-nit'-ze-a*, a genus of gasteropodus mollusca, having slender, elongated, many-whorled shells. They are found in various parts of the world, and about 180 fossil species have been described.

CHENOPODIACEÆ, *ke-no-po-de-ai'-se-e* (Gr., *chen*, a goose; *pous*, a foot), the Goosefoot or Spinach family, a natural order of dicotyledonous plants, in the sub-class *Monochlamydeæ*. There are 72 genera, which include 510 known species, distributed over all parts of the globe, but most adundant in extra-tropical regions. Several plants of this order inhabit salt-marshes, and yield by combustion the soda-ash called *barilla* (which *see*). Many are esculent; as beet and mangold-wurzel (*see* BETA), spinach (*Spinacia oleracea*), garden orach (*Atriplex hortensis*), and English mercury. (*See* CHENOPODIUM.) The seeds of others are nutritious. Several contain volatile oil, which renders them anthelmintic, antispasmodic, aromatic, carminative, and stimulant.

CHENOPODIUM, *ke-no-po'-de-um*, the typical genus of the natural order *Chenopodiaceæ*. The seeds of *C. Quinoa* contain starch granules, which are remarkable for being the smallest hitherto noticed. They are known under the name of *petty rice*, and form a common article of food in Peru. *C. bonus Henricus* ("good Henry") is the English mercury, a plant formerly much used as a pot-herb. The seeds of *C. anthelminticum* (wormseed) are largely employed in North America for their anthelmintic and antispasmodic properties. *C. vulvaria* (stinking goosefoot), an indigenous plant, is a popular domestic remedy for female complaints. *C. ambrosioïdes* is employed in Mexico and Columbia as tea; hence it is commonly known as Mexican tea.

CHERIMOYER, *ker-e-moi'-er*, the name commonly given to the fruit of the *Anona cherimolia*. It has been described as the finest of all fruits, and is generally eaten for dessert by the wealthy inhabitants of Peru and Brazil. It is sometimes called the cherimolia. (*See* ANONA.)

CHERRY AND CHERRY LAUREL. (*See* CERASUS.)

CHERT, *tchert*, a variety of quartz, common in the mountain limestone, oolite, and green sand formation, the coarser kinds being sometimes known as hornstone. The name chert is also given to the silicious concretions which occur as nodules and layers in limestone rocks, like flints in the chalk.

CHERVIL. (*See* ANTHRISCUS.)

CHEST. (*See* THORAX.)

CHESTNUT. (*See* CASTANEA.)

CHEVRETTE. (*See* GYN.)

CHICKEN-POX, *tshik'-en-pox*, the name given to an eruptive disease, usually of a mild nature, and bearing some resemblance to small-pox. It is mostly confined to children, and is of a contagious nature. The premonitory fever is very slight, and the vesicles are filled with a watery fluid, rarely with yellow matter or pus, and pass away in the course of four or five days, leaving only slight crusts or scales, which fall off without leaving any permanent mark. The disease is rarely attended with danger, and, generally, all that is necessary is to put the patient upon spare diet, and to administer a dose or two of some mild aperient.

CHICK-PEA. (*See* CICER.)

CHICK-WEED. (*See* STELLARIA.)

CHICORY, OR SUCCORY. (*See* CICHORIUM.)

CHIFF-CHAFF, a sprightly little bird, *Sylvia hippolais*, so named from its note; common in the south of Europe, but in Britain a bird of passage.

CHILBLAIN, *tshil'-blain* (Ang.-Sax., *chill*, cold; *blain*, a pustule or blister), is an inflammatory affection of the skin, occasioned by exposure to sudden alterations of heat and cold, and usually affecting the hands or feet. Young persons are more subject to it than adults, and females than males. The part is red and swollen, and is attended with heat and a great sense of itching. Chilblains are generally produced by persons holding their hands or feet to the fire immediately after they have been exposed to great cold. The itching is best removed by frequently rubbing the part with some stimulating application, as camphorated spirits of wine. If the parts should ulcerate, it is often very difficult to heal; but the best application to use is spermaceti ointment.

CHILLIES. (*See* CAPSICUM.)

CHIMÆRA, *kim-e'-ra*, a genus of cartilaginous fishes bearing some resemblance to the sturgeon, but now regarded as the type of a distinct family. The only known species is the *C. monstrosa*, found in high latitudes, and commonly known as "the king of the herrings," from its habit of pursuing the shoals. It is about three feet long, silvery white, in general colour, but on the upper part mottled with brown spots.

CHIMPANZEE, *tshim-pan-zee'* (*Troglodytes niger*), a species of ape, and one which in form and structure exhibits the greatest resemblance to man. It is a native of the warmest parts of Africa, and seldom attains a height exceeding four feet when in an erect position. Its skin is thickly covered with long black hair in front; and on the head, back, and limbs the hair grows thicker than elsewhere. The ears are thin, prominent, and naked, and not unlike human ears in shape. The appearance of the nasal organ is that of a mere pucker in the skin. The thumb of the hand is small and weak; that of the foot remarkably large and powerful. The great toe of the chimpanzee is shorter than the other toes, and opposed to them as a thumb.

The most man-like of this genus, however, is undoubtedly the gorilla. (*See* GORILLA.) The chimpanzee differs from the ourang-outang in having a cranium broader in proportion to its face, in eight more minute distinctions as to the characteristics of the skull; in the smaller size of the incisor and canine teeth, and inferior development of the jaws, giving it a more human and less beast-like head, in the possession of an additional dorsal vertebra, an additional pair of ribs; and in many other points relative to the conformation of the chest, loins, fingers, &c., amounting altogether to twenty points of difference.

CHINA BARK, a common name for cinchona. The name has nothing to do with China, but is derived from Kina or Quina, the Peruvian name of cinchona china.

CHINA ROOT, the rootstock of a shrub of the sarsaparilla kind, a native of China, Cochin-China, and Japan. It abounds in starch, is sometimes used as an article of food, and in medicine as a diaphoretic.

CHINCHILLA, *tshin-tshil'-la*, a small rodent animal, chiefly valuable for its fur, which is beautifully soft, downy, and of considerable length, but so loosely attached to the skin, that it falls off unless handled with considerable care. It associates in numbers, and excavates burrows, in which it resides, feeding chiefly on roots. In size and general form it resembles the rabbit, excepting the tail, which curls over, after the fashion of the squirrel's. It is a native of South America, and inhabits the valleys of the high mountain districts. The length of the body is about nine inches, and that of the tail five.

CHINESE GRASS. (*See* BŒHMERIA.)

CHIOCOCCA, *tchi-o-kok'-sa*, a genus of plants of the natural order *Cinchonaceæ*, *C. densifolia*, a bushy shrub, a native of Brazil, is in great favour as a remedy for snake-bites. An infusion of the bark is occasionally used in medicine as a drastic and emetic, but only in extreme cases and in small doses, so violent are the effects produced.

CHIQUICHIQUI, PALM, *tché'-ke-tché'-ke*, one of the plants which yield the Piassaba fibre of Brazil, so commonly used in brushmaking. It is the *Leopoldinia Piassala*, and grows in swampy land on the banks of rivers in the north of Brazil. The leaves, which are very large, are used for thatching.

CHIRATA, OR CHIRETTA, *tchi-ra'-ta*, a plant, *Agathotes Cherayta*, or *Ophelia Chirata*, of the natural order *Gentianeæ*, a native of the mountains of the north of India. The herb and root are both intensely bitter, and are used by European practitioners in India as a tonic and febrifuge.

CHIRU, *ki'-ru*, a species of antelope, *Antelope Hodgsoni*, a native of the pine-forests and elevated plains of Tibet. It is larger than the chamois (*see* CHAMOIS), lives in great herds, and is remarkable for watchfulness against the approach of danger.

CHITIN, *tchi-tin*, a white amorphous body, which forms the skeleton of crustaceans, and the skeleton scales and trachea of insects, and even forms one of the layers of the intestinal canals. In making preparations for the microscope, insects are treated with a solution of potash, which dissolves all but the chitin, leaving the most delicate parts exposed to observation.

CHITONIDÆ, *ki'-ton-i-de*, a family of gasteropodus molluscs, occupying a place in systematic arrangements close to limpets. The shell is composed of eight narrow transverse calcareous pieces, overlapping each other in a row along the back, and strongly attached to the fleshy and fibrous mantles. These molluscs have the power of rolling themselves up into a ball. More than 200 species are known; some of the foreign species are three or four inches larger, but those found on the British coasts are smaller.

CHIVE, *tchive*, a plant of the genus Allium (which *see*), cultivated in kitchen gardens, and the young leaves of which are used for flavouring. It averages nine or ten inches in height, has small flat clustered bulbs, and has red or flesh-coloured flowers. The plural form of the name, "chives," is generally used.

CHLAMYDOSAURUS, *kla-mi-dos-au'-rus* (Gr., *klamudos*, a cloak, and *sauros*, a lizard), commonly known as "the frilled lizard," a singular genus of reptiles, marked by a large plaited frill on the neck. The best-known species is the *C. Kingii* of Australia. It is nearly three feet long. When at rest, the frill lies back in plaits upon the body.

CHLAMYPHORUS, *kla-mif'-o-rus* (Gr., *klamus*, a cloak), a small mammal of Chili, which appears to form a connecting link between the edentates and the insectivora. The native name is "pichiciago;" the name now adopted by naturalists indicates the long covering of the top of the head and back, consisting of 24 rows of plates of thick skin. The lower parts are covered with soft fur. The animal is five or six inches long, and lives underground like the mole, which in many respects it resembles.

CHLORANTHACEÆ, *klo-ran-thai'-se-e* (Gr., *chloros*, green; *anthos*, a flower), a small natural order of dicotyledonous tropical plants, in the sub-class *Monochlamydeæ*, consisting of about fifteen species, which are arranged into three genera. The typical genus *Chloranthus* includes some useful species. The roots of *C. officinalis* and *brachystachys* have been employed in Java as stimulants in malignant fevers, and for their antispasmodic effects. The leaves of *C. inconspicuus* are used in China to impart to tea what is known as the "cowslip flavour." Aromatic stimulant properties are common to all the plants of this order.

CHLORINE, *klor'-ine* (Gr., *chloros*, green), a transparent gas of a greenish-yellow colour and a powerfully suffocating odour, which, even largely diluted with air, produces great irritation of the air-passages. It is prepared by oxidising hydrochloric acid by heating it with binoxide of manganese. One hundred cubic inches weigh between 77 and 78 grains. It is, therefore, about two and a half times heavier than atmospheric air. The symbol (*See* CHEMICAL NOTATION) is Cl, the specific gravity 2·411. Water absorbs about twice its volume; it can, therefore, be only collected by displacement or over warm water. Under a pressure of four atmoshperes it condenses into a yellow limpid liquid, rather heavier than water, and remains fluid and unfrozen at a temperature of 220° Fah. With water, *chlorine* forms a definite hydrate, which, when subjected to a cold of 32° Fah., solidifies in the form of large yellow crystals. Chlorine is not combustible, but supports combustion to a certain degree. A wax taper burns in it with a reddish smoky flame, the hydrogen of the wax combining with the chlorine to form hydrochloric acid, and the carbon being set free. Chlorine, in common with several other elementary bodies, has the property of replacing hydrogen in its organic compounds. It is in this manner that chlorine bleaches textile fabrics. The brownness of the fabric is due to some brown organic substance, which, when submitted to the action of chlorine, parts with its hydrogen and assumes a colourless form, containing chlorine. This fact is proved on a large scale by the action of chlorine on indigo. Another property of chlorine is that of destroying noxious vapours and miasmata. For the same reason, it is used as a disinfectant, the action being the same as that mentioned above. Chlorine is possessed of powerful affinities, and unites with all the metalloids and metals. With hydrogen it forms hydrochloric acid, and with nitrogen a fearfully explosive substance—perchloride of nitrogen. With carbon it forms several chlorides. (*See* CARBON.) The oxygen compounds of chlorine are *chloric acid*, *chlorous acid*, *hypochlorous acid*, *perchloric acid*, and other oxides of unimportant properties and less definite composition.

Chloric Acid is a colourless syrupy liquid, very powerful as an oxidising and bleaching agent. With bases it forms well defined salts, the most important of which are *chlorate of barium* and *chlorate of potassium*, which are decomposed by heat with evolution of oxygen, and detonate when heated with combustible bodies. Chlorate of potassium is largely used as a source of oxygen gas, as an oxidising agent in calico-printing, and in the manufacture of lucifer matches, fireworks, and percussion caps.

Chlorous Acid is a yellowish-green gas, which, with bases, forms some unimportant salts.

Hypochlorous Acid is a pale reddish yellow gas, with an odour strongly resembling that of chlorine. When slightly heated, it decomposes with explosives, and unites with bases to form salts, three of which, *calcium*, *sodium*, and *potassium salts*, are of great use as bleaching substances and disinfectants.

Perchloric Acid, a colourless, oily liquid, very volatile and easily decomposed. It is the most powerful oxidising agent known; a single drop brought into contact with charcoal, or other combustible body, induces combustion with explosive violence. It unites with bases to form well defined salts, the most important of which is *perchlorate of potassium*.

CHLORINE, SPECTRUM OF.—Chlorine absorbs the coloured portion of the spectrum where the coloured rays are most abundant. (*See* SPECTRUM.) Absorption lines are distinctly visible in the spectrum of light which has traversed a tube filled with chlorine.

CHLORITE, *klo'-rite*, a mineral of a green colour, consisting of silica, alumina, magnesia, and protoxide of iron. It is sometimes found foliated like talc, and more rarely in hexagonal crystals; is soft and easily broken.

Chlorite-Schist, a green slatey rock, in which chlorite is abundant, usually blended with minute grains of quartz, or with felspar or mud.

CHLOROPHYLL, *klo'-ro-fil*, the green colouring matter of leaves. In the purest state in which it has been obtained it is a dark green powder, unaffected by any heat below 392° Fah., insoluble in water, but dissolved by alcohol, acids, and alkalies. Light is indispensable to its formation.

CHLOROPS, *klo'-rops*. (*See* CORN-FLY and WHEAT-FLY.)

CHLOROSIS, *klo-ro'-sis* (Gr., *chloros*, green), is the name of a disease to which young females are subject, and which is characterized by a peculiar sallow, or greenish-yellow, hue of the countenance, and hence known as the green sickness. It occurs at the age of puberty, and is connected with the development of the female constitution. The principal means to be employed in the cure of this disease are gentle exercise, nutritious and rather stimulating diet, tonics, and sea-bathing. The term is also applied to a diseased state of plants, in which a greenish-yellow hue takes the place of the natural colour.

CHLOROSPORÆ. (*See* ALGÆ.)

CHLOROXYLON, *klo-roks'-e-lon* (Gr., *chloros*, green; *xulon*, wood), a genus of tropical trees belonging to the natural order *Cedrelaceæ*, or Mahogany family. All the species have dotted leaves, which yield by distillation an essential oil. *C. Swietenia* furnishes Indian satin-wood, which is sometimes imported into this country for the use of cabinetmakers.

CHOCARD, OR CHOQUARD, *tcho'-kard*, a genus of birds, *Pyrrhocorax*, of the crow family. The only European species is the Alpine crow, which is about the size of a jackdaw, of a brilliant black colour, with yellowish bill and red feet.

CHOKE-DAMP, *tshoke'-damp* (Ang.-Sax.), a name given by miners to carbonic acid, as distinguished from fire-damp, which is carburetted hydrogen.

CHOLERA, *kol'-e-ra*, (Gr., *chole*, bile, and *rheo*, I flow), the name given to two or three different forms of disease, each of which is characterised by vomiting and purging, with great pain and debility. The mildest form of this disease is known as *bilious* or *British cholera*, and usually prevails to a greater or less extent in this country every summer or autumn. It apparently proceeds from some disordered condition of the bile, which is either in excess or too acrid, and seems to be produced by cold, suppressed perspiration, unripe or acid fruits, &c. It generally commences with griping pains of the bowels, followed by vomiting and purging, together with heat, thirst, a hurried respiration, and a frequent but weak and fluttering pulse. In favourable cases these symptoms subside in a few days, leaving the patient in a very weak and exhausted condition; but in severe cases great depression of strength ensues, attended with great anxiety and lowness of spirits, violent spasms, cold, clammy sweats, a hurried and short respiration, hiccup, a low and irregular pulse, and the patient sinks rapidly, being sometimes carried off in twenty-four hours. In the earlier and milder form of this disease, when the strength is not much exhausted, tepid demulcent liquids are to be frequently administered, so as to lessen the irritation and facilitate the discharge of the bile. Where the symptoms are severe and the patient rapidly sinking, opium is to be administered freely, but in small quantities, and effervescent saline draughts given to check the sickness, and enable the stomach to bear the frequent doses of opium. When the urgent symptoms are relieved, the strength is to be restored by gentle tonics and a light and nutritious diet.

The severer form of this disease is sometimes called spasmodic cholera, from being usually attended with violent spasms. The *Asiatic*, *malignant*, or *pestilential cholera*, is a much more violent form of disease, and first became known in this country in the autumn of 1831. It is epidemic, commonly comes on without any warning, and the patient is frequently a corpse in a few hours. The attack usually begins with sickness and purging; the discharge in this case not being bilious, but a thin colourless fluid like rice-water, accompanied with great prostration of strength and cold clammy sweats. In a short time dreadful cramps assail the extremities, and afterwards the abdomen and other parts of the body; the body becomes bent, the limbs twisted, the countenance cadaverous, the pulse almost imperceptible, the eyes sunken and surrounded by a dark circle, the patient sinks into a state of apathy, and, unless a favourable change speedily takes place, he soon expires. When reaction takes place, the pulse gradually returns, the natural warmth of the body is restored, and the spasms and difficulty of breathing give way. Frequently, however, the reaction is accompanied by fever closely resembling typhus, and which often terminates fatally, in from four to eight days. As regards the treatment of this disease, the only advice that can be given here is to seek the aid of a medical man without delay.

CHONDRUS, *kon'-drus*, a genus of *Algæ*. The most important species is *C. crispus*, commonly called carrageen, or Irish moss, which is used medicinally for its nutritive, emollient, and demulcent properties, being administered in the form of a decoction or jelly. It is also used for making *bandoline* (which *see*), and as a substitute for size. *C. mamillosus*, which has similar properties, is always found in the carrageen moss of the shops.

CHONETES, *ko'-ne-tes*, a genus of fossil brachiopodus mollusca, of which 29 species have been found, in the pantæozoic formation.

CHORD, *kord* (Lat., *chorda*), in Geometry, is a right line drawn from one part of an arc of a circle to another.

CHOREA, *kor-e'-a* (Gr., *choreia*, a dancing or jumping), is the name of a disease otherwise known as St. Vitus's Dance, and characterised by convulsive motions of the limbs, as of a person dancing. The muscles of voluntary motion are no longer under the complete control of the will, and the power of walking or of using the arms or hands is impaired. It is common to both sexes; but rarely attacks before the age of eight or after that of sixteen years. Those of a weakly constitution, or whose health has been impaired by confinement or improper nourishment, are chiefly subject to it. The great cause of it is a disordered state of the digestive organs, producing a certain degree of mental weakness. This disease usually disappears under judicious treatment, or as the patient grows up; but occasionally it terminates in epilepsy, paralysis, or idiocy. The proper mode of treatment is to restore the tone of the system by tonics, a nourishing diet, and frequent exercise in the open air.

CHOUGH, *tshuff* (Sax., *ceogh*) (*Fregilus graculus*), an European bird, much resembling in size and habits the jackdaw; its colour, however, is in parts different. It is of a jet black over its upper parts, while the head and neck feathers are tinted with purple. The beak is bright vermilion, bent from the base, and very strong. The legs and feet are of the same colour as the beak, and powerfully formed. Its length, when full grown, is about fifteen inches. It is most common in mountainous districts, and builds its nests on lofty cliffs, or ruined towers. It lives in societies like the rooks. Like the jackdaw, the chough is easily tamed, and just as mischievous and entertaining when its domestication has been accomplished.

CHROMATES, *kro'-maits* (from *chromium*), salts formed by the union of chromic acid with certain bases. (*See* BASE.) There are three kinds—basic, neutral, and acid, most of which are highly coloured. (*See* CHROMIC ACID.)

CHROMATICS, *kro-mat'-iks* (Gr., *chroma*, colour; terminal, *ikos*), that part of the science of optics which explains the properties appertaining to colours. (*See* COLOUR, LIGHT, OPTICS, SPECTRUM.)

CHROMIC ACID, *kro'-mik*, Cr_2O_3.—This acid occurs in nature in combination with lead as chrome yellow, and with iron as chrome ironore. It is prepared by adding one measure of a warm saturated solution of bichromate of potash to one and a half of concentrated sulphuric acid. The acid is added in small portions at a time, the solution being allowed to cool between each addition. Chromic acid crystallizes out, and bisulphate of potash remains in solution. The most useful of the compounds of chromic acid is the bichromate of potash. Both the chromate and the bichromate are extensively used in dyeing and calico-printing. Bichromate of potash is employed in conjunction with sulphuric acid in the laboratory as an oxidizing agent, and in commerce in the same manner in bleaching sperm oil. The bichromate of ammonia is used in photography. Except the chromate of lead, or chrome yellow, the other chromates and bichromates are unimportant.

CHROMIUM, *kro'-mi-um* (Gr., *chroma*, colour)—symbol Cr, atomic weight 26·21, specific gravity 5·9—a rare metallic element discovered by Vanquelin, in 1797. Its most important ore is the chrome iron-stone, a compound of protoxide of iron and sesquioxide of chromium. It is also found as chromate of lead, from which mineral Vanquelin obtained it. Its compounds are remarkable for their numerous and brilliant colours, whence its name. To effect its reduction, oxide of chromium is intimately mixed with powdered charcoal, and made into a paste with oil. It is then introduced into a crucible lined with charcoal, and carefully luted down. The whole is exposed to the action of a powerful wind-furnace for several hours, and an impure mixture of carbon and chromium is formed in the crucible. Chromium is a light-grey metal, very brittle, non-volatile, and non-magnetic. As might be inferred from the difficulty with which it is reduced, chromium, in the metallic state, has not yet received any useful application. Its oxide and many of the chromates have received useful applications in calico-printing and china-painting. The manufacture of bichromate of potash is very important, not less than 1,500 tons of chrome iron-stone being annually imported from the United States and Norway, to be converted into this useful salt.

Chlorides of Chromium.—There are two principal chlorides of chromium,—the *protochloride* and the *sesquichloride.* The former is formed by passing a dry current of hydrogen over the sesquichloride heated to redness; hydrochloric acid is given off; and the protochloride remains in the form of a white powder, soluble in water, with which it forms a bluish-green solution that rapidly absorbs oxygen from the air.—*Sesquichloride of chromium* is formed in beautiful transparent plates of the colour of peach-blossoms by passing a current of dry chlorine over a mixture of sesquioxide of chromium mixed with charcoal contained in a porcelain tube heated to redness. Being volatile, the sesquichloride condenses at the cool end of the tube in the beautiful form just described. Thus prepared, it is quite insoluble in water and acids. Solution of sesquichloride of chromium is prepared from the hydrated sesquioxide by dissolving it in hydrochloric acid. The solution, on evaporation, yields green crystals, containing two equivalents of hydrochloric acid and ten equivalents of water. It is a singular fact, that only two-thirds of the chlorine contained in the solution of this salt is precipitated by nitrate of silver. A violet chloride may be formed by precipitation from the violet sulphate by chloride of barium, from the solution of which the whole of the chlorine can be precipitated by nitrate of silver.

Chromium, Oxides of.—Chromium forms several compounds with oxygen, of which the most important are four:—Protoxide, sesquioxide, chromic acid, perchromic acid.—*Protoxide of chromium* can only be obtained in the state of hydrate on adding caustic potash to a solution of the protochloride. It absorbs oxygen with great avidity, decomposing water and setting free the hydrogen, becoming converted into a hydrated intermediate oxide. The protoxide of chromium forms a double sulphate with sulphate of potash, closely corresponding to the double sulphate of iron and potash, in form and composition. The crystals are of a fine purple colour.—*Sesquioxide of chromium* is obtained as a greyish green hydrate, by boiling with alcohol a solution of bichromate of potash acidulated with sulphuric acid. The anhydrous green oxide is not decomposed by heat; hence it is of great use in china and enamel-painting. It is generally prepared for this purpose by exposing chromate of mercury to a red heat. The difficulty with which this oxide is decomposed by ordinary chemical re-agents has rendered it useful as a pigment for printing bankers' cheques and other important documents. Oxide of chromium is the colouring matter of the emerald, pyrope, greenstone, and other minerals.—*Chromic acid* has already been considered under that head.—*Perchromic acid* is formed by adding an aqueous solution of peroxide of hydrogen to chromic acid.

CHROMOSPHERE, *kro'-mo-sfere,* the name given by Mr. Lockyer to the layer of red matter which surrounds the sun. The existence of this solar envelope was first pointed out by Secchi, and recent investigations have fully established the truth of Secchi's statement. (*See* SUN.)

CHRYSALIS. (*See* INSECT TRANSFORMATIONS.)

CHRYSANTHEMUM. (*See* CORYMBIFERÆ.)

CHRYSIS, *kris'-is,* a family of hymenopterous insects (*Chrysidæ*) forming a connecting link between the *Ichneumonidæ,* and bees, wasps, &c. In this country they are popularly known as golden-tailed and ruby-tailed flies. They may be seen poised in the air, in the sunshine, and so rapid is the motion of their wings, that only the body of the insect is visible.

CHRYSOBERYL, *kris'-o-be-ril,* a beautiful gem, of a yellowish-green colour, almost transparent, and having a double refraction. It is found in six-sided crystals, in granite and alluvial soils in some parts of Southern Asia, America, and Siberia. It is very hard, and exhibits an opalescent play of light.

CHRYSOCOLLA, *kris-o-kol'-la* (Gr., gold glue), an ore of copper, sometimes known as copper green, found in Cornwall, and very abundantly in North America. It was formerly much used as a pigment.

CHRYSOLITE, *kris'-o-lite* (Gr., golden stone), a mineral of a fine green colour, and a vitreous lustre, composed of silica, magnesia, and oxide of iron, transparent, and having a double refraction. Jewellers use it as an ornamental stone. It is found in Egypt and some parts of Eastern Asia, and also in Brazil. In the New Testament, the chrysolite is mentioned as one of the precious stones of the New Jerusalem; but the stone referred to was probably a species of topaz.

CHRYSOPRASE, *kris'-o-prase,* a very valuable variety of chalcedony of an apple-green colour, found in Lower Silesia, and in the state of Vermont, United States. It is used for rings, necklaces, brooches, and other articles of jewellery. One of the precious stones forming the foundation of the New Jerusalem is named in the book of Revelation, chrysoprasus.

CHRYSOBALANEÆ, *kri-so-bai-lai'-ne-e* (Gr., *chrusos,* gold; *balanos,* a nut), a sub-order of the natural order *Rosaceæ.* The plants belonging to this division are trees or shrubs, principally natives of the tropical parts of America and Africa. Many of them produce edible fruits. The typical genus *Chrysobalanus* includes two valuable fruit-trees. *C. Icaco* yields the cocoa-plum of the West Indies; and in Brazil the roots, bark, and leaves are prescribed against diarrhœa and other similar maladies. *C. luteus* yields a fruit which is eaten in Sierra Leone.

CHRYSOPHYLLUM, *kri-so-fil'-lum* (Gr., *chrusos,* gold; *phullon,* a leaf), a genus of tropical trees belonging to the natural order *Sapotaceæ.* The species *C. Cainito* yields a delicious fruit known as the star-apple. *C. Buranheim* furnishes astringent bark called Monesia bark, which has been much employed in France and Germany. This bark contains an acrid principle called *monesine,* which is analogous to *saponine.*

CHUB, *tshub* (Ang.-Sax.) (*Leuciscus cephalus*), a freshwater fish of the same genus as the roach, dace, bleak, &c. It is plentiful in many of the rivers of England and of the south-west of Scotland. The chub spawns in May, and comes into condition again about the end of June or beginning of July. It bites freest, and is in the best condition for bottom-fishing, between the middle of October and November. The colours of the chub are blue-black on the upper part, silvery white below; cheeks and gill-covers golden yellow. Weight seldom exceeding five pounds. Is not considered a great dainty.

CHURCHYARD BEETLE. (*See* BLAPS.)

CHYLE, *kile* (Gr., *chulos,* juice), is the milk-like fluid which is formed by the action of the bile and pancreatic juice upon the chyme in the duodenum, and absorbed by the lacteal vessels. The use of the chyle is to supply the matter from which the blood is formed and the waste of the living organs repaired. *Chyme* is the ingested mass formed by the action of the stomach upon the food, and which passes from the stomach into the duodenum. (*See* DIGESTION.)

CIBOTIUM, *si-bo'-te-um,* a genus of ferns, natural order *Filices,* including several species which produce silky hairs useful to man. The styptic called *penawar,* which is often used in

Holland and Germany, consists of the fine hairs from the caudex of *C. Barometz*, the "Scythian lamb" of old writers. These hairs are imported from Sumatra, and are sometimes employed for stuffing cushions. Similar hairs are brought from the Sandwich Islands, and are known under the name of *pulu*.

CICADA, *se-kai'-da* (Lat., grasshopper), a genus of insects of the order *Hemiptera*, common in tropical and warm temperate regions, and remarkable for the loudness of the sounds they emit. The organs that produce these shrill sounds consist of membranes and fibres connected with powerful muscles, and situated on the underside of the abdomen. The largest insect of this genus does not exceed an inch in length; yet it is asserted that it may be heard in the still night at a distance of at least half a mile, and that the sound emitted is like grinding a knife on a whetstone. Notwithstanding the name given to the insect, it has no resemblance to the grasshopper, and no power of leaping. The Italian name is *cicale*; the French, *cigale*.

CICATRIZATION, *sik'-a-tri-zai'-shun* (Lat., *cicatrico*, I heal up), is a term applied to the healing or skinning over of an ulcer or broken surface of the skin.

CICELY, *sise'-le*, a genus of umbelliferous plants (*Myrrhis*), nearly allied to chervil. It is most common in the southern parts of Europe and Asia. In this country it is commonly known as sweet chervil, and in Scotland as myrrh. In Germany soup is made of the seeds, roots, and young leaves.

CICER, *si'-ser* (from Gr., *kikus*, strength, in reference to its qualities), a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Papilionaceæ*. *C. arietinum*, a native of the countries around the Mediterranean, produces the edible seeds called chick-peas. These are the most common parched pulse of the East.

CICHORIUM, *si-kor'-e-um* (Lat.), a genus of plants belonging to the natural order *Compositæ*. The species *C. Intybus* is the wild chicory or succory, a plant indigenous to this and many other countries of Europe, having numerous heads of bright-blue handsome flowers. It is extensively cultivated for the sake of its roots, which are sliced, roasted, and ground, to form the chicory of the shops, which is sold as a substitute for, or more frequently as an addition to, ground coffee.

CICINDELIDÆ. (*See* TIGER-BEETLES.)

CICUTA, *si-ku'-ta*. (*See* HEMLOCK.)

CIDARIS, *si'-dar-is*, a genus of *Echinidæ*, or sea-urchins, only one species of which, *C. papillator*, is found in the British seas, and that only on the coast of Zetland. The markings of the shell and spines are very beautiful.

CILIUM, *sil'-i-um* (Latin), a name given to the eyelid or eyelash; and hence the term *ciliary* is applied to the arteries, glands, &c., belonging to the eyelids.

CILIARY BODY, OR PROCESS.—The muscular fibres which control the crystalline lens of the eye. (*See* EYE.)

CIMOLITE, *si'-mo-lite*. (*See* FULLER'S EARTH.)

CINCHONA, *sin-ko'-na*, the typical genus of the natural order *Cinchonaceæ*. The plants of this genus are natives of the intertropical valleys of the Andes, and are found principally on the eastern face of the Cordilleras, growing commonly at heights varying from about 4,000 to nearly 12,000 feet above the level of the sea. The cinchona region extends from Santa Cruz de la Sierra, in Bolivia, about 19° S. lat., through Peru and Columbia, nearly to Caracas, in about 10° of N. lat. The plants are small shrubs or large forest-trees, with evergreen leaves and commonly showy flowers. They appear to require great moisture, and a mean temperature of about 62°. The cultivation of these plants has lately been commenced in India with some success, and so highly are the medicinal qualities valued, and so greatly is a "quinine famine" dreaded, that energetic steps have been taken in other parts of the world to cultivate them. The barks of several species and varieties are extensively used in medicine, and are undoubtedly the most valuable drugs known. They are imported into this country under the names of *Cinchona*, *Peruvian* and *Jesuits' Bark*. Twenty-six different varieties have been described by Pereira; and Weddell has enumerated no less than thirty-nine. The most important are *Loxa*, or crown bark; grey, silver, or *Huanuco* bark; *Calisaya*, or yellow bark; and red bark. These four are officinal in our pharmacopœias, and are the sources of the precious alkaloids *quina* or *quinine*, *cinchonia*, and *quinidia*, which are all used in medicine, and possess in an eminent degree tonic, febrifugal, and antiperiodic properties. The barks themselves have similar properties, and are, moreover, slightly astringent. The name cinchona was given to the genus by Linnæus, in compliment to the countess of Cinchon, whose husband was the viceroy of Peru. She had derived great benefit from the bark during her residence in South America; and on her return to Europe, in 1639, she brought with her several specimens. The medicinal use of the bark was first made known in Europe by the Jesuits.

CINCHONACEÆ, *sin-ko-nai'-se-e*, a natural order of dicotyledonous plants in the sub-class *Corollifloræ*, including 2,500 species, which are grouped into 318 genera. They are almost exclusively natives of tropical and warm regions. They yield many valuable medicinal agents, the most important being quinine (*see* CINCHONA) and ipecacuanha (*see* CEPHAELIS). They also furnish many substances useful in the arts and domestic economy; such as dye-stuffs, tanning agents, edible fruits and seeds, and ornamental woods. The coffee-plant belongs to this extensive order. (*See* COFFEA.) Most of the plants have beautiful and fragrant flowers, and some, such as the genipa of South America, and the native peach of Sierra Leone, produce fruit of agreeable flavour.

CINERARIA, *sin-e-ra'-ri-a*, a genus of herbaceous plants, of the natural order *Compositæ*, nearly allied to groundsel, and found in nearly all parts of the world. The flowers of some of the species are very pretty.

CINNABAR, *sin'-na-bar* (Gr., *kinnabari*), known also as *sulphide of mercury*, the principal ore of mercury, from which the greater proportion of all the mercury of commerce is obtained. It contains 86·2 parts of mercury and 13·8 parts of sulphur. Native cinnabar is found in masses, crystallized in six-sided prisms, rhombs, and octohedra. It is of various colours, sometimes appearing steel-grey, and at others bright red. It is not found in Britain, but occurs in France, Hungary, and Spain, in Siberia and Japan, and in large quantities in South America. It has also been imported from China. Under the name of *vermilion*, cinnabar is used as a pigment, when refined. Hepatic cinnabar is a variety containing a little carbon, and so called on account of its liver-brown colour, from the Greek word *hepar*, the liver.

CINNAMOMUM, *sin-na-mo'-mum* (Lat.), a genus of plants belonging to the natural order *Lauraceæ*, including many species remarkable for their aromatic properties. *C. Zeylanicum*, the cinnamon-tree, a native of Ceylon, is extensively cultivated in that island, also on the Malabar coast, in Java and Cayenne, for the sake of the aromatic bark of the young branches, which forms the *true cinnamon* of commerce. Cinnamon is much employed as a spice, and medicinally as a cordial, stimulant, carminative, astringent, antispasmodic agent, and as an adjunct to other medicines. It owes its properties to the presence of a volatile oil and tannin. The volatile oil is imported from Ceylon, where it is obtained from the rejected bark by distillation. It is known by the name of *oil of cinnamon*, and is used medicinally as a stimulant, and by cooks and confectioners for flavouring. From the leaves of the tree another volatile oil, similar to oil of cloves in odour and taste, is prepared. From the ripe fruits a concrete fatty substance called *cinnamon suet* is obtained by expression. The cinnamon-tree is the kinnemon or kinman of the Bible.

CINNAMON. (*See* CINNAMOMUM.)

CINNAMON-STONE, *sin'-na-mon*, a variety of garnet, also called *essonite*, of a light cinnamon-yellow colour and high lustre. If carefully cut and skilfully polished it commands a good price. It is a silicate of alumina and lime.

CINNYRIS, *sin'-ne-ris*. (*See* SUNBIRD.)

CINQUEFOIL, *sink'-foil* (Fr., five-leaved.) (*See* POTENTILLA.)

CIRCINUS, *sir-sin'-us*, a constellation of the southern sky, also known as the Compasses.

CIRCÆA, *ser-se'-a*, a genus of small herbaceous plants of the natural order *Onagraceæ*. One species, *C. Lutetiana* is found in shady situations in most parts of Europe. In England it is commonly known as the enchanter's nightshade, and Germans call it the witches' herb. It is not known why these names were given; but the botanical name is of similar import, being taken from Circe, the fabulous enchantress of ancient Greece, mentioned by Homer. Other species of the genus are found in the Himalaya.

CIRCLE, *ser'-kle* (Fr., *cercle*; Lat., *circulus*), is, according to Locke's definition, "a line continued till it ends where it began, having all its parts equi-distant from a common centre." The boundary line is called the circumference or periphery. Any straight line drawn through the centre and terminating in the circumference is called a diameter. The proportion of the circumference to the diameter is very nearly 3·14159; but cannot be exactly expressed with any number of decimals. Many attempts have been made to ascertain the quadrature of the circle; that is to find a square, the contents of which are exactly equal to the area of a given circle; but as the diameter and the circumference are in fact incommensurate, the problem is insoluble. The circle is one of the elements of plane geometry, the right line being the other; and those constructions only are regarded as geometrical which can be made by the aid of these two elements. The circle, however, derives its chief importance from its application in trigonometry to the measurement of angles. This application is dependent on the fact that if circles of the same radii be described from the vertices of angles as centres, the arcs of the circles intercepted between the sides are always proportional to the angles. It is for this reason that the circle is almost always employed to compare angles with each other. For this purpose the circumference of the circle is divided into four equal parts, each of which is called a quadrant; each quadrant is divided into ninety equal parts, called degrees; each degree is divided into sixty equal parts, called minutes; each minute into sixty equal parts, called seconds.

In Logic, the term "reasoning in a circle" is applied to a kind of false reasoning, in which the principle is supposed which it is intended to prove, and afterwards the principle is proved by the thing which it seemed to have proved. The same fault takes place in definitions, when an idea is defined by others which suppose the knowledge of the first.

Circle of the Celestial Sphere.—Any circle, the plane of which passes through the celestial sphere, as the ecliptics. (*See* ECLIPTIC.)

Mural Circle, an instrument used by astronomers for determining the meridian altitude or zenith distance of a star. It consists of an astronomical telescope firmly fixed to a graduated circle, which moves about a horizontal axis, the eye-piece and object glass of the telescope being crossed by five lines (generally of spider web) one horizontal and five vertical. When the instrument is properly adjusted, the line joining the optical centre of the object-glass with the intersection of the horizontal and middle vertical wire moves in the plane of the meridian and by very careful observations, the position of the star is ascertained.

CIRCUIT GALVANIC. (*See* ELECTRICITY.)

CIRCULAR NUMBERS are numbers the powers of which end on the same figures as they do themselves, as in the case of numbers ending in 0, 1, 5, 6.

CIRCULATION OF THE BLOOD, *sir-ku-lai'-shun* (Lat., *circulus*, a circle), is applied to the course of the blood through the body, from the heart to the capillaries, and from the capillaries back again to the heart. The several organs of circulation are the heart, arteries, veins, and capillaries. By the heart the blood is propelled through the arteries to all parts of the body. The capillaries are very minute vessels, connecting the extremities of the arteries with those of the veins, and by the veins the blood is returned again to the heart. (*See* HEART.) The pulse which is felt in the arteries is caused by the action of the heart propelling the blood in waves through the body. The discovery of the circulation of the blood is due to Dr. Harvey, afterwards physician to Charles I.; the opinion previous to his time being, that the blood circulated only in the veins, and that the arteries, from being always found empty after death, contained nothing but air; and hence their name.

Circulation of Sap, the ascent of the sap from the root to the leaves and bark of plants, and its partial descent after the elaboration which it undergoes in these organs.

CIRCUMPOLAR STARS (*circum*, around,

and *Polus*, the pole), stars which move round the pole of the heavens without setting. Their distance from the pole, thus, does not exceed the latitude of the plane of observation.

CIRRHOPODA, OR CIRRIPEDA, *sir-rop'-o-da* (Lat., curl-footed), animals of the class *Articulata*, of which barnacles and balani are familiar examples; all in their native state permanently attached to rocks, sea-weed, shells, and some are found imbedded in the skin of whales and the flesh of sharks. They are distributed over the whole world. Nearly all the species are hermaphrodite. The young possess the power of locomotion, and are furnished with eyes, which disappear after they have permanently fixed themselves to some of the objects mentioned; and they have also shells quite different from those of their native state.

CIRRHUS, OR CIRRUS, *sir-rus* (Lat., a curl of hair), a tendril or leaf assuming the form of a slender spiral, by which the plant clings to other objects, and is so enabled to climb. The vine, pea, and many other familiar plants afford examples.

CIRRUS. (*See* CLOUDS.)

CISSAMPELOS, *sis-sam'-pel-os* (Gr., *kissos*, ivy; *ampelos*, a vine), a genus of plants belonging to the natural order *Menispermaceæ*. The root of *C. Pareira*, a climbing plant indigenous in Brazil, is an article of our Materia Medica, and is commonly known as *Pareira brava*. It possesses bitter, tonic, and diuretic properties, which are chiefly due to the presence of an uncrystallizable alkaloid named *cissampeline* or *pelosine*.

CISTACEÆ, *sis-tai'-se-e* (Gr., *kiste*, a box or capsule), the Rock-rose family, a natural order of dicotyledonous plants in the sub-class *Thalamifloræ*, consisting of seven genera and 185 species, chiefly natives of the south of Europe and north of Africa; they are shrubs or herbs. The *Cistaceæ* have resinous and balsamic properties. From species of the typical genus *Cistus*, or rock-rose, a fragrant resinous substance, called *Ladanum*, is obtained in the Levant. This is used medicinally as an expectorant and emmenagogue, and is much esteemed by the Turks as a perfume. A gum called *Kuteera*, which is sometimes substituted in India for tragacanth, is the produce of a plant of this order, named *Cochlospermum Gossypium*.

CITRON, *sit'-ron*, *Citrus medica*. (*See* CITRUS.)

CITROSMA, *si-tros'-ma*, a genus of trees, natives of the tropical parts of South America, belonging to the natural order *Monimiaceæ*. An oil resembling the oil of citron is obtained from the leaves.

CITRUS, *si'-trus* (said to be from the town *Citron*, in Judea), a genus of plants belonging to the natural order *Aurantiaceæ*. The different species and varieties of this genus yield the fruits known under the names of orange, lemon, lime, shaddock, pompelmoose, forbidden fruit, kumquat, and citron. (*See* various headings.) *C. medica* yields the fruit called the citron, which is supposed to be the Hebrew *tappuach*, translated in the English version of the Old Testament as "apple." The rind of the citron is imported in a preserved state, and is used in confectionery. The pulp is less acid and juicy than that of the lemon. Besides the fruits already mentioned as obtained from the genus *Citrus*, we have the shaddock, from the species *C. decumana*; the forbidden fruit, from *C. Paradisi*; the pompelmoose, from *C. Pampelmos*; and the kumquat of China, from *C. japonica*.

CIVET (*Viverra*), *siv'-et*, a carnivorous quadruped, native of North Africa. Its size is about two feet six inches in length, and ten or twelve inches in height; head long; muzzle sharp, as in the weasel: a narrow bristly mane runs from the pole of the neck to the tail. Its colour is brownish grey with black bands and spots. It is a carnivorous animal, and preys on birds, small quadrupeds, and reptiles. The true civet's most remarkable feature consists of a sort of pouch between the anus and sexual organs, in which collects an odorous liquid of considerable value in the perfume-market. For the sake of this the animal is very commonly kept in confinement.

CLADIUM, *kla'-di-um*, (Gr., *clados*, a twig), a genus of plants of the natural order *Cyperaceæ*. One species only, the *C. Mariscus* is found in Britain. It attains a height of nearly 5 feet and grows freely in the fern districts where it is used for fuel and for thatching.

CLADONIA, *kla-do'-ne-a*, in Botany, a genus of lichens. *C. rangiferina* is the reindeer moss, so termed from constituting the principal food of the reindeer. *C. pyxidata* is commonly termed cup-moss; it has been employed as a remedy in hooping-cough.

CLAM, *klam*. (*See* CHAMA.)

CLAM, BEARS' PAW, a favourite shell for the cabinet, found in the South Seas and belonging to a bivalve mollusc (*hippopus maculatus*) of the family *Tridacnidæ*. It is most beautiful in form, texture, and colour, and is regarded as the best of the bivalves.

CLARY, *kla'-ry* (*Salvia sclarea*), a plant resembling the sage, and of the same genus. It is a native of the southern countries of Europe, and has been cultivated in English gardens for its aromatic properties. It is sometimes used for seasoning soups, and a fermented wine is sometimes made from its flowers. A species, the wild Clary (*Salvia Verbenaca*), is found in Britain.

CLASS, *klas* (Lat., *classis*), a group of orders in Botany possessing some important structural characters in common. (*See* BOTANY.) The word, as signifying a separate group or rank, has almost innumerable applications, scientifically and socially.

CLAVAGELLA, OR CLUB SHELL, a genus of lamellibranchiate molluscs, inhabiting holes in rocks or masses of coral, which they excavate for themselves. They belong to the same family as the Aspergillum (*q.v.*)

CLAVICLE, OR COLLAR-BONE, *klav'-e-kl* (Lat., *clavicula*, from *clavis*, a key), the bone which extends horizontally from the sternum to the scapula, and serves to keep the shoulders apart, that the arm may enjoy a freer and wider range of motion. It takes its name from its resemblance to the ancient Roman key, and it is curved somewhat in the form of an italic *f*.

CLAVICORNES, *kla-vi'-kor-nez* (Latin, club-horned), a large family of the *coleoptera*, remarkable for the club-shaped termination of their antennæ. There are many genera, nearly all of which feed upon animal substances. The burying

beetle affords a good example. (*See* BURYING BEETLE.)

CLAY, *klai* (Sax., *clæg*).—The common name for any earth which is plastic and tenacious, all this kind of earth appears to be formed from the disintegration of felspathic rocks by the combined action of the air and water. It necessarily varies in its composition, but its fundamental constituent is alumina, sometimes to the extent of 40 per cent. of the whole mass. Ordinary clay contains, in addition, small portions of undecomposed rock, potash, oxide of iron, lime, and magnesia, the character of the clay being much modified by the preponderance of one or other of the ingredients. One of the great characteristics of clay in its hydrated condition is its plasticity, and its capability of being made hard by heat—properties which render the different kinds of this substance available for various fictile purposes. The purest kind of clay is *kaolin* or *china-clay*, which is formed by the disintegration of felspathic rocks. (*See* PORCELAIN MANUFACTURE.) *Pipe-clay* is a white clay nearly free from iron, and found in large quantities in the island of Purbeck. Common *potter's clay* contains a considerable amount of iron. The blue clay of Devonshire and Dorsetshire is much valued, being very plastic, and yielding a very white paste when burnt. The coarser varieties, which contain a large proportion of sand, are used for making brown stone-ware. *Brick-clay* contains varying proportions of iron; hence different counties build houses of different colours. The clay of the midland counties contains large quantities of iron, and the bricks made from it are of a bright red hue, while London bricks are yellow or brown, from deficiency of colouring material. When the proportion of iron is very much increased, we get the different coloured ochres. *Marl* is clay containing a notable proportion of carbonate of lime. *Fuller's-earth* is a clay of a peculiar kind, which, when dried, possesses the property of absorbing grease from woollen fabrics, and is employed for that purpose. It contains a small percentage of magnesia.

CLAY SOILS. (*See* SOILS.)

CLAY IRON-STONE. (*See* IRON ORES.)

CLEAVAGE, *kleev'-aj* (Sax., *cleofan*, to split), a term applied to the property possessed by crystals of separating into natural layers. (*See* CRYSTALLOGRAPHY.) In Geology, the term implies a condition of rocks in which they split easily into thin plates. Though generally confined to clay slate, cleavage occurs in lime and sandstone.

CLEAVERS. (*See* GALIUM.)

CLEG, *kleg*, a troublesome insect of the dipterous family *Tabanidæ*, very annoying to horses, cattle, and even human beings in hot weather, piercing their skins with the sharp lancet with which the mouth is furnished and sucking blood. It is about one-third of an inch long, black in colour, and with yellow markings on the stomach.

CLEMATIS. (*See* CLEMATIDEÆ.)

CLEMATIDEÆ, *klem-a-ti'-de-e* (Gr., *klema*, a tendril), a tribe of plants in the natural order *Ranunculaceæ*. The typical genus of the tribe is *Clematis*, which includes several beautiful climbers commonly cultivated in our gardens; also one indigenous species, *C. vitalba*, usually called "traveller's joy."

CLERUS, *kle'-rus*, a beautiful beetle, found on flowers, belonging to the order *Coleoptera*, section *Pentamera*. It is about half-an-inch long, of greenish hue, with scarlet wing-cases. Its larvæ feed upon the larvæ of bees, but how this can be done in a bee-hive with impunity is still one of the secrets of nature.

CLEVELAND IRONSTONE. (*See* IRON.)

CLICK BEETLE, OR SKIP-JACK, the common name for many species of coleopterous insects of the tribe *Elaterides*, the larvæ of which are well known to farmers by the name of wire-worm. When laid on their backs, they regain their feet by a sudden spring, and give forth a "clicking" sound—hence their names. They are dull in colour and small in size; the largest is only half-an-inch long.

CLIMATE, *kli'-mat* (Gr., *klima*, a slope), also signifying certain zones on the earth's surface from their supposed inclination to the pole. Formerly, the ancient geographers divided the earth into zones or slopes (called *climates*), according to their descent from the equator to the poles, and having different temperatures in the various slopes or regions. The old "climates," therefore, served the same purpose as our parallels of latitude. In its present and most general acceptation, the word *climate* may be said to signify all those atmospheric conditions, such as heat, moisture, winds, &c., pertaining to any country or district. The principal elements that go to constitute climate are heat and moisture, the latter being dependent upon the former. The sun being the great source of heat, it follows that, as a general rule, the temperature of a place would depend upon its latitude, or distance from the equator, and that all places in the same latitude would enjoy the same kind of climate. Were the surface of the earth composed of a homogeneous fluid mass, or of strata of rock perfectly alike in colour, density, and smoothness, this would actually be the case; for all places in the same latitude would receive the solar rays at the same angle, and having the same capacity for absorbing and radiating heat, would possess exactly the same climate. This, however, is not the case. Geographers now therefore divide the earth into three zones or belts of climate—the Arctic or Frigid, the Temperate, and the Torrid (*see* ZONE), according to the distance of these surfaces from the equator, and the consequent cold, warmth, or heat which is the distinguishing feature of the zone. The other causes which modify climate are—1. Elevation above the sea-level, the air becoming gradually colder as we ascend; so that even in the torrid zone the summits of very high mountains are covered with perpetual snow. 2. The slope of a country. The power of the sun's rays in imparting heat to the earth depending upon the angle at which they strike the surface, it follows that this must have been an important influence upon its climate. Hence in the Alps of the Valais, for instance, on the one side may be seen the vine in luxuriant growth, whilst the other is thick-ribbed with ice. 3. The ocean is a very important element in determining the nature of a climate. Islands and districts near the sea uniformly enjoy a milder and more uniform climate than inland regions in the same latitude. In summer the sea is not so much heated by the sun's rays as the land; and hence cooling sea-breezes temper the warmth of that season, while in winter the cold is mitigated in consequence of the water retaining its heat longer than the land. Thus Dublin, though 4° farther north than Heidelberg, has nearly the same mean annual temperature; whilst its winters are almost 6° warmer and its summers nearly 5° cooler. 4. Mountains affect climate in various ways, by influencing the direction of currents, and by attracting and condensing the vapours in the atmosphere. 5. The nature of the soil and the state of cultivation operate materially upon climate. Different kinds of soil have different powers of radiating and absorbing heat; and a region shrouded in forests, or covered with swamps and marshes, will have a different temperature when cleared and drained. Marshes, by evaporation, deprive the surface of much of its heat; and forests, by intercepting the sun's rays, and by the increased exhalant surfaces exposed to the air, undoubtedly affect the temperature. Hence in hot climates forests tend to cool the air, and in frigid regions to prevent the loss of the earth's heat by chilling blasts. 6. The prevalence of particular winds also influences the character of a climate; as also does 7, the proximity of an oceanic current bringing water of a higher or a lower temperature than that of the surrounding sea. It will thus be seen that there are numerous circumstances that tend to modify the climate of any particular place, and that mere lines of latitude afford but an imperfect indication of the temperature. Hence geographers have had recourse to other lines, called *isothermal*, which are carried through all places having the same mean annual temperature. (*See* ISOTHERMAL LINES.) These lines diverge more and more from the parallels of latitude as they recede from the equator. In the American continent they descend much lower than in Europe; and in the southern hemisphere the mean annual temperature is much lower than in the northern, on account of its having much less land. But places having the same mean annual temperature may yet have very different climates; for places having a moderate summer and winter may yet have the same mean annual temperature as others where the summer and winter are extreme. In addition to heat, another great constituent of climate is moisture, which takes the forms of Rain, Vapour, Fog, and Dew (*see* various headings). In the torrid zone there are but two seasons, the wet and the dry. In India, the rainy and dry seasons are not regulated by the position of the sun, but by the change of the monsoons. In some districts there are two rainy and two dry seasons; and in others rain seldom or never falls. Only in the temperate zones can the year be properly said to be divided into four seasons, exhibiting the agreeable vicissitudes of heat and cold—the temperate heats of summer and the healthful rigours of winter in kindly union with the varied charms of spring and autumn. In the frigid zones only two seasons are known—a long and severe winter, followed by a short but fervid summer. This harsh and abrupt transition is occasioned by the great length of the day in summer, when for a time the sun never sets, and by the total absence of that luminary in winter. It is to the varieties in the climate of different places that we are indebted for the great variety that exists in the vegetable and animal kingdoms. Every species of plant has certain climatic boundaries, some much more extended than others, within which alone it will flourish. Animals, too, have their climatic bounds. (*See* ACCLIMATIZE.) To man alone is it given to subsist in any climate, but different climates affect him very differently—some being favourable to health, others tending to disease. The study, therefore, of the effects of different climates upon different constitutions and in different diseases, forms an important branch of medicine. Indeed, there are few diseases that may not be influenced by climate; and hence the necessity to the physician of making himself acquainted with the atmospheric conditions of different localities.

CLIMBERS, the name given to an order of birds (*Scansores*) having toes on their feet both before and behind, so that they can climb trees or similar objects with ease.

CLIMBING PERCH (*Anabas scandens*), *kli'-ming pertsh*.—This singular fish is an inhabitant of the ponds and rivers of most parts of the East Indies. Its general form resembles that of the common English perch; but it seldom attains a greater length than six inches. Its most remarkable characteristic is the structure of the superior pharyngeal bones in which are numerous cells, where a supply of water may be carried for the purpose of moistening the gills when the creature, as its habit is, quits the water for a time. This occurs at times when the pool is in danger of drying up, when the perch travels in search of water. It has been asserted, by explorers whose veracity is beyond question, that this singular fish has been seen *to climb trees* which it does by suspending itself by its spiny gill-covers and fixing its anal fin in cavities of the bark, and urging its way upwards by distending and contracting its body. Its migrations are usually performed at night, or in early morning, whilst the grass is yet wet with dew. Climbing perches are plentiful in the Ganges, and they have been kept in a perfectly lively and healthy condition for five or six days in an earthen pot without water.

CLIMBING PLANTS, plants which have weak stems, and consequently fasten themselves to or twine around other objects in order to raise themselves from the ground. Some, like the well-known Virginia Creeper, attain this object by means of little adhering discs which they put forth; others, like the ivy, shoot out little rootlets from their stems; others again twine their own stems around those objects up which they climb (these are often known by the Latin name *Lianas*), and others put forth *cirri* or tendrils.

CLINKSTONE, OR PHONOLITE, *fo'-no-lite*, a compact greyish green felspathic rock occurring in volcanic districts and remarkable for its liability to laminate, *i.e.*, to split into plates like slates, in consequence of which it is often used for roofing houses.

CLIO, *kli'-o*, a genus of shell-less molluscs, one species of which, *Clio Borealis*, is so extremely abundant in the Arctic seas, that it constitutes a chief part of the food of whales. *Whales' food* is the name by which they are known to the fishermen. Sometimes the water is so full of them that it would be impossible for the whale to open his jaws without engulfing thousands.

CLOACA *klo-a'-ka*, an enlargement of the lower intestine near its termination in birds, reptiles, most fishes, and one order of mammals (the *Monotremata*), answering the purpose of the bladder in other animals.

CLOTHES-MOTH, *kloathz'-moth* (Anglo-

Saxon), a name common to a number of small moths of the genus *Tinea*, whose larvæ are extremely destructive to woollen fabrics, &c. They begin not only to eat as soon as they are hatched, but to hack to bits the substance in which they are hidden, and, uniting the fragments with a glutinous silk of their own production, make cases to live in. Cleanliness and exposure to light are safeguards against these tiresome insects, and spirit of turpentine may be used for killing them.

CLOTHO, *klo'-thō*, a species of spider, *C. quinquemaculata*, about half-an-inch long, found in the south of Europe and north of Africa, and chiefly remarkable for the fact that it spins a tent for itself, shaped like a limpet shell, and about an inch in diameter, in which it deposits its eggs and brings up its young.

CLOUD, *klowd* (Lat., *claudo*, I shut), a condensed mass of watery vapour that floats in the atmosphere or rests on the surface of the earth. In the latter case, the vapour is called fog or mist; and it is only when it rises above us that it is termed a cloud. The height to which clouds rise above the surface of the earth varies with a number of circumstances; such as the temperature of the air, its humidity, the climate and seasons, and the neighbourhood of the sea or mountains. Heavy rain-clouds are frequently about 200 or 300 yards in height; while light fleecy masses of vapour rise to the height of four or five miles. The following is a brief outline of the theory of the formation of clouds. Vapour rising from the moist surface of the earth, or from water warmed by the heat of the sun's rays, is held in suspension in the atmosphere, and remains invisible until the air at some distance above the earth's surface is completely saturated with it; but if the evaporation from below still continues, the atmosphere becomes overcharged with moisture, and the vapour condenses and appears in a visible form. Clouds are primarily defined as *cirrus* (cloud curl), *cumulus* (day or summer cloud), and *stratus* (night cloud). The term cirrus is applied to long streaky white clouds spreading in all directions; they are commonly called mares' tails, and are the forerunners of windy weather; cumulus, to clouds consisting of thick white masses of vapour, ragged and broad at the base, ascending in the form of mountain-peaks; this form of cloud is commonly seen by day. The name stratus is given to a dense horizontal mass of cloud rising above the horizon, and commonly resting on the surface of the land. The mists that rise from valleys, marshes, and water, in the evening, belong to this class of clouds, which are considered as the precursors of fine weather. There are compound modifications of these classes of clouds, composed of the primary modifications variously blended together; they are termed *cirro-cumulus*, *cirro-stratus*, *cumulo-stratus* and *cumulo-cirro-stratus*, or *nimbus*. The nimbus is the dark heavy rain-cloud.

CLOUD BERRY (*Rubus Chamæmorus*), a plant about 10 inches in height having a single stem, free from prickles, few leaves, and a large white flower. It is rarely found in Britain, and then only on high moors. It is more abundant in Sweden and Norway, and the fruit, which somewhat resembles the blackberry or bramble-berry, is highly valued.

CLOVE BARK.—The bark of the tree *Myrtus caryophyllata*, a native of Ceylon and the Marcarene Isles. It is thin and hard, of a deep brown colour, has a taste like cloves, and properties resembling those of cinnamon. CULILAWAN BARK (*q.v.*) is also known as Clove Bark.

CLOVER, *klo'-ver*, a name commonly extended to many plants belonging to the same natural order (*Leguminosæ*), having the leaves formed of three leaflets. The true clover, or trefoil (*Trifolium*), includes a large number of species, chiefly natives of temperate climates, and very abundant in Europe. Many of the species afford important food for cattle. About 17 species are indigenous to Britain. The common red clover (*T. pratense*) is most generally cultivated in this country. The zigzag, or meadow clover, and the white Dutch clover, are also extensively grown. The clovers were not cultivated in Britain till the latter part of the last century; but are now generally grown as alternations with wheat crops. The leaflets of the common clover are almost always marked with a whitish patch in the shape of a horse shoe, and from that cause, perhaps, were in conformity with old superstitious beliefs considered as a charm against witchcraft.

CLOVER-WEEVIL (*Apion*), *weev'-il*, a small coleopterous insect which feeds on the leaves and seeds of clover. The red clover weevil (*A. apricum*) lays its eggs among the flowers, and the grubs eat their way through the calyx into the pod. It is of a bluish-black colour, and about the tenth of an inch long.

CLOVES. (*See* CARYOPHYLLUS.)

CLUB FOOT, *Talipes*, a distortion of the foot, occasioned by the greater contractions of some muscles than others, by which means the foot is drawn out of its natural position, it may be inwards or outwards, with the elevation of the heel and depression of the toes, or the depression of the heel and elevation of the toes and fore part of the foot. Such deformities are usually congenital; but sometimes they may arise from some disordered state of the system, or be occasioned by convulsions. This deformity may now, in almost every case, be cured by a careful subcutaneous division of the contracted tendons.

CLUB-MOSS. (*See* LYCOPODIUM.)

CLUBBING, a diseased growth of tubercular excrescences in the root and stem of cabbages, turnips, and similar vegetables, caused by the larvæ of the cabbage fly.

CLUPEIDÆ, *klu-pe'-e-de* (Lat., *clupea*, a shad), a family of fishes, allied to the *Salmonidæ*, but differing from them because wanting an adipose fin. The herring may be regarded as the type of this family, to which belong also the pilchard, sprat, anchovy, and sardine. They generally congregate in shoals, and periodically visit certain coasts; and are very widely diffused all over the world.

CLUPESOCIDÆ, *klu-pe-sos'-i-de*, a family of malacopterous fishes, which are regarded as intermediate between the *clupeidæ* and the *Esocidæ* (pike, &c.). Some are marine and some fresh water, and they are mostly found in tropical climates, none being British.

CLUSIA, *klu'-se-a* (in honour of Charles de l'Ecluse, a French botanist), a genus of trees belonging to the natural order *Guttiferæ*. The balsam-tree of Jamaica is *C. flava;* and this, with the species *C. alba* and *rosea*, yield a glutinous resinous matter, used in some parts of the West Indies in place of pitch. In Nevis and St. Kitt's the three species are known indiscriminately by the names of fat pork, monkey-apple, and mountain or wild mango. The *C. insignis* is the wax-flower of Demerara.

CLYSTER, *klis'-ter* (Gr., *kluzo*, I wash out), is a name given to certain medicines administered in a liquid form, by means of an injecting syringe, by the rectum, for the purpose of procuring evacuation of the bowels, or otherwise affecting the intestines or the system generally. In cases of lock-jaw, &c., when nutriment cannot be conveyed by the throat, it is sometimes administered in this way.

CLYTUS, *kli'-tus*, a genus of coleopterous insects, abounding in species. A few are found in this country; but North America is their chief abiding-place. There one of the largest of the genus, *Clytus speciosus*, is a great destroyer of the sugar-maple. It is about an inch long, and its colour black, banded and spotted with yellow.

COAL, *kole* (Sax., *col* or *coll*), a mineral consisting chiefly of carbon, and of vegetable origin. Sir Charles Lyell, who paid great attention to the phenomena of the production of coal, thus states his views:—"It appears from the researches of Liebig and other eminent chemists, that when wood and vegetable matter are buried in the earth exposed to moisture, and partially or entirely excluded from the air, they decompose slowly and evolve carbonic acid gas; thus parting with a portion of their original oxygen. By this means they become gradually converted into lignite, or wood coal, which contains a larger portion of hydrogen than wood does. A continuation of decomposition changes this lignite into common or bituminous coal, chiefly by the discharge of carburretted hydrogen, or the gas with which we illuminate our streets and houses." According to Bischoff, the inflammable gasses which are always escaping from mineral coal, and are so often the cause of fatal accidents in mines, always contain carbonic acid, carburetted hydrogen, nitrogen, and olefiant gas. The disengagement of all these rapidly transforms ordinary or bituminous coal into anthracite.

Varieties of Coal.—Mineralogists commonly divide coal into the *non-bituminous* and the *bituminous*. The non-bituminous variety includes anthracite (*see* ANTHRACITE). Anthracites differ much in hardness and readiness of combustion. *Fossil coke* is an American variety, more compact than artificial coke, some kinds containing considerable bitumen; its origin is attributed by Genth to the action of a trap eruption on bituminous coal. *Culm* is a kind of anthracite shale: in parliamentary returns the term is made use of to designate anthracite. Of *bituminous* coal there are several varieties. *Pitch*, or *caking coal*, when heated, breaks into small pieces, which, on the heat being raised, unite in a solid mass: its colour is velvet-black, or greyish black; specific gravity, 1·269: it burns readily with a yellow flame; but requires frequent stirring to prevent its caking, by which the ingress of air for combustion is prevented. Caking coal containing about 87 per cent. of carbon is the most valuable of all coals, and is the most abundant product of the British coal-measures. *Cherry coal* resembles caking coal, but does not soften and cake when heated: it is very frangible; and hence, in mining it, there is considerable waste. Near Birmingham, the loss in mining, including the pillars, amounts to two-thirds of the whole. It burns more rapidly than caking coal, with a clear yellow flame. *Splint* coal is a dry coal, harder than cherry coal: it is a coarse kind of cannel coal. There are other varieties which are still less bituminous; the *flint* coal, which approaches anthracite, being of this kind. The *flew* coal of Wednesbury, in Staffordshire, is of a similar nature; and the *crow* coal of Cumberland, at Alston Moor, is almost without bitumen. (*See* CANNEL COAL, JET, and LIGNITE.)

Coalfields.—Extensive beds of mineral coal occur in Great Britain, in France, in Spain, in Belgium, covering nearly one-twentieth of the whole area;—in the Netherlands, Prussia, Austria, Northern Italy, Spain, Russia on the south, near the Azof. It is found in Asia, abundantly in China, in Persia, in the Cabul territory, and in Khorassan, or Northern Persia; in various parts of India and Upper Assam; in Borneo, Labuan, Sumatra, several of the Philippine islands, Formosa, Japan, New South Wales, and New Zealand. In America, besides the United States, in Chili, at the Straits of Magellan, on Vancouver's Island, as well as in the British provinces of Nova Scotia, New Brunswick, and Newfoundland. In England the principal coal-fields are the Manchester, the Lancashire and Cheshire; the Great Central, of South Yorkshire, Nottingham, and Derby; that of South Wales, Glamorganshire, &c., and the Newcastle field, of Northern England. In Scotland a range of beds extends from the Firth of Forth to the Firth of Clyde. The coal-fields of Great Britain are estimated to occupy an area of 5,400 square miles; and at present about 25,000,000 of tons are consumed annually in this country. In Ireland there are the Limerick fields, about the mouth of the Shannon, the Kilkenny fields to the eastward, and those of Ulster in the north. In the United States there are four extensive coal areas: one of these areas, the Appalachian coal-field, commences on the north in Pennsylvania and South-eastern Ohio, and sweeping south over Western Virginia and Eastern Kentucky, and Tennessee, it continues to Alabama. A second coal area (the Illinois) lies adjoining the Mississippi, and covers the greater part of Illinois, the western portion of Indiana, and a small north-west portion of Kentucky. A third occupies a portion of Missouri and Iowa, west of the Mississippi. A fourth covers the central portion of Michigan. Besides these, there is a smaller coal region in Rhode Island, which crops out across the north end of the island, and appears to the northward as far as Mansfield, Massachusetts. Beyond the borders of the United States on the north-east commences the coal area of Nova Scotia, New Brunswick, and Newfoundland. It has been estimated by the highest authorities that there are probably 146 billions of tons of available coal in the world.

Coal Formation. (*See* CARBONIFEROUS SYSTEM.)

COAL-FISH (*Merlangus carbonarius*), a somewhat common fish, extensively distributed through the principal seas of Europe, being abundant in the Baltic, the Mediterranean, and the Northern seas; also found in large quantities on the coast of Great Britain. It belongs to the same family (*Gadidæ*) as the cod and haddock. It is not unlike the whiting in form, but is much larger, being in many instances nearly three feet in length. It owes its singular appellation to the curious nature of its skin, which, upon being handled, soils the fingers in the same way as would result from touching coal. It is likewise known, during its progress from birth to maturity, by the names of *cuddy*, *sythe*, and *sillock*. The fishermen of Yorkshire, however, have given it two more aliases: when young, they call it *parr*, and the old fish are named *lillets*.

COATI, *ko'-a-ti*, a genus of quadrupeds (*Nasua*) of the family *Ursidæ*, or bear. They are nearly allied to the racoon, and are exclusively American. The snout is elongated and flexible, and is employed in turning up the earth to obtain worms and insects. In South America, the coati, or *coati-mondi*, as it is sometimes named, is often domesticated.

COBALT, *ko'-bawlt* (Germ., *kobold*, from *kobolden*, the name of certain mischievous demons who were supposed to haunt mines, and to manufacture those ores which looked rich to the eye, but were really of little value. Among these were supposed to be the ores of this metal, and hence its name.) Cobalt is a metal very similar to nickel in its physical and chemical properties. It generally occurs in the same ore as nickel, and the separation of the two metals is a task requiring great patience and expertness. Cobalt is obtained as a metal either by reducing the oxide by hydrogen, or by calcining the oxalate. In the metallic state, it closely resembles steel. It fuses with great difficulty, and oxidizes at a high temperature. It remains unaltered in moist air, dissolves slowly in sulphuric and hydrochloric acid, but readily in nitric acid. It is reddish-grey in colour, and is highly magnetic. It is obtained principally from two ores—*Speiss cobalt* and *cobalt glance*.

Compounds of Cobalt.—The compounds of cobalt are remarkable for their beauty of colour. The two colours *zaffre* and *smalt* are compounds of cobalt. Zaffre is an impure oxide of this metal, made by calcining the crushed ore in a reverberatory furnace. The sulphur and arsenic are thus roasted off, and the impure oxide remaining is ground to an impalpable powder with two or three parts of fine sand. Zaffre is used largely in the manufacture of stained glass and in the ornamentation of pottery. *Smalt* is a finely-powdered blue glass coloured with cobalt. Cobalt ore is partially roasted, and combined with an equal quantity of carbonate of potash and twice its weight of well-ground quartz. The whole is melted in suitable pots in a furnace, silicate of potash being formed, in which the oxide of cobalt melts, the other impurities falling to the bottom. The clear blue glass is ladled out, poured into water, and ground, when cool, into an impalpable powder. Smalt is used by paper-makers as a blue pigment for staining paper; and it is also used in the production of the beautiful blue colour in porcelain, glass, encaustic tiles, and other artistic productions. With oxygen, cobalt forms a protoxide and a sesquioxide. The *anhydrous protoxide* is obtained by calcining the hydrate or carbonate. It is a black powder, which, when heated in the air, changes into an intermediate oxide. Oxide of cobalt gives to glass a very intense blue, which resists the action of a very high temperature. Dissolved in ammonia, it gives a fine red liquid. Fused with potash, a brilliant blue compound is obtained. With magnesia, alumina, and oxide of zinc, it produces, when fused at a high temperature, pink, blue, and green compounds. The last two are used as pigments. The hydrated oxide is a pink precipitate thrown down by adding a solution of potash to the solution of a cobalt salt. Protoxide of cobalt forms salts with the acids, which are light blue when hydrated, but turn red when the water is driven off by heat. Protonitrate of cobalt is obtained by dissolving the oxide or the metal in nitric acid. It crystallizes in small deliquescent crystals containing six equivalents of water. A solution of this salt is often employed as a sympathetic ink, being light blue when cold, but bright red when the water of hydration is driven off by a gentle heat. The *sulphate of cobalt* is generally employed as the source of salts of this metal. The *sesquioxide of cobalt* is a brownish powder obtained by passing chlorine through a dilute solution of potash, in which the protoxide is mechanically suspended. Its salts are at present unknown. *Chloride of cobalt* is prepared by dissolving the oxide in hydrochloric acid: the pink resulting yields, on evaporation, rose-coloured octahedra of the hydrated chloride. The other salts of cobalt are uninteresting. A solution of the nitrate is used in blowpipe analysis. *Thénard's blue* is a beautiful pale-blue pigment, consisting of a mixture of phosphate of cobalt and phosphate of alumina.

Cobalt Ores.—The principal ores of cobalt are, *white cobalt ore*, which is the most common (it contains cobalt associated with arsenic, iron, and sulphur); *grey cobalt ore*, containing arsenic, iron, cobalt, and silica; and *glance cobalt*, which is a double bisulphide of arsenic and cobalt. All the ores of cobalt contain more or less nickel.

Cobalticyanogen. (*See* CYANOGEN.)

Cobaltine, *ko-bawlt'-een*, an arsenical ore of cobalt, also containing sulphur. It occurs in reddish silver-white trapezohedral crystals, at the mines of Wehna, in Sweden. It contains from 33 to 37 per cent. of metal.

COB-NUT. (*See* HAZEL-NUT and HOT-NUT.)

COBRA DI CAPELLO. (*See* HOODED SNAKE.)

COCA. (*See* ERYTHROXYLON.)

COCCO, *kok'-ko*. (*See* EDDOES.)

COCCOLOBA, *kok-ko-lo'-ba* (Gr., *kokkos*, a berry; *lobos*, a lobe), a genus of plants belonging to the natural order, *Polygonaceæ*. From the leaves, wood, and bark of *C. uvifera*, a very astringent extract, commonly known as Jamaica kino, is obtained. The fruit, called the seaside grape, has an agreeable acid flavour.

COCCOSTEUS, *kok-kos'-te-us* (Gr., *kokkos*, berry; *osteon*, bone), a fossil fish peculiar to the Devonian measures, so named from the small berry-like tubercles with which the plates of its cranial buckler and body are thickly studded. The remains found in the Caithness flagstones show that its length was from a few inches to about two feet, and it was nearly related to Cephalaspis. (*See* CEPHALASPIS.)

COCCULUS INDICUS, *kok'-u-lus in'-di-kus* (Latin, Indian berry), the fruit of the *Anamirta paniculata* (which *see*). It has some resemblance to the bay-berry, and is imported into this country from the Eastern archipelago. Cocculus indicus is chiefly used for adulterating cheap beer. Its use has been forbidden by Act of Parliament under a penalty of £200 to the brewer, and one of £500 to the druggist who sells it to a brewer. In large dozes it is poisonous to all animals, and it has long been used by poachers for stupefying fish and game. In medicine it has been employed as an external remedy for certain skin diseases. It owes its active properties to a very poisonous crystalline alkaloid called *picrotoxine*. The names *Levant nut* and *Bacca orientalis* are sometimes applied to this narcotic berry.

COCCUS, *kok'-kus*, a genus of insects of the order *Hemiptera*, the type of a family allied to the aphis. They are sometimes known as scale insects. The destructive coffee-bug belong to this family. The males have two wings, but the females are wingless. The females of some of the species yield valuable and beautiful dyes.

COCHLEARIA, *kok-le-air'-e-a* (Lat., *cochleare*, a spoon), a genus of plants, so named from the leaves being spoon-shaped, belonging to the natural order *Cruciferæ*. The species *C. officinalis* is the common scurvy-grass, an indigenous annual found in muddy places near the sea-shore. It has white flowers, which blossom in April and May. When rubbed, it evolves a pungent odour, and its taste is acrid and penetrating. It is esteemed for its antiscorbutic properties.

COCK, DOMESTIC, *kok* (Sax., *coc*; Fr., *coq*) (*Gallus domesticus*). At what period of the world's history this valuable bird was brought under the control of man, it is almost impossible to determine. Without doubt, they were well known over many parts of Europe and Asia many hundred years before the Christian era. Our domestic cock is supposed to be derived from the Jago cocks (*Gallus giganteus*), a large and wild species inhabiting the island of Sumatra, and from the species *Bankiva*, another primitive bird found in the Javan forests. The domestic cock has his head surmounted by a notched crimson fleshy substance, called a comb; and under the throat hang two other pendulous fleshy bodies, called wattles. In both sexes there is below the ear an oblong spot, the interior of which is reddish and the remainder white. The feathers arise in pairs from each sheath, touching by their points within the skin, but diverging in their course outwards. On the neck the feathers are long and narrow; on the rump they are of the same form, but droop laterally over the extremity of the wings, which are quite short, and terminate at the origin of the tail, the plumes of which are vertical. In the centre of the cock's tail are two long feathers, which fall back in a graceful arch. When the cock reaches the age of six months, he attains maturity, and his powers remain undiminished till he is three years old. Then, if younger male birds be about, he will find himself slighted by his numerous wives, and be compelled to yield to a rival the empire of the yard. The domestic cock is one of the most combative, jealous, and arrogant, as well as the handsomest of birds.

COCKATOO, *kok-a-too'*, a genus of birds of the parrot family, but with greater height and different curve of the bill, and a lengthened and broad tail. Cockatoos (*Plyctolophia*) are confined to the Eastern Archipelago and Australia; in the latter country they are very abundant. Like others of their congeners, they make their nests in decayed trees; indeed, if the tree should not be very much decayed, it makes little difference to the cockatoo, who can speedily dig for himself a hole in the trunk with his iron-like bill. They are easily tamed, and learn to imitate the human voice in some respects, although with little accuracy. The name cockatoo is taken from the peculiar cry of the bird. Of this there are several species:—*Broad*, or *Rose-crested Cockatoo* (*Psittacus cristatus*).—This is the largest of the cockatoos, being about two feet in length. It is distinguished from the other species, not only by its size, but also by its crest, which is arched over the head, and of a bright orange-red colour beneath. The general colour of this bird is white, with a pink tinge. It is sometimes domesticated. *Great Sulphur-crested Cockatoo* (*Psittacus galeritus*).—This species is at the same time the handsomest and most common of the family. Its plumage is white, tinged with yellow on the tail and orange or lemon-colour on its crest, which is pointed, and about seven or eight inches in length. In Australia, these birds abound in large flocks of thousands in number. They commit frightful havoc in the corn-fields, and the sight of this handsome bird is sufficient to create the utmost dismay in the mind of the agriculturist, who knows too well the affinity betwixt ripe corn and the lemon-crested cockatoo. *Lesser Sulphur-crested Cockatoo* (*Psittacus sulphureus*). — Greatly resembling the preceding, only some few inches smaller. It is a native of the Moluccas; but of its habits little or nothing is known. It is very pretty, affectionate, and good-tempered, a rare combination of excellent qualities. Another species, very rare, is about fifteen inches in length, of a white colour, tinged with pink.

COCKCHAFER, *kok'-chai-fer* (Ang.-Sax.), (*Melolontha vulgaris*), a well-known species of beetle, belonging to the *Lamellicornia*. It is very common throughout the greater part of Europe, and in this country is particularly abundant. In its larva state it lives for nearly four years, and feeds, very voraciously, on corn, &c. The perfect insect has an exceedingly short existence, sometimes living only a week, and occasionally so long as a month, after arriving at maturity. At this stage it feeds on the leaves of various trees; and, at certain times, commits frightful ravages in agricultural districts. It is about an inch in length, of a black colour, with a whitish down, and the sides of the abdomen are marked by triangular spots.

COCKER, a small spaniel, very similar to the Blenheim. It is used in pheasant and woodcock shooting.

COCK OF THE PLAINS (*Tetrao*, or *Centrocercus urophasianus*), the largest of the North American species of grouse, but smaller than the capercailzie of Europe. (*See* CAPERCAILZIE.) It is a very handsome bird.

COCKLE, *kok'-l* (*Cardium*), a genus of Mollusca, belonging to the *Cardiaceæ*. There are numerous species of this animal, some two hundred of which are known. The structure of the cockle is somewhat curious; it has two adductor muscles, which serve the animal to draw the valves of the shell together. Its foot is very large, compared with the size of the animal, and bent in the middle. This member is not only used for the purpose of progression, but also for excavating holes in the mud and sand in which it lives. By suddenly straightening the foot, the cockle moves with a jump. As the foot is smaller than the shell, it may appear a little singular how it is enabled to bore a hole sufficiently large to admit the whole animal. This is accomplished by distending the foot with water, and then, by a rotary motion, the seemingly impossible feat is easily achieved.

COCKROACH (*Blatta*), a genus of orthopterous insects, very commonly, but incorrectly, called the black beetle. (*See* BLACK BEETLE and BLATTIDÆ.) The American cockroach, the kakerlac, has made its way into Europe. A small species of the insect (*B. Lapponica*), is very common and destructive in Lapland.

COCKSCOMB, *koks'-kome*, an annual plant (*Celosia cristata*) of the natural order *Amarantaceæ*. It is a native of the East Indies, but is cultivated in this country in conservatories and warm borders. It presents a mass of beautiful flowers, forming a kind of crest, and generally of very brilliant hues.

COCK'S-FOOT GRASS, a genus of grasses, having the panicle of flowers much on side of the stem, common in all the northern continents, and very abundant in Britain, and much liked by cattle. In America it is known as orchard grass.

COCOA, OR CACAO. (*See* THEOBROMA.)

COCOA, OR COCOA-NUT. (*See* COCOS.)

COCOA-NUT BEETLE, a large beetle (*Batocera rubus*) of the family *Longicornes*. They are repulsive in appearance, but are eaten with relish by the coolies of the East. The larvæ are very destructive in cocoa-nut plantations.

COCOON, *kok-oon'* (Fr., *cocon*), the silky tissue or envelope which the larvæ of many insects spin, as a covering for themselves immediately before passing into the pupa form. The name is also given to coverings made of other materials. Some caterpillars work into the silky envelope the hairs which cover their bodies; other imbed in the network a leaf, or several leaves fastened together. The larvæ of some insects produce the silken substance of which the cocoons are formed in much greater quantity than others. One of the most useful producers is the ordinary silkworm, whose cocoon is a close and compact oval ball, surrounded with a gauze-like glossy covering. It consists of one long continuous thread, sometimes a thousand feet long. Some parts of the thread are weaker than others; but the greater portion can be unwound as easily as a ball of cotton thread. Different insects vary in the time occupied in spinning their cocoons: several days are spent by the silkworm in this task. In covering the pupa, many insects proceed with an almost mathematical nicety with regard to the direction and disposition of their threads.

COCOS, *ko'-kos* (Gr., *kokos*, a kernal), a genus of Palms *C. nucifera*, the cocoa or cocoa-nut palm, is perhaps the most useful member of the great family.

COD, *kod* (Ang.-Sax.), a fish of the family *Gadidæ*, and scientifically known as *Gadus Morrhua*, or *Morrhua vulgaris*. It sometimes attains a length of nearly three feet, and specimens weighing a hundred pounds have been caught. It is a very favourite article of food, and, salted, is in great demand during the season of Lent. The reproductive power of the fish is extraordinary. The roe of the female generally contains five or six millions of eggs. For more than four centuries has the cod-fishery been carried on without any interruption; yet the supply at the present day is something enormous. A single fisherman has been known to capture 500 of this fish in a day of ten hours. The fishing is carried on by means of lines and hooks. Our great supply of cod is from the banks of Newfoundland; but the cod-fisheries off our own eastern coast, and near the coasts of Scotland, Sweden, and Iceland, are by no means insignificant. The cod fisheries of the United States are chiefly carried on from Massachusetts and Maine.

CODARIUM, *ko-da'-re-um* (Gr., *kodarion*, a leathern pouch), a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Cæsalpinieæ*. *C. acutifolium*, and *obtusifolium*, both natives of Sierra Leone, yield fruits known as the brown and the velvet tamarinds.

CODLIN, *kod'-lin*, a name given to many varieties of apples best adapted for culinary purposes.

Codlin Moth, a small moth (*Pyralis pomona*), very injurious to the apple, in which it deposits its eggs.

CO-EFFICIENT, *ko-ef-fish'-ent*, in Algebra, the known or constant factor of an unknown quantity.

CŒLENTERATA, *se-len-ter-ai'-ta* (Gr., *koilos*, hollow, *teras*, an anomaly), one of the two sub-kingdoms into which the *Radiata* of Cuvier have recently been divided. It corresponds to the class *Polypi* of former writers, and includes most of those curious stationary creatures which are introduced into marine aquaria; as the sea-anemones and sertularia.

CŒLOCLINE, *se'-lo-kline*, a genus of plants belonging to the natural order *Anonaceæ*. The species *C. polycarpa* is the herberine, or yellow-dye tree of Soudan. When reduced to a coarse powder, the bark is a remedy in the treatment of ulcers.

COFFEE, *kof'-fe* the product of one species of a genus of plants belonging to the natural order *Cinchonaceæ*. The species *C. erabica* is the coffee plant, the seeds of which, when roasted and ground, are used to prepare the daily and most cherished drink of probably more than a hundred millions of human beings. The plant is a native of Arabia Felix and Southern Abyssinia. From the former region it has been carried to various countries within the tropics, and, at the present time, it is cultivated wherever the climate is suitable. In some countries it seldom attains a greater height than eight or ten feet; but in others, its average height, when full grown, is from fifteen to twenty feet. It is covered with dark, smooth, shining, and evergreen foliage. It is raised from the seed in nurseries, and is transplanted when about six months old. In three years it comes into full bearing, and, under favourable circumstances, will continue to bear for twenty years. It blossoms throughout the year, so that mature fruit and opening flower-buds may be seen at the same time. The roasted seed or bean has been used to form a beverage in Abyssinia from time immemorial. In Persia it is known to have been in use as early as the year 875. From Abyssinia it was introduced into Arabia in the beginning of the 15th century, and about the middle of the following century it began to be used in Constantinople, where it soon became an article of general consumption. Nearly 80,000 tons are annually imported into Great Britain. The Arabian, or Mocha coffee, is small, and of a dark yellow colour; the Javan and East-Indian are larger and of a paler yellow; the Ceylon, West-Indian, and Brazilian have a bluish or greenish-grey tint. Coffee owes its valuable properties chiefly to the presence of an alkaloid called *caffeine*, and a volatile oil. It is remarkable that tea should contain precisely the same principle, *theine* and *caffeine* being identical. The sensible properties and effects of coffee, like those of tea, are too well known to require to be stated in detail. It exhilarates, arouses, and keeps awake; it counteracts the stupor occasioned by disease, by fatigue, or by opium; it allays hunger to a certain extent; gives to the weary increased strength and vigour, and imparts a feeling of comfort and repose. Its physiological effects upon the system, so far as they have been investigated, appear to be, that, while it makes the brain more active, it soothes the body generally, makes the change and waste of matter slower, and the demand for food in consequence less. In Sumatra and some of the neighbouring islands an infusion of the roasted leaf is used as a substitute for tea, and is called coffee-tea. The leaf contains the same principles as the seed, and therefore has analogous properties. Besides the real *C. arabica*, some other species are cultivated for their seeds; as *C. Benghalensis*, grown in Nepaul; *C. Mozambicana*, on the coast of Mozambique; and *C. mauritiana*, in the Mauritius.

Coffee Bug, an insect (*Lecanicum Coffeæ*) of the Coccus family, which is extremely destructive in coffee plantations.

COINCIDENCE, *ko-in'-si-dens*, in Geometry, the similarity in size and shape of two separate figures.

COIR. (*See* COCOA-NUT FIBRE.)

COLCHICUM, *kol'-tshe-kmu* (after *Colchis*, its native country), a genus of plants belonging to the natural order *Melanthaceæ*. The most important species is *C. autumnale*, the common meadow-saffron. It blossoms during the months of August and September, its flowers being crocus-like, and of a purple colour. This plant offers a strange contrast to most others in the mode of producing flowers and fruit. The flowers appear during the autumnal months named, rising from the ground without any leaves; and, when they fade, nothing further is seen of the plant until the following spring, when tufts of leaves make their appearance, inclosing the seed-vessel or capsule, which ripens about hay-harvest. Both the seeds and corms of this plant are employed medicinally in gout and rheumatism.

COLD. (*See* CATARRH, HEAT, TEMPERATURE.)

COLEOPTERA, *kol-e-op'-ter-a* (Gr., *koleos*, a sheath; *pteron*, a wing), the name applied to an order of insects possessed of four wings, the external pair not being formed for flight, but as sheaths for the interior pair. The coleoptera comprehend all the Beetle tribe. The larvæ of coleopterous insects undergo a complete transformation; those which burrow in the ground generally prepare for the pupa state by removing the earth that surrounds them, so as to form an open oval space; others form a kind of cocoon or web round them; and some assume the perfect state without any sort of preparation. Although some of these insects may be injurious to vegetation, taken as a whole, there can be no doubt that their existence is conducive to man's comfort, and in some cases to a much greater extent than he suspects. Thus, the tiger-beetles (*Cicindelidæ*), the predacious ground-beetles (*Carabidæ*), the diving-beetles (*Dytiscidæ*), the lady-birds (*Coccinellidæ*), and many others, do mankind great service by preying upon caterpillars, plant-lice, &c., while the many dung-beetles (*Copridide*, *Histeridæ*, *Geotrupidæ*, &c.) do good work as removers of carrion and as scavengers generally. Others there are which subsist on the various poisonous fungi; and others, again, which attack dead but still standing trees. There are many thousand species; and many of those in tropical regions are remarkable for their splendid metallic tints.

COLEWORT, *kole'-wurt*, a name given to some of the many cultivated varieties of *Brassica*, generally to those which, unlike cabbages, have open heads of leaves.

COLIBRI. (*See* HUMMING BIRD.)

COLIC, *kol'-ik* (Gr., *kolon*, the colon), a name given to several diseases which are characterized by severe pain of the bowels, with distension or flatulence, but without looseness or diarrhœa. Medical men distinguish no fewer than seven different kinds of this complaint. Among the most frequent causes of this disease may be named poisonous or unwholesome substances, long-undigested food, redundancy of vitiated bile, intense cold, worms, &c.

COLLAPSE, *kol-lapse'* (Lat., *collapsus*, from *collabor*, I shrink down), is a wasting or shrinking of the body, or of a part of it, or a sudden and extreme depression of its strength and energies.

COLLYRIUM, *kol-lir'-i-um* (Gr., *kollurion*), a term formerly applied to any medicament employed to restrain defluxions; but it is now confined to topical remedies for disorders of the eyes;—an eye-salve, or eye-wash.

COLOCASIA, *kol-o-kai'-se-a*, a genus of plants belonging to the natural order *Araceæ*. The species *C. esculenta* and others have large fleshy corms, which are much used as food in Madeira and the West Indies, where they are known as *cocoes*, *eddoes*, or *yams*. (*See* DIOSCOREA for the true yams.) *C. himalensis* has also edible corms, which are used as food in the Himalayas.

COLOCYNTH, *kol'-o-sinth* (Gr., *kolokunthis*), the bitter cucumber or bitter apple, a well-known drastic hydragogue cathartic. It is the fruit of the *Citrullus colocynthus*, a plant belonging to the natural order, *Cucurbitaceæ*, and supposed to be the "wild vine" of the Old Testament. Two kinds of colocynth are known in commerce; namely, *Turkey*, or *peeled colocynth*, which is imported from the Levant, the north of Africa, and Spain, and *Mogadore*, or *unpeeled colocynth*, which comes from Mogadore. The former is the best, and is generally employed in medicine; the latter being principally used by chemists for their show-bottles. The seeds possess the purgative property to a slight extent; but the pulp is by far the most active part of the fruit. In large doses, colocynth is an irritant poison. It owes its properties to a peculiar bitter principle, which has been named *colocynthin*; and it is generally administered in the form of pills, and associated with aloes, scammony, and sometimes calomel.

COLOGNE EARTH, *ko-lone'*, an earthy mass of lignite, occurring in a large irregular bed forty or fifty feet thick, near Cologne and is composed of wood partially fossilized. When livigated, it forms a pigment of a brown colour.

Cologne Yellow, a pigment composed of yellow chromate of lead, and sulphate of lead and gypsum.

COLON, *kol'-lon* (Gr., *kolon*, a member or limb), is the largest of the intestines, or, rather, the largest division of the intestinal canal. This canal is divided into the small and great intestines. The colon is divided into four parts—the ascending, transverse, descending, and the sigmoid flexure. The colon, in man, averages from 4 to 5 feet in length, and about 2 inches in diameter, being about a fourth part as long, and twice as wide, as the small intestine. The canal is not smooth and uniform, as in the small intestines, but bulges out between the bands of muscular fibre into various prominences, more or less regular in their form, in which the fæces lodge for a time, and become deprived of much of their moisture as they are rolled onwards by the peristaltic action. The colon is enveloped in the serous membrane called the peritoneum, which forms the external covering of all the abdominal viscera. (*See* INTESTINES.)

COLQOUINTIDA. (*See* COLOCYNTH.)

COLORADO BEETLE, *kol-o-ra'-da*, a small beetle (*Doryphora decemlineata*) of a yellowish colour, with ten black lines (whence the name) running down the wing-covers. The larvæ are most destructive, and have greatly injured the potato crop of America. Extraordinary precautions have been taken to prevent the arrival of the "potato beetle" in this country.

COLOSTRUM, *kol-los'-trum*, the first milk yielded by the breast of a woman after delivery.

COLOUR, *kul'-ur* (Lat., *color*).—The source of all colour is light, as may readily be seen on calling to remembrance the colourless and almost indistinguishable appearance of objects in a room from which the light has been nearly entirely excluded. When the light is wholly shut out, all is dark, and we cannot distinguish anything in the room; but as it is gradually re-admitted, we begin to recognize the forms of objects, all of which appear to be of a dark neutral tint, and at last, when the sun's rays, or rays of artificial light, are permitted to illumine the apartment, everything appears in its proper and peculiar colour. The pure white light of the sun can be separated by a simple experiment (*see* DISPERSION, RAINBOW, PRISMATIC COLOURS, and SPECTRUM) into tints which range in the following order:—red, orange, yellow, green, blue, violet, and indigo. These tints were supposed to be the primitive colours; but it is now known that light consists of rays of the three *primitive colours*, red, blue, and yellow, and that the others, which were originally ranked among the primitive colours, are in reality *secondary* or *complementary colours*, formed by the union of any two of the primitive tints. Now, when the sunlight falls on any object, it either reflects or absorbs the whole of the rays of which light is composed, or it reflects some and absorbs the remainder. When the whole of the incidental light is reflected, the object, if it be unpolished, appears to be white; if all the rays are absorbed, it seems to be black; but if part of the rays are absorbed and part reflected, it appears to be of the colour of those rays that are reflected; thus, simply, if all the rays except red are absorbed, and the red rays only are reflected, the object will appear to be red; if all except the blue rays are absorbed, it will seem to be blue. All variations of colour are produced by the reflection of certain rays in combination: thus, if the surface of any object or material absorbs all the red rays, reflecting those of blue and yellow, these will form green by combination, and the article will reflect or scatter rays of a green tint, and appear of a green colour. When light, therefore, falls on any body, if it be polished, the rays are almost entirely reflected; but if its surface be without polish, and opaque, a part of the rays of which light is composed are absorbed, and part reflected, which causes the surface to assume the apparent colour which it presents to our sense of sight.

COLOUR BLINDNESS is a curious defect of vision, from which the eye is incapable of distinguishing colours. It is of three kinds: (1) An inability to distinguish any colour, properly so called, the person being only able to distinguish white and black, light and shade. (2) An inability to distinguish between the primary colours, red, blue, and yellow, or between these and the secondary or tertiary hues, such as green, purple, orange, and brown. (3) Inability to distinguish nicer shades and hues, as greys and neutral tints. The first form is rare; the second and third are common. This peculiar defect of vision was formerly known as "Daltonism," from the the circumstance that the famous chemist and originator of the atomic theory, John Dalton, was so affected. The story of his selecting and wearing a scarlet coat (albeit he was a member of the Society of Friends), in utter unconsciousness that it was not of a sober hue, will be found in every memoir and notice of him. It is asserted on the highest authority, that very nearly 5 per cent. of men in this country are more or less affected with colour-blindness, and it is a curious fact that the defect is almost confined to the male sex, for only about one woman in every 4,000 is colour-blind. Of deaf-mutes, about 13½ per cent. are colour-blind, and it is a remarkable fact, that there is with some persons a notably analogy between sounds and colours, many instinctively associating musical notes with certain colours, almost being able, as one person remarked, to "paint a tune." The most prevalent, and, in the interest of public safety, the most serious form of this disease, or optical disorder, is that of the inability to distinguish between red and green, the colours principally used in railway and maritime signals. (*See* SIGNALS.) So-called "violet-blindness" is comparatively unimportant so far as railway servants and sailors are concerned. Professor Holmgren, of Sweden, and Dr. William Thomson, an eminent oculist of Philadelphia, have devised methods of testing the ability to distinguish colours by the use of a large number of skeins of worsted of various colours. Professor Holmgren proposes that a quantity of skeins of Berlin wool (his entire gamut of colour contains 150 different shades) shall be presented to the person to be examined. These are spread out on a white cloth in bright daylight. The examiner picks out a skein of the test colour, lays it down on a clear space on the cloth, and requests the candidate to select from the rest all those skeins which match the sample in colour, and to place them by the side of it. Dr. Thomson employs only 40 skeins of wool, and his method is very efficacious in indicating those persons whose vision is imperfect.

COLOURING MATTER, *kul'-ur-ing*. Most vegetable substances contain colouring matter that can be separated from them. Many of them are used as dye-stuffs. Colouring matters which are capable of fixing themselves to fabrics without the intervention of any other substance, are called *substantive colours*; those which require a mordant are called *adjective colours*. The colouring matter of animal substances appears to be due in a great measure to iron. In minerals colour results from a variety of different elements—iron, chromine, and copper appearing to play the largest part in painting the earth.

COLTSFOOT. (*See* TUSSILAGO.)

COLUBER, *kol'-u-ber*, a genus of serpents, including a vast number of species, but agreeing in respect of having a double row of plates on the under side of the tail. None are of very large size. The common ringed snake (*Natrix torquata*) is the only British species.

COLUMBARIA, *ko-lum-bair'-i-a*, a sepulchral chamber used by the Romans to receive the ashes of bodies which had been burned; and so named from the resemblance of the niches in the walls to the spaces in a dovecot, "pigeon-holes" in modern language.

COLUMBIDÆ, *kol-um'-bi-de* (Lat., *columba*, a dove), a family of birds comprising the pigeons, doves, and turtle-doves. The *Columbidæ* are chiefly remarkable for the way in which they feed their young. The bird's crop is furnished with numerous glands, which, in both sexes, become developed during incubation. These glands secrete a sort of milky substance, with which the food that passes into the crop is moistened. Saturated with this fluid, the food is regurgitated by the old birds for the nourishment of the young. (*See* DOVE, PIGEON.)

COLUMBINE, *kol'-um-bine*, a genus of plants (*Aquilegia*), of the natural order *Ranunculaceæ*. The common columbine grows wild in this country, and is also cultivated in gardens. It is generally three or four feet high, and is a perennial.

COLUMELLIACEÆ, *kol-u-mel-le-ai'-se-e*, a small natural order of dicotyledonous plants in the sub-class *Corolliforæ*, natives of Mexico and Peru.

COLYMBIDÆ, *ko-lim'-bi-de*, a family of web-footed birds, distinguished by short wings, legs placed so far back that an erect position is necessary when standing, and a compressed bill pointed at the tip. The loons, divers, and grebes belong to this family.

COMA, *ko'-ma* (Gr., *koma*, from *koe*, I lie down), a diseased condition of the brain, manifesting itself in a state of insensibility resembling sleep, from which the patient cannot be aroused, or only in a very partial degree. Coma may result from congestion or hæmorrhage in the brain, or from any abnormal pressure on that organ; from the agency of narcotic poisons or alcohol; from exhaustion arising from the loss of blood, or from the action on the blood of various morbid products generated within the system. Slight coma differs but little from profound sleep; but in complete coma the patient is entirely shut off from the external world, and is quite dead to all external impressions. Medical writers distinguish several varieties of coma, the chief of which are the *coma vigil* and the *coma somnolentum*. The former is characterised by a constant disposition to sleep, without falling into a quiet, sound, or natural slumber, accompanied by delirium, muttering, and agitation; the latter is marked by profound sleep, without the power of awakening spontaneously, and, if roused, almost immediately sinking into the same state. Any of the forms of coma may come on suddenly, and terminate speedily in death; or they may come on gradually, and be of short duration, sense and voluntary motion as slowly returning. When its accession is slow, it often commences with drowsiness or headache. The causes and characteristics of this disease being so various, its treatment must also necessarily vary; generally, the object is by means of stimulants and counter-irritants to arouse the patient to consciousness. Coma can be produced by mesmeric influence. (*See* MESMERISM.)

COMA BERENICES, *ko'-ma be-re-ni'-ses* (Lat., hair of Berenices), a small and close cluster of stars south of the tail of Ursa Major.

COMBRETACEÆ, *kom-bre-tai'-se-e*, the Myrobalan family, a natural order of dicotyledonous plants, in the sub-class *Calyciflora*. There are 22 genera and about 200 species, which are exclusively natives of the tropical parts of America, Africa, and Asia. The order is remarkable for the presence of an astringent principle, which renders the barks of some species, and the fruits and flowers of others, useful for tanning and dyeing. Some yield excellent timber. *Combretum butyrosum*, a native of South-Eastern Africa, produces a kind of vegetable wax, which is called *chiquito* by the Caffres, who make use of it to dress their victuals. (*See* TERMINALIA.)

COMBUSTION, *kom-bust'-shun* (Lat., *comburo*, I burn), a term applied to the phenomenon that takes place when chemical action is sufficiently intense to produce light and heat. Gases are sometimes divided into combustibles and supporters of combustion. The idea conveyed by such a classification is an erroneous one. Air is taken to be a supporter of combustion, and hydrogen gas burning in it as a combustible; but if the conditions are reversed, we are obliged to alter our classification; for a jet of atmospheric air may be burnt in an atmosphere of hydrogen.

Combustion, Spontaneous Human, is a subject that has from time to time given rise to a considerable amount of discussion among its believers and disbelievers. Numerous apparently well-authenticated cases are given of this phenomenon; but the difficulties of accounting for the chemical changes involved in such a case have caused many eminent persons to reject the whole matter, and contend that none of the cases have been sufficiently well authenticated. The cause to which it is usually traced is gross intemperance. The flame is described as of a bluish colour, obscure in the light, and extinguished with difficulty by water. Sometimes the body is said to have been consumed so as to crumble to pieces when moved, without the clothes being burned; in other cases the combustion has extended to neighbouring objects. The ashes are always a fatty kind of soot; and a similar greasy matter, of fœtid odour, is deposited on objects around.

COMET, *kom-et* (Gr., *kometes*, from *kome*, hair), in Astronomy, the name given to luminous celestial bodies which occasionally appear in the heavens, consisting of a round body, termed the head, to which a long stream of light is generally appended, called the tail, which stretches across the heavens for some considerable distance. The head consists, for the most part, of an ill-defined luminous haze, with a bright mass of light in the centre, called the nucleus, which resembles a star or small planet in apparent size and appearance. The tail is a long train of light, streaming out like hair behind the head, whence the name comet. In some comets, the head is without any nucleus whatever, and others have the luminous head without any tail appended to it. The tail is often of great length; that of the comet of 1858, called Donati's comet, being about 50,000,000 miles in length, while that of the comet of 1843, one of the most brilliant ever observed, was quite three times as long. These bodies travel round the sun in the path of an ellipse, having the sun as one of its foci, or in a parabolic curve. They are only seen when they are at their perihelion, and the tail is always turned away from the sun. Comets differ considerably from each other in form, some being without any tail, as it has been said; but they generally have a broad, luminous tail, slightly curved in shape, which trails behind the head. They were supposed by the ancients to prognosticate some disastrous event, and they were considered to be within the region of the atmosphere that surrounds the earth. Newton showed that they travelled in elliptical orbits of great eccentricity, the curvature of which did not differ much from that of a parabola. Considering this to be the case, and assuming the path of the comet of 1682 to be parabolic in form, the astronomer Halley calculated its orbit from Newton's observations, and predicted its reappearance about the end of 1758 or the early part of 1759, making allowances for the disturbing action of the planet

Jupiter. Halley's prediction was verified. When it reappeared, it was first observed on Christmas-day, 1758, by a German astronomer, and it passed its perihelion in March, 1759, thus adding to Halley's fame as an astronomer, and confirming the theory that Newton had advanced respecting the revolution of these bodies. This comet, now known as Halley's comet, which had been noticed in 1378, 1456, 1531, 1607, 1682, and 1759, appeared again in 1835, and, assuming seventy-six years to be the mean time that elapses between its successive appearances at its perihelion, it will be seen again in 1911. A description of the principal comets that are known to return to their perihelion at fixed periods will be found elsewhere (*see* BIELA'S COMET, ENCKE'S COMET), as well as an account of the great comet of 1858. (*See* DONATI'S COMET.) The comets of Faye, Brorsen, and D'Arrest, discovered in 1843, 1846, and 1851, respectively, have also reappeared at the time calculated for their return to their perihelion. A splendid comet was visible in June and July, 1861. The nucleus was about 400 miles in diameter, with a long tail, travelling at the rate of about 416,000 miles an hour. A strange glare in the atmosphere on the 30th of June led some observers to the conclusion that on that day the earth passed through the tail of the comet. Two comets were visible in Europe in 1881. It is beyond the bounds of possibility to state how many comets there are revolving round the sun, which is the centre of our solar system; but it may be said that more than two hundred have been observed up to the present time, the orbits of which have been calculated. Of these, about fifty revolve in elliptic orbits, and six at least have been observed at several successive appearances at their perihelion. A great number of comets are invisible to the unassisted eye. Mr. Norman Lockyer says:—"The majority of comets that come into our system from outside are attracted toward the sun, pass by it, and then continue on away from our system again; while there are others that belong to our system, and revolve round the sun, as the planets do; only, instead of having nearly circular orbits, their paths are very eccentric, so that the comets approach near the sun at one time, and then recede to immense distances away. The majority go round the sun the contrary way to planets, and are said to have a retrograde motion." With respect to their dimensions, it was ascertained by micrometric measurement that the great comet of 1811, which is supposed to arrive at its perihelion about once in 3,000 years, had a head 1,270,000 miles in diameter, with a nucleus in the centre, the diameter of which was about 2,640 miles, and a tail 100,000,000 miles in length. The nucleus of Donati's comet was 800 miles in diameter, while the diameter of the surrounding nebulous haze was about 100,000 miles, and the tail, 51,000,000 miles at its greatest length. It is not known of what substance comets consist; but it is evident that, whatever it may be, it must be extremely thin, and without any sensible weight, as stars have been observed shining *through* comets with undiminished lustre, which a slight fog would altogether hide from view. The great comet of 1843 was only 475,000 miles distant from the sun at its perihelion, and is considered to have been exposed to a heat more than 2,000 times greater than that of red-hot iron. It is not known what causes the tail of the comet; and scientific speculation is active on the subject. That it is of almost inconceivable tenuity is settled, as stars can be seen through it with no apparent diminution of brightness and as no disturbing effect is exercised by it on the planetary bodies.

COMMELYNACEÆ, *kom-mel-e-nai'-se-e* (after J. and G. Commelin, celebrated Dutch botanists), the Spider-wort family, a natural order of monocotyledonous plants, in the sub-class *Petaloideæ*. There are sixteen genera, which include 200 species, chiefly natives of India, Africa, Australia, and the West Indies. They have flattened, narrow, and usually sheathing leaves. The rhizomes of some species, as *Commelyna tuberosa*, *angustifolia*, and *striata*, contain much starch, and in a cooked state are edible. Some species have been reputed astringent and vulnerary, and others emmenogogue.

COMMISSURE, *kom-mish'-ure* (Lat., *commissura*, a joining together), is a joint or seam, the place where two bodies or parts of a body meet and unite. (*See* BRAIN.)

COMPLEXION, *com-plek'-shun* (Lat., *complecto*, I comprise), a term employed to signify the colour of the face and skin, although properly it means the temperament, and natural disposition of the skin. Formerly, the human skin was supposed to consist of only two parts—the cuticle, or epidermis, and the cutis, or real skin; but Malpighi showed that between these two was a soft gelatinous cellular texture, which he distinguished by the title *rete mucosum*. On this discovery that anatomist offered a suggestion as to the colour of negroes. The *rete mucosum* is of very different colour in different nations; and the difference of its colour corresponds so exactly with the difference of their complexions, that there can be little doubt that it is the principal seat of the colour of the human complexion. Of the different colours observed amongst mankind, Dr. Hunter gives the following view:—Black—Africans under the line, and the inhabitants of New Guinea and New Holland. Swarthy—the Moors in the northern parts of Africa, and the Hottentots in the southern parts. Copper-coloured—the East Indians. Red-coloured—the American Indians. Brown-coloured—the Tartars, Persians, Arabs, Africans on the Mediterranean coast, and Chinese. Brownish—the inhabitants of Southern Europe, Sicilians, Spaniards, and also the Abyssinians in Africa. The Turks, Samoides, and Laplanders, are also brownish. White—most of the European nations, including the Swedes, Danes, English, Germans, Poles, &c., together with the inhabitants of the islands in the Pacific Ocean.

COMPOSITÆ, *kom-poz'-e-te* (Lat., *compono*, *compositum*, I put together), a natural order of dicotyledonous plants, in the sub-class *Corolliflorœ*. It is one of the largest and most important orders in the vegetable kingdom, and its members are to be met with in all parts of the world. In northern regions the plants are generally herbaceous, but in warm climates they sometimes become shrubby, or even arborescent. The following botanical characters clearly define this great order:—The leaves are alternate, or opposite, and without stipules; usually simple, but often much divided. The flowers, which are termed *florets*, are hermaphrodite, or unisexual, are collected in dense heads or *capitula*, each collection of florets being on a common receptacle, and surrounded by an involucre. The separate florets are also frequently furnished with scale-like bractlets, termed *paleæ of the receptacle*. The calyx is superior, closely adhering to the ovary, its limb being entirely abortive, or membranous, or pappose. The corolla is monopetalous, tubular, superior, and usually deciduous; it is ligulate (strap-shaped), bilabiate (two-lipped), or funnel-shaped; and in the latter case, four or five-toothed. The stamens are five in number, rarely four, and are inserted upon the corolla; the filaments are either distinct or monadelphous, and the anthers are united in a tube. The ovary is inferior and one-celled, with a single erect ovule. The style is simple, undivided below and bifid above; the stigmas are placed upon the inner surfaces of the two divisions. The fruit, termed *cypsela*, is dry, indehiscent, one-celled, and crowned with the limb of the calyx, which is often pappose. The seed is solitary, erect, and exalbuminous. The order has been subdivided by De Candolle into the following sub-orders:—1. *Tubuliflorœ*—florets tubular or ligulate, either perfect, unisexual, or neuter; when perfect they are tubular, with five, or rarely four, equal teeth. 2. *Labiatifloræ*—hermaphrodite florets, or at least the unisexual ones divided into two lips. 3. *Liguliflorœ*—florets all ligulate and perfect. The first of these sub-orders includes the sections *Corymbiferœ* and *Cynarocephalœ*, proposed by Jussieu; the last corresponds to the *Chicoraceœ* of the same writer. Plants belonging to the sub-order *Tubulifloræ* abound principally in hot climates. They are remarkable for their bitter, tonic, and aromatic properties. (*See* ANTHEMIS, ARTEMISIA, ARNICA.) A few are used for dyeing. (*See* CARTHAMUS.) Some are cultivated as esculent vegetables, as the *artichoke* and *cardoon*. (*See* these words.) The *Labiatifloræ* are almost confined to the extra-tropical parts of South America. They do not furnish many useful products. The *Liguliflorœ* are most abundant in cold and temperate climates. Their chief characteristic is the presence of a milky, bitter, astringent, or narcotic juice, which possesses alterative, diuretic, aperient, or narcotic properties. The roots of some are esculent, and others, by cultivation with diminished light, become edible, as salads. (*See* CICHORIUM, LACTUCA, TARAXACUM.)

COMPLEMENT, *kom'-ple-ment*, that which completes or makes up a given magnitude and some fixed magnitude. In Arithmetic, it signifies the number by which one number falls short of the next higher number expressible by tens. In mathematics, the complement is the arc or angle by which a given arc or angle falls short of a quadrant or right angle.

COMPOSITE NUMBER, in Arithmetic, is one which can be divided by some other number greater than 1, in opposition to a prime number, which cannot be thus divided. Thus 12, 15, and 27 are composite numbers; whilst 11, 47, 89, are not composite.

CONCHIFERA, *kon-kif'-e-ra* (Lat., *concha*, a shell; *fero*, I bear), the name given by the naturalist Lamarck to certain bivalve shells, whose inhabitants are susceptible of no other impressions save those of immediate contact.

CONCHOID, *kon'-koid*, a curve invented by Nicomedes, and used by the ancients in the construction of solid problems. It had for its objects the trisection of an angle, the construction of two geometrical means between two given lines, and the doubling of the cube. Mechanically the curve may be easily described, and is often used in architecture as a boundary-line of the vertical section of columns.

CONCHOIDAL, *kon-koy'-dal* a term applied to that peculiar fracture of stones and minerals which exhibits convex and concave surfaces. Flint, cannel coal, and glass, are examples of substances possessing a conchoidal fracture.

CONCHOLOGY, the science which treats of shells and the animals inhabiting them. (*See* MOLLUSCA.)

CONCRETIONS, *kon-kre'-shuns*, are hard substances that occasionally make their appearance in different parts of the human body. When formed by chemical precipitation from the fluids, a concretion is known as a calculus. (*See* CALCULUS.) Solid substances, as peas, cherry-stones, needles, &c., accidentally introduced into the body, sometimes become the nuclei of concretions. In some animals, concretions of a large size are formed, and are produced sometimes in horses by the habit of eating the hair on other horses' bodies.

CONCUSSION, *kon-kus'-shun* (Lat., *concutio*, a shaking together), a violent commotion or shock communicated to the brain, or the whole nervous system, by collision of the body with some external object. In its slightest form, a stunning sensation is merely communicated, which passes away in a few minutes; in its severest form, death rapidly ensues.

CONDOR, *kon'-dor* (*Sarcoramphus gryphus*), a large bird of the Vulture species, and the largest of flying birds, the expanse of its wings having been known to reach fourteen feet. The wings are very powerful; the general colour black, with, in the males, great part of the wings white. Around the neck is a white ruff of downy feathers, above which the skin is bare and corrugated. The head of the male bird has a large cartilaginous comb, and there is a dilateable wattle on the neck. It feeds mostly on carrion, and is extremely voracious, sometimes gorging itself so that it cannot fly. It is almost strictly confined to the immense chain of the Andes, as is called the vast mountain-range that runs along the whole west coast of South America. The condor builds no nest, but lays its eggs, which are three or four inches in length and perfectly white, on the bare rocks. (*See* VULTURE.)

CONDUCTORS AND NON-CONDUCTORS OF ELECTRICITY, terms applied to substances according to whether they receive and communicate electricity readily or not. (*See* ELECTRICITY.)

CONDYLURA, *kon-di-lu'-ra* (*Condylura cristata*), a small insectivorous animal of mole-like appearance, found in North America. It is about four inches and a half long, and has a bushy tail more than three inches long. Its head is remarkably large, body thick and short, and nose rather thick, and projecting beyond the mouth. At the end of the nose is a flat star-like process composed of seventeen cartilaginous points. These animals do not make such hills as the European moles do, but only little subterraneous walks, forming banks about four inches broad by two inches thick.

CONE, *koan* (Gr., *konos*), in Geometry, denotes a solid body, which terminates in a point and has a circle for its base. The axis of a cone is a straight line drawn from the apex to the centre of the circle forming the base. When the axis is perpendicular to the plane of the base, the cone is said to be *right;* and when the axis is inclined to the plane of the base, the cone is said to be *oblique*. A *truncated* cone is the lower part of a cone cut by a plane parallel to the base. The area or surface of a right cone, exclusive of the base, is equal to a triangle, the base of which is the periphery, and its height the slant side of the cone, or equal to the sector of a circle whose radius is the slant side, and its arc equal to the circumference of the base of the cone. Every cone, whether right or oblique, is equal to one-third part of a cylinder of equal base and altitude: the solid contents are therefore found by multiplying the base by the altitude, and taking one-third of the product. The centre of gravity of a cone is in the axis, at a distance from the centre of the base equal to one fourth the distance from the vertex. (*See* CIRCLE, CONIC SECTIONS, PARABOLA.)

In Botany, a collective more or less elongated fruit, composed of a number of indurated scales, each of which bears one or more naked seeds. The fruit is seen in the fir, larch, spruce, araucaria, and many other plants of the natural order *Coniferæ*. A peculiar modification of the cone is seen in the cypress and in the juniper, and is termed the *galbulus*. It differs from the true cone in being more or less rounded in form, and in having the heads of the scales greatly enlarged. In the galbulus of the juniper the scales are fleshy, and are united together into one mass, so that it resembles at first sight a berry. The fruits of the Scotch fir and the cypress are familiar instances of the cone.

CONE-SHELL, a family of gasteropodus molluscs of the order *Pectinibranchiata*, having a conical shell. The inhabiting animal, carnivorous, has a proboscis capable of much extension. It is found in banks of sandy mud, chiefly within the tropics, but occasionally in the Mediterranean. The shells are very beautiful, and valued by collectors. Fossil cone-shells are found in the chalk, and in more recent formations.

CONFERVOIDÆ, *kon-fer'-voy-de*, a sub-order of the *Algæ* (which *see*).

CONFORMABLE STRATA, *kon'-form-a-bl*, in Geology, beds which lie parallel to each other.

CONGELATION, *kon-jel-ai'-shun* (Lat., *congelo*, I freeze), the process of passing from a fluid to a solid state, whether through the effect of pressure or the lowering of the temperature. (*See* ICE.)

CONGER EEL, *kong'-gur*.—This fish may easily be distinguished from the fresh-water species of eel by the upper jaw being the longest, and the dorsal fin commencing much nearer the head. It is darker on the upper parts than the common eel, and brighter beneath. There are not many species, and one only (*C. vulgaris*) is a native of the British seas. It attains a very large size, weighing occasionally from seventy to a hundred pounds, and measuring six and eight feet in length. The principal conger-fishery is on the Cornish coast. The fishing takes place at night (the darker the more chance of success), and the ordinary bait is a pilchard. It is dreadfully voracious, and devours even its own species.

CONGESTION, *kon-jest'-shun* (Lat., *congestio*, from *congero*, I amass), is a term employed to denote an unnatural accumulation of blood in the capillary vessels of any part, accompanied with disordered function of the organ in which such accumulation takes place. The organs most liable to congestion are the brain, lungs, and liver; but other parts are also subject to it. It is usual to distinguish two kinds of congestion—a passive and an active. In passive or simple congestion there is merely an accumulation of blood arising from distension and diminished vital energy in the capillaries; in active congestion, on the other hand, the blood-vessels are in a state of inordinate activity, and a preternatural quantity of blood is determined to them. Anything may be the cause of congestion which diminishes the vital energy of the capillaries, or which increases the quantity of blood which they contain. (*See* INFLAMMATION.)

CONGLOMERATE, *kon-glom'-e-rait* (Lat., *con*, together; *glomerare*, to gather in round heaps), a rock composed of rounded and water-worn fragments of stone, bound or cemented together by silicious, ferruginous, or calcareous matter. The component fragments may vary from pebbles the size of a pea to boulders half a ton in weight. Some conglomerates are commonly known as *pudding-stones*, from the resemblance of the pebbles in the mass to the fruit in a plum-pudding.

CONIC SECTIONS, *kon'-ik sek'-shuns*, the curves formed by the intersection of a right or oblique cone and a plane. If the cone is cut by a plane parallel to the base, the section is a *circle;* if the section is made obliquely, that is, nearer to the base at one end than the other, a curve is obtained which is called an *ellipse;* if the section is made parallel with the axis, perpendicular from the vertex, or so as to make a greater angle with the base than is made by the side of the cone, the curve obtained is called a *hyperbola;* and if the section is made parallel with one side of the cone, the curve is called a *parabola*. (*See* various headings.) The ancient Greeks investigated the properties of conic sections with great acuteness; and a work on them is still extant, written by Apollonius of Perge.

CONIFERÆ, *ko-nif'-e-re* (Gr., *konos*, a cone; Lat., *fero*, I bear), the Pine family, a natural order of dicotyledonous plants, in the division *Gymnospermia*—resinous trees, or evergreen shrubs, with branched continuous stems. The leaves are needle-shaped or lanceolate, parallel-veined, fascicled, or imbricate. The flowers are naked (without floral envelopes), and monœcious or diœcious, the male flowers being arranged in deciduous amenta, and the female flowers in cones. The fruit is either a cone or a galbulus. The seeds are naked, hard externally, and albuminous, with two or many cotyledons. The plants of this order abound in temperate climates, and also occur in cold and tropical regions. There are about 30 genera, which include about 120 known species. They possess very important properties; many supply valuable timber, and most of the species contain an oleo-resinous juice, or turpentine, which is composed of a volatile oil and resin. (*See* ABIES, PINUS, JUNIPERUS, CEDRUS.)

CONIROSTRES, *ko-ni-ros'-tres*, birds of the order *Insessores*, including finches, sparrows, starlings, linnets, larks, crows, and many other well-known birds, characterised by strong conical bills, and feet adapted for walking on the ground as well as perching.

CONIUM, *ko'-ne-um*, the Hemlock, a genus of plants belonging to the natural order *Umbelliferæ*. The most important species is *C. maculatum*, an indigenous plant, which is extensively employed in medicine to relieve pain, relax spasm, and compose general nervous irritation. It owes its properties chiefly to the presence of a colourless oily liquid, with a penetrating mouse-like odour, to which the name of *Conia* has been given. In improper doses hemlock is a powerful poison, and many fatal accidents have arisen from its having been mistaken for harmless umbelliferous plants; it may, however, be readily distinguished by its botanical characters. The stem is large, round, and smooth, with spots upon it of a purplish-black colour; the leaves are dark green, and shining; the general involucre consists of from three to seven leaflets, the partial involucre of three leaflets; the fruit has undulated, crenated primary ridges; and the whole herb, when bruised, evolves a disagreeable smell. No chemical antidote is known for hemlock.

CONJUNCTION, *kon-junk'-shun* (Lat., *conjungere*, to join together), when two heavenly bodies have the same longitude or right ascension (*see* ASCENSION, RIGHT), they are said to be in conjunction. If they also had the same declination, or latitude, north or south of the celestial equator, the nearer heavenly body would apparently cover the disk of that which is more remote. When any heavenly body is in a line between the earth and the sun, it is said to be in conjunction with the latter; but it is said to be in opposition to it when the earth comes between the body in question and the sun. Geocentric conjunction is the conjunction of two heavenly bodies as viewed from the earth; but when heliocentric conjunction is spoken of, the conjunction is understood to be considered as if viewed from the sun. True conjunction is the observation at the earth's surface reduced to what it would be if witnessed from the centre of the earth, by which means the observations of astronomers in different parts of the world are made mutually available.

CONNARACEÆ, *kon-na-ra'-se-a*, a natural order of exogenus plants, consisting of trees and shrubs, sometimes climbing, and without resinous juice. Nearly 50 species are known, all tropical. One a native of Guiana, *Omphalobium Lamberti*, supplies the beautiful zebra-wood.

CONSERVATION OF FORCE. (*See* FORCE.)

CONSTANT, *kon'-stant*, in mathematical analysis the quantity which remains the same for all cases in a problem.

CONSTIPATION, *kon-stip-ai'-shun* (Lat., *constipatio*, from *constipo*, I crowd together), a torpid or sluggish condition of the bowels, occasioned by an excessive action of the absorbents of the bowels, or defective secretion of the juices of the intestines, or by an impaired peristaltic action of the intestines. (*See* DIGESTION.) It arises most frequently from a deficiency or vitiated secretion of the bile, which is the natural stimulus of the bowels. Sedentary habits predispose to constipation, as does also the use of certain kinds of food. When severe and obstinate, it gives rise to inflammation of the bowels, and may soon prove fatal. The treatment consists in moving the bowels by means of purgatives, and then restoring the natural state of the system by means of active exercise in the open air, sea-bathing, and the use of food of a laxative nature; as brown bread, green vegetables, &c.

CONSUMPTION. (*See* PHTHISIS.)

CONTAGION, *kon-tai'-jun* (Lat., *contagio*, from *con*, and *tango*, I touch), ought, properly speaking, to be confined to the communication of disease to a healthy body by actual contact with the sick, or with the palpable matter from their bodies, and infection to be applied where disease is communicated through the medium of the atmosphere, or by means of other intermediate substances. This distinction, however, is frequently lost sight of, and the term contagion applied to all cases in which the disease is conveyed to the person of the recipient by particles of matter proceeding from the person of the sick, whether these particles are in a solid or a gaseous form, whether they are imparted by direct contact of the two bodies, or by being wafted through the air, or carried upon articles of clothing. There are two kinds of contagious diseases:—(1) Those that can only be communicated by direct contact, as itch, syphilis; and (2) those which are capable of being produced either by direct contact or without it, as small-pox, typhus, fever, &c. Some contagious diseases seem to effect some radical change upon the system, so that it is not again liable to attack from the same disease, as small-pox; and some diseases, that do not generally manifest any contagious disposition, do occasionally, under unfavourable circumstances, assume a malignant and contagious form. The term contagion is also applied to the poisonous matter by means of which the disease is communicated. In this latter sense, it is a morbific matter *sui generis*, which, on entering the blood, produces a definite train of morbid phenomena, and communicates to the blood the property of generating a similar poison capable of producing precisely the same disease.

CONTORTED STRATA, in Geology, beds which are bent or twisted.

CONVOLVULACEÆ, *kon-vol-vu-lai'-se-e* (Lat., *convolvo*, I roll or bind together), the Convolvulus or Bindweed family, a natural order of dicotyledonous plants in the sub-class *Corolliflorœ*. Herbs or shrubs generally twining or trailing and milky. In this order there are 47 known genera, with about 665 species, which are chiefly found in the plains and valleys of hot and tropical regions. A few flourish in temperate climates, but none in the coldest latitudes. They are remarkable for the presence of an acrid milky purgative juice in their roots. Jalap and scammony are products of this order.

CONVOLVULUS, *kon-vol'-vu-lus*, the Bindweed, a genus of plants, the type of the natural order *Convolvulaceæ*. It is characterised by a bell-shaped corolla, with five prominent plaits and five shallow lobes. Three species are natives of Britain; namely, *C. arvensis*, *Calystegia sepium*, and *C. soldanella*. *C. scammonia*, a native of Asia Minor, is a valuable medicinal plant, being the source of the purgative gum-resin called scammony. This is obtained from the fresh root, by cutting the top obliquely off, and allowing the milky juice which exudes to be collected in shells or other vessels. The root of *C. Panduratus*, is used in America as a purgative. A shrubby specimen, *C. scoparius*, a native of the Canary Isles, yields a wood which has an odour like that of a rose.

CONVULSIONS, *kon-vul'-shuns* (Lat., *convello*, I pull together), a violent and involuntary contraction of the muscles of the human body, generally with corresponding relaxations, but sometimes with rigidity and tension. The fits vary much in extent and violence, sometimes attacking the whole body, at other times only particular parts; sometimes lasting only for a few minutes, at other times continuing for hours. When the affected muscles are rigid and tense, and their contraction persistent or not quickly alternating with relaxation, the convulsion or spasm is said to be *tonic;* when contractions and relaxations rapidly alternate, it is called *clonic;* when slight contractions rapidly alternate with relaxations, it is called *tremor*. Sometimes the attack is sudden and without any warning; but generally it is preceded by certain premonitory signs, such as giddiness, dimness of vision, coldness of the extremities, tremblings, and a cold air creeping up the back or up a limb. During the fit the teeth gnash and often bite the tongue, the eyes roll wildly about, and the whole face is distorted. The muscular force exerted is sometimes so great as to overcome the strength of several attendants. Great languor commonly succeeds, attended frequently with headache and giddiness; but these generally pass quickly away. In partial convulsions the mind is rarely affected; but when general, it is in most cases lost during the fit. The causes of convulsions are many and varied, and their treatment must in each case depend very much upon the cause. Convulsions are exhibited in connection with epileptic attacks. (*See* EPILEPSY.) In children the common cause is irritation of the bowels, arising from indigestible foods, teething, or worms. These are to be treated by the administration of appropriate purgatives and the lancing of the gums. In puerperal convulsions bleeding and opiates are the usual remedies; and in cases where they arise from violent affections of the mind, the exciting causes must be studiously avoided. During the fit the patient should be immediately surrounded as much as possible by fresh cool air, the face, neck, and bosom freely exposed to it, and everything tight about the body loosened. For children a warm bath is strongly recommended. The after-treatment consists in the judicious use of tonics and nervous stimulants, with cold bathing, regular exercise in the open air, plain but nourishing diet, and attention to the state of the bowels.

CONY, OR CONEY, *ko'-ne* (Lat., *caniculus*), an old English name for the rabbit, used in the authorized version of the Old Testament, as a translation of a Hebrew word, which probably referred to the *Hyrax Siniacus*, a small animal about the size of a rabbit. (*See* DAMAN.) Rabbits are not known in Palestine.

CONYZA, *ko-ni'-za*, a genus of plants of the natural order *Compositæ*, sub-order *Corymbiferæ*. One species, the fleabane, or ploughman's spikenard (*C. Squarroso*), is well-known in England, from its peculiar odour, which is said to drive away fleas and gnats.

CO-ORDINATES, *ko-or'-di-nates*, in Geometry, "the method of co-ordinates" is otherwise known as analytical, and sometimes as algebraical geometry. (*See* GEOMETRY.) Co-ordinates are lines so measured off from a fixed point, "the origin of co-ordinates," along fixed lines passing through it, as to determine by their quantities the position of any other point relative to the origin. The method is not capable of demonstration without the use of diagrams. It was invented by Descartes, and is a means by which algebra and the calculus may be employed in geometrical investigation.

COOT, *koot*, a genus of birds (*Fulica*) of the order *Grallæ*. Coots are found in various parts of Europe, Asia, and America, but abound in larger numbers in Holland than elsewhere. The common coot (*F. atra*) is about sixteen inches in length; its upper parts are slatey black, and its under lead-colour, and there is a white bar across the wings. From the bill almost to the crown of the head there is a fleshy excrescence, destitute of feathers, and smooth and round. On this account it is sometimes called the bald-headed coot. In northern regions it is a summer bird of passage. The flesh of the coot, although not a great delicacy, is a good article of food.

COPAIBA. (*See* COPAIFERA.)

COPAIFERA, *ko-pai'-fe-ra* (from *copaiba*, the Brazilian name, and Lat., *fero*, I bear), in Botany, a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Cæsalpinieæ*. The species are natives of tropical America, and several yield the valuable oleo-resin which is used in medicine under the name of *balsam of copaiba*. This is obtained by making incisions into the stems of the trees. Most of the copaiba of commerce is brought from the Brazils, a very little being imported from Guiana and the West Indian islands. It is stimulant and diuretic, and in large doses aperient; and is used in the treatment of affections of the urino-genital system, and in chronic catarrhs. The timber known as the purple-heart, or purple-wood of Guiana, is the produce of *C. pubiflora*, and probably *C. bracteata* also. It is largely employed for making musket ramrods and for ornamental purposes.

COPAL. (*See* HYMENÆA.)

COPALCHE BARK. (*See* CROTON.)

COPERNICAN SYSTEM, is the term applied to that system of astronomy propounded by the celebrated Polish astronomer Nicholas Copernicus, who was the first to affirm that the sun and stars are stationary; that the moon alone revolves about the earth; that the earth is a planet, whose orbit is between Venus and Mars; that the planets revolve about the sun; and that the apparent revolution of the heavens is caused by the rotation of the earth on its axis. (*See* ASTRONOMY, PTOLEMAIC SYSTEM.)

COPERNICIA, *ko-per-nish'-ya*, a genus of palms. The species *C. cerifera*, the Carnahuba palm, is a native of the Brazils. On the lower surface of its leaves wax is secreted, and this is occasionally imported into this country under the name of *Carnahuba* or Brazilian wax.

COPPER, *kop'-per*, one of the six primitive metals. The symbol of this important metallic element, Cu, is an abbreviation of its Latin name *cuprum*, which word is itself derived from that of the island of Cyprus (Gr., *kupros*), where it was first worked on an extensive scale. It was called *Venus* by the alchemists, who gave to it the symbol of that planet. Copper is a hard, sonorous, ductile, and malleable metal, of a characteristic reddish-brown colour. The specific gravity is 8·78 when cast, and 8·96 when rolled or hammered. Very thin films have been obtained, which were of a beautiful green colour by transmitted light, although of the natural colour by reflected light. It is one of the best conductors of heat and electricity, and expands one part in 582 between the freezing and boiling points of water. By slow voltaic reduction, it may be obtained in cubes and octahedral forms, which are also taken by several deposits of native copper. The melting point of copper is 1996° Fah.; and by exposing it to a very intense heat, it boils and volatilizes, burning with a brilliant green flame. Heated to redness in the open air, copper combines rapidly with oxygen; but even moist air at ordinary temperatures has but little effect on it. In sea-water it becomes gradually corroded by the formation of an oxychloride of copper. Nitric acid oxidizes and dissolves it with great rapidity; sulphuric does not act on it at ordinary temperatures, but dissolves it rapidly if heated, sulphurous acid being evolved and oxide of copper formed, which unites with the excess of acid to form the sulphate. Hydrochloric acid dissolves it with access of air; if the air is excluded, no action takes place. It is but little affected by the fixed alkalies; but, with access of air, ammonia slowly oxidizes it.

Compounds of Copper.—There are two oxides, the *protoxide* and the *sub-oxide*, the protoxide is found native in dark steel-grey crystals, but can be prepared artificially by heating copper in contact with the air, or by igniting the sulphate, carbonate or nitrate of copper. It is also prepared by adding caustic potash to a hot solution of a capric salt, and thus formed it is a black powder which melts at a red heat. The sub-oxide of copper occurs native in red translucent crystals; prepared artificially, it forms a beautiful crimson powder. *Proto-chloride* of copper is brown in the anhydrous state, and green when hydrated (*see* ANHYDRIDE); is very soluble in water, forming a beautiful emerald green solution when concentrated, but pale blue when dilute. There are several sulphides of copper, the principal being the *proto-sulphide* and the *bi-sulphide*, corresponding in composition to the oxides. They are both found native, but the proto-sulphide is often formed in analytical operations. The pigment known as blue verditer consists of a hydrated oxide of copper. The salts of copper are characterised by their green or blue colour. They are nearly all soluble, and have a strong, disagreeable, metallic taste, acting as poisons on the human system. The most characteristic reactions of copper salts are as follows: Ammonia in excess gives a dark blue solution; yellow prussiate of potash gives a red-brown precipitate. A strip of bright metallic iron precipitates copper from acid solutions in a metallic form.

Poisoning by Copper.—The symptoms of poisoning by copper are violent and irrepressible purgings and vomitings, followed by exhaustion and death. The best antidote is albumen, or white of egg, with which they form an insoluble and almost inert compound.

COPPER ORES.—The ores of copper are somewhat numerous and widely spread over the earth's surface. Native copper is occasionally found crystallized in cubes, octahedra, or dendritic crystals, or in amorphous masses, in North America and Siberia. Near Lake Superior is a vein of metallic copper associated with silver, two feet in thickness. The commonest ore of copper is copper pyrites, which is the ore found in Cornwall, from which more than two-thirds of the copper used in Great Britain is obtained. After being sorted and sifted, it is sent to Swansea to be smelted. North America and Saxony also supply this ore. The Australian ore, chiefly from the Burra-Burra mines of South Australia, large quantities of which are annually imported, is a mixture of the green and blue carbonate, and contains from 25 to 30 per cent. of metal, the average of Cornish pyrites containing only 8½ per cent. Certain ores found in Chili are valuable from the amount of silver they contain. The red and black oxide also occur in Cornwall, Siberia, Brazil, and Germany. *Copper pyrites* is an important ore of copper, occurring as a double sulphide of iron and copper, $Cu_2S.F_2S_3$, in various parts of the world. Copper pyrites have a brassy lustre, and are found generally in amorphous masses with a conchoidal fracture; sometimes they occur crystallized in tetrahedra. *Copper indigo* is an ore of copper found in spheroidal masses in Thuringia and near Vesuvius, in Italy. It is very nearly pure sulphuret of copper, and is of a blue colour, whence its name.

COPRIDÆ, *kop'-ri-de*, a family of four-winged insects allied to the *Scarabææ*. The name is from the Greek word for dung (*kopros*), in which these beetles are generally found.

COPROLITES, *kop'-rol-ites* (Gr., *kopros*, dung; *lithos*, stone), are the excrements of animals found in a fossil state in the secondary and tertiary strata. They consist chiefly of the voidings of saurians and sauroid fishes. The true nature of coprolites was first discovered by their occurrence near the region of the intestinal tube in the bodies of several fossil ichthyosauri. Scales, bones, teeth, and other parts of undigested food, are often found in them, and occasionally they are found exhibiting the spiral twisting noticeable in the excrement of some living fishes. Coprolites contain a considerable proportion of phosphate of lime, for which reason they are largely employed in the manufacture of artificial manures.

COPTIS, *kop'-tis* (from Gr., *kopto*, I cut), a genus of plants belonging to the natural order *Ranunculaceæ*. The species *C. trifoliata*, commonly called "gold thread," is a native of North America, and is much prized for its root, which is a pure and powerful bitter, and forms an excellent stomachic and tonic. The root of *C. Teeta* is found in the bazaars of India, under the names of *mishmee bitter* and *mahmira*. It is intensely bitter, and is a very valuable tonic.

COQUILLA NUTS. (*See* ATTALEIA.)

CORACOID BONES, *ko'-ra-koid*, bones connected with and strengthening the scapula in birds and reptiles.

CORAL, *kor'-al* (Greek, *korallion*, maiden, or daughter, of the sea), the calcareous secretion of a jelly-like creature (sometimes known as the corallet) adapted for a sedentary mode of life, with no locomotive organs, but provided with a circle of retractile tentaculæ (slender thread-shaped organs, capable of being extended and withdrawn, and very sensitive) around the surface of the mouth, and with a central gastric cavity, or stomach, below and around which are pairs of fleshy plates extending to the sides of the polyp. Within these plates is secreted the hard matter known as coral, consisting of carbonate, and when the animal dies the soft part decays, and these external skeletons (if such a term be allowable) remain, uniting to form the masses of coral, which on examination will be found to consist of millions of starlike or radiating forms, each the secretion of one polyp. coral polyp produces eggs and young, but some species multiply also through a process of budding, forming what is known as branching coral; the new product beginning as a small prominence on the side of an old coral, the mouth and tentacles soon appear, the progress of calcareous accumulation is carried on, and in time buds are seen in their turn on these new growths, and so the process is continued. The branching form of some species of coral, especially the red coral found chiefly in the Mediterranean, Red Sea, and Persian Gulf, is well known. The coral forms a considerable article of commerce, "coral fisheries" being extensively carried on, and is used in the manufacture of ornaments. Other species do not produce the branching form; but the star-shaped polyps (the *astræa*) unite, putting forth young animals in the spaces between the older ones, and maintaining a hemispherical form of the mass, which in some cases reaches the dimensions of twelve feet in diameter, accumulated by at least 100,000 of the larger corallets (or individual corals), and as many as 5,000,000 of the smaller species. The "brain coral" is a mass of this kind, exhibiting certain peculiarities, and so named from the rather fanciful resemblance the surface exhibits to the convolutions of the human brain. It is nearly spherical in shape, and traversed by ridges formed by the regularly arranged tentacles of the animals, the mouths being visible along the furrows. It is now believed that the coral polypi perform an important function in purifying the waters of the ocean, and maintaining the uniformity of its composition. Rivers are continually pouring soluble impurities into the sea, and lime salts are formed. As the fresh water alone is carried off by evaporation, there would be an injurious accumulation did not the coral polypi and marine shell fish carry off the superfluity, and so preserve the balance in this department of nature. They perform, in fact, an office analogous to that of vegetation, which keeps down the excess of carbonic acid gas in the atmosphere; and "the great ocean currents spread the water among the coral groves as the wind conveys the air through the forest."

Coral Masses and Islands.—The corallet can only live near the surface, and cannot exist if left dry. All the masses of coral, therefore, above the level of the sea, and all at a greater depth than about twenty-five or thirty fathoms, are dead coral—that is, accumulations of the calcareous secretion, the animal itself being dead. The question naturally arises, How, then, could they have been formed? As the coral cannot float, and as it is known to exist at the deepest parts at which the ocean has been sounded, some powerful cause must exist to produce such a result. The explanation is most probably afforded by the volcanic agency which we have seen to be so active and potent. There have been subsidences by which the coral formations have gradually been lowered into the sea. In some cases the living animals have continued their work on the top of the receding mass, and so maintained the level. The phenomenon of upheaval has chiefly produced the elevation of the coral mass above the surface of the sea, but the sea itself has contributed to the results by breaking off and washing together large blocks, and, by the tremendous force of the waves, throwing them in confused masses on each other. An exposed surface thus formed is rapidly increased in extent. Myriads of marine animals deposit their shells, which, as well as the coral, are ground up by the action of the waves, and fill up the interstices formed by the irregular masses, and the heat of the sun in the tropical regions splits up the more solid blocks. In time, a height is reached at which the new island is protected from the sea; and then, unless too far from any land, sea-birds rest, and their guano contributes to the formation of a fertile soil, in conjunction with the vegetable matter contributed by the driftwood, leaves, and stems washed by the ocean currents to the new shores. Seeds, especially of cocoa-nut and other palms, accumulate; smaller seeds are contributed by birds; and, in time, the coral blocks are covered with a rich soil, well wooded and grassed, and fit for the occupation of man, and having sands of dazzling whiteness, composed of powdered coral and shells on the sea-shores. Coral islands frequently exhibit a remarkable formation, and are described as Atolls (from a Malay word), or lagoon islands. (*See* Atoll.)

Coral Reefs.—In some places, reefs of coral, like those forming atolls, encircle islands of volcanic formation, at a distance of two or three miles from the shore. Instances of this formation are found in the Society Islands, including the Tahiti group, in the South Pacific, where the islands, of volcanic origin, rise in irregular conical form to a great elevation—in Tahiti to 7,000 feet—with a narrow belt of fertile ground between the mountains and the sea, and are enclosed by coral reefs, which, indeed, form large atolls, with islands in the centre. There are openings in the reefs giving access to the islands. Two islands of the group, Raiatea and Tahaa, are enclosed within one reef, of an irregular oval shape. *Barrier reefs* are walls of coral, extending in straight lines in front of the shores of continents or large islands, not encircling the latter, as in the instances above mentioned, and generally at a greater distance from the coast. There is such a reef, 400 miles long, off the coast of New Caledonia, in the South Pacific; but the most extensive formation of the kind is the Great Barrier reef, a narrow ridge, and extending for 1,100 miles from lat. 9° 15′ S. to lat. 24° 36′ S., generally parallel to the east coast of Australia, but varying in distance from the shore from twenty to seventy miles. There are, however, openings by which vessels enter the interior ocean, and reach the ports on the eastern side of Australia. *Fringe reefs* is the name given to narrow belts of coral immediately adjoining the coast, with no intervening lagoons.

CORAL RAG, in Geology, a group of the Middle, or Oxford oolite, consisting of beds of petrified coral, interstratified with oolitic limestone. They occur in Berkshire, Wiltshire, and Yorkshire, and are in some places more than 180 feet in thickness.

CORAL TREE, or CORAL FLOWER, a genus (*Erythrina*) of trees and shrubs of the natural order *Leguminosæ*, sub-order *Papilionaceæ*, natives chiefly of tropical and sub-tropical regions. The flowers form long spikes of a rich crimson or scarlet colour, resembling coral. An Indian species, *C. Indica*, has the stem covered with thorns, and is used for hedges, and the wood being light and spongy is used to make substitutes for corks. A Brazilian species, *E. crista galli*, is cultivated in this country in green-houses. A plant of a very different kind, belonging to the order *Euphorbiaceæ*, is sometimes named the Coral Tree.

CORALLINE, Algæ of the sub-order *Ceremiaceæ*, remarkable as being covered with a calcareous incrustation. The common coralline, a beautiful object with branching filaments is very abundant in the rock pools on the British coasts. In tropical seas, the corallines are seen in the greatest perfection. Various small zoophytes, found on the British coast, are popularly known as corallines.

CORCHORUS, *kor′-kor-us* (from Gr., *koreo*, I purge), a genus of plants belonging to the natural order *Tiliaceæ*. The most important species is *C. capsularis*, the jute-plant, a native of India. The fibre called *jute*, or *jute-hemp*, is obtained from the bark. (*See* Jute.) The species *C. olitorius*, commonly called Jews' mallow, is used in some parts of the world as a pot-herb.

In Panama, the leaves of *C. mompoxensis* are employed as a substitute for Chinese tea.

CORDYCEPS, *kor'-di-seps*, a genus of Fungi, including many species which are very destructive to living plants and animals. The disease called ergot, which occurs in the grains of rye and other grasses, is produced by *C. purpurea*. (*See* SECALE.) Caterpillars are frequently killed by other species growing in them. The remains of the caterpillar, with the developed fungus of the species *C. Sinensis*, is a highly esteemed drug in China, where it is much used as a tonic.

CORNACEÆ, *kor-nai'-se-e*, the cornel or dogwood family, a natural order of dicotyledonous plants of the sub-class *Calyciflorœ*. They are trees, shrubs, or rarely herbs. There are nine genera and forty species natives of the temperate parts of Europe, Asia, and America. They are chiefly remarkable for tonic, febrifugal, and astringent properties. (*See* CORNUS.)

CORN-CRAKE. (*See* LANDRAIL.)

CORNEA, *kor'-ne-a* (Lat., *cornu*, a horn), one of the coats of the eye, from its being of a horny consistence.

CORNEL, OR CORNELIAN CHERRY, *kor'-nel*, a tree or shrub of the natural order *Cornaceœ*. It is a native of middle and southern Europe and of the greater part of Asia, and in Germany and other places is cultivated as a fruit tree. It stands nearly twenty feet high, has oval leaves and small heads of flowers, which abound in honey. The fruit is oblong, about the size of a small cherry, and generally of a shining red colour, but sometimes yellow or white. The wood of the tree is very hard and tough, and is much used for making mathematical instruments. The dwarf cornel (*C. Suecica*) is a small plant found in mountain pastures and bogs. The sweet red fruit is tonic, and so increases the appetite, that the plant has a Gaelic name, signifying the "plant of gluttony."

CORNS, *korns* (Ang.-Sax.), small, hard, troublesome excrescences on the feet, arising from a thickening of the cuticle or epidermis, and owing generally to irritation, caused by excessive pressure or friction on the part. Corns are of two kinds—hard and soft, the latter being situated between the toes. Frequently a bursa, or bag, is formed beneath the corn, which is apt to inflame and cause great pain and irritation. Every person troubled with corns must have noticed that they are most painful in wet weather. In the treatment of corns, the great object is to remove all undue pressure or friction; and for that purpose, the boots or shoes should be easy and pliant. This will be still further effected by protecting the corn with a small piece of thick soft leather, spread with diachylon or other emollient plaster, and having a hole in the centre corresponding with the size of the corn. The feet should also be frequently bathed with warm water, and as much as possible of the corn carefully picked away. The practice of paring corns with a knife is dangerous, and although it may afford temporary relief, rather encourages the growth of the corn. If the corn is very sensitive, it ought to be occasionally touched with lunar caustic; and if much inflamed, a warm bread poultice should be applied to it. Horses suffer much from corns, which are very painful and often cause lameness. They require careful treatment on the part of the groom, or, in severe cases, of the veterinary surgeon.

COROLLA, *ko-rol'-la* (Lat., a little crown), the inner envelope of the flower, consisting of leafy organs called *petals*, and situated in a complete flower, between the calyx and the stamens. It is generally the most conspicuous whorl of organs, being more or less coloured. It is, in fact, that part of the plant which usually delights us most by its gay appearance and fragrance. Petals are rarely green, though occasionally this colour is met with. When there is but one whorl of enveloping organs in the flower, it is regarded as the calyx (which *see*), and the flower is said to be *apetaloid*. A petal is often narrowed below into a stalk-like portion analogous to the petiole of a leaf, as in the wallflower; the narrowed portion is then termed the *unguis* or *claw*, and the expanded portion the *limb*. Such a petal is said to be *unguiculate* or *clawed*. The shapes of petals are indicated in botanical descriptions by terms easily understood; such as *oblong*, *lanceolate*, *elliptic*, *orbicular*, *ovate*, and *cordate*, applied to the outlines, and *concave*, *tubular*, and *boat-shaped*, applied to the forms of petals which are not flat. In describing their direction, the terms *erect*, *connivent*, *divergent* and *reflexed*, are used in the same sense as when applied to the parts of the calyx. When the petals are all of the same size and form, the corolla is termed *regular*; when they vary in these particulars, it is said to be *irregular*. In some flowers the corolla has an appendage known as the *corona*, or crown, sometimes appearing like an interior corolla, and sometimes assuming very peculiar forms.

COROLLIFLORÆ, *ko-rol-le-flor'-e*, a sub-class of *Dicotyledones*, comprising those plants which have flowers furnished with both calyx and corolla, the latter being composed of united petals; the stamens are inserted on the corolla or ovary, or free and arising from the thalamus.

CORONELLA, *ko-ro-nel'-la*, a genus of serpents of small size, belonging to the family *Colubridœ*. They inhabit the warm and temperate parts of the world, and are non-venomous.

CORPULENCE, *kor'-pu-lens*, (Lat., *corpulentia*, from *corpus*, the body), is an undue bulkiness or size of the body, arising from an excessive accumulation of fat in certain parts. It most commonly takes place after the age of forty, but is not confined to any particular period of life, being found also in childhood and youth. The causes of corpulence are both natural and acquired. There are some persons who have a natural tendency to corpulence; in others it may be induced by modes of life, indolent and sedentary habits, and the use of certain kinds of food. The undue accumulation of fat produces a variety of effects, interfering with the vital energies of the body, and incapacitating for exertion. The chances of life are not so great among persons of a corpulent habit as among those of a normal condition. All sudden or violent measures to get rid of corpulence are attended with harm; and not the least dangerous is the popular remedy of vinegar, which has the effect of destroying the digestive powers. Attention to diet, and the avoidance of such articles as tend to generate fat, together with active exercise and the counteracting of indolent habits, are among the best means that can be employed. There are numerous very remarkable cases of corpulence on record. Among modern instances known in this country, was Bright of Maldon, in Essex, who died on the 12th of November, 1750, in the twenty-ninth year of his age. He weighed 616 lbs; and it is said that seven persons of ordinary size could be inclosed in his waistcoat. Daniel Lambert, who is supposed to have been the heaviest man that ever lived, died at Stamford, in Lincolnshire, at the age of forty, on the 21st June, 1809. He is said to have weighed 52 stones 12 lbs., or 740 lbs.

CORPUS, *kor'-pus*, (Lat., body), is a term applied to certain parts of the animal structure; as the *corpus callosum*, the *corpora quadrigemina*.

CORPUSCLES, *korp'-us-kls*. (*See* Blood.)

CORRELATION OF THE PHYSICAL FORCES, *kor-rel-lai'-shun* (Lat., *con*, with; *relatio*, a throwing back), the reciprocal relation between gravitation, the molecular forces, heat and light, electricity, and animal force. (*See* Force.)

CORSAC, *kor'-sak*, an animal of the dog family, found in the deserts of Tartary and India. It is about the size of a fox, which it resembles in the head, tail, and colour; but it is not nocturnal in its habits, and lives in burrows in large communities.

CORUNDUM, *kor-un'-dum*, a mineral containing pure alumina, and occurring in hexagonal prisms of great hardness. When coloured and transparent, corundum constitutes *sapphire*, and the granular variety is known as *emery*.

CORVIDÆ, *kor'-vi-de*, a family of birds of the order *Insessores*, and including ravens, crows, jackdaws, rooks, magpies, jays, and choughs.

CORVUS. (*See* Crow.)

CORYLACEÆ, or CUPULIFERÆ, *kor-il-ai'-se-e* (Gr., *korus*, a helmet, the calyx enwrapping the fruit), in the Oak family, a natural order of dicotyledonous plants, in the sub-class *Monochlamydeæ*. The plants of this order abound in the forests of temperate regions, and a few occur in the high lands of tropical climates. They are of great importance as timber-trees: many yield edible seeds, and some have astringent barks and cupules. There are about 280 known species, which have been arranged into 10 genera, the most noteworthy being *Quercus* (the oak), *Corylus* (the hazel), *Fagus* (the beech), *Castanea* (the chestnut), and *Carpinus* (the hornbeam).

CORYLUS, *kor'-e-lus*, the typical genus of the natural order *Corylaceæ*, including the common hazel (*C. avellana*). (*See* Hazel.)

CORYMB, *kor'-imb* (Lat., *corymbus*), the name given to a particular form of inflorescence. It is a kind of raceme (which *see*), in which the peduncles (flower-stalks) become gradually shorter as they approach the top, so that all the flowers are about on a level. It occurs in some species of *Cerasus*, in the hawthorn, and many familiar plants. When the stalks or secondary axes of a corymb, instead of bearing flowers immediately, divide and form tertiary axes, a *compound corymb* is produced, as in some species of *Pyrus*.

CORYMBIFERÆ, *kor-im-bif'-ere* (Lat., *corymbus*, and *fero*, I bear), a sub-order of the *Compositæ*, consisting of plants having florets all tubular and perfect, or having tubular and perfect florets in disk, and tubular and pistilliferous, or ligulate, florets in the ray. The genus *Chrysanthemum* may be taken as an example. Two species of this genus grow wild in Britain; namely *C. leucanthemum* (the ox-eye) and *C. segetum* (the corn marigold). In our gardens a number of beautiful varieties of the species *C. indicum*, *sinense*, and others are cultivated. They are hardy plants, and are remarkable for the number and the varied colours of their flowers, which appear late in the autumn. Fine displays of Chrysanthemums are made in the parks and ornamental gardens of London.

CORYPHA, *kor-i'-fa* (Gr., *koruphe*, the summit, the leaves growing only on the top), a genus of palms. It includes one remarkable species, namely *C. umbraculifera*, the talipot palm of Ceylon, from which large quantities of sago are obtained.

CORYPHENE, *ko'-re-fene*, a genus of fishes of the family *Scomberidæ*, commonly called dolphins. (*See* Dolphin.) They are found in the seas of warm climates, and some species are seen in the Mediterranean. The largest (*C. hippuris*) is about five feet long. They move with great rapidity, and will leap out of the water twenty or thirty feet. The colours are very brilliant, and change rapidly when the fish is dying. The body is long and compressed, covered with small scales, and the head rises in a sharp crest.

CO-SINE. (*See* Trigonometry.)

COSMOGONY, *kos-mog'-o-ne* (Gr., *kosmos*, the universe; *gone*, generation), the science which relates to the formation of the universe, as distinguished from *cosmography*, which treats of the universe as we see it, and from *cosmology*, which treats of the actual and permanent state of the earth as it is. Cosmography has been embodied as a science by Baron Humboldt, in his celebrated work entitled "Cosmos." All cosmogonists may be divided into two great classes—those who believe that the world sprang into existence at the order of the Almighty, and those who hold that the universe is in itself the body and being of Deity, and, as such, has been in existence through all eternity. The former are termed Theistical cosmogonists, and the latter Pantheistical.

COSMOS. (*See* Cosmogony.)

COSSUS, *kos'-sus*, a genus of night-flying moths. (*See* Goatmoth.)

COSTMARY, *kost'-ma-re*, the *Balsamita vulgaris*, formerly known, as "the plant of the Virgin Mary," or "ale cost," a perennial plant of the natural order *Compositæ*, sub-order *Corymbiferæ*. It is a native of the south of Europe and is cultivated for the sake of the fragrant leaves. It stands nearly three feet high, and has yellow flowers. The leaves were formerly put into ale and negus, and in France are used in salads.

COTIRGA, *ko-tir'-ga*, a genus of birds (*Ampelis*) of the family of the Chatterers, natives of South America. The males are remarkable for the beauty of their plumage, mostly azure and purple, in the breeding season; but at other times they are of a grey or brown colour.

COTONEASTER, *kot'-on-ees'-ter*, a genus of plants, of the natural order *Rosaceæ*, sub-order

Pomaceæ. They are shrubs or small trees, some evergreen. The fruit is small and of disagreeable flavour, but of bright colour, and as it remains on the tree in winter makes it ornamental. Most of the species are natives of mountainous regions especially in Asia; but they thrive in this country and are cultivated as ornamental shrubs.

COTTON, *kot'-ton* (probably from Arabic *kotun*, fine), one of the most important of all vegetable fibres—commercially, perhaps, the most important—the produce of plants of the genus *Gossypium*, of the natural order *Malvaceæ*, or mallow family. They are partly shrubs and partly herbaceous, and either perennial or annual, are natives of the tropical parts of America, Africa, and Asia, but are cultivated in the temperate zones. Several species furnish cotton, which consists of hairs covering the seeds. These hairs upon the seeds, and the occurrence of three leafy bracts, united at their base outside the flower, constitute the distinctive characters of the genus. There appear to be four distinct species from which our commercial cotton is derived. Many other so-called species have been described, but they are probably mere varieties. The first cotton fabrics were manufactured from the hairs of the species *G. herbaceum*, or *Indicum*, the common cotton-plant of India, cultivated also in China, Egypt, and other places. The stems are less woody than in other species; hence its specific name, which signifies herbaceous. It is a pretty plant, and rises from eighteen inches to two feet in height during the first year of growth. It is usually cut down annually; but if allowed to grow, it will attain a height of five or six feet, and its branches will become rather woody. All the younger parts of the stem are covered with short hairs, and marked with black spots. The flowers are bright yellow, each petal being marked with a purple spot near the base. The flower is succeeded by a fruit, which gradually becomes dry, and then bursts into three or four valves, when the cotton-wool is seen issuing from it in all directions. This is the Surat cotton of commerce. The cotton is generally white; but much of that produced in China is of the yellow or tawny colour, peculiar to the fabric called "Nankeen." *G. arboreum*, the tree-cotton, is another Indian and Chinese species, but, unlike the last, it assumes the aspect and dimensions of a small tree, from fifteen to twenty feet in height. The flowers are of a bright red colour. The cotton hairs are remarkably soft and silky, and are woven by the natives into a very fine muslin used for turbans by the privileged religious classes only. *G. Barbadense* is the species which yields all the best cotton. It is called the Barbadoes, or Bourbon cotton, but does not appear to have been originally a native of the New World. It is a perennial plant, and has a shrubby stem, from six to fifteen feet in height. The flowers are yellow, like those of *G. herbaceum*, and have a dark spot at the base of each petal. The fruit is capsular, and contains in its interior from eight to twelve black seeds, which, on being freed from the cotton-wool, are found to be destitute of down, unlike those of the preceding species, which are covered with firmly-adhering short hairs. The plant was introduced into Georgia from the Bahama Islands, where it had been grown from seed obtained in the West Indies. In the small American islands which fringe the coast of Georgia from Charlestown to Savannah, this plant has produced the celebrated Sea Island cotton, which is unrivalled for the length of its staple, its strength, and its silkiness. This cotton, when cultivated in the cooler and drier climates of the hill country of Georgia, is inferior in quality, and shorter in staple. This fact shows how great is the influence of external circumstances on the growth of the cotton-plant. The species *G. Peruvianum* is supposed to be indigenous to America. Like the Bourbon cotton, it has black seeds and yellow flowers. The seeds adhere together, however, in a peculiar way, forming a kidney-shaped mass. This plant furnishes the South American varieties of cotton; as Pernambuco, Peruvian, Maranham, and Brazilian. After the Sea Island and Egyptian, these South American cottons obtain the highest price in the market. Cotton is now extensively cultivated in South Africa (Natal), in the West Indies, and in Queensland (Australia). The seeds of the cotton-plants, after the cotton has been separated from them, on being submitted to pressure, yield a fixed oil, which may be used for burning in lamps. If examined under the microscope, the cotton hair will be found apparently to consist of two delicate transparent tubes, the one twisted round the other. If, however, the hair be examined in its young state, it will be found to be an untwisted cylindrical tube. Its changed appearance when it reaches to maturity can be accounted for by the circumstances under which it is developed. As the seeds and hairs grow, the capsules do not appear to expand with equal rapidity; and, consequently, the hair is exposed to pressure on all sides. The result of this is, that the hair collapses in the middle, leaving a half-formed tube on each side. These uncollapsed portions of the hair give it the appearance of a flat ribbon, with a hem or border at each edge. The hair does not, however, grow out straight, but, coming in contact with other hairs and the sides of the capsular fruit, it becomes twisted. This twisting is undoubtedly the great fact that makes the cotton hair of value. The twisting gives the power of uniting and forming a cord strong enough to be woven.

COTTON GRASS, a genus of plants (*Eriophorum*), of the natural order *Cyperaceæ*, generally natives of the colder northern regions, some of the species being found in Britain. The fruit has long silky hairs, which is sometimes used for candle-wicks and common stuffing. The fibre of an Indian species is strong, and is used for cordage and twisted into cables. The leaves of cotton grass were at one time in repute as a remedy for diarrhœa, and the pith of the stem for tape-worms.

COTTONWOOD. (*See* POPLAR.)

COTTUS, *kot'-tus* (Gr., *kotta*, a head), the name of a genus of spiny-finned fishes, characterized by the large size of the head; whence their name. Some of the species are marine, others inhabit fresh water. There are two species of this genus to be found in British seas—the sea scorpion (*Cottus scorpio*), and the Father-lasher (*Cottus bubalis*).

COTURNIX, *ko-tur'-nix*. (*See* QUAIL.)

COTYLEDON, *ko-til-e'-don* (Gr., *kotule*, a cavity, in allusion to the cup-like leaves), a rudimentary leaf, forming part of the embryo of a flower plant. (*See* EMBRYO.)

COTYLEDON, the Navelwort, a genus of plants belonging to the natural order *Crassulaceæ*.

The species *C. umbilicus* is a common plant on walls and rocks in the West of England. It has long been in use as a popular remedy in hysteria, and as an external application to destroy corns and warts, and is employed as a remedy for epilepsy.

COUCAL (Egyptian), *koo'-kal* (*Centropus ægyptus*), a bird about 15 inches long. The feathers of the head and neck are of a metallic greenish hue, which colour, passing to a duller tint, marks the bird's upper parts generally, while the under portions are white. It is solitary in its habits, breeding in holes in trees, and feeding on insects and small reptiles. Its note somewhat resembles that of our cuckoo; indeed, the Arabs call the bird *hou-hou*, from its repetition of these syllables.

COUCH-GRASS, *kowtch*, known also as wheat, or dog-grass, quitens and squitch, or quitch, a weed, which botanicaly is of the same genus as wheat. In some parts of Italy, the roots are used for feeding horses, and in times of scarcity, have been ground into meal to make bread. A kind of beer is made from them, and they are used as an aperient medicine.

COUCHING. (*See* EYE, DISEASES OF THE.)

COUGH, *kof*, a spasmodic action of the respiratory organs, occasioning a violent and sonorous expulsion of air from the lungs. Coughing most frequently occurs as a symptom of some other complaint, as catarrh, pleurisy, phthisis, &c.; and hence some nosologists have been led to regard it as always so. At times, however, it is as truly idiopathic as any other disease. It is of the utmost importance that the air-passages to the lungs should be perfectly free from any obstruction; and hence the larynx, trachea, and bronchi are endowed with a very high degree of irritability, so that the slightest contact of a foreign body causes the most violent excitement. Coughing, then, is occasioned by an irritant in these parts, and is an attempt to get rid of the irritation. The air from the lungs is suddenly driven up with great force through the air-passages, so as to carry with it any causes of irritation that may be present in them. Cough may also be excited by irritant vapours or gases, or may arise from an abnormal sensibility of the lining membrane. In most cases cough is attended with expectoration, but sometimes it is quite dry. When the mucous membrane of the air-passages is unduly stimulated, the vessels become overloaded with mucus, and coughing is produced to effect its discharge, as is frequently observed in catarrh. This kind of cough is often a chronic disease in old age, and is frequently very troublesome. The dry cough which is mostly unattended by any expectoration, is obviously of a nervous character, and is observed in highly irritable, nervous, and hysterical constitutions. The treatment of cough, when symptomatic of any other disease, will be found noticed in other parts of this work; as CATARRH, BRONCHITIS, PHTHISIS. Coughs should never be neglected; for they are frequently symptomatic of organic disease, or may induce it. If they do not yield to simple remedies, medical advice ought to be sought.

COW, *kow*, the female of the bovine species.

COW BUNTING (*Molothrus pecoris*), known also as the cowpen bird, cow-blackbird, and by other similar names, a passerine bird of North America; like the cuckoo, it deposits its eggs in strange nests. It is about the size of the thrush, and is chiefly black, with a violet tinge. The tail is slightly forked; legs and claws glossy black, and very muscular.

COW PARSNIP, a genus of plants (*Heracleum*) of the natural order *Umbelliferæ*. In this country it is known as hog-weed, a coarse rank weed, with hairy leaves, and about four feet high. It is used occasionally as food for cattle and for fattening hogs.

COW PLANT (*Gymnema lactiferum*), a perennial plant of the natural order *Asclepiadaceæ*, a native of Ceylon. The name is derived from the milky appearance of the juice.

COW-POX. (*See* VACCINATION.)

COW TREE, a popular name for several species of trees, natives of tropical countries, which yield a juice sometimes used instead of milk. Some are allied to the fig, some to the bread-nut. The best known are the Hya-hya and the Palo de Vaca, both natives of equatorial America.

COWAGE, OR COWITCH, short, brittle hairs which grow on the pods of plants of the genus *Mucuna*, natural order *Leguminosæ*, natives of the tropical parts of America and Asia. They are used in medicine, being administered in syrup or honey for the purpose of killing and expelling intestinal worms. The pods of the unripe plants are sometimes boiled and eaten, and are said to be of agreeable flavour.

COWBARE. (*See* HEMLOCK.)

COWBERRY. (*See* WHORTLEBERRY.)

COWRY, *kow'-re*, a genus of gasteropodous molluscs, the type of the family *Cypræidæ*. The shells, sometimes known as "porcelain shells," are remarkable for the brilliancy of their colours, and the high polish of which they are susceptible. They abound both in the old and new world, but their greatest development, both in point of size and number of species, takes place in warm climates.

COWSLIP (*primula veris*), a pretty little flower, found abundantly in pastures in England and in most parts of Europe. The flowers, fermented with sugar, make a kind of wine, in much favour in rural places.

COW WHEAT (*melampyrum*), a genus of plants of the natural order *scrophulasiaceæ*, natives of the northern temperate regions. They are annuals, growing in cornfields and pastures, and are supposed to be fattening to cattle, and to improve the butter made from the milk of cows feeding on it.

COYPU, *koi'-pu* (*Myopotamus Copyus*), a rodent animal, smaller than the beaver, but with many similar characteristics. Its habits are aquatic; it burrows near the margin of rivers, and swims with the greatest ease. Its hind feet are webbed; its head large and depressed: ears small and rounded; muzzle long and pointed, and ornamented with bristle-like whiskers. Its tail is round and slender, instead of being flattened like the beaver's. It is peculiar to South America, and its skin forms the staple of a considerable trade, the fur being known as racoonda and putria.

CRAB, *krab* (Sax., *crabba*).—This name is popularly applied to the whole of the crustaceans belonging to the order *Decapoda*, which is divided into three sub-orders—the *Macroura*, or *long-tailed crustacea*, to which the lobster and crayfish belong; the *Anomoura* which appears to hold an intermediate position between the former and the third sub-order—the *Brachyoura*. To the latter the common crab belongs. This animal is thus characterized:—The abdomen is always converted into a short jointed tail, quite destitute of terminal appendages, and bent round so as to fold closely under the breast. The cephalo-thorax is usually of a more or less rounded form, generally broader than long, and often produced in front into a point. The upper surface is entirely covered by a single plate (the carapace, or back). The eyes and the inner antennæ, the latter of which are very short, can be entirely concealed within small cavities of the forehead. The outer antennæ are never of any great length, and the anterior feet are always converted into nippers. The four other pairs of legs are generally terminated only by single claws. The feet of the crab, although sometimes flattened, which assists the animal greatly in making progress through the water, are, as a rule, essentially made for pedestrianism. Its walk or run is of a very curious nature; and when alarmed it shuffles along sideways, but with great rapidity. In some species of the *Brachyoura* the young crabs undergo several metamorphoses before arriving at maturity; but in many others immediately they are hatched they resemble their parents in all but size. The common crab *(Cancer Pogurus)* inhabits deep water, and is caught either on the rocks at low tides, or by means of a trap—a basket—baited with meat or some animal garbage, into which the animal is easily enabled to crawl, but out of which the intellects of the crab are too dull to devise a means of escape. The small edible crab *(Cancer mœnas)* is also very common on all parts of our coast, but not so much valued as the former. A very curious species is the hermit-crab, belonging to the sub-order *Anomoura*. This creature possessing a very soft abdomen, it would be very likely to be seized by some predacious fish, if it were exposed. To prevent this, the hermit-crab seeks for some empty tenement, wherein it may take up its abode. The habitation usually chosen is the shell of some univalve mollusk.

CRACIDÆ, *kra'-si-de* (Gr., *kraxo*, to vociferate), a family of large gallinaceous birds, natives of America. (*See* CURASSOW.)

CRAG, in Geology, several groups of strata, containing masses of shelly sand.

CRAKE, a genus of birds (*Crex*) of the family *Rallidæ*, with shorter heads and thicker bills than the true rails. The common corncrake or land rail (*C. pratensis*) is well-known in all parts of England, where, however, it is only seen in summer, being a bird of passage. The name is taken from the peculiar call-note of the male. It weighs rather less than half-a-pound, and is a delicacy for the table.

CRAMBE, *kramb* (Gr.), a genus of plants belonging to the natural order *Cruciferæ*. The species *C. maritima*, or sea-kale, grows wild on the sandy sea-shores of Britain. About the middle of the last century it was first introduced into gardens and grown like asparagus, under a covering which shielded it from the action of light. So cultivated, the stem and leaf-stalks form a delicious vegetable which is preferred by many to asparagus.

CRAMP, *kramp* (Sax., *kramma*; Du., *kramp*), is an involuntary and painful contraction of one or several of the voluntary muscles connected with a certain part or organ, as of the leg, foot, or arm. It is often the result of cold, particularly when it attacks bathers; is sometimes occasioned by a greatly disordered state of the bowels, and frequently comes on without any obvious cause. In general, cramp is readily removed by a forcible exertion of the antagonist muscles, so as to overcome the spasmodic contraction, or by friction and warmth. Cramp of the stomach is to be combated by the external and internal use of stimulants, and antispasmodics. (*See* SPASM.)

CRANBERRY. (*See* OXYCOCCUS.)

CRANE, a genus of birds belonging to the order *Grallatores*, and the type of the family *Gruidæ*. Cranes are found in considerable flocks in the northern parts of Europe. The bird, which differs chiefly in the position of the toes from the heron, measures about five feet in length; general plumage ash-coloured, but forehead black; sides of the head and hind part of the neck white. On the upper part of the neck there is a bare ash-coloured space of about two inches, and above this the skin is naked and red, with a few coloured hairs. The pinion of each wing is furnished with an elegant tuft of curled feathers. The bill is long, straight, and compressed, obtuse towards the end, and with the lateral base deeply channelled. Its nest is usually constructed in some swampy tract or insulated ruin. It lays two eggs, of a pale dull-greenish colour, blotched with brown. Its food is frogs, snails, grain, vegetables, &c. When a flock congregated on a marsh compose themselves for slumber, some few are invariably wide awake, and stand perched on one leg, looking out for danger. The crane is a bird delighting in the wastes that lie on the edges of marshes, or that are subject to periodical overflowings by rivers. The common crane (*Gras cinerea*) breeds in the northern parts of Europe and Asia, and in the winter seeks the warmest of tropical regions. Once very abundant in England, it is now very rarely seen there. It feeds on roots and seeds, as well as on reptiles and worms. The flesh is considered a delicacy. The Demoiselle or Numidean crane (*Arithropoides virgo*) is a native of Africa. It is, although smaller than the common crane, of much more graceful build and handsome plumage. The chief peculiarities are a tuft of snowy feathers, which pass off backwards from behind each eye, and the long pointed feathers which hang loosely from the upper part of the breast. Its chief colours are silver-grey and black. The crowned crane (*Ardea pavoniara*) is somewhat smaller than the last-mentioned, and is chiefly known by the possession of a close tuft of velvety black feathers covering the forepart of the head, while behind them rises a remarkable crest of fine feathers twisted spirally, and fringed along its edges with a series of black pointed hairs. Its cheeks and temples are entirely naked, and covered with a bright rosy red. The whooping crane of America is a large bird.

CRANE-FLY, a genus of two-winged insects (*Tipula*), nearly allied to the gnat family. They are of large size, with very long legs, and spreading wings. One species (*T. oleracea*, the "Daddy longlegs," of children) abound in summer, and the larvæ, are extremely destructive to crops.

CRANIUM. (*See* SKULL.)

CRASSULACEÆ, *kras-su-lai'-se-e* (Lat., *crassus*, thick, from the thickness of its leaves), the Houseleek or Stonecrop family, a natural order of dicotyledonous plants in the sub-class *Calyciflorœ*—succulent herbs or shrubs with exstipulate leaves. The flowers are perfectly symmetrical, the sepals, petals, and carpels being equal in number (from three to twenty), and the stamens being also equal to them, or twice as many. The *Crassulaceæ* are found in very dry situations in all parts of the world; a large number occur at the Cape of Good Hope. Astringent, refrigerant, and acrid properties characterize them, and have given a few some importance as medicinal plants.

CRATÆGUS, *krat-e'-gus*, a genus of plants belonging to the natural order *Rosaceæ*. The species *C. oxyacantha* is the Hawthorn, Whitethorn, or May, so well known for the beauty and fragrance of its flowers, and for being the best hedge-plant in Europe. It is the only species indigenous to Britain. The azarole and the aronia, natives of the south of Europe and the Levant, bear edible fruit, about the size of a crab-apple. Some varieties of this species are highly ornamental, producing double pink or scarlet blossoms.

CRATER, *krai'-ter* (Gr., *krater*, a cup or bowl), the mouth or orifice of a volcano, so named from its cup or bowl shape. (*See* VOLCANO.)

CRAYFISH, OR CRAWFISH, *krai'-fish* (*Astacus fluviatilis*), a crustaceous animal, differing little in general appearance from the lobster. It belongs to the order *Decapoda*, sub-order *Macroura*. Species of this genus are found in almost all parts of the world. The flesh is reckoned cooling and nutritious. It lives best in rivers, where it takes up its habitation beneath stones and in holes in the banks, there lying in wait for the larvæ of insects, decomposing animal substances, and small fish.

CREASOTE, *kre'-a-sote* (Gr., *kreas*, flesh; *sozo*, I preserve), a fluid containing oxygen, hydrogen, and carbon, first found by Reichenbach, in the heavy oil obtained by the distillation of wood-tar. When pure, it is a colourless oily liquid of high refractive power, boiling at 398°. It is not easily kindled, but, when burnt, it gives forth a sooty smoky flame. It has a burning taste, and its odour is peculiar. From its great power of coagulating albumen, it is employed as a cure for toothache, a drop placed on the exposed nerve destroying its vitality. It is sparingly soluble in water, to which it gives its odour and taste. It is freely soluble in acetic acid, alcohol, ether, benzol, and tersulphide of carbon. It coagulates albumen immediately, and is the most powerful antiseptic known. Meat that has been plunged into a solution containing only 1 per cent. of this substance becomes dry and hard on exposure to the air, and does not become putrid.

CREATINE, OR KREATINE, *kre-a-teen'* (from Gr., *kreas*, flesh), an organic base obtained from the juice of flesh. Strong acids convert it into *Creatinine*, by the abstraction of the elements of water. Creatinine is one of the normal constituents of urine.

CREEPER, *kreep'-er* (*Certhia*).—With the exception of the yellow-crested wren, the common creeper (*Certhia familiaris*) is probably the smallest-bodied British bird: when fully grown its weight is only five drams. The bill is hooked, the legs slender, and the toes and claws very long. The nest of the common creeper is built in a hole in the bark of a tree, and is formed externally of hay and lined with feathers. It is a constant resident in Britain, but, owing to its bustling habit and swift movements, is seldom seen even in localities where it abounds. The wall-creeper (*Certhia muraria*), is a more rare bird in every other part of Europe save the south. Its colour is of a deep bluish-grey; the wing-coverts and middle quill-feathers black, those nearest the body edged with white. This bird clings to the vertical faces of walls and rocks, just as the common creeper attaches itself to the perpendicular surface of trees.

CRENIC ACID, *kre'-nik*, produced by decaying vegetation, especially in marshes and peat-bogs.

CRESS, a general name for many plants, the leaves of which have a pungent flavour, adapting them for salads, mostly belonging to the genus *Lepidium*, natural order *Cruciferæ*. The common Cress (*L. Sativum*) is well known as a salad ingredient, easily grown, even in winter, and generally combined with mustard. There are many other varieties of cress both in Europe and America, none of them, however, so familiar as the water-cress (*Nasturtium officinale*), one of the most wholesome of spring vegetables. It grows best in clear running water, and is extensively cultivated.

CRESCENTIACEÆ, *kres-sen-te-ai'-se-e*, the *Crescentia* or Calabash-tree family, a natural order of dicotyledonous plants in the sub-class *Corolliflorœ*. The order includes about 34 species, which have been arranged in 11 genera. They are natives exclusively of tropical regions. The sub-acid pulp, the fruit of *Crescentia Cujete*, the calabash-tree, is eaten by the negroes in Jamaica, and the hard shell is used for holding liquor or snuff, and for many other purposes. The fruit of *Parmentiara edulis*, another plant of this order, is eaten by the Mexicans, and that of *P. cerifera* is greedily devoured by cattle in Panama. The latter fruit resembles a candle in shape, and the plant is commonly called the candle-tree.

CRETACEOUS SYSTEM, *kre-tai'-she-us* (Lat., *creta*, chalk), in Geology, the name given to the last or uppermost of the secondary formations. (*See* GEOLOGY.) The life of the whole cretaceous period was abundant, as the known fossils within the British area represent land plants, fresh-water, and marine shells and fish, large terrestrial and marine reptiles, and species of every class of animal having hard parts capable of preservation, except birds and mammals; and even as regards these, most geologists believe their absence to be accidental, as both existed during the preceding period, though their fossil remains are very rare. The more important useful products of this system are chalk, flint, fuller's earth, phosphatic nodules, and the so-called "firestone rock." The two latter are extensively employed as manures.

CRETINISM, *kre'-tin-izm*, idiocy arising from imperfect formation or development of the brain, and generally accompanied with great bodily deformity. The name is of uncertain origin. Some derive it from *Chrétien* (Fr., a Christian), because they were generally regarded as beings incapable of sinning, and thus were viewed with some kind of respect. According to others, it is from the Romance of Grison *cretina*, a corruption of the Latin *creatura*, a creature. These unfortunate beings are chiefly to be met with in the valleys of the Alps, particularly in the Swiss cantons of Valais, Vaud, Grisons, Glarus, Uri, and Aargau; but they are by no means confined to these parts, being much more extensively spread than was at one time supposed. Cretinism is often accompanied with goitre (which *see*). There are various degrees of Cretins; some seem to be sunk in intelligence below the level of many of the brutes; while others are able to go about and attend to some easy labour. Many are deaf and dumb, and without the sense of smell. Their habits are usually dirty and obscene. The Cretin seldom attains more than 4½ feet in height. The cranium is deformed, and has a conical shape, the forehead being thrown backwards, narrowed, and flattened, and the occiput being nearly on a line with the neck. The eyes are small, the nose broad and flat, the mouth large and open, with the tongue often protruded, and the whole countenance is idiotic. The flesh is soft and flaccid; the skin wrinkled, yellowish, or pale and cadaverous; the belly large and pendulous; the limbs crooked, short, distorted; and the gait imperfect and waddling. The cause of this infirmity is still matter of dispute among physicians. Some attribute it to the nature of the water, by which an undue amount of calcareous matter is conveyed into the system; others to the stagnation of the atmosphere in the deep narrow valleys. M. St. Lager, after long and careful investigation, decided that Cretinism is confined to metalliferous districts, and occurs most frequently where iron pyrites and copper pyrites abound. There are other causes that may possibly exert an influence upon it; as the poor diet and filthy, lazy, and intemperate habits of the people among whom it exists, together with the intermarriages among near relatives. There can be no doubt that it is in some measure hereditary, though all the children of a family are not affected by it. Many attempts have recently been made to improve the condition of the Cretin. The first thing to be done as soon as the disease manifests itself (for in many cases it does not appear till some time after birth—sometimes not before the sixth or seventh year) is to remove the sufferer to a pure bracing atmosphere. The treatment required is first to get the body into a healthy condition, by simple and nourishing food, warm clothing, frequent bathing and friction of skin, and gentle exercise. The development of the mind will follow that of the body, but must be done very gradually. Dr. Guggenbühl was the first that made any systematic attempt to educate the Cretin. He opened his institution on the Abendberg, in the canton of Bern, Switzerland, in 1840; and since that time several other institutions for the same purpose have been established on the Continent.

CRICKET, *krik'-et* (Dut., *krekel*), a genus of orthopterous insects, allied to grasshoppers and locusts, and the type of a family, *Gryllidæ*, or *Achetidæ*. The hinder legs are long, and adapted for leaping. The wings are folded horizontally. The cause of the chirping noise made by the cricket, and which is so familiar to the fireside listener during the cold winter evenings, is simply the friction of the wing-covers against each other. The house-cricket is about an inch in length, and the *antennæ* often half again as long as the whole body. It is found in various parts of Europe, more particularly in the south. In Great Britain it is very abundant. Only in the winter months does the cricket take up its abode with man, usually selecting rooms on the lower floor, and greatly affecting the kitchen, where there is generally no lack of food lying about. Sometimes it selects chinks and crevices in which to hide, and often burrows in the mortar, where, through the long evenings, it chirps continuously. There is a prevalent superstitious notion that the presence of a cricket in a house is a sign of good luck, and that suggested the title of Dickens' famous Christmas book, "The Cricket on the Hearth." The field-cricket is also found in this country, but is not nearly so common as the preceding species. It is exceedingly reserved in its habits, avoids man, and prefers hot, sandy localities; it burrows in the ground, and there lies all the year round. The field-cricket is carnivorous, and preys upon other insects. It is larger than the common species, and its chirp is much louder. Another interesting species is the mole-cricket (*Gryllotalpa*) whose habits are very singular, and greatly resemble those of the animal from which it is named. In its structure, too, there is a remarkable similarity. This insect is continually engaged in excavating galleries under the earth, some of which are of considerable dimensions. To enable it to do this with perfection, its anterior limbs are connected into a pair of flat fossorial (digging) organs, which are in appearance much like the hand of the mole. In its burrowing processes, it does great injury to the roots of plants. The female of this species prepares a large chamber wherein to lay her eggs, which are said to be from two to four hundred in number. Until after the first moult, the young remain together, but then take their departure, and commence burrowing on their own account. The mole-cricket is usually about two inches in length, and is of a brown colour. The most extraordinary cricket is that found in Sicily (*Gryllus megacephalus*), which chirps sufficiently loud, it is said, to be heard distinctly at a mile distant.

CRINOIDEA, *kri-noid'-e-a* (Gr., *krinon*, lily; *eidos*, likeness), an extensive order of animals, chiefly fossil, belonging to the class *Echinodermata*, and so named from their lily-like appearance. In existing seas, the crinoids are represented by the *Comatulæ*, or feather-stars of our own shores, and by the rare and all but extinct *Pentacrinites* of the West Indies. The principal fossil families are described under the head of ENCRINITE.

CRINUM, *kri'-num*, a genus of plants with bulbous roots, of the natural order *Amaryllideæ*, having large tubular flowers. There are many species, natives of tropical and sub-tropical regions, and cultivated in our hot-houses on account of their great beauty. An Indian species

(*C. amabile*) flowers four times a year. The bulbs of an Asiatic species are sometimes used as powerful emetics in cases of poisoning.

CRISIS, *kri'-sis* (Gr., *krino*, I decide), the decisive period or event of a disease—a sudden and considerable change of any kind, occurring in the course of its progress, and producing an influence upon its character. Among ancient physicians, it was applied to that tendency which fevers were supposed to possess, of undergoing a sudden change at particular periods of their progress. Hence there were what were called *critical* days—certain days in the progress of an acute disease on which a sudden change, either favourable or unfavourable, would take place. The seventh, fourteenth, and twentieth or twenty-first days, were regarded as eminently critical.

CRITHMUM, *krith'-mum*. (*See* SAMPHIRE.)

CROCODILE FAMILY, *krok'-o-dile* (Gr., *krokodeilos*), the largest order of the Saurian order of reptiles. The tail is flattened at the sides; there are five anterior and four posterior toes, of which the three inner ones only on each foot are armed with claws; all the toes are more or less joined by membranes. There is a single row of pointed teeth in each jaw; and the tongue is fleshy, fat, and attached very nearly up to the edges, which led to the ancient belief that the crocodile was without a tongue. The back and tail are covered with large and strong square scales, elevated into a ridge on their middle. There is a deeply denticulated crest on the tail, at the base of which the crest becomes double. The scales of the belly are squared, small, and smooth. The nostrils are opened at the end of the muzzle by two small crescent-shaped slits, closed by small valves, and lead, by a long and straight canal pierced in the palatine and sphenoidal bones, to the bottom of the back part of the mouth. As the lower jaw is prolonged behind the skull, the upper jaw has the appearance of mobility, but it only moves in concert with the whole of the head. The external ear is shut at will by two fleshy lips. The eye has three lids. Under the throat are two small glandular orifices, whence issue a musky secretion. Crocodiles are oviparous. Their eggs are deposited in the sand or mud on the banks of the rivers they frequent; and the young, when hatched, immediately proceed to the water. The egg of the crocodile is not much larger than that of the goose; but it is very much harder, and its form more oblong. The prey of the crocodile is chiefly fish, but it derives a considerably part of its sustenance by lying in wait in the evening at the water's edge, and hauling into the water any small quadruped that may come to drink. Crocodiles exceeding thirty feet in length have been killed in Upper Egypt. The colour, when full grown, is blackish-brown above, and yellowish-white beneath; the upper parts of the legs and the sides are varied with deep yellow, and parts of the body bear a green tinge. No living specimen of this family is found in Europe, nor has any at present been discovered in Australia. The double crested, or Indian crocodile (*C. biparcatus*), is very abundant, and also very dangerous in many parts of Asia. The crocodiles are generally considered as forming a natural passage from the saurians to the chelonians, to the last genera of which, in certain points of their conformation and habits, they nearly approximate. The *Crocodilidæ* are divided into two great families,—The crocodiles proper, which are distributed in the Old and New world and the alligators (including caymans), which are peculiar to America.

CROCUS, *kro'-kus* (Gr., *krokos*), a genus of plants belonging to the natural order *Iridaceæ*. From the species *C. vernus* and *versicolor* numerous varieties have been produced by cultivation, which are of great value in the flower-garden, on account of the early appearance and remarkable brilliancy of their flowers. *C. sativa* is the saffron crocus. (*See* SAFFRON.)

CROSS, THE SOUTHERN, the most conspicuous constellation in the southern hemisphere, consisting of four bright stars. The two stars which mark the summit and foot of the cross serve as pointers to the Antarctic pole.

CROSSBILL, *kros'-bil* (*Loxia*), a genus of birds of the family *Fringillidæ*, having some resemblance to the bullfinch. The range of the crossbill extends from the north of Europe and Asia to Greenland and North America. The most singular characteristic of this bird is its beak, the upper and lower mandibles being equally curved, hooked, and the elongated points crossing each other. Its favourite food is the fruit of the pine, and of the efficacy of the crossed mandibles in splitting and extracting the kernels from nuts there can be no doubt. The chief colour of the crossbill's plumage is ashy-grey, with a greenish tinge on the upper parts, while the lower parts are yellowish green. Its bill is horn-colour; its length about six inches. This is the plumage of the adult bird; after the first moult, however, and until the bird is a year old, all its upper and lower parts are of a tarnished red, more or less tinged with green and yellow; while the lower coverts of the tail are white, with a brown spot in the centre. Only three species are known; but one, the common crossbill (*L. carvirostra*) is frequently met with in this country.

CROSSOPODIA, *kross-o-po'-de-a*, a genus of annelids, now extinct, and the existence of which is inferred from markings on the surface of Silurian slates. They are supposed to have been worms about six inches in length.

CROTALARIA, *kro-ta-lai'-re-a* (Gr., *krotalon*, rattle; on account of the rattling of the seeds in their inflated pods, when shaken), a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Papilionaceæ*. *C. juncea*, an Indian plant, furnishes a coarse fibre, called *sun*, *sunn*, *shunum*, *taag*, or *Bengal hemp*, which is often confounded with *sunnee*, the fibre of the *Hibiscus cannabinus*. *C. tenuifolia*, another Indian species, is the source of the Jubbulpore hemp.

CROTALUS. (*See* RATTLE-SNAKE.)

CROTON, *kro'-ton* (Gr., *kroton*, the dog-tick, in reference to the resemblance of the seeds to that vermin), a genus of plants belonging to the natural order *Euphorbiaceæ*. The seeds of the species *C. Tiglium*, and probably also those of *C. Pavana*, constitute the *croton*, or *tiglium seeds*, of the materia medica. The seeds are used without preparation, in India, as purgative pills. *C. Eleuteria* and *Cascarilla*, natives of the Bahama islands and Jamaica, yield the aromatic tonic bark commonly known as *cascarilla* or *eleutheria bark*. *C. pseudo-China* yields the *quilled copalche bark* of Pereira, and *C. suberosum* the *corky copalche* *bark* of the same author. In their medicinal properties the copalche barks resemble cascarilla. The aromatic bark known as *Malambo bark* is the produce of *C. Malambo*. It is extensively used in Columbia as a remedy in diarrhœa and as a vermifuge; also externally, in the form of an alcoholic tincture, in rheumatism.

CROTOPHAGA, *kro'-to-fa-ga* (Gr., tick-eater), a genus of birds of the order of the Climbers. *C. ani*, the Savanna blackbird, is common in the West Indies and tropical America. It feeds on berries and insects, and perches on the backs of horses or cattle and picks out and devours the troublesome ticks.

CROUP, *kroop* (Ang.-Nor.), an acute inflammation of the mucous membrane of the larynx, but frequently extending also to the trachea and bronchial tubes. It is very prevalent and fatal among infants, and is usually preceded by the symptoms of a common cold, with hoarseness and a harsh cough, pain in the head, fever, and swelling and redness in the back of the throat; but it may make its appearance suddenly during the night, and in the midst of apparent health. In a short time the respiration becomes noisy and difficult, accompanied by a crowing sound during inspiration; the face is red and swollen, the eyes suffused, the head thrown back, and everything indicates the great sufferings of the patient. In extreme cases as the disease advances, the breathing becomes more difficult, the cough more suffocating, the voice stifled, and the countenance livid; and gradual insensibility or convulsions at length close the scene. The fatal issue often takes place in thirty hours, and even less; but most frequently it happens about the end of the second day, though it has sometimes been known to run on to the fourth, fifth, or sixth day. The disease is most common between the first and tenth year, and rarely occurs after the age of puberty, though occasionally it is to be met with among adults. It is most common in cold, damp seasons and in low marshy localities. In so rapid and fatal a disease, medical advice ought to be immediately obtained. Bleeding, except by leeches, is not now generally approved of by medical men: some recommend emetics and purgatives; others opium and calomel. Warm bathing, or sponging with warm water, should be had recourse to, as well as the inhalation of a watery vapour.

CROW, COMMON, OR CARRION, *kro* (Sax., *crawe*) (*Corvus Corne*), the type of the family *Corvidæ*. The raven, jackdaw, and rook belong to the same genus. This common bird is spread over the Old and New continents, and feeds, like the ravens, on any sort of animal offal, or, when this is not attainable, on worms, moles, mice, caterpillars, grubs, beetles, &c. In the winter it associates with the rooks, and may be seen with them busily turning over the earth in search of food. The nest, like that of the rook, is constructed at the summit of a tree of slender branches, matted with clay and horse-dung. The hen lays four or five eggs of a palish green, sometimes blurred and spotted with a darker colour. They lay but once in the year, unless the young or the eggs be destroyed by accident. The hooded crow (*Corvus cornix*) is rather larger than the common crow, with black head, throat, wings, and tail. Its name is derived from the contrasted black head and grey body. It is more ferocious than the carrion crow, and has been known to pick out the eyes of lambs, and even of horses helplessly hampered in bogs. The Alpine crow, or chocard (*Pyrrhocorax alpinus*), has the compressed arched and sloped beak of the blackbird; but its nostrils are covered with feathers like those of the crow, to which it has been annexed. It builds in the clefts of rocks of the higher mountains, descending in immense flocks to the valleys. The nut-cracker crow is, although not a true crow, allied to the family in several particulars. It is not uncommon in many parts of Europe, but rarely visits England.

CROWBERRY. (*See* EMPETRACEÆ.)

CROWFOOT. (*See* RANUNCULUS.)

CROZOPHORA, *kro-zo-fo'-ra*, a genus of plants belonging to the natural order *Euphorbiaceæ*, and containing one remarkable species, namely, *C. tinctoria*, a native of the south of France. This yields, by expression, a green juice, which is converted, by the combined action of ammonia and the air, into the purplish dye called *turnsole*.

CRUCIAN, *kru'-se-an*, a fish (*Cyprinus carassius*) of the Carp genus, but larger. It is a native of the northern parts of Europe and Asia; but is occasionally found in the Thames (to which it has been perhaps introduced), and is known as the German carp.

CRUCIFERÆ, OR BRASSICACEÆ, *kru-sif'-e-re* (Lat., *crux*, cross; *fero*, I bear), the Cruciferous or Cabbage family, a natural order of exogenous plants in the sub-class *Thalamifloræ*. There are 195 genera, consisting of about 1,600 species, which are principally herbaceous plants. The general properties of the *Cruciferæ* are almost as definite as the botanical characters. The possession of antiscorbutic and stimulant properties, combined with an acrid flavour, may be said to constitute a universal character. The pungency of cruciferous plants depends on a volatile oil composed of carbon, hydrogen, nitrogen, oxygen, and sulphur. An oil expressed from the seeds is one of the most important products. None of the plants of the order, with one or two doubtful exceptions, are poisonous; many of them are esculent vegetables. The disagreeable odour emitted by them when decaying is attributed to the sulphur and nitrogen which they contain.

CRUST OF THE EARTH. (*See* GEOLOGY.)

CRUSTACEA, *krus-tai'-she-a* (Lat., *crusta*, a hard shell), a class of articulated animals whose external covering is less solid than that of the majority of testaceous mollusca, but much firmer and harder than the skin of the naked mollusca. In the larger animals, this covering contains a large amount of phosphate and carbonate of lime, and may be considered as intermediate between shell and bone. This skeleton may be regarded as a kind of epidermis, for beneath it is found a membrane like the true skin of higher animals. At certain times this solid envelope detaches itself and falls off, assisted by the efforts of the animal. Crustaceans have articulated limbs, and breathe by gills, being in that respect adapted for an aquatic life. The digestive organs are very simple, consisting of a short gullet, a large stomach, and a straight intestinal tube. The principal organ of locomotion in some crustacea, as the lobster and shrimp, is the abdomen, which terminates in fan-like appendages; and by bending the abdomen suddenly down under the thorax, they move swiftly backwards. The eggs are carried, during incubation, under the abdomen or thorax of the female. Many crustacea, especially the crab, undergo curious metamorphoses. The greater number are marine, some inhabiting fresh water.

CRYOLITE, *kri'-o-lite*, a double fluoride of aluminium and sodium, the source of the metal aluminium. (*See* ALUMINIUM.)

CRYOPHORUS, *kri-of'-or-us* (Greek, *kryos*, cold, and *phero*, I carry), a glass tube, with a bulb at each end, used for performing the experiment of making ice. In one of the bulbs is water, in the other water vapour. When the apparatus is placed in a freezing mixture (*see* FREEZING MIXTURES) the vapour condenses, and more vapour rises from the water in the other bulb, causing an abstraction of heat and the freezing of the water. The operation of the instrument is thus explained—We know that heat determines the form in which matter exists, and that as gas is a liquid *plus* heat, and therefore requires heat for its production. In the cryophorus we have a certain amount of aqueous vapour, the pressure of which upon the water in the distant bulb prevents further evaporation—in fact, the vacuum is saturated; but when the vapour is condensed by the freezing mixture, the pressure disappears and the water emits its vapour into the resulting vacuum, and thereby loses heat, since the water requires heat before it can become vapour. When this vapour is condensed, a further quantity is supplied by the water which is still more chilled, and this action continues until it is frozen by its own evaporation.

CRYPTOGAMOUS PLANTS, *krip-to-ga'-mus*, the lowest in organization of all the members of the vegetable system. They have no true flowers, and no known organs of fructification. The seeds, or spores, germinate indifferently from any point. (*See* ACOTYLEDONS.)

CRYSTALLINE LENS, *kris'-tal-line* (Lat., *crystallus*, a crystal; *lens*), the lens of the eye. (*See* EYE.)

CRYSTALLIZATION, *kris-tal-li-zai'-shun*, the spontaneous assumption of well-defined geometrical forms by bodies in passing from the fluid or aëriform state to the solid condition. Bodies not capable of assuming the crystalline form are termed *amorphous* or *colloid*; those which form crystals, *crystalloid*. When a substance crystallizes in two distinct forms, which cannot be derived from the same original, it is said to be *dimorphous*. Sulphur, for instance, will crystallize in octahedra or prismatic crystals. Some substances are even *trimorphous*. Sulphate of nickel crystallizes in right rhombic prisms, square-based octahedra, and oblique rhombic prisms, according to the temperature at the time of evaporation. Bodies crystallizing in similar forms are called *isomorphic*. The alums and fluor spar: carbon, gold, copper, and their compounds; the potassium compounds of chlorine, iodine, bromine, and fluorine, form *isomorphous* groups.

CTENOID FISHES, *te'-noid*, an order of fishes characterised by rounded or ovoid scales, with sharp projections on the outer margin. Turbot, flounders, and perches are examples.

CUBE, *kube* (Gr., *kubos*, a die), a solid body with six square equal faces, and occupying among bodies a place analogous to that of the square among surfaces. It is also called the hexahedron, by reason of its possessing six sides. One of the most perplexing of all geometrical problems has exercised the minds of mathematicians from the time of Hippocrates of Chios to that of Descartes—to find the side of a cube the contents of which should be twice the size of another given cube. It was known as the Delian problem, from the tradition that the oracle of Apollo in the island of Delos, told the people that they must make the altar of Apollo, of cubic form, twice the size, to obtain relief from a pestilence. The alter was enlarged by adding another cube of the same size, but that did not satisfy the oracle, as the form of a cube was lost. Descartes proved that the solution was impossible by geometry; but in arithmetic it can be arrived at by the extraction of the cube root.

Cube Root.—In Arithmetic, the cube of a number is the product of its multiplication three times by itself, and that number is the "cube root." Thus, 5 is the cube root of 125, because $5 \times 5 = 25 \times 5 = 125$.

Cubic Equations. (*See* EQUATIONS.)

CUBEBA, *ku-be'-ba* (Arab., *cubabah*), a genus of plants belonging to the natural order *Piperaceæ*. The species *C. officinalis*, a native of Java and Prince of Wales' Island, yields the berries called cubebs, which are extensively employed in medicine for their peculiar power of arresting excessive discharges from the urethra. Cubebs resemble black pepper, but may be distinguished by the network of raised veins on their surface, also by the short stalks which they possess.

CUCKOO, *koo'-koo* (Lat., *cuculus*; Fr., *coucou*) (*Cuculus canorus*).—This bird (the type of the family *Cuculidæ*, which includes many species), which derives its name from the peculiar sound of its note, is very widely diffused. It is found in India and in Africa, and migrates northward in summer, even to Lapland and Kamtchatka. It makes its appearance in England in April, and disappears again by about the middle of August. The tail is long and rounded, the wings long, and the toes are so placed as to give great facilities for grasping branches. There is no pairing or continued attachment between the male and female, and the latter generally, if not always, lays her eggs in the nest of some other smaller bird, leaving their hatching and future maintenance to fate. The gratitude of the foster child is of a piece with its parent's heartlessness; for as soon as it attains sufficient size and strength, it ejects the eggs or the young birds, the true offspring of the birds which have hatched it. The hedge-sparrow, the pied wagtail, and the yellow-hammer, are the birds commonly selected by the cuckoo for imposition. The gilded cuckoo (*Cuculus auratus*) is an inhabitant of the Cape of Good Hope, and extremely common in Kaffraria. It is a very beautiful bird, the chief of the plumage being brilliant green with golden reflections. It is about seven inches long. Like the common cuckoo, it deposits its eggs in the nests of other birds, but is supposed to carry them thither in its mouth. The spotted cuckoo (*Oxylophus glandarius*) is an inhabitant of the north of Europe; the oriental cuckoo (*Eudynamys orientalis*) is found in the East Indies; and there is also the yellow-billed American cuckoo (*Coccyzus americanus*), likewise called the cow-bird and the rain-crow.

CUCKOO-FLOWER. (*See* CARDAMINE.)

CUCKOO-PINT. (*See* ARUM.)

CUCUMBER, *ku'-kum-ber* (*Cucumis*), a genus of plants belonging to the natural order, *Cucurbitaceæ*. The fruit of *C. sativus* is the common cucumber, a native of Asia, but which has been cultivated in Europe for very many centuries as a favourite article of food. There are many varieties, some only a few inches long, some approaching two feet. Although in some of the southern counties of England cucumbers are grown in open fields, hotbeds with lights are generally required. Long cucumbers, "gherkins," are pickled. Cucumbers were brought into England from the Netherlands about 1538.

CUCURBITACEÆ, *ku-kur-bit-ai'-se-e*, the Gourd or cucumber family, a natural order of dicotyledonous plants in the sub-class *Calyciflorœ*. Upwards of 60 genera have been described, and these include more than 300 species. The plants are mostly herbaceous, natives of hot climates in almost every part of the world; they abound in the East Indies; many occur in Peru and Brazil; a few are found in Europe and North America; and one species only, *Bryonia dioica*, in the British isles. They are all herbs with tuberous or fibrous roots, which are annual or perennial, and with stems which are generally succulent, and either prostrate or climbing by means of tendrils. An acrid, bitter, purgative principle characterises the plants of this order, and is especially evident in the pulp surrounding the seeds. In some cultivated species the acridity is scarcely perceptible, and the fruits are edible. To this order belong the cucumber, melon, pumpkin, vegetable marrow, and the numerous gourds. (*See* separate headings.)

CUDBEAR. (*See* LECANORA.)

CUDWEED, *kud'-weed*, a name commonly given to various species of plants of the natural order *Compositæ*. They are small, and the heads of the flowers may be kept for a long time without decaying.

CUICHUNCHULLI, *kwi-kun-kool'-e*, a plant (*Ionidium parviflorum*) of the natural order *Violaceæ*, a native of Peru. It is shrubby, with very small leaves, possessing active emetic and purgative properties. The species is commonly known as white ipecacuanha.

CULEX, *ku'-leks* (Lat., a gnat), a genus of the *Diptera* or two-winged insects, constituting the Gnat family. They are characterised by their length of proboscis and their finely-tufted antennæ. (*See* GNAT, MOSQUITO.)

CULM, *kulm*, a slaty kind of anthracite, occurring in Wales and North Devon. The strata in which it is found are often called the *culm measures*.

CULMINATION, *kul-min-ai'-shun* (Lat., *culmen*, the top of anything).—When any heavenly body is on the meridian, it has then attained the highest point of its daily course, and is therefore said to culminate. The sun culminates at mid-day, the moon at midnight, when it is full moon.

CUMINUM, *ku-mi'-num* (Gr., *kuminun*), a genus of composite plants. *C. Cyminum*, the cumin, is a dwarf fennel-looking plant, cultivated in the south of Europe and Asia Minor, for its fruits, which are hot and aromatic, like those of the caraway and anise. The fruit is used as a carminative, and with resin as a plaster, but chiefly in veterinary practice. In Germany it is often put into bread.

CUNNINGHAMIA, *kun-ning-ha'-mi-a*, the name given to a genus of trees of the natural order *Coniferæ*, in general characteristics resembling the pines and firs, but differing in the foliage.

CUNONIACEÆ, *ku-non-e-ai'-se-e*, a natural order of dicotyledonous plants in the sub-class *Calyciflorœ*. They are nearly allied to the *Saxifragaceæ*, but differ from them in being trees or shrubs, with opposite leaves and large interpetiolar stipules. They are natives of South America, the Cape, the East Indies, and Australia. Most of them have astringent properties, and some have been used for tanning.

CUPANIA, *ku-pai'-ni-a* (in honour of Cupani, an Italian monk and botanist), a genus of plants belonging to the natural order *Sapindaceæ*. The species *C. sapida* flourishes in the West Indies, and the distilled water of the flowers is used by the negro women as a cosmetic, and the seed is eaten for dessert. The fruit containing the seeds is commonly known as the akee-fruit.

CUPILIFERÆ, *ku-pil-i-fer'-e*, a name given by some botanists to the Oak or Mastwort order. (*See* CORYLACEÆ.)

CUPPING, *kup'-ping* (from the cup-like form of the glasses employed), the application of cupping-glasses, from which the air has been previously extracted, to the skin, with the view of attracting blood to the part, and, if necessary, abstracting it. Cupping was practised by the ancients, and is frequently had recourse to in the present day. In performing the operation, a small bell-shaped glass, from which the air has been partially expelled by holding it for an instant over the flame of a spirit-lamp, is applied to the spot, and the usual amount of pressure on the part being thus diminished, the blood flows towards it, producing a distension of the blood-vessels and an elevation of the surface. This is called *dry cupping*, and is frequently of great service in the removal of certain kinds of pain. When it is intended to abstract blood, the cupping-glass is removed as soon as the part is sufficiently swollen, and the scarificator applied to it. This instrument contains a number of lancets (usually about ten or twelve), which, by touching a spring, are made to inflict a corresponding number of wounds, the depth of which may be regulated by the operator. Immediately on the wounds being made, the cupping-glass is applied, exhausted as before, and the blood allowed to flow into it until a sufficient quantity has been extracted. Cupping is preferable to any other method of blood-letting in many kinds of inflammatory disease; and the operation requires so much skill that it is generally practised as a separate branch of the surgical profession.

CUPRESSUS, *ku-pres'-sus* (Gr., *kuo*, I produce; *parisos*, equal, because it bears equal branches), the Cypress, a genus of plants belonging to the natural order *Coniferæ*. *C. sempervirens* is a common timber-tree in some parts of the Levant. Its dark foliage is particularly impressive when seen near architectural works; and on this account the tree was always planted by the Moors round their splendid palaces, and by the Romans near their villas. In the burial-grounds of Turkey and Arabia, the tombs of the faithful are generally shaded by the cypress. The timber of this and other species are very durable, and is said to resist the worm. The doors of St. Peter's church at Rome are of cypress-wood, and have lasted upwards of 1,100 years. It is supposed that the gopher-wood of the Bible was chiefly obtained from a species of this genus.

CUPULIFERÆ, OR CORYLACEÆ, *ku-pu-lif'-e-re*, a natural order of exogenous plants, so named from bearing cupules, or cups formed by a number of cohering bracts, surrounding the fruit or the base of the fruit, as in the acorn and hazel-nut.

CUPRITE, *ku'-prite*, the red oxide of copper, which is also known as octahedral copper-ore, from the form of its crystals.

CURASSOU, OR HOCCO, *ku-ras'-so, hok'-ko*, a genus (*crax*) of large gallinaceous birds of the family *Cracidæ*. They are natives of the forests of tropical America. The bill is strong, and surrounded at the base with a skin sometimes brightly coloured. They live in flocks, and are easily domesticated. The most familiar species (*C. Alector*) is about the size of a turkey, and of black colour. It is commonly kept in poultry yards in South America, and the flesh is tender and of agreeable flavour.

CURCULIO, *ker-ku'-li-o*. (*See* WEEVIL.)

CURCUMA, *kur-ku'-ma* (Arab., *kurkum*), a genus of plants belonging to the natural order *Zingiberaceæ*. The dried tubers or rhizomes of *C. longa* constitute the *turmeric* of the shops. (*See* TURMERIC.) The rhizomes of another species, *C. angustifolia*, contain much starch, which forms East Indian arrowroot, or curcuma starch.

CURLEW, *kur'-lew* (Fr., *courlis* or *corlieu*, a bird of the genus *Numenius* of the order *Grallatores*, and of the same family as the snipe and woodcock. The common curlew (*N. arquata*) is characterized by a long, slender, incurved bill, slightly compressed and furrowed for three-fourths of its entire length; it has a blunt tip; wings ample; tarsi naked above the joints. In length the curlew measures about two feet, and, in the case ef the male, the whole plumage is bright ash-colour, with longitudinal brown spots on the head and breast; upper mandible blackish brown; lower mandible flesh-colour; iris brown; feet deep ash. The curlew is very common in most parts of Europe, and occurs in parts of Asia. It inhabits the vicinity of waters and marshy wastes, and feeds on earth-worms, slugs, small testaceans, and insects. Its nest, a careless construction of dried grass and leaves, is usually placed among the rushes. Its eggs are large, over two and a half inches in length, of an olive-green colour blotched with deep brown. A smaller species is known as the whimbrel (*N. phæopus*), and there is the Esquimaux curlew (*N. borealis*).

CURRANTS, *kur'-rants* (from Corinth, where they were originally grown), the dried fruits of a variety of the grape-vine, now extensively cultivated in Zante and several other of the Greek islands. The currants of English gardens, red, white, and black, are the produce of species of *Ribes* (which *see*).

CURRENTS, *kur'-rents* (Lat., *currere*, to run), the name given to water running in any direction, and, in navigation, to the courses in which the water in certain parts of the ocean is always moving, with a constant and generally uniform motion and in the same direction. These currents greatly tend to accelerate or retard the motion of any vessel that comes within their influence. Two different kinds are to be distinguished in the ocean—the drift current and the stream current. Ocean currents are of great breadth, and in some cases sweep across from one continent to another. (*See* EQUATORIAL CURRENT, GULF STREAM, OCEAN, and TIDES.)

In Electricity, the electrical current is the passage of the electric fluid from one pole of an apparatus to another. (*See* ELECTRICITY.)

CURVE, *kerv*, in Geometry, a line which, running on continually and gradually in all directions, may be cut by a right line in more points than one. The theory of curves forms a very important branch of the higher portion of mathematical science; but only those curves that follow some law in their change of direction can form the subject of geometrical speculation. The law of the circle is that all portions of the curve are equidistant from one point called the centre. Descartes divided all curves into two classes—*geometrical* and *mechanical*. It is now the custom to indicate the same distinctions by the the terms *algebraic* and *transcendental*. The curve is called algebraic when its equation only contains the powers of x and y; and it is called transcendental when the equation contains other functions, such as logarithms of x and y. Algebraic curves are divided into different orders, according to the degree of the equation which expresses the relation between their co-ordinates. Straight lines are said to be of the first order, because the equation of a straight line contains no powers or products of the variables x and y. Curves of the second order are those of which the equation rises to two dimensions, and the curves which it includes are the circle, the ellipse, the hyperbola, and the parabola. Out of the infinite number of curves that can be drawn, very few comparatively have received definite names. Subjoined is a list of the curves that are of usual occurrence: circle, ellipse, hyberbola, parabola, semi-cubical parabola, cissoid of Diocles, conchoid of Nicomedes, trisectrix, lemniscata, cycloid, companion of the cycloid, harmonic curve, trochoid, epicycloid and cardioide, hypocycloid, epitrochoid, hyptrochoid, curves of sines, cosines, tangents, &c., exponential or logarithmic curve, spiral of Archimedes, logarithmic spiral or equiangular spiral, reciprocal spiral, lituus quadratus of Dinostratus, quadratrix of Tchirnhausen, octenary tractory, tractrix, syntractory, ovals of Cassini, Watt's parallel-motion curve.

In Geology, the terms *anticlinal* and *synclinal curves* are applied to the elevations or depressions in undulating strata. The wave of the ridge in the anticlinal, and the trough of the valley, the synclinal curve.

In Magnetism.—The lines into which iron filings arrange themselves under the influence of a magnet are called magnetic curves. The lines thus traced are of great interest, as they show the lines of magnetic force due to the particular arrangement of magnetic matter used.

CUSCO-CHINA, *kus'-ko*.—Three different barks pass under this name, one the produce of *Cinchona scrobiculata*, called in Peru red Cusco bark. The second appears to be the produce of *Chinchona pubescens*. There is also a third, which is, perhaps, the white Jaen. The alkaloid is procured by the same process as is used for cinchonia, which it resembles in its physical qualities; but differs from in its chemical habitudes. The taste is more bitter, rather heating, and sub-astringent.

CUSCUTACEÆ, *kus-ku-tai'-se-e*, the Dodder family, a small natural order of dicotyledonous plants, which is generally regarded as a subdivision of *Convolvulaceæ*. The plants composing it are distinguished from those of that order by their parasitic habit, by the absence of leaves, by the tube of the corolla being furnished with scales alternating with the segments, and by having a thread-like coiled embryo with almost obsolete cotyledons. They are chiefly natives of temperate climates, and are often very destructive to flax, clover, and other crops.

CUSP, *kusp* (Lat., *cuspis*, a point).—When two curves touch, or appear to touch each other, and terminate in a point at which they have a common tangent, this point is called the cusp of the curve. Cusps are of two kinds: in one, the tangent lies on one side of both curves, and their convexities are both turned in the same direction towards the tangent; in the other the tangent lies between the curves, and their convexities are turned towards the tangent in opposite directions.

CUSPARIA BARK. (*See* ANGUSTURA BARK.)

CUSSO. (*See* KOSSO.)

CUSTARD-APPLE. (*See* ANONA.)

CUTANEOUS DISEASES. (*See* SKIN, DISEASES OF THE.)

CUTICLE. (*See* SKIN.)

CUTTLE-FISH, *kut'-tl fish* (Ang.-Sax.), a molluscous animal of the genus *Sepia*, order *Cephalopoda*. The body is somewhat oval, but broader at the head than at the extremity, which is obtusely pointed, The eyes are very large; and the head is furnished with eight arms and two feet, the latter being nearly similar in structure to the arms or tentacula, but considerably longer in their dimensions. A neck divides the head from the body, which is furnished on each side, throughout its entire length, with a narrow fin. The back of the cuttle-fish is strengthened by a calcareous plate, well known as the *cuttlefish-bone*. This bone was in former times in great repute among apothecaries as an absorbent; but now it is chiefly used in the form of a powder, to polish the softer metals. The term bone, however, is properly inapplicable to the calcareous shield of the cuttle-fish; as in its composition it is exactly similar to shell, and consists of various membranes hardened by carbonate of lime, without the smallest mixture of phosphate. This animal is sometimes termed the ink-fish, a name that arises from the circumstance that beneath its throat is a bladder, in which is secreted a fluid black as the blackest ink, and which, when annoyed or pursued, it ejects, so staining the water around it, that it is an easy matter for it to escape unperceived. This fluid furnishes the valuable pigment sepia. It likewise possesses the chameleon-like power of changing its colour. The eggs of the cuttlefish are cast ashore, often in clusters, and are commonly known as sea-grasses.

CYANIC ACID, *si an'-ik*. (*See* CYANOGEN.)

CYANITE, *si'-an-ite* (Gr., *kuanos*, blue), a mineral belonging to the garnet family, occurring in broad prisms in mica and talc schists, and composed of alumina and silica. Transparent cyanite is often used for sapphire; but it may be known by its inferior hardness.

CYANOGEN, *si-an'-o-jen* (Gr., *kuanos*, blue, and *gennao*, I produce). Cyanogen, or bicarbide of nitrogen, is one of the most interesting of the carbon compounds, its discovery by Gay-Lussac in 1814 having thrown considerable light upon two important facts in chemical science—the existence of compounds acting as elements, and of substances having the same ultimate composition, but different properties. In fact, it was the means of originating new theories with respect to organic bodies generally. The name *cyanogen*, was bestowed on this substance in consequence of its forming an essential ingredient in Prussian blue.

CYANOSIS, OR BLUE DISEASE, *si-an-o'-sis* (Gr., *kuanos*, blue), a diseased condition of the system, arising from a malformation of the heart, which, allowing the intermixing of the venous with the arterial blood, in consequence of which the former is not properly oxygenized, and a blueness is imparted to the skin, whence the disease takes its name, and the capillaries and minute veins, especially of the face, are overcharged.

CYATHEA, *si-a'-the-a*, a genus of ferns of the sub-order *Polypodiaceæ*. There are many species, tree-ferns of great beauty, natives of tropical and sub-tropical regions. The common tree-fern (*C. arborea*) is a native of the West Indies and Brazil. The roots of a New Zealand species (*C. medullaris*) are baked and eaten as food.

CYATHOPHYLLUM, *si-ath-of-il'-um*, fossil corals, very abundant in the Devonian strata.

CYCADACEÆ, *si-ka-dai'-se-e*, the *Cycas* family, a natural order of dicotyledonous plants, in the sub-class *Gymnospermia*, consisting of small palm-like unbranched trees or shrubs, with stems marked by the scars of leaf-stalks. In a few species the stem divides in a forked manner, and leaves are clustered at the summit. The plants are principally natives of the temperate and tropical parts of America and Asia, and are also found occasionally at the Cape of Good Hope, in Madagascar, and Australia. Their stems and seeds yield mucilage and starch. The product known as Japan sago is obtained from the cellular substance of the interior of the *Cycas revoluta*, and a similar product is obtained from other trees in the Indian Archipelago and in Mexico.

CYCADITES, *si'-ka-dites*, fossil plants of the oolite and chalk, apparently allied to the existing *Cycadaceæ*. The leaves are only known.

CYCHLA, *si'-kla*, a genus of fishes of the *Chromidæ* family, found in the rivers of tropical America. They are remarkable for the beauty of their colours, and their flesh is considered a delicacy.

CYCLAMEN, *si'-kla-men*, a genus of plants of the order *Primulaceæ*, chiefly natives of the south of Europe, and herbaceous perennials. They are cultivated in this country as spring garden flowers, being very beautiful and fragrant. The underground stems are acrid, but pigs are very fond of them, which gives rise to the common name "sow-bread;" and an ointment is prepared from them which, applied externally, assists to expel intestinal worms from children.

CYCLOBRANCHIATA, *si-klo-brank-i-a'-ta* (Greek, circle-gilled), an order of gasteropodus mollusca including the limpets and chitons. The gills generally form a series of lamellæ, surrounding the body.

CYCLOID, *si'-kloid* (Greek, circle-like), the curve described by a point on the circumference of a circle rolling along a straight line on its own plane. The properties of this curve are very interesting to geometricians; and it is sometimes known as the isochronous, or equal time curve, from the fact that the time occupied in the descent of a body from rest from any point in the arc of an inverted cycloid, is the same from whatever point of the curve the body begins to descend; and having reached the lowest point, will, through the impetus received in the fall, ascend the opposite side of the curve to a height equal to that from which it fell, occupying exactly the same time in ascending as it did in descending.

CYCLOID FISHES, fishes having scales formed of concentric layers, not always overlapping, and not covered with enamel. Fossil fishes of this character are very numerous in the more recent strata.

CYCLONES. (*See* STORMS.)

CYCLOPS, *si'-klops*, a genus of minute crustaceans of the order *Branchiopoda*. The soft and gelatinous body is divided into two portions, one consisting of the head and thorax, the other of the tail. There is only one eye, generally of a bright crimson colour. There are many species, both in salt and fresh water, generally found among aquatic plants.

CYDONIA. (*See* QUINCE).

CYGNET, a young swan. In Heraldry, a cygnet royal is a swan with a ducal coronet and a chain.

CYGNUS, *sig'-nus*, (Lat., *cygnus*, a swan), a constellation in the northern hemisphere, situated between those of Cassiopeia and Lyra. Its brightest star is one of the second magnitude.

CYLINDER, *sil'-in-der* (Gr., *kulindo*, I roll), a solid body which has three surfaces, one of which is convex and continuous, and the other two parallel. A right cylinder is one in which the line joining the centres of the limiting circles is perpendicular to their plane. All other cylinders are oblique. A right cylinder, taken in this view, may be conceived as described by a rectangular parallelogram, revolving about one of its sides.

CYMA RECTA, *si'-ma rek'-ta* (Lat., *cyma*, a little shoot, a branch; *recta*, right), in Architecture, the name given to a moulding which somewhat resembles the letter S, hollow in the upper part and projecting below. When this order is changed, and the projection is above instead of below, the moulding is called *cyma reversa*. The upper part of the cornice of an entablature, being generally in the form of this moulding is known as the *cymatium*.

CYME, *sime* (Gr., *kuma*, a sprout, a common, term for the different kinds of definite inflorescence; that is to say, for every inflorescence formed of a terminal flower, beneath which are lateral branches, each having a terminal flower, and the lateral branches again similarly dividing, and so on.

CYNANCHUM, *si-nan'-kum*, a genus of plants of the natural order *Asclepiadaceæ*, having a wheel-shaped corolla. The *C. Monspeliacum*, a herbaceous twining plant, growing on the shores of the Mediterranean, yields a strong purgative drug known as Montpellier scammony. From *C. ovafolium*, a native of Penang, caoutchouc is obtained.

CYNARA, *sin-ai'-ra* (from Gr., *kuon*, a dog, in allusion to the spines of the involucrum), a genus of plants belonging to the natural order *Compositæ*. It includes the *artichoke* and *cardoon* (which *see*).

CYNODON, *si'-no-don*, a genus of grasses, with epitelets on one side. The principal pasture grass of India known as *dhob*, or *doorba*, belongs to this genus.

CYNOMORIUM, *si-no-mor'-i-um*, a genus of parasitic plants of the natural order *Rhizanthaceæ*. A fungus-looking species, *C. coccineum*, grows abundantly in Malta and the neighbouring island Gozzo, and is highly valued as a styptic and astringent. The old knights of Malta valued it so highly, that the grand master sent it as a present, of this "fungus Melitensis" to kings and princes. A keeper of the rock on which it grows is still appointed by the Government.

CYNOSURE, *si'-no-sure* (Greek, *kunosoura*, the tail of the dog), the constellation Ursa Minor, or the Little Bear, of which the principal star is the pole-star. As the other constellations appear to revolve round this, the word is used in poetry (especially by Milton, in *L'Allegro*), to express some central object on which all eyes are fixed.

CYPERACEÆ, *si-per-ai'-se-e*, the Sedge family, a natural order of monocotyledonous plants in the sub-class *Glumaceæ*, consisting of grass-like or rush-like herbs, natives of all parts of the world, and found especially in marshes, ditches, and the neighbourhood of running streams. The stems are solid, often angular, and are without joints or diaphragms. Although closely allied to the *Graminaceæ* (grasses), the plants of this order are of little use to man, their seeds being deficient in those nutritive qualities which render the seeds of the cereals so valuable. There are about 2,000 known species. The rhizomes, tubers, or corms, of some species of the typical genus *Cyperus* were formerly employed in medicine as aromatic tonics and astringents. The *C. esculentus*, or rush-nut is cultivated in southern Europe, and the farinaceous tubers are called by the French earth-almonds. They contain oil, and on that account are largely exported. In India, the tubers of some species are cooked and eaten; and the fibre of *C. textilis* is used for making mats.

CYPRINIDÆ, *si-prin'-i-de*, a family of malacopterous (soft-finned) fresh-water fish, including carp, barbel, dace, roach, and other well known fish abounding in lakes and rivers. *Cyprinadontidæ* is the name given to a family of fishes, found in America and Asia, both in fresh and salt-water, similar in general characteristics to the *cyprinidæ*, but with more protractile and toothed jaws. (*See* ANABLEPS.)

CYPRIS, *si'-pris*, a genus of minute thin-shelled crustaceans, of the order *Branchipoda*. (*See* BRANCHIPODA.) They are found in almost any pool of stagnant water, and the long fringed bristles attached to the antennæ and feet enable them to move with great rapidity.

CYRILLACEÆ, *si-ril-lai'-se-e* (in honour of Cyrillo, a Neapolitan botanist), the *Cyrilla* family, a small natural order of dicotyledonous plants in the sub-class *Thalamifloræ*, consisting of evergreen shrubs, nearly related to *Olacaceæ*, but distinguished by their petals, which are altogether free from hairiness on the inside, and by the stamens being all fertile, and, if equal in number to the petals, alternate with them. They are natives of North America.

CYST, *sist* (Gr., *kustis*, a bladder), the urinary bladder, gall-bladder, and similar vessels in the human body; but the term is also applied to morbid growths within the body, having the form of a bag or bladder, and inclosing matter.

CYSTIC WORMS. (*See* ENTOZOA and TAPEWORM.)

CYTISUS, *si'-tis-us*, a genus of leguminous trees and shrubs, of which the laburnums and broom are well-known examples. There are many species, chiefly natives of the warmer temperate parts of the world. The yellow, white, or purple flowers are very beautiful. The timber of the tree-laburnum (*C. alpinus*) is much prized by cabinet-makers and turners for its hardness, beauty of grain, and durability.

CYTTARIA, *sit-tai'-re-a*, a genus of fungi. *C. Darwinii* and *Berteroi* are employed for food; the former in Terra del Fuego and the latter in Chili.

D.

DAB, *dab* (*Pleuronectes limanda*), a common flat fish known in the London market. Its average size is eight or nine inches in length, and six or seven in breadth. Its upper side is pale brown, and its under parts white. It abounds on all sandy parts of the British coasts, and is usually caught with plaice and flounders.

DABCHICK. (*See* GREBE.)

DACE, *dais* (Du., *daas*) (*Leuciscus vulgares*), a small fish of the family *Cyprinidæ*, found in clear and quiet streams. Its head is small, muzzle pointed; back a little elevated, and tail slightly forked. The scales of the dace are rather small. It is gregarious. The food is worms and other soft animal substances.

DACRYDIUM, *da-krid'-i-um* (Gr., *dakru*, a tear), a genus of plants belonging to the natural order *Taxaceæ*, or Yew family. It includes several valuable timber trees; as, the Huon pine of Australia (*D. Franklinii*), the Kakaterro of New Zealand (*D. taxifolium*), which grows to a height of 200 feet, and is valuable for the timber, and the Dimon pine (*D. cupressinum*).

DACTYLIS, *dak'-til-is* (Gr., *daktulos*, a finger), a genus of Grasses. The species *D. cæspitosa*, is the tussac-grass of the Falkland Islands, which forms an excellent kind of fodder for cattle. It is now grown to some extent in Shetland and other parts of Britain.

DADYL. (*See* CAMPHENE.)

DAHLIA, *da'-li-a* (from Dahl, a Swedish botanist), a genus of perennial herbaceous plants of the order *Compositæ*, sub-order *Corymbiferæ*. They are natives of Mexico, from which they were brought by Spanish botanists in 1789. Early in the present century they became favourite ornaments of English flower-gardens. There are two species, *D. variablis* and *D. coccenæ*, from which by the skill of the cultivators about 2,000 varieties have been produced. The "points" of a fine dahlia are fulness of flower, and the absence of an eye or disc. The roots are tuberous, and require to be taken up for the winter, and stored in a dry place out of the reach of frost till the spring. Dahlias are propagated by seed, by cuttings, and by tubers, and sometimes the finer varieties are grafted on more ordinary stocks. The dahlia was introduced into Russia and Germany by a botanist named Georgi, and from that circumstance it is known in Germany as the Georgina.

DAISY. (*See* BELLIS.)

DAISY, MICHAELMAS. (*See* ASTER.)

DALBERGIA, *dal-ber'-je-a*, (after Dalberg, a Swedish botanist), a genus of leguminous plants of the sub-order *Papilionaceæ*. Several species are good timber trees, the most valuable being *D. Sissoo*, which furnishes the Indian wood called sissoo or sheeshum. From *D. latifolia*, East-Indian ebony or black-wood is obtained; and *D. monetaria*, a native of Surinam yields a resin.

DALTONISM. (*See* COLOUR.)

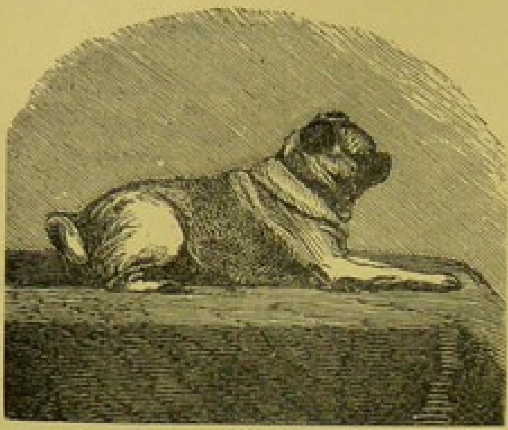
DAMAN, a genus of small quadrupeds (*Hyrax*) forming a connecting link between the *Rodentia* and *Pachydermata*. Cuvier spoke of them as, "except the horns, little less than rhinoceroses in miniature." The Syrian daman is supposed to be the cony of the Bible. (*See* CONY.) Other species differing in some particulars are met with in Abyssinia and South Africa.

DAMMARA, *dam'-ma-ra*, a genus of coniferous trees, including two remarkable species. *D. Australis*, the kawrie or cowdie pine of New Zealand, furnishes excellent timber for masts and spars, and also yields a gum-resin, which is now largely imported into this country under the names of Australian copal, kawrie gum, and Australian dammar. It is chiefly used in the preparation of varnishes. *D. orientalis* yields a somewhat similar gum-resin, which is known as Indian dammar.

DAMSON, *dam'-son* (from *Damascere* of Damascus), a small variety of the common plum, with fine flavoured acid fruit. Preserves, tarts, and so called "cheese" are made from this fruit.

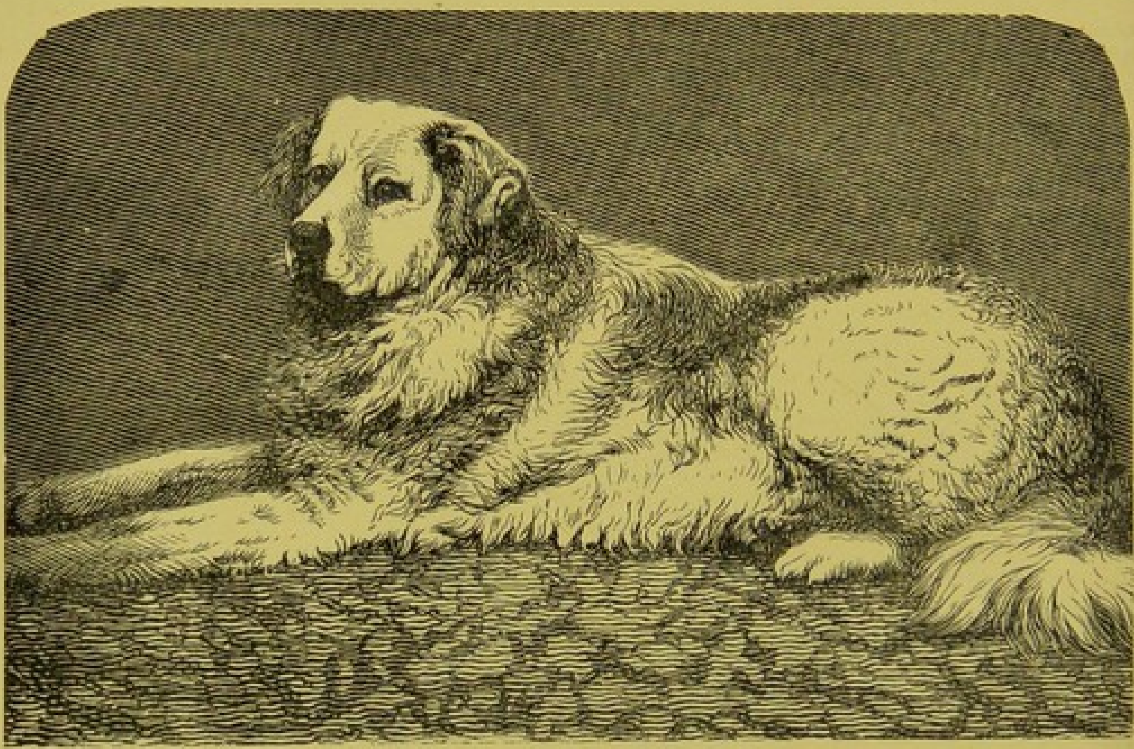
DANÆEÆ, a sub-order of Ferns. (*See* FILICES.)

DANCING MANIA, an epidemic disorder among susceptible subjects, in which imitation is brought about under high excitement. It is



PUG.

SKYE TERRIER.



MOUNT ST. BERNARD.

DALMATIAN.

BULL TERRIER.

DOGS.

closely allied to hysteria, and principally occurs among persons who are desirous of notoriety or sympathy. During the Middle Ages, epidemics of this class were common in Germany: and in Italy they were ascribed to the bite of the tarantula spider. Towards the close of the 14th century, a number of men and women appeared at Aix-la-Chapelle, on the festival of St. John, dancing and screaming in a frantic manner in the streets. Many foamed at the mouth, and danced till they fell down insensible: others dashed their brains out against the walls. While dancing, they were unsusceptible of outward impressions, but were haunted by visions. The epidemic spread over the Low Countries, and bands of wretched ignorant people traversed the country, and, excited by wild music, danced themselves into convulsions, singing all the time in derision of the priests. At the beginning of the 17th century, St. Vitus's dance (*see* CHOREA), as it was then called, was on the decline, and it is now only heard of in isolated cases.

DANDELION. (*See* TARAXACUM.)

DAPHNE, *daf'-ne* (the Greek name of the laurel), a genus of plants belonging to the natural order *Thymelaceæ*. The species are mostly shrubby evergreens of great beauty, with leaves of a peculiar velvet texture, and very fragrant flowers. The root-bark of *D. Mezereum*, the mezeron, or spurge olive, is officinal in the British pharmacopœias. It may be used as a vesicatory, and as a masticatory in toothache; but it is principally employed as a stimulant, diaphoretic, alterative, and diuretic. It owes its properties to an acrid resin and an acrid volatile oil. The stem-bark has similar virtues, but is generally considered to be less active. The fruit is acrid and poisonous. The bark of *D. Laureola*, the spurge laurel, is sometimes substituted for the officinal bark. The inner barks of *D. cannabina* and other species are used in some parts of the world for making paper. *D. Japonica*, recently introduced from Japan is valuable for its lemon scented leaves. Some of the species yield a bitter, astringent, crystalline substance known as *daphinine*.

DARTER, *dar'-ter*, in general form this bird (*Plotus*) resembles the cormorant, but the head is smaller, and supported on a very long and slender neck. The beak is perfectly straight and pointed, with the edges of the mandibles denticulated. Buffon, in allusion to the darter, says, "It offers us a reptile grafted on the body of a bird." It is sometimes called the snake-bird. Its habits while in the water have contributed not a little to its name. It generally swims with its body immerged, especially when apprehensive of danger, its long neck extending above the surface, and vibrating in a peculiar manner. Its long tail, composed of strong and elastic feathers, serves as a rudder when swimming submerged in pursuit of fishes, upon which it principally feeds. It makes a sudden dart at its prey, and from that quick action its name is derived. The darter is found in the warmer parts of the world, in America, and Africa.

DASYURES, *da-se-u'-res* (Gr., *dasus*, hairy; *ouros*, tail). This family includes the largest of the rapacious marsupials, nearly allied to the oppossum, but differing from them in some important particulars. The largest of the species (*Dasyurus ursinus*) measures about eighteen inches long in the body, and is covered with long thick hair, of a black colour. It is a native of Van Diemen's Land, where it is commonly known as "the devil." It is chiefly destructive among sheep, and, despite its small size, is capable of doing immense mischief among the penned flocks. The feet of the dasyures are formed for terrestrial progression; the anterior have five toes, and the hind ones four, all perfectly separate, and armed with curved claws. The dasyures are evidently analogous to the ordinary carnivorous quadrupeds, not only in their ferocity and carnivorous propensities, but also more or less in form.

DATE-PALM AND DATES. (*See* PHŒNIX.)

DATHOLITE, *dath'-o-lite*, a boro-silicate of lime, found in various parts of the world in oblique rhombic prisms. It also occurs in botryoidal or grapeolite forms, when it receives the name of *botryolite*.

DATISCACEÆ, *dai-tis-kai'-se-e*, the *Datisca* family a natural order of dicotyledonous plants in the sub-class *Monochlamydeæ*, consisting of herbs and trees, chiefly natives of the temperate regions of the western hemisphere. The whole order includes but four species, which are widely distributed over the world. The only noteworthy plant is *Datisca cannabina*, the root of which is employed in Cashmere for dyeing yellow.

DATURA, *dat-u'-ra* (from *tatorah*, its Arabian name), a genus of plants belonging to the natural order *Atropaceæ*. The species *D. Stramonium* is the thorn-apple, a plant possessing extraordinary narcotic properties. It is much employed in medicine as an anodyne and antispasmodic, its effects resembling those of belladonna. A strong decoction of the leaves in water is used in Cochin-China as a remedy in hydrophobia, in which terrible disease it is reputed to be very efficacious. *D. Tatula*, *metel*, *ferox*, *fastuosa*, and *sanguinea*, have similar properties to *D. Stramonium*. The fruit of *D. sanguinea*, the red thorn-apple, is used by the Indians of the Andes and of Central America for preparing a narcotic drink which produces a peculiar kind of intoxication, and is supposed to put those who partake of it in comunication with the spirits of their ancestors.

DAUCUS, *daw'-kus* (Greek, *daio*, I make hot), a genus of plants belonging to the natural order *Umbelliferæ*. *D. carota*, variety *sativa*, is the cultivated or garden carrot so much esteemed for its esculent roots. These roots are occasionally used in medicine as a poultice, for their moderately stimulant properties.

DAWALLA, *da-wal'-la*, a fish (*hypophthalmis dawala*) of the *Siluridæ* family about thirty inches long, somewhat resembling a pike in the snout, but with very small teeth. It has no scales, and the colours, green, brown, and crimson are very brilliant. It is a native of Guiana, but is in such favour for the table that it is becoming scarce.

DAY, *dai* (Sax., *dæg*, probably from Lat., *dies*), that period of the earth's revolution on its axis in which its surface is presented to the sun. The term is, however, applied to any astronomical space of time which depends directly on the earth's rotation. But the only days distinguished by that name in astronomy are the sidereal day, the real solar day, and the mean solar day. The sidereal day is the period between the two transits of the same fixed star, that is, a complete revolution of the earth. It is divided into twenty-four hours, and begins when the equinox is on the meridian of the place. The real solar day is the interval between two transits of the sun over the meridian. The length of the real solar day varies at different periods of the year, on account of the unequal motion of the sun and the obliquity of the ecliptic. The mean solar day is the average of all the real solar days. The mean solar time is thus arrived at by imagining a sun moving uniformly in the celestial equator and completing its circuit in the same time as the real sun. The real and mean solar days only coincide in four days of the year. In the intervals the sun is either too fast or too slow. The difference is called the Equation of Time (which *see*). The mean solar day is 24 hours, 3 minutes 56·55 seconds of sidereal time; and the sidereal day is 23 hours 56 minutes 4·09 seconds of a mean solar day. The astronomical day begins at noon, and is divided into twenty-four hours, instead of two parts of twelve hours each. The face of the astronomical clock on the wall of Greenwich observatory is divided into twenty-four hours. Thus, our ordinary 10 o'clock in the morning is with astronomers 22 o'clock. The ancients generally began their day at sunrise, with the exception of the Egyptians, who began at midnight, and the Arabians, who began at noon. The latter nation still retains the same custom; and most of the modern Eastern nations reckon the commencement of the day from sunrise. The Chinese divide the day into twelve parts of two hours each.

DAY-LILY, a genus of plants (*Hemorocallis*) of the natural order *Liliaceæ*. The yellow day-lily (*H. flava*), a native of Siberia, the north of China, and south eastern-Europe, is grown in our gardens on account of its fragrance; and other species are also cultivated by florists. The leaves are excellent food for cattle.

DAY-FLY. (*See* EPHEMERA.)

DEADLY NIGHTSHADE, OR DWALE. (*See* ATROPA.)

DEAF AND DUMB, *def dum* (Sax., *deaf dumb*).—A person is said to be deaf when he is either entirely or in a great measure destitute of the sense of hearing, and dumb when he is without the power of speech or of articulating sounds. Such individuals are also sometimes called deaf mutes. Deafness is either congenital or acquired. When congenital, it arises from an original malformation of the ear, and is always accompanied with dumbness; when acquired, it is the result of some disease affecting some of the delicate parts connected with the organ of hearing. (*See* DEAFNESS, EAR, HEARING.) The ear is necessary to articulation, which is acquired by imitating the sounds we hear uttered by others; and, therefore, if a person is unable to distinguish between articulate sounds, he is incapable of acquiring speech, at least in the ordinary way, and is dumb in consequence of his deafness. It is rare indeed to find dumbness in deaf persons resulting from any imperfection in the organs of speech or from feebleness of mind. What the causes are which produce deafness are as yet but very imperfectly known or understood. There can be no doubt, however, that there exists some connection between the physical conditions of a country and deafness. In mountainous districts it is generally found to be more prevalent than in plain and flat districts, and in rural parts than in cities or towns. A marshy district, or an impure atmosphere, undoubtedly tends to render it more common. The greater number of these unfortunate persons are to be found among the poorer classes; and hence there is reason to believe that the defect is frequently caused by the want of necessary supplies and attention during infancy and childhood. Among the other causes that doubtless tend to produce deafness, are intermarriages among near relations, hereditary predisposition, and certain conditions of life.

DEAFNESS, *def'-ness*, is a considerable or entire loss of the sense of hearing. Hearing is produced by the vibrations of the air striking on the tympanum, or drum of the ear, and is communicated to the auditory nerve by means of a series of small bones, connected in a very remarkable manner. (*See* EAR.) Deafness may be congenital—arising from some original malformation of the organ, or it may result from disease or accident, impairing or destroying some portion of the delicate organism of the ear. It frequently results from some obstruction in the external passage of the ear which interferes with the transmission of sound to the tympanum. This is often occasioned by an unusual accumulation of cerumen, or wax of the ear, which is secreted by the glands of the passage. The most speedy and effectual way of removing this is by syringing the ear with warm water three or four times a day, until it is brought away. Insects and other foreign bodies sometimes lodge in the ear, and occasion deafness; or ulcers or morbid growths may form in the passage, and thus interrupt the transmission of sound. The tympanum may be inflamed, thickened, or injured, to such a degree as to be wholly incapable of performing its office of transmitting sound. Obstruction of the Eustachian tube, which conveys air from the back part of the mouth into the internal cavity of the ear, will often occasion a considerable degree of deafness. Hence, inflammation and other diseases of the throat have frequently this effect. Deafness also sometimes results from derangements in the minute and complicated parts of the organs which are beyond the reach of direct observation, and consequently are but imperfectly understood. The nerve by which impressions are communicated from the internal ear to the brain is also subject to disease, and may occasion deafness, which may also result from diseases of the brain itself. Long exposure to loud deafening noises, a cold, various fevers and inflammations, rheumatism, headache, and repelled cutaneous eruptions, frequently produce deafness. The particular plan of treatment to be pursued will depend upon the nature of the cause, and will necessarily vary considerably in different cases; while the exercise of the greatest attention is often necessary, in order to ascertain the real nature of the case. The diseases that affect the ear are the same as those that affect the other organs, and are to be treated upon the same principles. When they result from inflammation, the inflammation is to be removed in the usual way; when from polypi or morbid growths, these are to be removed by lunar caustic or a surgical operation; when from nervous debility, the general tone of the system is to be strengthened. When an obstruction of the Eustachian tube is the cause of deafness, it is often removed by perforating the tympanum.

When it results from a partial or entire loss of the tympanum, an artificial one may be employed, the best being of vulcanized india-rubber, attached to the end of a fine silver wire, by means of which it may be inserted or withdrawn at pleasure.

DEAL-FISH, a genus of fishes belonging to the Ribbon family, and so called because of their resemblance to a piece of deal. The Vaagmaer, one species of this genus, is a native of the coast of Iceland and Norway.

DEATH, *deth*, in common language, is opposed to life, and is considered as the cessation of it. It supervenes as the necessary termination of all that long succession of phenomena of which life consists. In every part of a living organism there is a continual destruction of old particles and the formation of new ones going on; and, generally, the greater the vital activity of the part the more rapidly do these changes take place. Even the most solid portions of the animal frame are not free from this change, though in them it goes on less rapidly than in the softer tissues. Every movement of the body, nay, even every thought of the mind, is attended with the death and disintegration of a certain amount of muscular or nervous matter as its necessary condition; hence, in the performance of each of those functions whose aggregate makes up the life of man, the particular organ which ministers to that function undergoes a certain loss by the decline and death of its component particles; and this the more rapidly in proportion to the activity of the changes which are effected by their instrumentality. If the regenerative processes be performed with due vigour, no deterioration of the organ takes place; but with the advance of years this regenerative power gradually diminishes, and the entire organism progressively deteriorates, until at last death supervenes. We have thus two kinds of death—molecular, or that which is constantly taking place among the molecular particles of the body, and which is, in fact, essential to its life and well-being; and systemic, which is the death of the body as a whole. Death may result either from the general failure of the vital powers, as in old age, or from some disease or injury in some of the vital organs, which extends itself to the organism in general. It may be due to failure in the propulsive power of the heart, which constitutes *syncope*; and this may occur either in consequence of the heart losing its irritability, and so ceasing to contract, or by being affected by tonic spasms, and so remaining rigidly contracted. In both cases death is instantaneous. Or death may take place by the gradual cessation of the action of the heart; in which case it is termed *asthenia*. Death may also be occasioned by an obstruction to the flow of blood through the capillaries of the lungs, or to the entrance of air to these organs, thus constituting *asphyxia*, or *apnœa*. Death by *coma*, or beginning at the brain, is caused by various influences, which primarily destroy the functions of the superior masses of the nervous system. Death may also be occasioned by a disordered condition of the blood itself, which at the same time weakens the power of the heart, impairs the activity of the nervous system, and prevents the performance of those changes in the capillaries which afford a powerful auxiliary to the circulation. Death may also result from the direct agency of cold stagnating all the vital operations of the system. It is to be borne in mind, that death is frequently produced by a conjunction, or by the rapidly-following results, of two or more of these modes; indeed, the perfect distinction of these different modes of death is almost exclusively confined to cases where the dissolution is speedy or sudden. The signs of approaching death are necessarily various, and depend, in a great measure, upon the nature of the disease. In some cases there is a dulness of the senses, inactivity of the muscles, vacancy of the intellect, and extinction of the sentiments, as in death resulting from old age. There is, also, frequently some degree of delirium. The sense of hearing is frequently also affected, and imaginary voices, and sounds of tolling bells, &c., are heard. *Dementia*, or mental debility, sometimes comes on shortly before death. The voice generally becomes low and weak as death approaches; but sometimes it has a shriller pitch than natural; sometimes it is husky and thick; and not unfrequently it dwindles to a mere whisper. The muscular system generally becomes feeble and relaxed; the pulsations of the heart gradually feebler, but more frequent; the respiration sometimes hurried and panting, sometimes ceasing gradually; and sometimes slow, laborious, and stertoreous. There is frequently, also, an accumulation of fluids—mucous, serous, or purulent, in the bronchial tubes. What is known as the "death-rattle" is produced by the passage of the air from the lungs through the fluid collected in the trachea and upper respiratory passages. The consequences of death first become apparent in the organs of sense and motion; the eye loses its brightness, and the flesh its elasticity; the muscles become stiff, and coldness and paleness spread over the whole body. Yet it is often a very difficult matter to distinguish between real and apparent death. The most reliable test is afforded by the condition of the muscular substance; for after real death this gradually loses its irritability, so that it can be no longer excited to contraction by any kind of stimulation; and this loss of irritability is succeeded by the appearance of cadaveric rigidity. The most satisfactory proof, however, is given by the occurrence of putrefaction, which usually first manifests itself in the blue-green colouration of the cutaneous surface, especially of the abdomen, but which speedily extends to other parts.

DEATH'S-HEAD HAWK-MOTH (*Acherontia atropos*), a lepidopterous insect of the family *Sphingidæ*. It is a species of hawk-moth found in several places in England and in nearly every quarter of the globe. Its length across the wings is nearly five inches; its body is of a yellowish colour, with black stripes; the markings upon the back of the thorax are faint, but bear a close resemblance to a skull or death's-head, from which it derives its name. The wings are dark-coloured, being mottled with yellow, brown, and black. The caterpillar of the death's-head moth is greenish-yellow; the back is covered with black specks, with transverse lines of blue and white. It is often found feeding upon the leaves of potatoes. The moth itself is mostly seen flying during the morning and evening in autumn. As it flies, it utters a low, plaintive sound, and this, together with the death's-head mark upon the thorax, have caused it to be generally regarded with disfavour. How it contrives to make the noise is not known. Another strange property possessed by the death's-head hawk-moth, is that it is able to enter and plunder bee-hives with perfect impunity.

DEATH-WATCH (*Anobium tesselatum*).—The ticking sound which superstitious persons believed to be a sure presage of the death of some person in the house, where it is heard, is now known to be produced by certain beetles belonging to the timber-boring genus *Anobium*. The insect is of a greyish-brown colour, about a quarter of an inch in length, and thick in proportion: the wing-shells are marked with irregular variegations lighter than the ground-colour. The ticking noise is thus produced:—raising itself upon its hind legs, with the body somewhat inclined, it beats its head with great force and agility against the woodwork on which it is standing. The general number of distinct strokes in succession is from seven to eleven. They follow each other quickly, and are repeated at uncertain intervals. The ticking is merely the call of either sex to its mate, and may be considered analogous to the call of birds.

DEBACLE, *de-ba'-kl* (French, breaking up of the ice), a term used by geologists to express a sudden flood of water, which carries forward and scatters masses of débris.

DEBILITY, *de-bil'-e-te* (Lat., *debilitas*, weakness or decay of strength), that departure from the healthy condition of the frame which consists of a diminution of its vital energies—of an enfeebling of its powers, manifested in numerous conditions and grades throughout the whole frame, or more or less remarkably in particular systems or organs. It is intimately connected with the nature of most diseases, and often constitutes disease of itself. Besides the conditions that characterize general debility, there are also specific or partial states of debility, manifesting themselves more particularly in certain of the tissues, organs, or systems; as the circulating or nervous system, the organs of digestion or secretion, the cellular tissues, &c. A particular class of remedies called *tonics* are in general more beneficial than any other, although other articles, as diffusive stimulants and antispasmodics, may often be used with great advantage. Change of air, moderate exercise, agreeable occupation, and pleasant society, are also among the most beneficial means of restoring the depressed or exhausted powers of the frame. Sea-bathing, and in some cases medicated baths, are likewise often of great benefit.

DÉBRIS, *dai-bree'* (Fr.), a French term which has been generally adopted by geologists, and applied to masses of broken rocks, &c. In ordinary conversation, the fragments of any fallen building, such as a house or bridge, are called the débris.

DECAGON, *dek'-a-gon* (Gr., *deka*, ten; *gonia*, angle), a geometrical figure which has ten sides and ten angles. When the sides and angles are all equal, the figure is called a regular decagon, and is inscribable in a circle. An irregular decagon can be formed from a pentagon by describing any irregular triangles upon its sides, so that no two of them shall have their sides in the same straight line.

DECAISNEA, *de-kais'-ne-a*, a plant of the order *Lardizabalaceæ*, a native of the Himalaya mountains. Only one species is known. Several erect stems spring from the root, with leaves, two feet long, standing out horizontally. The fruit resembles a short cucumber, of a yellow colour, full of a milky pulp, sweet and wholesome, and used as an article of food.

DECAY, *de-kai'* (Lat., *decado*, to fall).—The comparatively slow oxidation or burning which moist organic matter undergoes when exposed to air. Substances rich in nitrogen are especially liable to decay; consequently, most animal substances decay more rapidly than any vegetable matter, except the softest and most nitrogenous. The decay of animal substances after death is probably but the continuation of the normal dis-assimilation which goes on throughout life; but as the corresponding processes of repair have ceased, the decay becomes apparent for the first time after death.

DECIDUOUS TREES, *de-sid'-u-us* (Lat., *de*, and *cado*, falling away), trees which annually lose and renew their leaves—the opposite of evergreens. Nearly all the trees and shrubs of temperate regions are deciduous.

DECIMAL FRACTIONS, *des'-i-mal frak'-shuns* (Lat., *decem*, ten), are fractions which have 10, or some power of 10, for their denominator; as one tenth, one hundredth, one thousandth, &c. In ordinary practice, it is often convenient to use decimal fractions, which, for the sake of brevity, are not written out fully. The numerator alone is expressed, with a point on the left-hand side: thus, ·3 represents $\frac{3}{10}$, ·03 represents $\frac{3}{100}$, ·003 represents $\frac{3}{1000}$, &c. Decimal fractions seem to have been introduced about the middle of the 15th century, by Regiomontanus. The first treatise on the subject was written by Stevinus, in his "Practique d'Arithmetique," published in 1582. They are now generally adopted amongst all civilized nations in arithmetical calculations.

DECLINATION, *dek-lin-ai'-shun* (Lat., *declinare*, to incline).—The position of a star in the heavens is determined by its right ascension (*see* ASCENSION, RIGHT) and declination, as the position of any place on the earth's surface is determined by its latitude and longitude. If we suppose a great circle to pass through any star in the heavens and the north and south poles, being consequently perpendicular to the equator, that portion of the circle which lies between the star and the equator, whether it be north or south of that line, is the declination of the star. Declination circles are small circles drawn on the celestial globe parallel to the equator, similar to lines of latitude on the terrestrial globe.

DECLINATION OF THE NEEDLE. After the use of the mariner's compass became general, it was observed that the needle did not invariably point to the geographical north, but was subject to variations. Andrew Bianco, an Italian navigator, specially noted this fact in 1436. Columbus was apparently familiar with the phenomenon, as in 1492 he noted as something remarkable that at about 2° E. of the Azores, there was no variation. In 1604, Gillebrand, an English observer, comparing the results of his investigations with others previously made, noted that, wherever about 50 years before the needle pointed to 11° 15' E., it then pointed to only 4° E. About a hundred years afterwards, the needle pointed to 15° W., and in 1818 the maximum resting position, 24° 4', was reached. Then a retrograde movement set in, and the needle began to travel slowly towards the east. It is now ascertained that it makes an oscillation from its eastern to its western limit, and back again, in about 320 years, the rate of movement being faster as the meridian is approached, and gradually slower towards the limit of the oscillations. The variation is ascertained and measured by an instrument constructed for the purpose, called a declinometer, and by the dipping-needle. (*See* DIP OF THE MAGNETIC NEEDLE.)

DECOMPOSITION, *de-kom-po-zish'-un* (Fr., *décomposer*).—This term is applied, in common parlance, to the separation of the constituents of a substance during putrefaction. In chemistry, it is applied to any process during which a compound body undergoes the separation or re-arrangement of its elements.

Decomposition of Light. (*See* LIGHT.)

Decomposition of Forces. (*See* FORCES.)

DECREPITATION, *de-krep-it-ai'-shun* (Lat., *decrepo*, I crackle), a term applied to the crackling noise, attended with the flying asunder of their parts, made by many minerals and salts when heated.

DECRESCENDO, in Music, the reverse of CRESCENDO (which *see*).

DEDICATION, *ded-e-kai'-shun* (Lat., *dedico*, I inscribe, dedicate), is a complimentary address to a particular person, prefixed by an author to his work. The practice arose from the slight remuneration that in early times was to be derived from literary labour. Hence authors came to be in many cases dependent upon wealthy patrons, to whom they dedicated their works; and hence, too, many authors sought the patronage of a powerful or wealthy individual, by dedicating their works to him. It thus came to be a common practice to acknowledge a dedication with a sum of money. Dedications have in a great measure passed away, and where we still find them they are generally either a token of private friendship or a mark of public esteem.

DEEP SEA SOUNDINGS. (*See* OCEAN.)

DEER, *deer* (Sax., *deor*) (*Cervus*), ruminant quadrupeds, constituting the family *Cervidæ*. The chief characteristics of the deer tribe are, gracefulness of form, fleetness, and neatness and strength of limb; they have a long neck, small head, which is carried high, large full eyes, and large ears; they have no cutting teeth in the upper, but eight in the lower jaw; the males have usually two short canines in the upper, but neither sex has any in the lower jaw. They are distinguished from all other ruminants by their branching antlers, or horns, which in most of the species, exist in the male only. Unlike the horns of the ox, the antlers of the deer are deciduous, falling off every year after the breeding season, and renewed before that exciting period again returns. Each year, until the animal attains old age the horns increase in size both in breadth of palmation and number of branches; when, however, the animal grows so old as to cease to be affected at one season more than another, the horns, although renewed, diminish in size at each renewal. It has been clearly ascertained that the size and development of the antlers are closely connected with the sexual system. The deer's horns are produced by an action analogous to that by which injuries to the bones are repaired. The process forming the base of the horn is covered by a skin, beneath which a sort of inflammation is set up; this produces cartilaginous matter, which increases rapidly in amount, gradually becomes ossified, and finally forms the horn, which, when mature, is still covered with the vascular skin beneath which it has been formed. This, however, dries up and peels off soon after the complete development of the organs, and the latter then consist of bare bone. The growth of the horn is attended by considerable heat and the blood-vessels which supply the head enlarge in size. The species of Cervidæ are very numerous, and dispersed generally through the world, excepting Australia and the South of Africa. Deer are pretty uniformly clothed with hair, longer and thicker on those which inhabit cold than those which inhabit hot climates. Professor Owen thinks that fallow deer are not natives, but were introduced into England at an early period, probably in the Saxon times. The term "fallow" is from the Saxon *falewe*, indicating the yellowish-red or brick-dust colour. The flesh of deer (venison) is considered a great delicacy. Remains of many species of fossil deer have been found in recent geological deposits. The best preserved is the gigantic Irish elk, intermediate between the fallow deer and reindeer. It is found in the later deposits of Ireland, in Scotland, the Isle of Man, and in some of the English bone caverns.

DEERMOUSE, *deer'-mous* (*Meriones*), a genus of American rodent quadrupeds allied to the jerboa. The deermouse, or "jumping mouse" (*Meriones Canadiensis*), is common in Canada. It is about the size of a mouse, with a very long tail, and very long and slender hind legs. It is capable of making leaps of four or five yards. It burrows, and passes the winter in a lethargic state.

DEFICIENT NUMBER, *de-fish'-ent*. A number, the aliquot parts of which, when added together, make a sum less than the number itself. Thus, 8 is a deficient number, the aliquot parts, 1, 2, 4, amounting only to seven.

DEFLAGRATION, *def-la-grai'-shun* (Lat., *de*, concerning; *flagro*, I burn). A term applied to the sudden combustion of substances by throwing them into a red-hot crucible.

DEFLEXION OF RAYS OF LIGHT. (*See* LIGHT.)

DEFORMITY, *de-form'-e-te* (Lat., *deformitas*, from *de*, and *forma*, a form), is the want of that regularity of form necessary to constitute the beauty or symmetry of an object. In the human subject deformities may be either congenital or acquired—*i.e.*, occurring before or after birth. Modern research has shown that congenital deformities are all to be traced to natural causes, which are generally reduced to two main divisions—1, to the original malformation of the germ; or, 2, to the subsequent deformation of the embryo by causes operating upon its development. To the former class are attributed such malformations as are repeatedly produced by the same parents, and hence are in some degree hereditary. Subsequent deformation of the embryo may be produced by various causes affecting its development. A very prevailing opinion is that deformities may be occasioned by strong mental impressions on the mind of the female during pregnancy. Of this, however, there is no satisfactory proof, and it is generally discredited by medical men. Deformities, however, are frequently produced by physical injuries suffered by the mother during pregnancy; and hence a strong mental impression may so affect the mother physically as to transmit its effects to the fœtus. A third cause is attributed to diseases of the ovum and fœtus. A fourth, and assuredly a very general and frequent cause of malformation, consists in impeded development of the fœtus by some remote and unknown cause. The various kinds of artificial deformities will be found treated of under their proper heads.

DEGLUTITION, *deg-loo-tish'-un* (Lat., *deglutitio*, from *deglutio*, I swallow), is the act of swallowing, or the passage of a substance, either solid, liquid, or gaseous, from the mouth to the stomach. Though simple in appearance, deglutition is yet the most complicated of all the muscular actions that serve for digestion. It is effected by the contraction of a great number of muscles and requires the concurrence of many important organs for its accomplishment. It is divided into three stages. In the first, the food passes from the mouth to the pharynx; in the second, it passes the opening of the glottis, that of the nasal organs, and arrives at the œsophagus; and in the third, it passes through this tube and enters the stomach.

DEGREE, IN MATHEMATICS, the circle is divided into 60 equal parts, called degrees; each degree into 60 equal parts, called minutes; each minute into 60 seconds, each second into 60 thirds; and so on. (*See* CIRCLE, TRIGONOMETRY.)

DEGREE, ASTRONOMICAL AND GEOGRAPHICAL.—The imaginary great circles that are supposed to be described on the surface of the earth, and on the apparent surface of the heavens, are similarly divided to aid us in effecting astronomical and geographical calculations, and in determining the position of stars and other celestial bodies on the latter, and the situation of places on the former. These divisions are known as degrees of latitude and longitude, according to the direction in which they are measured. Degrees of latitude are measured from the equator towards the north and south poles, along the meridian, or any great circle in a plane perpendicular to that of the equator. They are numbered, in either direction from the equator, from 0° to 90°. As the earth is not a complete sphere, the length of a degree of latitude is not exactly the same at all parts of the earth's surface, being rather less at the equator than at the poles; for all practical purposes, however, they are assumed to be equal everywhere, having a mean length of 60 geographical miles, or 69·1 English miles, which would be the case if the earth were spherical instead of being an oblate spheroid. The small circles which are supposed to be described on the earth's surface through every degree of latitude, in planes parallel to that of the equator, are called parallels of latitude. Degrees of longitude are measured east and west along the equator, from the meridian of Greenwich on the terrestrial globe, and from the first point of Aries on the celestial globe, and are numbered in either direction from the points that have been indicated from 0° to 180°. Each degree of longitude is 60 geographical miles, or 69·1 English miles at the equator. It will readily be seen, that as the meridians are at 60 geographical miles distance from each other at the equator, and meet in a point at the poles, the degrees of longitude become less and less in length as they are measured along every successive parallel of latitude between the equator and the poles. The following table shows the length of a degree of longitude in English miles measured along every fifth parallel of latitude—the distance at which parallels of latitude are usually inserted in maps of ordinary size.

Deg. of Lat.	English Miles.	Deg. of Lat.	English Miles.	Deg. of Lat.	English Miles.
0	69·1	35	49·1	70	20·5
5	59·8	40	46·0	75	15·5
10	59·1	45	42·4	80	10·4
15	58·0	50	38·6	85	5·2
20	56·4	55	34·4	90	0·0
25	54·4	60	30·0		
30	32·0	65	25·4		

It should be remembered that, in describing the position of a place on the earth's surface, we must mention the latitude as north or south of the equator, and the longitude as east or west of the first meridian. In most countries, geographers assume the meridian of the capital as the first meridian.

DEINACRIDA, *di-na-kri'-da*, a genus of the Cricket tribe, abundant in New Zealand, where it inhabits decaying trees and chink sand crannies in old woodwork. It is carnivorous, and its bite is very severe.

DELIQUESCENCE, *del-e-kwes'-ens* (Lat.), the property possessed by certain substances of absorbing water from the atmosphere and becoming liquid in it. Advantage is taken of this property in the case of chloride of calcium, which is much used by chemists for drying gases, and for promoting the crystallization of other less deliquescent salts.

DELIRIUM, *de-lir'-e-um* (Lat., from *deliro*, I rave or am furious), is a confusion of ideas, which occurs in the progress of certain diseases, from disturbed function of the brain. Sometimes the term is employed to include every form of mental alienation; but generally a distinction is made between insanity and delirium, the latter occurring principally in fever and inflammatory diseases, while the former is unattended by these disorders. (*See* INSANITY.) Delirium may be either violent and frantic (*delirium ferox*), as in acute inflammation of the membranes of the brain, or low and muttering (*typhomania*), as in low fever. It supervenes on fever during any part of its course. It occurs in the hot state of some intermittents, but rarely makes its appearance in typhoid or continued fever until the disease has reached its height.

DELIRIUM TREMENS, DELIRIUM EBRIOSITATIS, OR MANIA A POTU, is a disease of the brain usually caused by an abuse of spirituous liquors, but sometimes also by great mental anxiety and loss of sleep; or it may result from bodily injuries or accidents, loss of blood, &c. Delirium sometimes makes its appearance in consequence of a single debauch; but more frequently it is the result of protracted or long-continued intemperance. It usually supervenes on a fit of intoxication; but it not unfrequently occurs, also, when the habitual drunkard omits his accustomed draught. The predominant emotion with the delirious patient is fear, and in his efforts to escape from an imaginary enemy, he may be guilty of a murderous assault, or, as is more frequently the case, he may take his own life; and hence he requires to be very carefully watched. The delirium continues until the patient sinks into a sleep, from which he awakes comparatively rational, or dies from exhaustion. In such cases death is often sudden. This disease, however, is rarely fatal, unless where the strength of the patient has been seriously impaired by long-continued excesses. This disease is to be carefully distinguished from inflammation of the brain, with which it has many symptoms in common; for bleeding, which is resorted to in the latter disease would be of the utmost danger in this.

DELPHINAPTERA, *del-fin-ap'-te-ra*, a genus of *Cetacea*, of the dolphin family, differing from the Beluga (which *see*) in not having a dorsal fin, and in the snout which is beak-shaped. The most familiar member of the family is the Right Whale Porpoise (*D. Peronii*), abundant in the South Seas. It is about six feet long, black on the back, but white on the belly and snout.

DELPHINIUM, *del-fin'-e-um* a genus of plants belonging to the natural order *Ranunculaceæ*. (*See* LARKSPUR.)

DELPHINIUS. (*See* DOLPHIN.)

DELPHINUS, *del-fi'-nus* (Lat., *delphinus*, the dolphin), one of the constellations described by Aratus, an old Greek astronomer. It is close to the constellation Aquila. Its brightest star is one between the third and fourth magnitude, and it has four of the fourth magnitude.

DELTA, *del'-ta*, the Greek letter Δ.—The lower portion of Egypt, between the eastern and western branches of the Nile and the sea, was, from its resemblance to the letter above, called the Delta. In modern times, whenever a river, before entering the sea, diverges so as to form a triangle, with the sea-line for the base, the alluvial deposit included by the three lines is called a *delta*. The deltas of the Ganges and of the Mississippi are of great size. The existence of a delta at the mouth of a river depends not so much on the amount of sediment held in suspension as on the presence or absence of currents met with at the point of discharge. Deltas are not to be found where there are strong ebb tides; in such case deposit is washed away. But in sheltered bays and gulfs, in the Mediterranean Sea, where there are scarcely any tides, and in inland lakes, deltas almost invariably occur.

DELTOID, *del'-toid*, a muscle of the shoulder, which moves the arm either forward, backward, or upward. It is so called from its resemblance to the Greek letter *delta*. In Botany, the term is applied to a leaf of triangular form.

DEMENTIA. (*See* INSANITY.)

DEMOISELLE, *dem'-o-sel*. (*See* CRANE.)

DEMULCENTS, *de-mul'-sents* (Lat., *demulceo*, I soften), a name given to such medicines as are especially useful in obviating the action of acrid and stimulating matters, and that not so much by correcting or changing their nature as by involving them in a mild and viscid fluid, which prevents their acting, or by covering the surface exposed to their influence. They are generally divided into two classes—mucilages and expressed oils; and are principally used in catarrh, diarrhœa, dysentery, gravel, and a few other complaints.

DENDRERPETON, *den-drer'-pe-ton* (Gr., *dendronata*), the name given to a lizard-like batrachian, between two and three feet long, the bones of which were found in Nova Scotia in a fossil tree. Professor Owen showed it to be nearly related to Archegosaurus. (*See* ARCHEGOSAURUS.)

DENDRITE, *den'-drite*, a mineral crystal having the appearance of moss found on rocks, especially limestone and trachyte. It is generally composed of hydrous oxide of manganese.

DENDROLEGUS, *den-drol'-e-gus* (Gr., *dendron*, tree; *lego*, I choose), a genus of Marsupialian animals belonging to the Kangaroo family. They, however, differ considerably from the rest by their adaptation to an arboreal life. The size of the animals belonging to this family differs considerably, some of them measuring more than four feet in length, independent of the sweeping tail; while others (*see* KANGAROO RAT) are no larger than a small rabbit. The tree kangaroos are found rather plentifully in New Guinea.

DENDROLITES, *den'-dro-lites* (Gr., *dendron*, tree; *lithos*, stone), petrified stems of trees and plants found in the secondary formations, and especially in the coal strata. These remains are found in very different sizes, some being gigantic. Sometimes they are found with fossil branches, fruit, and even leaves; but in general, they are only found in fragments. The wood from which dendrolites originally were formed mostly belongs to the Filices, the Cycadeæ, and the Coniferæ; and it is generally converted into agate or pitch-stones. There is considerable doubt as to their origin, and some of them are so hard that they are cut and used for artistic purposes. When cut into very thin plates and examined under the microscope, they show the structure of the wood perfectly, and it is possible for the botanist not only to name the order or family, but to specify the genus and species of plants to which it belongs.

DENDROPHIS, *den'-dro-fis* (Greek, tree-snake), a genus of serpents of the *Colubridæ* family, mostly living among branches of trees. They are very slender and lively, with prominent eyes, and are beautifully coloured. They are natives of tropical regions.

DENDROSAURA, OR TREE-LIZARDS, *den-dro-saw'-ra* (Gr., *dendron*, tree; *sauros*, lizard), the term applied to a genus of reptiles of which the chameleon may be regarded as the type.

DENGUE, OR BREAK-BONE FEVER, *deng(r)*, is the name of a disease that has, on several occasions, recently made its appearance in the southern states of North America and the East and West Indies, and is characterised as a severe inflammatory fever, accompanied with rheumatic pains in the joints and muscles. Though very severe, it is not often fatal, and usually terminates in a few days with a copious discharge of perspiration.

DENSITY, *den'-si-te* (Lat., *densitas*), a term which has exactly the same practical meaning as specific gravity. If two substances are of equal bulk, but one contains more matter than the other, it is said to have more density. The quantity of matter is measured by the weight; and thus specific gravity and density become proportional. Rarity is opposed to density, and the rarest body known is hydrogen, and the densest body iridium, which is upwards of forty times the weight of water.

DENTINE, *den'-tine*, the enamel which coats the teeth of mammalian animals. It consists mainly of phosphate of lime and gelatine.

DENTIROSTRES, *den-te-ros'-trees* (Lat., *dens*, tooth; *rostrum*, beak), a sub-order of birds of the order *Insessores* of predatory habits, and distinguished by the upper mandible being notched on either side. The butcher-bird belongs to this order. (*See* BUTCHER-BIRD.)

DENTITION, *den-tish'-un* (Lat., *dentitio*), is the breeding or cutting of the teeth, which takes place soon after birth, and is frequently attended with various disorders. At birth the teeth consist only of pulpy rudimentary substances, buried in the gum; and it is not till the third or fourth month after birth that they begin to assume shape and hardness. At this period children become uneasy and fretful; the gum is red and swollen, accompanied with a feeling of itching, which is manifested by the eagerness with which they press any hard substance against the gums. The salivary glands sympathize with the gums, and their is a copious discharge of saliva. Frequently these symptoms of local irritation are accompanied by others of a more constitutional nature. The skin becomes dry and hot, the face flushed, the bowels relaxed, and the child very restless and fretful. A red rash usually also appears on the skin, called the *red gum;* and if the irritation extends to the muscles of the chest, there is a dry and troublesome cough. When the infant is in a tolerably healthy state, these symptoms usually subside in the course of two or three weeks; but if it be in a weakly condition, they frequently lead to serious and sometimes fatal results. The mucous membrane which lines the stomach and intestines may be affected from that of the mouth, and griping pains, nausea, vomiting, diarrhœa, and other disorders, may be the result. The external skin sympathizing with the internal covering, may be affected with various kinds of eruptions; the air-passages and lungs may also become inflamed, or the brain and nervous system may become diseased, producing convulsions, epilepsy, tetanus, &c. The cutting of the teeth usually takes place between the seventh and ninth month, though sometimes it is much later. The gum again becomes extremely sensitive; but, instead of now being eased by the pressure of a hard substance, it cannot endure the slightest touch. It is red and swollen, but paler at the upper part, which, just before the tooth appears, seems covered with a flat whitish blister. The other symptoms are a repetition of those already described, with frequently eruptions about the head or lips, inflammation about the ears, and occasionally spasmodic movements of the mouth and jaws. These diseases are not always confined to the period of infancy; for in irritable and nervous constitutions they sometimes manifest themselves (though usually in a less aggravated form) at the irruption of the second or permanent teeth, and even occasionally when the *dentes sapientiæ* are about to make their appearance. The period of dentition in children cannot be too scrupulously watched over; for there are few diseases that require more prompt treatment than some that then make their appearance; and, if not of themselves fatal, they often lead to serious or fatal disorders.

DENUDATION, *de-nu-da'-shun*, removal of solid matter by the action of water. (*See* GEOLOGY.)

DEOBSTRUENTS, *de-ob'-stru-ents* (Lat., *de*, and *obstruo*, I obstruct), such medicines as have the property of removing obstructions in any part of the body, especially in the lymphatic system. They were formerly much used and depended upon in medical practice; but latterly they have fallen into disuse. Almost the only deobstruents now employed are mercury, iodine, and bromine.

DEPHAL, *de'-fal*, a tree (*Artocarpus lakoocha*) of the same genus as the bread-fruit tree, a native of the south of India, and yielding edible fruit. The timber is valuable, and from the root a yellow dye is extracted.

DEPHLOGISTICATED, *de-flo-jis'-te-kai-ted*, a term sometimes used to denote bodies which had been burnt or deprived of their phlogiston. (*See* PHLOGISTON.)

DEPOSITS, *de-poz'-its*, in Geology, those rocks which have been formed by the settling down of matter held in suspension in water. Deposits originate in denudation, the forming of alluvium, and the gradual collection of sand, gravel, &c., at the mouths of rivers. (*See* DELTA.) Deposits are called marine, lacustrine, fluviatile, &c., according to the circumstances which attended their formation.

DEPRESSION OF THE HORIZON. (*See* DIP.)

DERBYSHIRE SPAR, *der'-be-sheer.*—Fluor spar, or fluoride of calcium, is popularly known by this name, from the finest being found at the Blue John mine, in Derbyshire.

DERIVATION, *der-iv-ai'-shun* (Lat., *derivatio*, from *derivo*, I drain off), in Medicine, is applied to the removing or drawing away of a disease from its original seat to another part by artificial means; as by the application of a blister.

In Grammar. (*See* ETYMOLOGY.)

DERMATOLOGY, *der-ma-tol'-o-je* (Gr., *derma*, the skin, and *logos*, a discourse), is the science of the treatment of the skin and its diseases.

DERMATOPHYTES, *der-mat'-o-fites* (Greek, *phyton*, a growth or plant), vegetable growths formed in the skin, and giving rise to some forms of skin disease, as ringworm, &c.

DERMESTIDÆ, *der-mes'-ti-de* (Gr., *derma*, *esthio*, I eat), small beetles of a very destructive character. A well-known specimen of the dermestes is *D. dararius*, or bacon-beetle, a name applied through the insect's real or supposed fondness for bacon. It is about a third of an inch in length, and of a dusky brown colour, with the upper half of the wing-shells ash-coloured, and marked with black spots. The larvæ of other species abound in cargoes of hides brought from hot climates, and in long-kept stores of ship-biscuits.

DERMIS. (*See* SKIN.)

DERMOPTEROUS, *der-mop'-ter-us*, a name taken from the Greek for skin-finned, given to an order of fishes, having cutaneous vertical

fins, with very soft and delicate rays, and without pectoral and ventral fins. Lampreys and lancelets belong to this order.

DESCENT, *de-sent'*, in Mechanics, the Line of Swiftest Descent is that by which, under the action of force of gravity, passes most quickly from one point to another.

DESERT, *dez'-ert* (Lat., *desertus*, deserted, solitary), a waste or large tract of barren country. The term is applied very vaguely, but is more particularly appropriated to sandy and stony plains. Deserts are distinguished by different names in various parts of the earth. The term desert is more particularly applied to the waste tracts of Africa and Arabia. Those in Asia, especially in Thibet and Tartary, are called steppes. In South America, the large plains, rank with vegetation, but unfit for human settlements, are called llanos, pampas, and silvas, or desert-forests. The wide-stretching plains of North America are called prairies and savannahs. The desert of Sahara is the most famous of the properly so-called deserts. It stretches almost without a break from Cape Nun, on the north-west coast of Africa, eastward to the banks of the Nile, the eastern portion being generally known as the Desert of Libya. In some parts of this desert, as at Tegazza, rock-salt as white as snow extends in vast beds beneath a stratum of rock. Here and there, often at great distances, are a few small fertile spots, called *oases*, which serve as resting-places for the merchants, who travel on camels, hence called "the ships of the desert." To the east of the red sea, in Arabia, and stretching to Tartary, are extensive deserts, the most extensive being the desert of Gola, extending in a north-eastern direction from the western extremity of Thibet. The sand of the desert is not always a proof that at some former time the desert was the bed of an inland sea. It is frequently of local origin, formed from the soil of the desert plain by sudden changes of temperature and the action of the wind, and is formed from the underlying sandstone, quartz, salt, and gypsum.

DESSICANTS, *de-sik'-kants.*—In Medicine, substances with astringent properties, employed to check secretion and exhalation.

DESMIDIEÆ, *des-mi-dé-e*, a group of minute Algæ, of very low organization, appearing to connect the animal and vegetable kingdoms, resembling in some respects the *Diatomaceæ*, but having rounded instead of angular forms, the absence of silicious covering and their green colour. (*See* DIATOMACEÆ.)

DESMODIUM, *des-mo'-de-um* (Gr., *desmos*, a bond, in allusion to the stamens being joined), a genus of plants belonging to the natural order *Leguminosæ*. Some of the tropical species are remarkable for the periodical movements of their leaflets under the influence of light.

DESMONCUS, *des-mon'-kus*, a genus of palms, with slender stems climbing over shrubs and trees. There are many species, all natives of America.

DESVAUXIACEÆ, *dai-voze-e-ai'-se-e*, the Bristlewort family, a natural order of monocotyledonous plants, in the sub-class *Petaloideæ*. They are small, sedge-like herbs, with setaceous sheathing leaves, and are natives of Australia and the South Sea Islands.

DETERGENTS, *de-ter'-jents* (Lat., *detergo*, I wipe away), is a name given to such medicines as cleanse and remove viscid humours adhering to and obstructing the vessels; also such applications as cleanse foul ulcers.

DETRITUS, *de-tri'-tus*, in Geology, accumulations formed by the disintegration of rocks, consisting of gravel, sand, or clay, or an admixture of them.

DEUTEROPATHIC, *du'-te-ro-path'-ik* (Gr., *deuteros*, second, and *pathos*, suffering), an affection induced in a part through sympathy with the part originally affected; as where the stomach is disturbed through a wound in the head.

DEUTOXIDE, the oxide of a metal containing a double amount of oxygen. The word *binoxide* is, however, more generally used; and this remark applies to all compounds commencing with the word *deuto*.

DEUTZIA, *de-ut'-ze-a*, a genus of plants belonging to the natural order *Philadelphaceæ*, natives of the north of India, China, and Japan; and cultivated here generally as greenhouse plants, for the profusion and beauty of their white flowers. The leaves of some species, especially those of *D. scabra*, are covered with silicious fibres; hence, from their roughness, they are used in Japan for polishing purposes.

DEVELOPMENT. (*See* PHYSIOLOGY.)

DEVELOPMENT THEORY. (*See* EVOLUTION.)

DEVONIAN SYSTEM. (*See* OLD RED SANDSTONE.)

DEW, *dew* (Sax., *deaw*), the moisture or aqueous vapour which is deposited from the air on those bodies which are exposed to it. It is generally observed in the form of minute globules on the surfaces of leaves. When the cold is extreme, it takes a solid form, and appears as hoar-frost. When the atmosphere is at any given temperature and pressure, it holds a proportionate quantity of aqueous vapour in suspension. If that temperature is lowered to a certain point, called the dew-point, a quantity of aqueous vapour is set free in the form of water or dew, which can sometimes be seen falling as a fine rain or mist. Those substances which radiate heat rapidly are cooled soonest; and therefore the dew is deposited upon them first. All vegetable fibres are ready radiators of heat; consequently, the smooth leaves of trees, shrubs, and grasses cause the dew to be deposited upon them even upon moderately warm evenings. Radiation takes place most rapidly when there is a clear sky: when there are many clouds in the air, heat is radiated back by them to the earth, which nearly supplies the amount of heat lost. Thus dew is more readily deposited upon clear fine nights than when the sky is overcast. Hoar-frost is frozen dew.

DEWBERRY, *dew-ber'-re*, a plant (*Rubus cæsius*), of the same genus with the bramble. The name is taken from the dew-like bloom, of a bluish colour which covers the fruit. The fruit is of agreeable flavour. It is common in many parts of Europe and Asia. In Canada, the dewberry (*R. procumbens*) yields a much finer fruit than the English variety.

DEXTRIN, *deks'-trin*, a transparent brittle solid, with a vitreous fracture, formed by submitting starch to a heat of 400° Fah. Dextrin is a modification of starch, possessing the same composition, but different properties. It is, for instance, soluble in cold water, a property which renders it particularly valuable for manufacturing purposes, under the name of *British gum* (which *see*). It has received the name of *dextrin* from causing the rotation of a polarized ray from left to right. It may be always distinguished from starch by its pale buff colour, by not giving a blue colour with iodine, and from being insoluble in alcohol; and from gum, by giving a blue solution with potash and sulphate of copper.

DHOLE, *dole*, a wild dog of India (*Canis scylax*), found in the Western Ghauts and other mountainous districts. It is smaller than a wolf, which it in some respects resembles, but has longer legs and a straight, not bushy, tail. They are fierce, of great courage, and are especially dreaded by animals of the feline race. The name is sometimes extended to varieties of wild dogs in Nepaul, Ceylon, and other places in Asia.

DIABETES, *di-a-be'-tees* (Gr., *dia*, through, and *bainomai*, I pass), a disease characterized by an inordinate flow of urine. Medical men recognise two distinct kinds of diabetes—the *diabetes insipidus*, in which there is merely a greatly-increased flow of urine, accompanied by almost incessant thirst; and *diabetes mellitus*, in which the urine is found to contain a large quantity of saccharine matter. Persons of a debilitated constitution, and in the decline of life, are most subject to this disease. It commonly comes on slowly and imperceptibly, without any apparent disorder of the system, and may exist for a considerable time before it attracts any notice. One of the most constant symptoms of this disease is an inordinate degree of thirst; and yet the quantity of urine passed daily is usually much greater than that of the liquids drunk. A voracious appetite is also a usual characteristic of this disease. At length the constitution manifestly suffers, the body becomes emaciated, the strength and vigour fail, the pulse is frequent and small, a slight degree of fever prevails, and the skin is dry and rough. There are also usually aching pains in the back and loins, and uneasy sensations along the urinary passages. The symptoms gradually become more and more intense, until at length the patient sinks from exhaustion, or is cut off by dropsy, consumption, or some other incurable disease. Of the causes of this disease, unfortunately, little is known. The measures resorted to in its treatment are rather of a palliative than a remedial nature. It is possible, by judicious treatment, to greatly mitigate the symptoms, and to ward off the issue for a number of years. The treatment should be principally directed to restoring and strengthening the tone of the system, by abundant exercise in the open air, and the use of tonics and such medicines as tend to soothe the nervous system. The state of the skin is particularly to be attended to; and daily ablution of the whole body in warm or cold water is recommended. Flannel should also be worn next the skin. Those kinds of food that contain sugar, or matter easily convertible into sugar (*see* GRAPE-SUGAR) are to be as much as possible avoided.

DIAGNOSIS, *di-ag-no'-sis* (Gr., *diagignosko*, I discern or distinguish), is the art of discovering the nature of a disease, and of distinguishing it from other diseases of a similar nature. Much depends upon a correct diagnosis of disease; and the minute characteristics that frequently distinguish one disease from another render it often a matter of great skill and delicacy.

DIAGONAL, *di-ag'-o-nal* (Gr., *dia*, through; *gonia*, an angle), a straight line drawn from any angle to an opposite one in a rectilineal figure. A straight line drawn between two adjacent angles would obviously coincide with the boundary-line; consequently no triangle can have a diagonal. A quadrilateral figure has two diagonals, a pentagone five, a hexagon nine, &c. In order to calculate the number of possible diagonals in a given figure, the plan is to take three from the number of sides, multiply the remainder by the number of sides, and take half the product.

DIALIUM, *di-ai'-le-um*, a genus of leguminous plants. The only remarkable species *D. indicum*, which yields a fruit called the tamarind plum, the pulp of which has an agreeable slightly acidulous taste, somewhat resembling that of the common tamarind.

DIALLAGE, *di'-al-laj* (Gr., *diallege*, difference), a foliated silicio-magnesian mineral, so called from its changeable colour, and nearly allied to angite. A beautiful green diallage (smaragdite) found in southern Europe, India, and Labrador is valuable for ornamental purposes.

DIALLOGITE, *di-al'-lo-jite*, a carbonate of manganese occurring in crystalline masses of a rose-red colour. It is found chiefly in gneiss and porphyry veins, with silver, lead, zinc, and other ores, in Saxony and Transylvania.

DIAMAGNETISM, the property possessed by some substances of being repelled, not attracted, by a magnet. (*See* MAGNETISM.) Among the most familiar diamagnetic substances are alum, antimony, arsenic, bismuth, cadmium, carbonic acid, copper, glass, gold, lead, mercury, phosphorous, resin, and sulphur.

DIAMETER, *di-am'-e-ter* (Gr., *dia*, through; *metron*, a measure), a term generally applied to the line drawn through the centre of a circle, and bounded at either end by the circumference. Whenever any point is called a centre, any straight line drawn through that point is generally called the diameter.

DIAMOND, *di'-a-mond*, the word diamond is derived from the Greek *adamas*, unconquered, in allusion to its extreme hardness. Chemically speaking, diamond is pure crystallized carbon. As found in nature, diamonds occur crystallized in forms belonging to the regular system. The crystals are mostly derived from the octahedron; but the faces are frequently convex, and the edges rounded. In their rough state they present the appearance of semi-transparent rounded pebbles, covered with a thin brownish opaque crust. Freed from this coating, they are generally colourless; but they are also found tinged with red, orange, yellow, brown, and black. The pure white transparent variety are most highly prized, and are called diamonds of the first water. The finest diamonds occur in quartzose alluvial deposits at Golconda and Bundelcund, in India where the finest specimens have been found; also, in Borneo, in several districts in Brazil, in the Ural mountains, in Russia, and in one or two other localities. The origin of the diamond in nature is at present unknown. It is, however, evidently of vegetable origin. In 1879 and 1880, Mr. MacTear and Mr. J. B. Hannay, both of Glasgow, thought they had discovered a method of producing real diamonds by artificial means, but close scientific examination proves they had been unsuccessful. Diamonds are valued at so much per carat of four grains, and increase in price in a given proportion. The general rule for finding the value of cut diamonds, is to square the weight in carats, and multiply by £2. This rule does not apply to diamonds weighing more than 20 carats. Flaws in diamonds are often cut out by cleavage through the natural planes of the crystal. Diamonds are inflammable when heated red-hot, and plunged into an atmosphere of oxygen, burning with a steady light, and giving rise to pure carbonic acid. They are not, however, perfectly pure, a small residue being left behind, containing silica and iron. The specific gravity of diamond is about 3·6.

DIAMOND BEETLE, a name usually given to *Curculio imperialis*, a species of the tribe *Curculionidæ* (weevils), and order *Coleoptera*, found abundantly in Brazil. It is polished black in colour, the head, thorax, and limbs being slightly granulated and covered with metallic green scales, and the wing-cases (*elytra*) studded with regular lines of concavities, each depression thickly lined with bright green scales, so that the rays of light are reflected and heightened by the contrast of the shining black interstices.

DIANTHUS, *di-an'-thus* (Gr., *anthos*, flower; *dios*, of Jupiter—the divine flower), a genus of plants belonging to the natural order *Caryophyllaceæ*. Many of the species are highly valued for the beauty and the fragrance of their flowers. *D. barbatus*, the sweet-william, is an old inhabitant of the flower-garden, and was much esteemed in Gerard's time "for its beauty to deck up the bosoms of the beautiful, and garlands and crowns of pleasure." The flowers grow in fascicles, and are usually of a fine crimson colour. There are numerous varieties in cultivation. The species *D. caryophyllus*, which grows wild on old walls in the south of England, is supposed to be the source of the garden carnations, and, by some botanists, of the pinks also. The carnation has been cultivated from time immemorial in Europe, and its beauty and rich spicy odour make it a general favourite. It is the principal florist's flower of Germany and Italy, from which countries we derive the choicest varieties. The varieties of the carnation are arranged in three classes—*flakes*, *bizarres*, and *picotees*. Flakes have two colours only, the stripes being large; bizarres (Fr., odd or irregular) are variegated in irregular spots and stripes, with no less than three colours; picotees (Fr., *piquettée*, pricked or spotted) have a white ground spotted or pounced with red, purple, or other colours. The garden *cloves* have petals of a deep scarlet colour, and are derived, like the varieties of the carnation, from *D. caryophyllus*. The pink, as a florist's flower, received but little attention until the close of the last century, but many fine varieties have been developed since then. New varieties of the carnation and pink are procured from seeds, and thousands of seedlings are annually raised by florists and amateurs. Established or approved varieties are continued by layering and by cuttings, or, as they are commonly called, *pipings*. The soil in which they thrive best is a rich loam, rather sandy than otherwise.

DIAPENSIACEÆ, *di-ap-en-se-ai'-se-e* (Gr., *dia*, through; *pente*, five; in allusion to their being five-cleft), a small natural order of dicotyledonous shrubby plants in the sub-class *Corollifloræ*. There are but two genera and two species, natives of North America and northern Europe.

DIAPHANOUS BODIES. (*See* LIGHT.)

DIAPHORETICS, *di-a-fo-ret'-iks* (Gr., *diaphoreo*, I carry through), a name given to medicines that increase the natural exhalation of the skin. When they are so powerful as to produce actual perspiration they are called sudorifics, the difference between the two classes being only one of degree, not of kind. They are in general used to restore the cutaneous discharge when it has been suppressed through cold, and are hence useful in catarrh, rheumatism, or diarrhœa proceeding from cold. Among the more common diaphoretics are antimony, ipecacuanha, ammonia, opium, guiacum, camphor, and contrayerva.

DIAPHRAGM, *di'-a-fram* (Gr., *diaphragma*, a partition), the transverse muscle which separates the thorax or chest from the abdomen or belly. It is usually described as consisting of two muscles. The superior and larger of these arises from the cartilage of the sternum, and the ends of the lower ribs on each side; from which points the fibres converge, and terminate in a tendon, or aponeurosis, termed the *centrum tendinosum*, or central tendon. The second and inferior muscle springs from the vertebræ of the loins by two productions, or crura; that on the right side from the four upper lumbar vertebræ, that on the left from the three upper ones. From these points the fibres ascend, some of them crossing over and decussating to surround the œsophageal opening; but all of them ultimately uniting with the central tendon, and thus making but one muscular partition. The diaphragm is convex superiorly and concave inferiorly, and is covered on its upper side by the pleura, and on the lower by the peritoneum. In form it is nearly circular, and is fleshy at the edges, but becomes tendinous towards the centre. It presents three large openings and several smaller ones. The opening of the vena cava is quadrangular in form, and is situated in the tendinous centre. The œsophagal opening is posterior to that of the vena cava, and is of an elliptic form. The aortic opening is the most posterior, triangular, and between the crura. This muscle is the principle agent in respiration; for by contracting it enlarges the cavity of the chest, and allows the lungs to receive the air in inspiration, while by being relaxed, the cavity of the chest is again diminished, and the air suddenly expelled. Whatever occasions stoppage of the action of this muscle speedily proves fatal. It is subject to inflammation, called *diaphragmatitis*; but as this is rarely confined to the organ itself, but communicated either to the pleura or peritoneum, its symptoms and mode of treatment correspond with inflammation of these parts. (*See* PLEURITIS and PERITONITIS.)

DIARRHŒA, *di-ar-re'-a* (Gr., *dia*, and *rheo*, I flow), is a disease characterised by an increased discharge from the bowels, usually in a very liquid state, and sometimes containing a large quantity of bile. This disease may be occasioned by anything that stimulates or irritates the mucous surface of any portion of the alimentary canal. Besides the various purgative medicines, undressed or indigestible foods or vegetables, acid fruits, oily or putrid substances, frequently cause diarrhœa. Suppressed perspiration, occasioned by a sudden chill or cold applied to the body, or a draught of any cold liquid when overheated, may produce it. It is more apt to occur during the summer and autumn months than at any other period of the year. The effluvia arising from the decomposition of organic substances is a frequent cause of it. This is one of those diseases by means of which nature strives to get rid of impurities, and restore the system to its normal condition. Hence, when it is not very violent, and when the patient is strong, it is best to allow it to run its course, at all events for a time, and even to aid it by small doses of laxatives. In any case, great care is to be taken not to stop it too suddenly.

DIASTASE, *di'-as-taze* (Gr., *diastasis*, a separating of parts), a peculiar ferment found in all germinating seeds. It is this principle which causes the starch in malt to be converted first into dextrin and then into sugar. When barley is malted, diastase is developed in the grain, which converts the starch into sugar, on the application of heat and water in the operation of mashing.

DIASTOLE, *di'-as-tole* (Gr., *dia*, and *stello*, I stretch), a term applied to the dilatation of the heart and arteries, and opposed to systole, the contraction of these parts.

DIATHERMANCY, *di-a-ther'-man-se* (Greek, *dia*, through, and *therma*, heat), permeability to the rays of heat. Diathermanous bodies have the same relation to calorific rays that transparent ones have to rays of light; and these bodies which are impermeable to rays of heat, or bear the same relation to it that opaque ones do to light, are called athermanous.

DIATHESIS, *di-ath'-e-sis* (Gr., *diatithemi*, I dispose), a certain state of body predisposing it to certain diseases. Thus the scrofulous or gouty or cancerous diathesis denotes a certain constitution of body leading, under certain favourable conditions or exciting causes, to these diseases.

DIATOMACEÆ, OR DIATOMS, *di-at-om-ai'-se-e, di'-at-oms* (Gr., *dia*, across; *tome*, cut), the Brittleworts, a family of confervoid algæ, of very peculiar character, consisting of microscopic brittle organisms, found in almost all fresh, brackish, or salt water, sometimes forming a uniform yellowish-brown layer at the bottom of the water, at others adhering to various water-plants, decaying stems, and stones, or scattered between the filaments of *Confervæ*. They also occur among mosses and *Oscillatoriæ*, and on damp ground. The individual cells of the *Diatomaceæ* are called *frustules* or *testules*,, and are furnished with an external coat of silica. This flinty coat, of two usually symmetrical portions or valves, is comparable with those of a bivalve shell, but is in contact, at its margins, with an intermediate piece called the hoop, which varies in breadth according to age. The separate valves are of various forms. Fossil diatomaceæ are found in strata of every age.

DIBRANCHIATES, *di-brank-i'-a-tes*, a division of cephalopod molluscs, having two gills or branchiæ, an outer gland, and, with few exceptions, a rudimentary internal shell. The division includes the argonaut, cuttle-fish, octopus, squid, and spirula among living forms, and the extinct balemnites.

DICHLAMYDEOUS, *dik-lam-i'-de-ous* (Gr., *dis*, twice, and *chlamys*, a covering), a term applied to flowers which have both a calyx and a corona.

DICLINOUS, *di-kli'-nous* (Gr., *dis*, twice, and *kline*, a bed), a botanical term implying that flowers are uni-sexual, having stamens or petals only, and opposed to *monoclinus* or *hermaphrodite*.

DICHOTOMOUS, *di-kot'-o-mous*, a term used in botany to designate branching by repeated forkings, as in the veins of the fronds of ferns and the leaves of some coniferous trees.

DICHROISM, *di'-kro-ism* (Gr., *dis*, twice; *chroma*, a colour), the property possessed by many doubly-refracting crystals of exhibiting different colours when viewed in different directions.

DICOTYLEDONES, *di-ko-til-e'-dones* (Gr., *dis*, two; *kotuledon*, a cavity), one of the two great classes into which flowering plants are divided. It agrees with the *Exogenæ* of some botanists, and with the *Exogens Gymnogens* of Lindley. (*See* BOTANY.) The name *Dicotyledones* is derived from the condition of the embryo prevailing throughout the vast majority of plants included in the class: but, as in all other natural groups, instances occur wherein the particular character which has suggested the name is absent. In these exceptional cases, however, the plants agree with the rest in other prominent characters, as the structure of the stem, and the plan of the flower. The presence of a pair of cotyledons in the embryo must not, therefore, be regarded as an essential character of the *Dicotyledones*, though it is presented by most of the plants in this great natural group.

DICRANUM, *di'-kra-num*. (*See* MOSSES.)

DICTAMNUS, *dik'-tam-nus* (from *Dicte*, a mountain of Crete, where it grew), a genus of plants belonging to the natural order *Rutaceæ*, including two species, which are commonly cultivated in gardens for the sake of their handsome flowers. Of these, the more remarkable is *D. fraxinella*, so named in allusion to the similarity which exists between its leaves and those of *Fraxinus*, the ash. Its root was formerly much used in medicine, but it is now rarely, if ever, employed. The plant is commonly called the false dittany.

DICYNODON, *di-sin'-o-don*, a genus of fossil reptiles, remains of which have been found in South America. It has affinities with the tortoise, and also with the crocodile and the lizard, and is remarkable as possessing two sharp-pointed tusks, growing downwards as in the walrus.

DIDYMIUM, *did'-e-me-um* (Gr., *didumos*, twin), a very rare metal, closely allied to cerium, and occurring with it in its ores. It forms one oxide, which has the properties of an earth.

DIELYTRA, *di-e-li'-tra*, a genus of plants of the natural order *Fumariaceæ*, larger than the ordinary fumitories. *D. spectabilis*, a favourite flower of Northern China, was introduced into Britain in 1846, and is cultivated on account of the beauty of its large racemes of drooping pink flowers. It is now a common flower in open gardens.

DIET. (*See* FOOD.)

DIETETICS, *di-et-et'-iks* (Gr. *diaitetike*), that department of medical science which relates to the diet or ordinary food. (*See* FOOD.)

DIFFERENTIAL CALCULUS, *dif-fer-en'-shal* (Lat., *differo*, I move apart), a term applied to one of the most important branches of the higher mathematics. The object of the differential calculus is to find the ratios of the differences of variable magnitudes, on the supposition that these differences become infinitely small. In this study it is necessary to pay particular attention to the meaning of the terms infinitely and infinitely small. All magnitudes in mathematical reasoning are considered to be capable of augmentation and diminution without limit. A quantity, therefore, can be conceived to be so great as to exceed any finite quantity of its own nature, or so small as to be less. In the first case it is said to be infinite, and in the latter infinitely small. These magnitudes are of course imaginary, as in both cases quantities may be conceived either greater or smaller: so that an infinitely large quantity may be considered as nothing, or zero, and an infinitely small quantity as the same, when compared with one another. In the differential calculus, the infinitely small quantities which come under consideration are called *differentials*. The differential of a magnitude, or variable function, as it is called, is expressed by placing the letter d before the magnitude or function. Thus dx signifies the differential of the variable magnitude x. Formerly it was the custom to put a dot over the *fluxion* of a quantity, as it was then called. The use of the letter d was introduced by Leibnitz, who, contemporary with Sir Isaac Newton, gave much attention to the subject. These two philosophers, independently of one another, studied the science of the differential calculus at the same time; but of late years the method of Leibnitz has almost exclusively prevailed, to the exclusion of the name, notation, and method of Newton's fluxions, in such points as they differ.

DIFFRACTION OF THE RAYS OF LIGHT, *dif-frak'-shun* (Lat., *diffractum*), the modification which light undergoes in passing very near the edges of any opaque body. It was first observed by Grimaldi, who noticed that when a ray of light was allowed to enter a dark room, the shadows cast from any opaque body were larger than if the light passed by it in straight lines, and that those shadows have three bands of coloured light parallel with them. At first this phenomenon was attributed to the refracting power of the atmosphere; but this theory was disproved by Newton, who treats of the subject in the last book of his Optics. He endeavoured to explain its occurrence through the general properties of light. It is now looked upon as identical with many phenomena connected with the undulatory theory of light, and is assigned to the interference of undulations.

DIFFUSION, *dif-fu'-zhun* (from Lat., *diffundo*, I pour out hither and thither), the gradual dispersion of particles of one liquid or gas among those of another, or of the particles of a solid in a liquid holding it in solution.

Of Gases.—If two vessels be filled with two different gases, and connected by a tube, it will be found that, after a certain lapse of time, an intimate and equal intermixture of them will take place. If, however, means be taken to measure the velocity with which they mix, it will be found that the lighter of the two diffuses itself much more rapidly into the heavier than *vice versâ*. Professor Graham and others have determined the exact rates of diffusion of all gases, which appear to be in accordance with a law that the relative diffusiveness of gases is unity divided by the square root of their density, taking air as the standard. Diffusion of gases is a process that is continually going on around us. Were it not for this property, gases deleterious to animal and vegetable life would be constantly accumulating in poisonous masses, instead of being silently and harmlessly distributed through the atmosphere.

Of Liquids.—Liquids of different densities, like gases, gradually diffuse into each other when brought into contact. Thus, if a salt-jar be filled with water, and red wine be gradually and carefully conveyed to the bottom of the vessel, it will be found that, after the lapse of a few days, the wine will gradually diffuse itself into the water and the water into the wine, until the whole is uniformly mixed. By means of an apparatus of this kind Professor Graham was enabled to calculate the different velocities of a large number of substances. These velocities vary in the most remarkable manner, sulphuric acid, for instance, diffusing into water with twenty-four times the velocity of albumen. Pursuing these experiments, he was at last able to classify all soluble substances according to their velocities, and in doing so he made the remarkable discovery that a diaphragm covered with a layer of a solution of low velocity totally interrupted the passage of a solution of still lower power of diffusion through its mass. Carrying these ideas further, he has classified all soluble substances under two heads—*colloids*, or amorphous substances similar to gelatine, which he takes as the type of the class; and *crystalloids*, or substances taking a crystalline form, and having a high diffusive velocity. These two classes seem to be divided naturally by other characteristics than velocity of diffusion. All crystalloids are more or less rapid, while colloids, such as starch, dextrin, albumen, &c., are insipid, and soluble with difficulty. Colloids offer but little resistance to the diffusion of crystalloids through their mass, while they are in a manner impervious to substances of their own class. On this property Mr. Graham has founded his system of dialysis, or the separation of the crystalloid and colloid constituents of a liquid by the intervention of a colloid septum. (*See* DIALYSIS.)

DIGESTION, *di-jes'-tshun* (Lat., *digestio*, from *digero*, I carry to different parts, or dissolve), in Physiology, is that process by which the food of animals is converted into chyme in the stomach, and prepared for being ultimately taken into the blood. The principal processes connected with digestion are usually represented as—(1) Mastication; (2) insalivation; (3) deglutition; (4) chymification, or the action of the stomach; (5) chylification, or the action of the intestines; (6) defæcation; and (7) the absorption of the chyle. The operation of mastication is a very important auxiliary to digestion; since the more the food is broken down and mixed with the saliva the more readily and completely will it be acted upon by the stomach. Imperfect mastication is a frequent cause of indigestion. During this process the salivary glands yield up their contents, by means of which the dry food is moistened and rendered more fit for deglutition. The third process is the act by which the food is transferred from the mouth to the stomach. (*See* DEGLUTITION.) The alimentary matter being propelled by the contractions of the œsophagus into the cardiac extremity of the stomach, is there acted upon and dissolved by the gastric juice, which is secreted by glands lying in its inner or mucous coat. This process is assisted by the muscular contractions of the stomach, by means of which the mass is kept in motion until it is formed into chyme. When it has been sufficiently operated upon, it passes through the pyloric opening into the duodenum. The plyorus possesses a peculiar sensibility, that prevents any matter from passing through it but such as has been properly converted into chyme. Recent investigations have shown that the changes which the food undergoes in the stomach are essentially chemical. (*See* GASTRIC JUICE.) The process of gastric digestion is very slow. It is more than an hour before the food suffers any apparent change; and the ordinary time required for the digestion of animal food is from three to four hours. The chyme having passed through the pylorus into the duodenum, becomes mixed with the biliary, pancreatic, and intestinal secretions. These juices, by their action upon the chyme, separate it into two portions—one a milky fluid called chyle, the other the excrementitious portion. The bile seems to be of use principally in promoting the digestion of fatty matters, while the pancreatic juice serves mainly to convert starchy matters into sugar. Of the use of the intestinal juice little is known. The chyle attaches itself to those irregular circular folds of the mucous membrane of the small intestines, called the valvulæ conniventes, where it is absorbed by the lacteals. The large intestines also possess lacteals; so that, if any portion of the chyle should not have been absorbed in the small intestines, it is taken up in the large ones. The fæces pass gradually from the small to the great intestines, until they reach the rectum, where they are retained for some time and then discharged. The absorption of the chyle forms the last act in the process of digestion. It is, as we have already seen, taken up by the lacteals, and is by them conveyed to the mesenteric glands, where it is supposed to undergo some change. From thence it makes its way to the right side of the aorta, in the lumbar region, where it is finally discharged into an elongated pouch, called the receptaculum chyli. From this pouch the thoracic duct conveys the chyle upwards to the left side of the neck, where it is poured into the left subclavian vein at its junction with the internal jugular, and, being thus mixed with venous blood, it is carried to the lungs and there converted into new and perfect arterial blood.

DIGITALIS, *dij-it-ai'-lis* (Latin, *digitus*, a finger), a genus of plants belonging to the natural order *Scrophulariaceæ*. The most important species is *D. purpurea*, the purple foxglove, one of the handsomest of our indigenous plants. It is a biennial, blossoming during the months of June and July, and is found on hedge-banks and the sides of hills, in dry, gravelly, or sandy soil. The flowers are somewhat bell-shaped, and their remote resemblance to the fingers of a glove suggested the generic name. They are beautifully marked on the inside with purple blotches. The foxglove sometimes grows to the height of six, or even seven feet. A variety commonly met with in gardens has white flowers spotted with different shades of cream-colour and pearl. The wild foxglove is a most important medicinal plant. The leaves only are officinal in our pharmacopœias; but the seeds and roots possess similar properties. Digitalis is a diuretic, and greatly resembles tobacco in many of its properties. It is employed to reduce the action of the heart in diseases of that organ, in fever, and in inflammations. It is prescribed as a diuretic in dropsies of all kinds, but is most useful in those associated with a debilitated and generally diseased state of the constitution. It is a violent poison, and great care is requisite in prescribing it, as its use, even in small doses, has led to fatal results, for it accumulates in the system. The active principle of foxglove is termed *digitaline*.

DIGITIGRADA, *dij'-it-e-grai'-da* (Latin, *digitus*, a finger; *gradior*, I walk), in Cuvier's zoological system, a tribe of carnivorous animals distinguished by walking upon the toes, the heel being always raised from the ground. Those animals which place the heel or the sole of the foot on the ground belong to the tribe *Plantigrada*. Some of the most carnivorous mammalia belong to the digitigrada. The feline and canine families, hyænas, civets, &c., are all included in it. The Weasel family (*Mustelidæ*) appears to form a connecting link between the digitigrada and the plantigrada.

DIKAMALLI, *di-kam-al'-li*, a gum resin obtained from young shoots of an Indian tree, *Gardenia lucida*. It is very fragrant, and is used as a dressing for wounds and running sores.

DILL. (*See* ANETHUM.)

DILLENIACEÆ, *dil-len-e-ai'-se-e* (after the botanist Dillenius), the *Dillenia* family, a natural order of dicotyledonous plants, in the sub-class *Thalamifloræ*, consisting of trees, shrubs, and a few herbs. The order includes between 20 and 30 genera, and about 200 known species, occurring chiefly in Australia, India, and equinoctial America. They have astringent properties, and many are used for tanning and as vulneraries. The young calyces of some species of the typical genus *Dillenia* have an acid taste, and are employed to flavour curries in some parts of India. Many species of this genus grow to a large size, and form hard durable timber. Those of India are generally remarkable for fine evergreen foliage and very beautiful flowers. They are sometimes cultivated as stove or greenhouse plants in this country.

DILLESK. (*See* RHODOMENIA.)

DILUENTS, *dil'-u-ents* (Lat., *diluo*, I wash away), liquids administered to increase the fluidity of the blood, and render certain of the secretions and excretions less viscid. They likewise promote the operation of more active medicines, especially aperients and diuretics. Water is the simplest and frequently the best diluent; or it may be made more agreeable by the addition of acid or other substances, or in the form of toast-and-water. Gruel, barley-water, infusion of tea, mutton and chicken broth, beef-tea, and such like, come under this designation. Diluents are of great use in allaying the thirst of patients affected with fever or other inflammatory complaints, and are often very useful in subduing the more violent symptoms of the disease, and relieving the system by means of perspiration.

DILUVIUM, *di-lu'-ve-um* (Lat., *dis*, asunder; *luere*, to wash), a term applied to accumulations of gravel, sand, or stones, which are referred to the *extraordinary* action of water, the term alluvium implying the *ordinary* operations of water. At one time geologists merely used the word diluvium to distinguish accumulations supposed to have been formed during the Noachian deluge; but we now employ it as a common name for all masses which have apparently been produced by powerful aqueous agency.

DIMENSION, *dim'-en-shun* (Lat., *dimensio*), in Geometry, signifies the extent of anything. A line, whether straight or curved, has only one dimension—length; a surface has two dimensions—length and breadth; while a solid has three—length, breadth, and thickness. All forms of extension can be determined by these three dimensions.

In Algebra, the term dimension is applied to the number of true factors to a term, and is used very much in the same sense as *degree*. An equation is generally said to be of as many dimensions as there are units in the index of the highest power of the unknown quantity.

DIMORPHISM, *di-mor'-fizm* (Gr., *dis*, twice; *morphe*, form), the property possessed by certain bodies of assuming crystalline forms which cannot be derived from each other. Instances of this occur in the case of sulphur, which crystallizes as oblique prisms and as octahedra, according as it is crystallized by heat or from the solution in bisulphide of carbon.

DINGO, *ding'-go* (*Canis dingo*), the native dog of Australia, regarded by some naturalists as a distinct species, but more generally as the descendant of a race once domesticated, and returned to its wild state. It is found in Australia both in a wild and tamed state; the tame dingo being about the size of our familiar sheep-dog, and the wild one somewhat larger. The latter has a large head, with a fuller muzzle than the sheep-dog; ears short and erect; tail bushy; colour tawny. It does not bark, and is very destructive to the sheep of the colonists, it continues to strangle as many sheep as its strength will allow before it squats down to pick a bit of one.

DINORNIS, *di-nor'-nis* (Gr., *deinos*, wonderful or terrible; *ornis*, a bird), a genus of large birds of the tribe *Brevipennes*. No species of the dinornis now exists, but many bones belonging to birds of this class have been found in New Zealand, not only in the most recent deposits, but in the sand by the sea-shore, in caves, in swamps, in the soil of forests, and in river-beds. Among the natives there are many traditional reports about these birds, which were called *moa*, and are said to have possessed gorgeous plumage, for the sake of which they were hunted. They probably existed as late as the 17th century. The dinornis must have been considerably larger than any bird now existing; some of the bones found are twice as large as those of the ostrich; and the toe bones almost equal in size those of the elephant. The body must have been very bulky, and somewhat similar to that of the extinct dodo. The *Dinornis giganteus* must have been nearly eleven feet high. The number of bones of the dinornis that have beeen found is very great. Several species have been recognised, and some skeletons have been nearly completely restored.

DINOSAURIA, *di-no-saw'-re-a* (Gr., *sauros*, a lizard), a term applied to distinguish an order of extinct lizards found as fossils in the lias, oolite, and wealden formations. The dinosauria were enormous reptiles of the lizard class, which approached nearer to the mammal type than any other of their order. Four powerful limbs supported their bodies, and the sacrum was composed of five vertebræ amalgamated. The Megalosaurus, the Iguanodon, and the Hylæosaurus are the principal genuses of the order.

DINOTHERIUM, *di-no-the'-re-um* (Gr., *therion*, a wild beast), an extinct animal the cranial bones of which are found in the miocene formations of Germany, France, &c. Like the elephant, this remarkable animal was provided with a pair of formidable tusks, which projected downwards from the lower jaw. It was also provided on each side of its jaws with five double-ridged grinders. From the largeness of the nasal cavity, it is supposed that the animal had a trunk like the elephant. As none of the body or limb bones of the dinotherium have been found, its true position in the system of nature is not accurately determined.

DIODON, *di'-o-don* (Gr., *dis*, twice; *odous*, tooth), a genus of fishes of the family *Diodontidæ*. These fishes are about two feet in length, of a nearly spherical form, and possess the power of inflating or contracting themselves at pleasure. When their stomachs are thus distended with air, there are displayed over the entire surface numerous spines, as though to protect its now somewhat unwieldy body from attack. It is, doubtless, this latter circumstance that has procured for the fish the titles of sea-porcupine and globe-fish. When inflated, the globe-fish is incapable of swimming, but floats with the stream. They are found in warm seas. The sun-fish is of this family.

DIŒCIUS, *di-e'-se-ous* (Greek, *dis*, twice, and *oikion*, a habitation), a term applied to plants or flowers, the male and female flowers of which are produced on separate plants. Most species of willow are familiar examples.

DIONÆA, *di-o-ne'-a* (from Dioni, one of the names of Venus) a genus of plants belonging to the natural order *Droseraceæ*. The only species known is *D. muscipula*, a native of North America. This plant affords a remarkable instance of vegetable irritability. The leaf is two-lobed, and each lobe is furnished on its upper surface with three stiff hairs, which, on being touched by an insect or any other object, cause the two halves to collapse and inclose the object. The plant is commonly known as Venus's fly-trap, or Carolina Catchfly plant.

DIOPSIS, *di-op'-sis*, a genus of dipterous insects, remarkable for the great length of the pedicles on which the eyes are situated. On this account it is likewise termed the telescope-fly. All the species are found in warm parts of the old world.

DIOPTRICS, *di-op'-triks* (Gr., *dioptrikos*).—That portion of geometrical optics which treats of the passage of rays of light from one medium to another of a different kind. (*See* REFRACTION, OPTICS.)

DIOSCOREA, *di-os-kor'-e-a*, the typical genus of the natural order *Dioscoreaceæ*. Various species, as *D. alata*, *sativa*, and *aculeata* produce the tubers called yams, which, when boiled, are eaten in tropical countries as the potato is eaten in Europe.

DIOSCOREACEÆ, *di-os-kor-e-ai'-se-e*, the Yam family, a natural order of monocotyledonous plants in the sub-class *Dictyogenæ*, consisting of shrubby plants with twining stems rising from tuberous root-stocks, or tubers placed above or under the ground, and having net-veined leaves, and small-spiked bracteated flowers. They are natives chiefly of tropical countries, a few only being found in temperate regions. They are generally characterised by great acridity, though farinaceous matter adapted for food exists in the tubers of many species. (*See* DIOSCOREA, TAMUS, TESTUDINARIA.)

DIOSPYROS, *di-os'-pi-ros*, a genus of dicotyledonous trees, belonging to the natural order *Ebenaceæ*. Many of the species have hard and dark-coloured heart-woods, which constitute the different kinds of ebony; thus *D. ebenum* furnishes Mauritius ebony: *D. melanoxylon*, a native of the Coromandel coast, the sort commonly known as black ebony: and *D. ebenaster*, the bastard ebony of Ceylon. The beautifully variegated furniture-wood called Coromandel or Calamander wood, is obtained from *D. hirsuta*, and is brought to Europe from Ceylon. Other species also yield valuable timber. The fruit of *D. Kaki* is eaten in China and Japan, and is known in the latter country as the keg-fig. The fruit of *D. Virginiana*, a native of the United States, is sweet and edible when quite ripe, but very austere before then; hence it is frequently employed medicinally in its unripe state as an astringent.

DIP, *dip* (Ang.-Sax.), a miner's and geologist's term for the direction of any mineral vein or stratum in relation to the horizon.

DIP OF THE MAGNETIC NEEDLE. A very remarkable property of the magnetic needle was discovered in 1576, by Robert Norman, an English seaman; and was perfectly inexplicable till Gilbert's suggestion that the earth was a magnet threw some light on it. Norman observed that the needle had a tendency to "dip," that is, to point downwards as well as in a northerly direction, and that the tendency increased in a regular manner as the north or south pole was approached. Careful experiments and systematic records of observations have made known some striking results. A magnetized bar or needle, suspended by the centre so as to permit free movement, in tropical regions remains in a horizontal position; but dips as higher latitudes are reached, until at certain spots in the polar regions it becomes vertical, pointing directly to the earth. At these spots north and south are, it would seem, the magnetic poles. In 1832, Commander James Ross observed that the needle was in an exactly perpendicular position at a spot in that part of the Arctic regions named by Captain Ross Boothia Felix, lat. 70° 5′ N. and long. 96° 46′ W. A few years afterwards Commander Ross visited the Antarctic regions, and although he was unable to reach the south magnetic pole, the angle at which the needle continued to dip enabled him to fix the point at about lat. 70° S. and long. 125° E. As in the case of the horizontal variation of the needle, the angle of dip varies in the progress of time at the same place.

Dipping Needle.—The instrument with which the observations of the dip are made consists of a frame in which a graduated circle is fixed in a vertical position. The frame moves on a graduated circle in a horizontal position, fixed on a small tripod that can be adjusted by means of levelling screws. The needle is suspended on two knife-edges of agate, fixed in the frame exactly in the centre of the vertical circle, and moves freely in any direction in a vertical plane.

DIPHTHERIA, OR DIPHTHERITIS, *dif-the'-re-a* (Fr., *diphtherite*, from Gr., *giphthera*, a skin or membrane), a malignant and generally fatal disease of the throat. It was first observed and described by M. Bretonneau, of Tours, in France, where it prevailed as an epidemic in 1818. It subsequently broke out in other French towns, and in 1857 it made its appearance in England, where it has since been, unfortunately, by no means rare, and has already caused a large amount of mortality. It is characterized by a peculiar inflammation of the mucous membrane of the throat, or pharynx, accompanied by the production of a false membrane. At first this membrane appears in the form of a white spot on the pharynx or tonsils, from which it gradually extends forwards to the soft palate and into the nostrils, and backwards into the œsophagus, sometimes into the larynx, but seldom into the trachea, producing at length suffocation. It is usually accompanied by a fœtid discharge from the nose and mouth, and hæmorrhage frequently occurs. There is usually, also, a low and dangerous form of fever, with great depression of spirits and rapid decrease of the patient's strength, which is still further accelerated by his inability to take food. Various modes of treatment have been recommended; but success is in all cases extremely uncertain. The patient's strength is to be supported by means of tonics and stimulants. Quinine is generally recommended; and in most cases wine may be given with advantage. In the local treatment of the throat, nitrate of silver and chlorine are used.

DIPLACANTHUS, *dip-li-kan'-thus*, a species of fossil-ganoid fishes, found in the old red sandstone. Six species have been found.

DIPLOGRAPSUS, *dip-lo-grap'-sus*, a genus of fossil zoophytes, found in the anthracitic shales of the Silurian measures.

DIPPER (*Cinclus*), a genus of birds of the Thrush family, the British representative of which is the common dipper, or water-ousel, found also throughout the whole of Europe and the north of Asia. This bird is rather smaller than the thrush, of a dark-brown colour, with throat and upper parts pure white. The facility with which the dipper dives and pursues its prey beneath the water is very remarkable. It builds a very curious nest, composed of moss, domed, and with an entrance at the side: the site chosen is generally the bank of a stream, or sometimes under a cascade.

DIPSACACEÆ, *dip-sa-kai'-se-e*. (*See* TEASEL.)

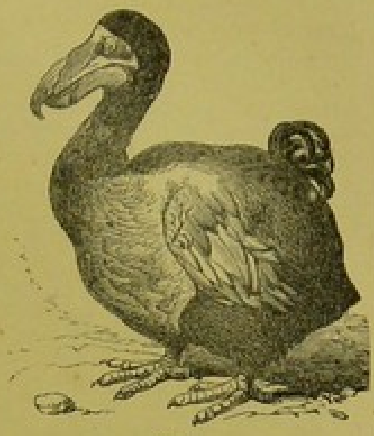
DIPSAS, *dip'-sas* (Gr., a kind of serpent), a genus of non-venomous tree snakes of the family *Colubridæ*. They are very long and slender, with broad obtuse heads. A very beautiful species, the *D. Cyanodon*, is found in Java and Sumatra.

DIPSOMANIA, OR OINOMANIA, *dip-so-mai'-ne-a* (Gr., *dipsa*, thirst; *oinos*, wine; *mania*, madness), a term recently applied to an inordinate or insane craving for alcoholic stimulants. Lately medical men have come to the opinion that the inveterate drunkard is to be regarded as habitually under the influence of an insane impulse which it is impossible for him to resist. (*See* INSANITY and INTOXICATION.)

DIPTERA, *dip'-ter-a* (Gr., *dipteros*, two-winged), an order of insects, having for their most conspicuous character only two wings, corresponding to the anterior pair of four-winged insects. They are also distinguished by having two clubbed appendages, called *halteres* or balancers, which seem to be the rudiments of two posterior wings. In ordinary language the diptera are called flies, usually with some character-

FLYING DRAGON.

DUCKBILL, PLATYPUS.



DODO.

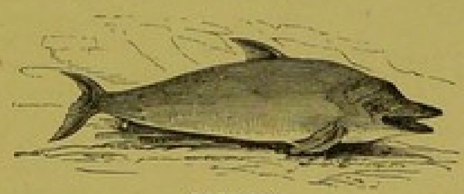
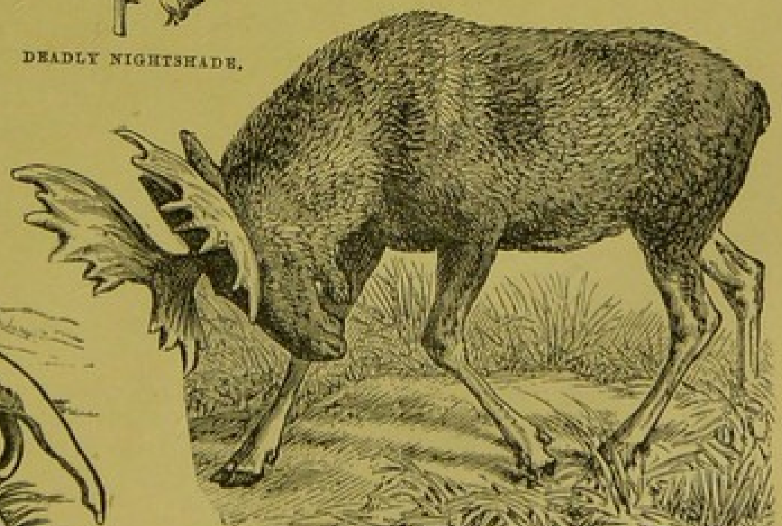
DINOTHERIUM. SKULL OF.

DEADLY NIGHTSHADE.



DOLPHIN.

DINOTHERIUM.



MOOSE DEER.

istic prefix; such as the housefly, blow-fly, &c. Mosquitoes, gnats, and midges belong to the diptera. It is one of the most extensive of the orders of insects, and some of the species are remarkable for the extraordinary numbers in which they appear. Dipterous insects are also distinguished by having the mouth in the form of a sucker, composed of from two to six lancet-shaped elongated scales, inclosing a canal upon the upper surface of the tongue or proboscis.

DIPTERACEÆ, *dip-ter-ai'-se-e*, the Sumatra camphor family, a natural order of dicotyledons, in the sub-class *Thalamifloræ*, consisting of large trees, with simple alternate involute leaves and large deciduous convolute stipules. The flowers are perfect and symmetrical. The plants of this order are all natives of the forests of the tropical East Indies, with the exception of the genus *Lophira*, which belongs to tropical Africa. The useful products of the order are oleo-resinous substances. (*See* DIPTEROCARPUS, DRYOBALANOPS, VATERIA.)

DIPTEROCARPUS, *dip-ter-o-kar'-pus* (Gr., double-winged carpel), a genus of plants belonging to the natural order *Dipteraceæ*. Several species, as *D. turbinatus*, *costatus*, *alatus*, and *incanus*, yield an oleo-resinous substance, called wood-oil or Gurjun balsam, which resembles in its properties the so-called balsam of copaiba, and which is used for similar purposes. In Java, banana leaves are smeared with this resin and used for torches. In India wood-oil has been employed for painting houses.

DIPTERUS, *dip'-ter-us*, a genus of fossil-ganoid fishes, deriving their name from the double anal and dorsal fins. They are peculiar to the old red sandstone.

DIPTERYX, *dip'-ter-iks*, a genus of plants belonging to the natural order *Leguminosæ*, sub-order *Papilionaceæ*. The seeds of *D. odorata*, a native of Guiana, have a very powerful and agreeable odour, which is due to the presence of a volatile oil containing coumarin. They are used for scenting snuff and in perfumery, and are commonly called Tonquin or Tonka beans.

DIRECT AND RETROGRADE, *di'-rekt ret'-ro-graid* (Lat., *directus*, *retro*, backwards, and *gradus*, a step), in Astronomy, when the motion of any heavenly body is from west to east, or in the direction and order of the signs of the zodiac, it is said to be direct; when the motion is in the contrary direction, or from east to west, it is said to be retrograde. The motion of all the heavenly bodies, except some of the comets, is direct.

DIRT-BEDS, *durt*, in Geology, dark-coloured loam-like beds that occur interstratified with the oolitic limestones and sandstones of Portland, and which are evidently the soils in which the cycads and zamias of the period grew. Stumps of trees in an erect position, with their roots extending beneath them, have been found in these strata.

DISC, *disk* (Lat., *discus*), a term now applied by botanists to whatever intervenes between the stamens and the ovary upon the thalamus. It presents great variety of forms: thus in the orange it forms a fleshy ring, surrounding the base of the pistil; in the tree pæony, a dark-red cup-shaped expansion, covering nearly the whole of the pistil except the stigmas; in the rose, a sort of waxy lining to the tube of the calyx; in umbelliferous plants, a swelling on the top of the ovaries, adhering to the styles. In other cases, the disc is reduced to little separate glandular bodies, as in cruciferous plants; or to scales, as in the vine; or to various petaloid expansions, as in the aquilegia.

DISC, the surface of a circular plate of metal or other substance; a thin circular plate of any substance.

In Astronomy, the body or face of the sun and moon, such as it appears to us; for though they are really spherical bodies, they are apparently circular planes.

Disc and Discobulus. (*See* QUOITS.)

DISCOBOLI, *dis-kob'-o-le*, a family of malacopterous fishes, known also as the *Cyclopteridæ*, having the ventral fins united to form a sucking disc on the under surface of the body; by which it is enabled to attach itself to fixed substances, and avoid being swept away by the current. The lumpsucker, *C. lumpus*, belongs to this family.

DISCUTIENT, *dis-ku'-te-ent* (Lat., *discutio*, I destroy), a term applied to remedies that discuss or disperse morbid matter.

DISEASE, *diz-eze'* (Ang.-Sax.), a negative of "ease," is a departure from the state of health in which the due balance between the several parts or properties of the animal frame is maintained. It is "a changed condition or proportion, in function or structure, in one or more parts of the body." Diseases of function are deviations from a standard furnished by physiology, and diseases of structure a departure from a standard supplied by anatomy. These, however, are usually combined; for there is seldom structural disease without some disorder of function; and in many instances functional diseases are, or ultimately will be, accompanied by change of structure. The causes of disease may be either intrinsic, existing within the body, or independent of any obvious external influence; or they may be extrinsic, having their origin without the body. The latter embrace all the external agencies that can operate either on body or mind; as temperature, air, food, poison, sensual impressions, and the like. Causes of disease, however, are often present without disease ensuing, some frames being less susceptible to particular causes of disease than others. Hence physicians distinguish two kinds of causes—predisposing and exciting; the former being circumstances which so influence the functions or structures of the body as to render it unusually susceptible to the influence of particular exciting causes—that is, of such circumstances and agents as seem to more immediately operate in producing disease, especially when in a state of predisposition. The classification and arrangement of diseases according to their external characters is termed Nosology; and that branch of science which more particularly regards the nature and progress of disease with a view to its cure, is called Pathology. (*See* NOSOLOGY, PATHOLOGY.)

DISINTEGRATION, *dis-in-te-grai'-shun* (Lat., *dis*, *integer*), the act of separating the integrant parts of a substance, as distinguished from decomposition, or the separation of constituent parts. Disintegration refers more particularly to the mechanical diffusion of a substance; decomposition, to the chemical division.

DISLOCATION, *dis-lo-kai'-shun* (Lat., *disloco*, I put out of place), is the displacement out of their natural position of bones articulated together or forming a joint. It is usually occasioned by external violence; but may also, in some cases, result from diseases of the joint. Dislocation is either complete or incomplete; being incomplete when the articular surfaces remain partially in contact, and complete when there is an entire separation. It is simple when there is no wound and the skin remains unbroken; compound, when there is a wound, by means of which the external air may communicate with the joint. When, besides the dislocation, there are fractures of the bones or laceration of important organs, then it is termed a complicated dislocation. Nearly all the bones of the human body are liable to displacement; but some are much more so than others; as those of the shoulder, hip, elbow, ankle, &c. Generally, those joints are the most liable to dislocation that admit of the greatest extent of motion. Dislocation is in most cases easily observable; but in some parts it is extremely difficult of detection. It is attended with loss of power and motion in the part, with more or less of swelling and pain, which is increased on moving the part; the patient feels sick and faint, and there is a sensation of numbness in the part. Dislocations should be reduced as soon as possible after their occurrence; for the longer it is delayed, the more difficult will be the operation. Dislocations are reduced by pulling gently, yet firmly and steadily, for some minutes, until the muscles are fatigued, and the head of the bone brought down below the level of the joint, when, by being gently lifted over the edge of the socket, it falls into its place, upon the extending force being slightly relaxed. The force required is often very considerable, and sometimes it is necessary to have recourse to a block and pulleys, in which case the body is securely fixed by proper bandages to a staple in the wall, or other sufficient support. In order to overcome the violent contraction of the muscles, it was sometimes necessary formerly to weaken the patient by blood-letting, emetics, &c.; but latterly chloroform has been most commonly resorted to for this purpose. After reduction it is necessary that the joint be kept in a state of perfect rest for some time, in order to allow the ruptured ligaments to unite; otherwise the accident will ever afterwards be liable to recur. When a dislocation has been left unreduced, the parts come to adapt themselves to their new situation; a new socket is formed for the head of the bone displaced, the old socket becoming absorbed or filled up. Compound dislocations are generally attended with danger, and, when occurring in the large joints, are usually fatal, or require amputation.

Dislocation, in Geology. (*See* FAULT.)

DISPERSION, *dis-per'-shun* (Lat., *dispergere*, from *dis*, a particle denoting separation, and *spargere*, to scatter), the term applied to the separation of a ray of white light into its several component coloured parts by refraction, through the instrumentality of a prism. (*See* PRISM and SPECTRUMS.) In Optics the term is often applied to the reflection or scattering of rays of light from any polished and reflecting surface. The amount of light actually reflected, according to the regular law, varies with the nature of the reflecting surface. The loss by this dispersion is about one-third for a perpendicular looking-glass, and a little less for highly polished speculum metal.

DISSECTION, *dis-sek'-shun* (Lat., *dis*, and *seco*, I cut), is applied to the cutting or dividing of the different parts of the body in anatomy. The practice of dissection is essential to a course of medical study. (*See* ANATOMY.)

DISSOCIATION, *dis-so-si-a'-shun* (Lat., *dis*, apart, and *socius*, a companion). The influence of heat and pressure on chemical action. The theory of M. Deville, who first used the word, was, that, by selecting a proper compound and heating it sufficiently, the distance between the molecules can be increased to such an extent that they will separate into their elementary condition. This is a spontaneous decomposition, not determined by any chemical action. There has been much controversy on the subject.

DISSOLUTION, *dis-so-lu'-shun* (Lat., *dissolutio*, from *dis*, and *solvo*, I set free), a term variously applied, but in its commonest and most general sense implying the separation of the parts of a body which in the natural condition are united. The state of being liquefied by heat or moisture is termed dissolution; thus, ice is changed from a solid into a fluid state by heat; metals, again, can undergo dissolution by the action of an acid menstruum. The separation of the soul from the body is termed dissolution, or, more generally, death. (*See* DEATH.) Dissolution of the blood denotes that condition of the vital fluid in which it does not readily coagulate on its cooling, out of the body, as in the case of malignant fever.

DISTEMPER, a disease to which young dogs are liable. It is supposed to have been derived from France, and is considered to be a typhoid inflammation affecting the upper air-passages. It closely resembles the strangles of young horses, and the scarlatina and such-like diseases to which young children are liable. The disease is contagious, occurs generally only once in a lifetime, runs a definite course, and is accompanied by low fever and debility. A dog with the distemper is easily recognised. The eyes become red, weak, and watery; the nose hot and dry; any movement in the air excites a cough or sneeze; and there is a general dulness, fever, and loss of appetite. The running from the nose, as the disease proceeds, becomes, after some days or weeks, mucous or purulent, loading the eyes and obstructing the nostrils. It then lodges in the bronchial tubes, preventing the free access of air and the purification of the blood. All dogs are subject to distemper; but highly-bred, delicate, and fancy dogs are most liable to the disease, and the mortality amongst them is the greatest. In the cure of distemper all irritating and reducing remedies must be avoided. If the stomach is overloaded, it should be relieved by a mild emetic; and if no effect is produced by the dose, it should be repeated in twenty minutes. To ward off distemper, young dogs should be very liberally and nutritiously fed. In such cases, in spite of all care if they are attacked with distemper, they are almost certain to pass over it very favourably.

DISTORTION, *dis-tor'-shun* (Lat., *distortio*, from *distorqueo*, I twist), in Surgery, is a permanent deviation from the natural shape or position of the body, producing visible deformity. Distortions may arise from various causes. They generally occur after birth, and thus differ from deformities, which are for the most part congenital. Distortions are frequently occasioned by affections of the muscles or nerves. It is well known that every movable part of the body is furnished with two sets of muscles acting in contrary directions, by means of which it is not only moved, but also retained in its natural position. Hence it is evident that if, by means of any injury to one of the sets of muscles, or of the nerves communicating with them, their contractility is destroyed or impaired, the part can no longer be maintained in its natural position, but will be drawn towards the antagonistic muscles. In this way various kinds of lameness, wry neck, squinting, &c., are produced. The most common cause of distortion, however, is disease of the bones. These are sometimes deficient in the earthy matter which gives them hardness and rigidity, and thus are incapable of supporting the weight of the parts which they are designed to bear, or of sustaining the muscular action, without becoming bent and distorted. From this arises the disease known as rickets (which *see*). The distortion known as the lateral curvature of the spine arises from weakness in the vertebral muscles, inducing a habit of resting the weight of the body more on one side than the other. Unlike rickets, which commence early, this does not usually make its appearance before the tenth year, and is most commonly found among slender and delicate females in the higher and middle ranks of life. It is generally occasioned by too much confinement and restraint, and is best got rid of by plenty of free exercise of the limbs in the open air. Angular curvature of the spine differs entirely from the above, and is occasioned, for the most part, by ulceration of the body of one or more of the vertebræ. The support in front being thus lost, the spine is bent sharply forwards, and one or more of the spinous processes project behind. Perfect rest in the horizontal position, issues and setons in the neighbourhood of the diseased bone, and attention to the general health, is the treatment to be adopted in this case. Diseases of a similar kind frequently occur in the bones and joints of other parts of the body, and require similar treatment. Distortions may also arise from a variety of other causes; as rheumatism, gout, burns, and various chronic and local affections; but these come more properly for consideration under their own heads.

DISTRIBUTION OF ANIMALS AND PLANTS. (*See* PHYSICAL GEOGRAPHY.)

DITHIONIC ACID, *dith-e-on'-ik*, also called hyposulphuric acid—the second of the *thionic* series of sulphuric and oxygen compounds, all of which contain five equivalents of the latter.

DITTANY, *dit'-ta-ne*, a genus of plants (*Dictomnus*) of the natural order *Rutaceæ*. The common dittany or fraxinella (*D. altus*) is found in the elevated forest regions of Southern Europe, and is cultivated as a garden flower. It is a perennial from two to three feet high, with flowers generally of a fine rose colour, but sometimes white. The plant contains a great amount of volatile oil, and is peculiarly fragrant.

DIURETICS, *di-u-ret'-iks* (Gr., *diouretikos*), those agents which have the power of augmenting the secretion of urine. Their action is beneficial whenever the system is troubled with an excess of fluids or of salts and nitrogenous substances derived from effete tissues.

DIVERGING LINES, *di-verj'-ing* (Lat., *divergo*, I tend from), a term employed in Mathematics and Optics to denote those lines which separate or recede from one another after proceeding originally from the same point. In Mathematics, a diverging series is one of which the terms increase more and more the further it is continued.

DIVERS, *di'-verz* (*Mergus*), a genus of birds of the family *Colymbidæ*. They closely resemble the grebes; indeed, the chief point of difference consists in the former having palmated feet. They have strong, straight, rather compressed pointed bills, about as long as the head; short rounded tails; short wings; their legs placed far back, and toes completely webbed. They fly well, and, as divers, are remarkably expert. They measure usually from two and a-half feet to three feet in length, and are essentially inhabitants of high northern latitudes, visiting our shores in the autumn, remaining through the winter, and quitting us in the spring to seek their northern breeding-stations. The great northern diver (*Colymbus glacialis*) is the largest of the tribe. It measures full three feet in length, and four feet six inches in breadth. The head and neck are black, shaded with purple and green. At the back of the neck there is a white crescent-shaped band, marked with black oblong strokes pointing downwards. The breast and underside of the body are white; the back, wing-coverts, and scapulars are black, thickly dotted with white. The red-throated diver (*Colymbus septentrionalis*) is smaller than the great northern, and lighter coloured. In habitat, however, they exactly agree.

DIVISIBILITY, *div-iz-e-bil'-e-te*, the property possessed by all bodies of being separable into parts. (*See* ATOMIC THEORY and HOMŒOPATHY.) The diffusion of odours through the atmosphere shows the minute division of material particles; and the tinging of large quantities of fluid with minute portions of colouring matter is an instance of the same. In the theory of numbers, the term divisibility indicates the capability of any number being divided by another without remainder.

DIVISION, one of the principal rules of arithmetic. By this operation can be determined how often one quantity is contained in another. The *dividend* is the number to be divided; the *divisor*, that by which the dividend is to be divided; and the *quotient*, the result. Division is divided into two classes—arithmetical division and algebraical division. In arithmetical division, when the numbers are expressed in the scale of tens, the following is the mode of working:—On the left-hand side of the dividend is written the divisor, separating them by a line. Beginning with the highest order of units of the dividend, the lower orders are passed over until the fewest number of figures is found that will contain the divisor; it is next determined how many times the divisor is contained in these figures, and the number is written on the other side of the dividend, beginning from the left for the first figure of the quotient. The divisor is then multiplied by this figure of the quotient, and the product placed under the figures of the dividend used, and subtracted from them, and the next figure of the dividend is brought down to the remainder. The number of times the divisor is contained in the result forms the second figure of the quotient. The operation is continued till all the figures of the dividend are used; the final result is the quotient sought. If the final remainder is 0, the division is said to be exact, or the dividend contains the divisor an exact number of times. Division of weights and measures or of money is known as compound division.

In Algebra, division is arranged under three heads:—First, the division of monomials, where, in order to get the co-efficient of the quotient, the co-efficient of the dividend is divided by the co-efficient of the divisor. After this, all the letters which enter the dividend and divisor are written, an exponent being given to each equal to the excess of its exponent in the dividend over that in the divisor. The result is the quotient sought. If the signs of the dividend and divisor are alike, the sign is *plus* (+); if they are unlike, it will be *minus* (−). The second division of algebraical division includes the division of a polynomial by a monomial. In this case each term of the polynomial is divided separately by the divisor. The algebraic sum of the separate results is the quotient. The third division is the division of polynomials. Both dividend and divisor are arranged with reference to the same leading letter. The first term on the left of the dividend is then divided by the first term on the left of the divisor, and the quotient forms the first term of the quotient. The divisor is then multiplied by the term of the quotient found, and the product subtracted from the dividend for the first remainder. The first remainder is then divided by the first term of the divisor for the second term of the quotient. The divisor is multiplied by this term of the quotient, and the product subtracted from the first remainder to make the second remainder. The operation is continued till a remainder is found whose first term is not exactly divisible by the first term of the divisor. The operation of the division of polynomials may sometimes be shortened by various methods. Among these may be mentioned *synthetic* division, which is applicable when the dividend and divisor are homogeneous, and contain only two letters. In the division of radicals, the process depends upon reducing the radicals to equivalent ones of the same degree. A number may also be divided by another by subtracting the logarithm of the divisor from the logarithm of the dividend: the number corresponding to the remainder in the logarithmic table is the quotient required.

DIVISOR, *div-i'-zor*, one of the factors of the Dividend—the factor by which the dividend is divided. Divisors of a number are those numbers by which it is exactly divisible. Thus, 1, 2, 3, 4, 6, and 12 are divisors of 12, because 12 may be divided by each of them without a remainder.

DIVI-DIVI. (*See* CÆSALPINIA.)

DOBCHICK, *dob'-tchik*. (*See* GREBE.)

DOCK, the common name for large, perennial herbaceous plants, forming a sub-species of the genus of Rumex (which *see*).

DODDER, *dod'-der*, a genus of plants (*Cuscuta*), regarded by some botanists as the type of a small distinct natural order *Cuscutaceæ*, of which there are about fifty known species, mostly natives of the warmer temperate regions. They are leafless climbing parasites, attaching themselves chiefly to leguminous plants, heath, hops, nettles, &c., by means of little rootlets. It resembles tangled catgut.

DODECAGON, *do-dek'-a-gon* (Gr., *dodeka*, twelve; *gonia*, an angle), a polygon which has twelve angles and twelve sides. When the angles and the sides are each of them equal, the dodecagon is a regular one, and may then be inscribed in or circumscribed by the circle, the sum of its interior angles equalling twenty right angles. (*See* REGULAR FIGURE.)

DODECAHEDRON, *do-de-kai-he'-dron* (Gr., *dodeka*, twelve; *edra*, a base), in Geometry, one of the five regular solids, being contained under a surface composed of twelve equal and regular polygons or bases. (*See* REGULAR BODY.)

DODO, *do'-do*, a genus of birds believed to be now extinct, but of whose existence within the last three centuries there is abundant evidence. When, in 1598, the island of Mauritius was discovered, the bird in question was plentiful and the sailors ate the flesh, which was much relished. It is described as being considerably larger than a swan, weighing sometimes fifty pounds, with a very bulky and heavy form. The bill was long and strong, depressed at the base, with a separate and much-arched apical portion, which was so sharp and strongly hooked at the tip that the dodo has been considered by some naturalists as approaching the predacious birds. The nostrils were placed on the sides of the depressed portion of the bill, which was covered by a naked skin; the face was similarly clothed. The feet, which were very short and stout, bore a considerable resemblance to those of the pigeon. The wings were also very short, and quite incapable of raising the bird in the air, even had they been furnished with the ordinary stiff quill-feathers; but, in place of these, they bore a few soft decomposed plumes like those of the ostrich and the teal, and were adorned with a tuft of similar but smaller feathers. This rudimentary condition of the wings led to the dodo's being placed among the cursorial birds by many writers. The general colour of the dodo was a blackish grey, but the plumes of the wings were of a light ash-colour. In Tradescant's catalogue ("Musæum Tradescantianum; or a collection of Rarities preserved at South Lambeth," by John Tradescant; London, 1656), we find, among the "whole birds, dodao, from the island Mauritius; is not able to flie, being so big." That this was a dodo there can be no doubt. Tradescant's stuffed specimen passed to the Ashmolean Museum at Oxford; but, being allowed to fall to decay, it was, by order of the curators, destroyed in 1755. Luckily, however, the head and one of the feet escaped destruction, and these, together with one other foot, safely stored in the British Museum, comprise the sole known remains of a creature commonly eaten within the last three hundred years.

DOG, *dog* (*Canis familiaris*), a genus of carnivorous quadrupeds. In all ages the *origin* of the domestic dog has been a question, and one most difficult of solution, with the most learned naturalists. Some are of opinion that the breed is derived from the wolf; others maintain that it is a familiarized jackal; all agree that no trace of it is to be found in a primitive state of nature. It is worthy of especial remark that the anatomy of the wolf, and its osteology in particular, does not differ from that of the dog in general more than the different kinds of dogs do from each other. The cranium is absolutely similar, and so are all, or nearly all, the other essential parts; and to strengthen still further the probability of their identity, the dog and the wolf will readily breed together, and their progeny is fertile. The obliquity of the position of the eyes in the wolf is one of the characters in which it differs from the dog. Another strong argument in favour of the identity of the dog and the wolf, is the fact that in both the period of gestation is the same—sixty-three days. The young of both wolf and dog are born blind, and see at the same, or about the same, time, namely, at the expiration of the tenth or twelfth day. A satisfactory classification of the different kinds of dog has not yet been arrived at. What some naturalists regard as types, others regard as mere mongrel races. It is hard to found a principle of arrangement; form does not afford it, neither does the character of the fur; kinds that are totally dissimilar associate as easily as those that are closely allied. One of the best arrangements is that made by Colonel Hamilton Smith, wherein the domestic dogs are grouped in six sections:—1, the Wolf-dogs, including the Siberian, Iceland, Esquimaux, Newfoundland, Nootka, sheep, great wolf, Great St. Bernard, Pomeranian dog, &c.; 2, Watch and Cattle dogs, including the German boar-hound, Danish dog, mâtin, dog of the North American Indians, &c.; 3, the Greyhounds, including the Brinjaree dog, different kinds of greyhound, Irish hound, lurcher, Egyptian street dog, &c.; 4, the Hounds, including the bloodhound, old Southern hound, staghound, foxhound, harrier, beagle, pointer, setter, spaniel, springer, cocker, Blenheim dog, water-dog, or poodle, &c.; 5, the Cur dogs, including the terrier and its allies; 6, the Mastiffs, including the different kinds of mastiffs, bull-dog, pug-dog, &c. (*See* various headings.)

DOG-BANE. (*See* APOCYNACEÆ.)

DOG-FISH (*Scyllinus catulus*), the common name of some of the smaller species of shark. The best known is the picked dog-fish, which is found in the European seas, and attains a length of about three feet. It belongs to the family *Spinacidæ*, of which one characteristic is the presence of a spine before the two dorsal fins. The body is long and tapering; the head flat; the snout conical; the teeth in both jaws sharp-edged, and formed for cutting. The tail fin is longer than it is broad. The upper parts are slate-grey, the under parts yellowish white. To use its spines offensively, the dog-fish bends itself into the form of a bow, and by a sudden motion causes them to spring asunder in an opposite direction. The dog-fish sometimes appear in prodigious numbers. They are said to afford the best food of any of the sharks, and are commonly brought to the markets of sea-side towns. The flesh is often dried. The liver yields oil, and the refuse parts are used as manure.

DOG-STAR. (*See* SIRIUS.)

DOG-WOOD BARK. (*See* CORNUS.)

DOG-GRASS. (*See* COUCH-GRASS.)

DOGWOOD, OR DOGBERRY, *dog'-wood*, a name commonly given to some of the arboreous and shrubby species of the genus *Cornus*. The common dogwood (*C. sanguinea*), a native of many parts of Europe and of the north of Africa, is a shrub averaging about 10 feet in height, with greenish-white flowers, with a disagreeable odour. The leaves become of a dark-red colour before falling off in autumn. The wood is very hard, and used for skewers, and formerly for arrows. The berries yield an oil which is used in France for lamps and in the manufacture of soap. The American dogwood (*C. Florida*) is a small tree, yielding excellent cross-grained timber, and the bark is used in medicine as a vermifuge. A powerful narcotic is obtained from the Jamaica dogwood. (*See* PISCIDIA.)

DOLERITE, *dol'-er-ite*, a mineral composed of felspar and anjike. It is a variety of greenstone.

DOLICHOS, *do'-li-kos*, a genus of plants of the order *Leguminosæ*, sub-order *Papilionaceæ*. There are many species, some shrubby, some annual, and some perennial. The flowers of some species are beautiful, and the seeds and young pods of others are cooked for the table.

DOLOMITE, *dol'-o-mite* (from Dolomieu, a French geologist), a crystalline variety of magnesian limestone, differing from the ordinary varieties, which are compact and amorphous. The crystalline structure is generally supposed to result from igneous influence.

DOLPHIN, *dol'-fin* (*delphinus*), a genus of *Cetacea*, and the type of a family *Delphinidæ*. It is usually from 6 to 8 feet in length, and bears a great resemblance to the porpoise, but has a much longer and sharper snout. The teeth in both jaws are nearly conical, though some of the species lose those of the upper jaw at an early age. They are very voracious, and are said to prey not only on fishes, medusæ, &c., but also on the wounded and feeble of their own species. They live, however, in herds, which often delight the voyager in the ocean solitude by the gambols which they perform around his ship. The common dolphin is found in the Mediterranean and in the North Atlantic Ocean. The French name is *Bec d'Oie*, goose-beak, or *Oie de Mere*, goose of the sea.

DONATI'S COMET, *do-na'-te*, a brilliant comet discovered at Florence by an Italian astronomer named Donati, early in June, 1858, when it was supposed to be nearly 230,000,000 of miles distant from the earth. It became visible to the naked eye in the beginning of the September following. It reached the point in its orbit nearest to the earth on October 10, when the diameter of its head appeared to be about 100,000 miles, and that of the nucleus 800 miles. When it first became visible without the aid of a telescope, its tail appeared to be 14,000,000 of miles in length. This gradually increased to 50,000,000 on October 10, but as it went away from the earth, the length of this part of the comet diminished with greater apparent rapidity than it had previously increased.

DONAX, *do'-nax*, a genus of molluscs, of the family *Tellinidæ*, with shells of two equal valves of a triangular form. The species, of which several are found on the British coasts, are generally small. Some fossils are found in the eocene formation.

DOOM PALM (*Hyphæne Thebaica*), a species of palms, natives of Upper Egypt and the central parts of Africa. It differs from most other palms in having a forked stem.

DOORNBOOM, or thorn-tree, a common tree in South Africa (*Acacia bronida*). It is about 30 feet high, and the timber is very useful.

DORADO, *do-ra'-do* (Fr., *dorade;* Sp., *dorado*, gilt, from *dorar*, to gild), in Astronomy, a constellation in the southern hemisphere, otherwise known as the Sword-fish. It lies in a direct line between the constellations Argo and Eridanus. Its largest star is of the third magnitude.

DORIS, *dor'-is*, a genus of naked marine mollusca of the order *Nudibranchiata*, somsetime known as sea-lemons. The body is oval, the abdomen flat; the back flat in some, and elevated in others; the mouth a small proboscis, with two small tentacula; the vent situated in the back, and surrounded by a circle of branched or plumed gills. They are plentiful on the coasts of Britain, where they may be found crawling on rocks, sea-weed, &c.

DORMOUSE, *dor'-mows* (from Lat., *dormio*, I sleep, and *mouse*), a genus of rodent quadrupeds (*Myoxis*) which is generally regarded as forming a connecting link between the *Muridæ* (rats, mice, &c.) and the *Sciuridæ* (squirrels, &c.). The chief characters by which the dormice are distinguished from the squirrels are derived from the structure of the skull, teeth, and intestine. The form of the skull resembles that of the mice, in being suddenly narrowed in the frontal region. There are four molar teeth on each side in each jaw; the upper jaw not possessing the anterior rudimentary fifth molar characteristic of the squirrels. The intestine is destitute of a cœcum, an organ which is of very large size in all other rodentia. The dormice have no cheek-pouches. The ears resemble those of mice. The body is about the size of that of the common mouse, but much plumper; the eyes large, black, and prominent; the tail between two and three inches in length, and more hairy at the top than elsewhere. With the exception of the throat, which is white, the dormouse is of a tawny-red colour. Dormice are found only in the temperate parts of the Old World, especially in Europe and Africa. In Asia they appear to be confined to the neighbourhood of the Caucasus. Only a single species, the common dormouse (*Myoxus avellanarius*), is found in Britain. It is extremely gentle and easily tamed, and feeds on beechmast, acorns, hazel-nuts, &c. It takes its food holding it in its hands, and sitting on its haunches like a squirrel (so do the rats), and often suspending itself by its hind feet, in which position it feeds as easily and comfortably as in the most ordinary position. Towards the winter it becomes exceedingly fat, and, having laid up a store of food, retires to its little nest, and coiling itself up into a ball, with the tail over the head and back, becomes completely torpid. There are two other beside the common dormouse—viz., the fat dormouse (*Myoxus glis*) and the garden dormouse (*Myoxus nitela*). The former is a large species, as big as a rat, and with a tail like a squirrel. It is a native of France and the south of Europe. The garden dormouse is smaller than the fat dormouse, and, breeding in gardens, is very destructive to wall and other fruit. It is a native of the temperate parts of Europe and Asia.

DORSAL, *dor'-sal* (Lat., *dorsalis*, from *dorsum*, the back), denotes something appertaining to the back, and in Anatomy it forms part of the name of ligaments, arteries, &c., belonging to that region.

DORSE, a fish of the same genus as the cod and haddock, found in the Baltic and other northern seas, but very rarely near the British coasts. It is generally about two feet in length. The flesh is much esteemed.

DORSTENIA, *dor-ste'-ne-a* (in honour of Theodore Dorsten, a German botanist), a genus of plants belonging to the natural order *Moraceæ*. The rhizomes and roots of several species have been supposed to be antidotes to the bites of venomous reptiles: those of *D. contrayerva* and *Braziliensis* have been employed in medicine for their stimulant, tonic, and diaphoretic properties.

DORY, OR JOHN DORY, *dor'-e*, a genus of fishes, of the family *Zeidæ*, a native of the Mediterranean, Northern, and Atlantic seas. Its name John Dory is probably derived from its French appellation, *jaune* (yellow) *dorée* (gilt). The British species (*Zeus faber*) is usually about eighteen inches in length, the general surface of the body is smooth and destitute of scales, but spiny scales or bony shields guard the dorsal and ventral edges. The anterior portions of the dorsal and oval fins are spiny, and very distinctly separated from the spineless portions. It is an extremely voracious fish, preying on small fishes and their spawn, as well as on the various kinds of crustacea and marine insects. It has an oval black spot on each side, and on this account shares with the haddock the traditionary repute of being the fish from whose mouth the tribute-money was taken by St. Peter, the impression of whose thumb and forefinger remained to record the event. Other species of the dory very similar to the European are found in the seas of other parts of the world.

DOSE, *dose* (Gr., *dosis*, from *didomi*, I give), is employed to denote a proper quantity of anything to be given or administered at one time, and is generally applied to medicines. A certain quantity, known as a full dose, is usually fixed upon as being suitable for a male from 15 to 40 years of age, diminishing proportionally for persons above or below that age. Besides age, there are frequently other circumstances to be taken into account; as the constitution, habits, &c., of the individual; and usually about one-fourth less should be given to an adult female than an adult male.

DOTTEREL, *dot'-tur-el* (*Charadrius morinellus*), a species of plover inhabiting the northern parts of Europe and Asia. The birds delight in high elevations. They are migratory, and appear in Britain on their northern migration, in spring, and on their southern migration, in the autumn. The length of the dotterel is about ten inches. Its plumage in summer is brown on the upper part; the cheeks, throat, and a band above the eyes, white; breast rusty red, with a white gorget on the upper part of it; a conspicuous black patch on the middle of the belly, and a few of the tail-feathers tipped with white. Its flesh is much esteemed, and the eggs are considered a great delicacy.

DOUBLE CONSCIOUSNESS, a mental condition arising from a morbid condition of the body, in which an individual is conscious of two independent trains of thought, and feels as if he were two persons at the same time. The cause of this strange phenomenon is probably to be sought in the alternate morbid activity of the two hemispheres of the brain. (*See* DUALITY.)

DOUBLE STARS, OR BINARY STARS.—In 1803, Sir William Herschel discovered the existence of sidereal systems composed of two stars, one revolving about the other, or both about a common centre. The stars are in some cases of different colours, the larger being red or orange, and the smaller blue or green.

DOUCHE. (*See* HYDROPATHY.)

DOUROUCOULI, *doo-roo-koo'-le*, a small monkey (*Nyctipitheus trivirgatus*) of Guiana and Brazil. It is about 9 inches long, with a very long tail, and is of a greyish white colour, with a brown line on its back and three dark stripes on the head. It resembles a cat more than a monkey, except in the hands; and the likeness is increased by bristly white hairs about the mouth. It is nocturnal in its habits and difficult to tame.

DOVE, *duv* (Sax., *daua*; Du., *duif*), a term sometimes extended, as the name pigeon also is, to the whole family of *Columbidæ*. (*See* PIGEON.)

DRACÆNA, *drai-se'-na* (from Gr., *drakaina*, a female dragon), a genus of plants belonging to the natural order *Liliaceæ*. The most remarkable species is *D. Draco*, the dragon-tree of Teneriffe, which attains a great size, and, unlike the majority of monocotyledonous trees, has forked branches. This plant yields a red resin, resembling dragon's blood. *D. terminalis*, the ti-plant, a native of the Sandwich Islands, has starchy roots, which are baked and eaten by the islanders; its juice is used for making a fermented beverage, and its leaves are employed as fodder for cattle.

DRACO, *drai'-ko* (Gr., *drakon*; Lat., *draco*, a dragon), a constellation in the northern hemisphere, between Ursa Minor, Cepheus, Cygnus, and Hercules. The largest star in this constellation is of the second magnitude. This star, known as γ *Draconis*, is the one which was used by Bradley when he discovered the aberration of light, to determine the coefficient of aberration of the fixed stars. (*See* ABERRATION.)

DRACONTIUM, *dra-kon'-ti-um*, a genus of plants of the natural order *Araceæ*. One species, *D. polyphyllum*, a native of tropical South America and also of India and Japan, is used as a medicine for asthma; and is thought to be efficacious as a remedy for snake-bite.

DRAGON, *drag'-on* (Greek, *drakon*, sharp-sighted), a term employed in modern Natural History to certain kinds of saurian reptiles. Some of these (the genus *Draco* of Linnæus) are furnished with a broad membranous lobe on each side. This is supported by the six first false ribs, which are extended straight outwards from the vertebral column. By the movement of these bones, the reptile is enabled to stretch its broad lateral membrane, which thus forms a sort of parachute, to support it in its long leaps from branch to branch. They, however, are quite destitute of any power to strike the air; so that their flight is nothing but a floating through space. As a rule, the species is harmless; there is, however, one, inhabiting the marshy plains of Guiana, and called the dragon-lizard, that bites severely if it should be handled. This creature has a long compressed tail, the back and tail crested, and the tongue forked, like that of a serpent; it sometimes attains a length of six feet. Both its flesh and eggs are eaten.

DRAGONET (*Callionymus*), a fish of the *Gobioidæ* family, inhabiting the Mediterranean and Northern Seas, remarkable for having the gill-opening reduced to a small hole on each side of the nape, and the ventral fins placed under the throat, separate and larger than the pectorals. The eyes are placed on the top of the head, looking upwards; the skin smooth and scaleless. The colours of the fish are yellow, blue, and white, making a beautiful appearance. There are three or four species; but that known with us as the gemmeous dragonet (*Callionymus*), and, by the Scotch, *gowdie*, is by far the most beautiful. All the species are about twelve inches long.

DRAGON-FLY (*Libellula*), a Linnæan genus of nedropterous insects, now constituting the family *Libellulidæ*, common in England, and to be seen in fine summer weather hawking about over the surface of ponds and rivers in search of insect prey. Their vulgar English name is "horse-stinger," which is no less inappropriate than ugly, as the insect possesses no means of annoying either horses or any other of the larger animals. hey are brilliant hues, love to bask in the suns ine, and prey on insects, They have strong horny mandibles and maxillæ, covered by the labrum and labium; their tarsi are three-pointed; their wings are equal; the posterior extremity of the abdomen is furnished with hooks or peculiar appendages. Their ferocity is so ungovernable, that when taken and imprisoned, they have been known to devour their own bodies. The great dragon-fly (*Æshna grandis*) is about four inches long, and the largest of the British species. It has been seen to dart upon a large cabbage butterfly, and to bite off the wings and devour the entire body in less than a minute. In the larva state, the *Libellulidæ* live entirely in the water, engaged in unceasing strife with other insects, for whose capture and destruction it possesses ample means, through a singular contrivance of its lower lip. This consists of two principal pieces, one of which is articulated to the head, whilst the second is attached to its extremity. At the apex of this second piece, two jaw-like organs are articulated. In repose this lip is folded beneath the head, but can be immediately extended to a considerable distance in front of the head, so as to seize any minute insects or small fishes that may pass before it. The respiration of the larvæ of some of these insects is singularly contrived. They are provided with the means of drawing water into their bodies to supply air for respiration, and expel it again by the same orifice at the extremity of the abdomen, with such force, that they thus propel themselves through the water, whilst their legs are at rest. The hooks at the extremity of the abdomen of the dragon-fly render the creature essential service at the period of transformation. Crawling out of the water, it attaches itself by these hooks to a stick or rush, and struggles out of the pupa-case. At first its body is quite soft and moist, and the wings folded up into a small compass. In a few hours, however, the wings are capable of expansion, and the body assumes a proper consistency. Dragon-flies abound most in warm climates, but are met with in very northern regions.

DRAGON ROOT, a plant (*Arisæma atro-rubens*), of the natural order *Araceæ*, a native of North America. The tube supplies a stimulant applied externally as a remedy for bronchitis, asthma, and rheumatism, and powders and ointments are also made from it.

DRAGON-TREE. (*See* DRACÆNA.)

DRAGON'S BLOOD. (*See* CALAMUS, PTEROCARAUS.)

DRASTICS, *dras'-tix* (Gr., *drastikos*, active, brisk, from *drao*, I effect), is a term generally applied to such medicines as are very violent in their action, particularly as purgatives; such as croton oil, jalap, &c.

DRAUGHT (Lat., *haustus*, a gulp, or one drink), is a liquid form of medicine intended to be taken at once, or at a draught; whence its name.

DREAMS, *dreems* (Du., *droom*; Ger., *traum*), are defined to be "trains of ideas presenting themselves to the mind during sleep." It frequently, if not always happens during sleep, that while some of the mental faculties are suspended, others are still active, and are busy with numerous ideas which succeed each other with more or less regularity. This is dreaming. It is characterized by an absence of consciousness with regard to external things, and an entire suspension of voluntary control over the current of thought, so that the principle of suggestion—one thought calling up another according to the laws of association—has unlimited operation. The balance of the mind, the mutually controlling influence of the mental faculties is disturbed, some being active, while others are dormant, and the reasoning powers are not exercised to test and harmonize the perceptions. The mind is in fact temporarily "like sweet bells jangled, harsh and out of tune," restored to healthy action when all the faculties are alike awake. One of the most remarkable features of dreaming is the rapidity with which the mind passes through a long series of events. Whole years may seem to the dreamer to have elapsed, and a multitude of images may have been successively piled up before him, though the time occupied therewith is known to have occupied only a few minutes, or even a few seconds. Many of those unpleasant dreams that are sometimes found to precede illness are doubtless occasioned by feelings or sensations of which in the ordinary waking state we are unconscious. It is in this way that indigestion is so fruitful a cause of unpleasant dreams. Of the five senses, touch is the most excitable during sleep, and most frequently modifies the character of our dreams. The sense of hearing is the next; and the least excitable of all our senses is that of sight. Our belief in the reality of the scenes brought before us, and in the presence of external objects not before us, are among the most curious and important of the phenomena of dreams. Everything seems real and vivid before us. Sometimes a particular dream will remain, as it were, latent in the mind, and be revived at a future period; and when the dreamer awakes, he has a consciousness that the dream he has just experienced is a continuation of a dream he had, perhaps, years before. This affords one of the obscure problems connected with memory which seems to defy solution.

DREISSENA, *dre-is'-se-na*, a genus of molluscs generally regarded as belonging to the Mussel family, from which, however, it differs in some particulars. *D. polymorpha*, a native of Western Asia, has recently appeared in the rivers and canals of Germany, Holland, and England.

DRIFT, *drift* (Dan., *drift*), in Geology, a term signifying "that which is driven;" as *drift-wood*, wood carried down by rivers, and driven by tides and currents to distant shores; *sand-drift*, sand driven and accumulated by the wind. The word is often used as an abbreviated term for the Glacial Drift of the Pleistocene period. (*See* GLACIAL DEPOSITS.)

DRILL, a species of baboon (*Cynocephalus leucophæus*), similar to the mandrill; but smaller and less ferocious. It is a native of Guinea.

DRIMYS, *dri'-mys* (Gr., *drimus*, acrid), a genus of plants belonging to the natural order *Magnoliaceæ*. The bark which is commonly known under the name of Winter's bark, is obtained from a species of this genus, namely, *D. Winteri*, or *aromatica*. It was first brought to Europe by Captain Winter, after a voyage to the Straits of Magellan, in 1579, and was formerly much used as a substitute for cinnamon, having similar aromatic and stimulant properties: at present it is rarely employed.

DROMEDARY. (*See* CAMEL.)

DROMIA, *dro'-me-a*, a genus of crustacea, of which the sponge-crab (*Dromia vulgaris*) may be taken as the type. The sponge-crab is furnished with two sharp curved claws, which enable it to hold fast to pieces of sponge, medusæ, &c.

DRONE. (*See* BEE.)

DROPSY, *drop'-se* (Gr., *hudrops*, from *hudor*, water, and *ops*, aspect or appearance), a disease characterized by the accumulation of a watery fluid in one or more of the shut cavities of the body, or in the areolar tissue, or in both, independent of inflammation. In a state of health, the capillaries, which ramify every part of the body, constantly pour out upon every surface, into the most minute cells as well as the great cavities, a watery fluid to moisten the parts, and thereby facilitate motion and prevent injury from friction. This watery fluid is speedily taken up by another class of vessels, called the *absorbents*, which carry it back to the general circulation. When the healthy condition of these organs is impaired, either from the exhalents acting too powerfully, or from the absorbents being deficient in action, an accumulation of fluid takes place, either in the general cellular membrane or in the natural cavities of the body. Dropsy is either active or passive. Active or acute dropsy is owing to excessive action of the exhalents, in consequence of increased action of the heart; it comes on suddenly and tumultuously, and sometimes can scarcely be discriminated from inflammation with serous effusion. It is induced by various causes; as exposure to a cold moist atmosphere, particularly when the body is in a state of perspiration from active exercise or long exposure to heat. Chronic or passive dropsies are occasioned by defective absorption, arising, in some measure perhaps, from an enfeebled state of the absorbents, strictly and anatomically so called, but more frequently, chiefly, and in some cases entirely, from undue fulness of the veins; this venous repletion being produced almost always by some impediment to the free return of the blood to the heart; as tumours pressing on the great blood-vessels, ossification of the valves of the heart, &c. When the veins are distended to a certain degree with watery fluid, the entrance of more of the same fluid through their sides is impeded or prevented; and when the distension is still greater, the aqueous part of the blood may even pass in the other direction out of the vessel. The difference between active and passive dropsy is chiefly in the rate at which the collection augments; in the one case the liquid is rapidly effused in quantity much beyond the natural amount of exhalation, in the other the exhalation goes on as usual, but the fluid exhaled is not taken back again into the circulating vessels with sufficient facility. In the treatment of this disease, the first object is to get rid of the preternatural accumulation of watery fluid; the second, to prevent its collecting again: for dropsy is generally a symptom or sequence of other disorders, and rarely a disease of itself. In general, the object is to augment the discharge of watery fluid from one or more of the secreting surfaces of the body. In some cases it is best to seek to promote this discharge by way of the kidneys; in others, by the mucous lining of the alimentary canal; in others, by the external skin. Sometimes great present relief is afforded to the patient by tapping; but it is generally only temporary, and can only sometimes be resorted to.

DROPWORT. (*See* SPIRÆA.)

DROSERACEÆ, *dros-e-rai'-se-e* (Gr., *droseros*, dewy), the Sun-dew family, a natural order of dicotyledonous plants in the sub-class *Thalamifloræ*. They are bog or marsh plants, and are found in almost all parts of the world with the exception of the Arctic regions. They possess slightly acid and acrid properties. The typical genus is *Drosera*, the sun-dew, the species of which are interesting, from the peculiar irritability of the hairs on their leaves. The plant commonly known as Venus's fly-trap is a species of *Dionæa*, another genus of this order, and exhibits in a most striking manner this irritability. (*See* DIONÆA.) Some of the sun-dews communicate a beautiful purple stain to the paper upon which they are dried, and also yield a yellow colour when treated with ammonia.

DROWNING, *drown'-ing* (Dan., *drugner*, to drown), is suffocation produced by the immersion of the body under water, or, according to some, by the exclusion of atmospheric air from the lungs by any liquid. The necessity of air to life is well known, and any exclusion of it, for even a few minutes, produces death. When a human being unable to swim falls into the water, if it is not of great depth, he first goes to the bottom; but on account of the air in the lungs rendering the specific gravity of the body lighter than the water, he immediately rises again to the surface. The efforts made by him to maintain himself at the surface diminish the quantity of air in the lungs, and he again sinks to the bottom, but soon rises again; and this alternate rising and sinking may occur several times in succession. The air which is expelled from the lungs is seen to rise to the surface in the form of bubbles, and with every expiration the specific gravity of the body is increased; the powers of sensation and voluntary motion rapidly diminish, and the body settles at the bottom. A feeble motion may still be perceived in the chest for a short time, but that, too, ceases, and death ensues. In drowning, death is effected by the impure condition of the blood. The impure or venous blood of the system is constantly being carried to the lungs, where, being brought into contact with the air, its impurities are carried off, and it is converted into pure or arterial blood. When, by any means, as in drowning, the lungs are shut out from communication with the external air, this operation cannot be carried on, impure instead of pure blood is carried through the system, the brain is immediately affected, sensation and volition rapidly diminish, and at length cease. (*See* ASPHYXIA.) The period during which life may continue in submersion varies in different persons. In some instances bodies submerged but one minute have been found to be lifeless; but in many cases recovery has taken place after a submersion of eight or even ten minutes. Occasionally, animation has been restored after a submersion of fifteen or twenty minutes, or even of half-an-hour. In general, if the body has not been in the water longer than from five to eight minutes, the prompt use of the proper means will restore animation. The following plan of treating a drowned person was proposed by the late Dr. Marshall Hall in 1856:—Treat the patient instantly, on the spot, in the open air, except in severe weather, freely exposing the face, neck, and chest to the breeze; send with all speed for medical aid and for articles of clothing, blankets, &c.; place the patient gently on the face, with one arm under the forehead, so that any fluids may flow from the throat and mouth, and without loss of time; *to excite respiration*, turn the patient on his side, and apply snuff or other irritant to the nostrils; dash cold water on the face, previously rubbed briskly until it is warm. If there be no success, again lose no time, but, *to imitate respiration*, replace the patient on his face (when the tongue will then fall forward, and leave the entrance into the windpipe free); then turn the body gently, but completely, on the side and a little beyond (when *in*spiration will occur), and then on the face, making gentle pressure along the back, when *ex*piration will take place, alternately. These measures must be repeated deliberately, efficiently, and perseveringly, fifteen times in the minute only. Meanwhile, *to induce circulation and warmth*, continuing these measures, rub the limbs *upwards* with firm pressure and with energy, using handkerchiefs, &c., for towels; replace the patient's wet clothing by such other covering as can be instantly procured, each bystander supplying a coat, waistcoat, &c.

DRUPACEÆ. (*See* AMYGDALEÆ.)

DRUPE, *droop* (Lat., *drupæ*), a succulent fruit containing a single seed, or kernel, usually enclosed in a hard covering, and commonly called a stone-fruit. Examples occur in the peach, apricot, plum, and cherry. A number of drupes aggregated together on a common receptacle form the raspberry and similar fruits.

DRY ROT, the name given to the decay of timber, proceeding from the fermentation of sap that is left in the wood, and which is brought about by the influence of warmth, combined with a certain degree of moisture and the want of proper ventilation. It appears in timber that has not been properly seasoned, or which has been cut in the spring of the year, when the sap is rising, as in the case of oak trees, which are cut at this time for the sake of the bark. When the sap has fermented, the vegetation of fungi follows, which spreads through the wood, destroying the fibres to such an extent that they crumble into dust under any slight pressure. To prevent dry rot in timber, it is necessary that it should be well seasoned, and that the air should at all times have free access to it. Various methods have been adopted for filling the pores of the wood with some solution, to render it proof against destruction by dry rot, among which may be mentioned Sir William Burnett's process, by which the wood is soaked in a solution of chloride of zinc; Mr. Bethell's use of creasote, and that of Kyan (*see* KYANISING), by which the pores of the timber are filled with a solution of bichloride of mercury, forced into them by the air-pump.

DRYOBALANOPS, *dri-o-bal'-a-nops* (Gr., *drus*, oak; *balanos*, acorn; *ops*, aspect), in Botany, a genus of plants belonging to the natural order *Dipteraceæ*. The species *D. aromatica* or *camphora* is a large tree found in Sumatra and Borneo. From its stem a liquid called liquid camphor, and a crystalline solid substance named Sumatra camphor, are obtained. (*See* CAMPHOR.)

DRYOPHIS, *dri'-o-fis*, a genus of serpents, of the family *Colubridæ*, natives of India, Madagascar, and tropical America. They are long and slender, and live mostly among the branches of trees. They are marked by a peculiar prolongation of the upper jaw, which sometimes is shaped like a leaf.

DUCHAI HEMP. (*See* ÆSCHYNOMENE.)

DUCK, *duk* (Ang.-Sax.; Lat., *anas*).—The group to which the name of duck is generally extended is characterized by greater breadth of bill than either swans or geese. Their food is chiefly animal, whilst that of both swans and geese is in great part vegetable. A well-known example of this family is the wild duck, or common mallard (*Anas Boschas*), the original of all the ordinary domestic varieties. It is found in all the countries of Europe, but abounds especially in the northern parts. It is nearly two feet in length, three feet in extent of wings, and weighs about three pounds. The bill is of a greenish-yellow colour; the head and upper part of the neck of a glossy green, terminated in the middle of the neck by a white collar. The scapulars are white, barred with fine brown lines; the back is brown, and the rump black, shaded with green. The lower part of the neck and breast is of a chestnut-colour; the belly pale grey, barred with dusky bars. The legs are orange-yellow. Like the rest of the duck tribe, the mallards quit the north at the end of autumn, and, migrating southward, arrive at the beginning of winter in large flocks, and spread themselves over the marshy wastes of Britain. In bygone times, when the tracts of marsh land in England were much more extensive than now, the mallard was among the commonest of our wild-fowl; and even now our fen countries are patronized by them in such vast numbers as to keep the London market fully supplied in the season. The extreme wariness of these birds renders necessary much patience and ingenuity in obtaining large quantites of them. They fly at a considerable height in the air, in the shape of a wedge or triangle; before they alight on any spot, they take several wheels in the air, as though to reconnitre, and then descend with extreme precaution. When at rest on the water, they take care to keep at a considerable distance from the shore, and when they compose themselves for sleep, some of the company are always awake to keep guard and to apprise the remainder of the approach of danger. They are much more active by night than by day. The wild duck usually makes her nest amongst the tall grass or rushes skirting the water; but instances have occurred of the birds building in trees. The food of the duck consists of worms, mollusca, and aquatic insects, which they separate from the mud by the agency of lamellæ at the margins of the bill. In his first division of true ducks, Mr. Yarrell includes the sheldrake, Muscovy duck, wild duck, gadwell, shoveller, pintail, widgeon, bimaculated duck, garganey, and teal; accounts of all of which will be found in their proper places. The domestic duck is duller of plumage and less graceful in form than the wild. The most obvious distinction between them, however, lies in the colour of their feet; those of the wild ducks being yellow, and the tame ducks black. The tame duck does not, like the wild, pair and remain with one mate, but takes the control of an entire troop of hens. Whatever its species may be, the tame duck is a desirable bird to have in a poultry-yard. Nor is water indispensable to its existence; so far from it, indeed, that, instead of being absolutely necessary, it is often injurious to the young; in fact, they should never be allowed to swim till more than a month old. Instead of allowing young ducks to go out in the morning to eat slugs and worms, they should be shut up, since this food, notwithstanding their partiality for it, is injurious. They lay a great number of eggs, require very little attention, and, with respect to ducklings, they may be easily fattened in the course of a month with any kind of pulse, or grain and water.

DUCKBILL, ORNITHORHYNCHUS, OR PLATYPUS, *duk'-bil*, a genus of mammalia, order *Monotremata*. Only one species is fully ascertained (*O. paradoxus*, or *panatinus*), generally known as the water-mole in the Australian colonies. The entire length of the animal, including bill and tail, is about two feet; body long and compressed, and thickly covered with very glossy hair, at the roots of which is a layer of waterproof felt-like material. The head is round and small, eyes small and bright, no external ear, and instead of the muzzle, mouth, and teeth of an ordinary quadruped, the creature is furnished with a bill like that of a duck (but broader in proportion), and possessing small transverse laminæ like the duck's bill. The legs are short; the fore feet have each five toes, with strong burrowing claws and a connecting membrane for swimming. The hind feet are likewise webbed, but the web does not extend beyond the base of the claws. The tail is strong, broad, and flattened, about half as long as the body, covered with longer and coarser hairs, and nearly naked on its under surface. It lives chiefly in the water, and, like the duck, seeks its food among the mud. Its burrowing powers are said to exceed those of any other animal, fifty feet being no very uncommon length for it to run. It is wary and active, and by no means easily shot. Its voice resembles that of a young puppy.

DUCKWEED, *duk'-weede*, a genus of plants, *Lemna*, consisting chiefly of floating flat green fronds, with roots hanging loosely in the water. They are found in nearly all parts of the world.

DUCT, *dukt* (Lat., *duco*, I lead or conduct), denotes generally any tube or canal by which a fluid is conducted or conveyed. It is especially used in anatomy and botany.

DUCT, ALIMENTARY. (*See* ALIMENTARY CANAL.)

DUCTILITY, *duk-til'-e-te* (Lat., *ductilis*, from *duco*, I lead, draw), the power possessed by certain bodies, and especially the metals, in virtue of which they are capable of being drawn out in length, while their diameter is diminished, without fracture or separation. Among the metals it may be called the property of being able to be drawn out into wires. The order of the metals which are ductile is almost similar to the order of those which are malleable; it is as follows:—

Gold, silver, platinum, iron, copper, zinc, tin, lead, nickel, palladium, cadmium. Glass is exceedingly ductile at a high temperature, and can be drawn into flexible threads finer than any hair. The property is also possessed by other substances; such as gums, glues, resins, &c., when softened by moisture or heat.

DUDLEY LIMESTONE.—A Silurian limestone, very rich in fossils, belonging to the Wenlock series, and very abundant near the town of Dudley, in Worcestershire.

DUGONG, *du'-gong-* (*Halicore Dugong*), a marine animal belonging to the family *Manatidæ* or herbivorous cetacea. Its length varies from twelve to twenty feet. It feeds on the algæ which grow on submarine rocks in shallow seas. Its affection for the young is remarkable; and if the latter can be surprised and captured, the mother may be easily taken. It's flesh is eaten, and said to resemble beef in texture and flavour. It is found among the islands of the Indian archipelago. The osteology of the dugong exhibits some remarkable points of correspondence with that of pachydermatus animals.

DUGUETIA, *du-gu-e'-she-a*, a genus of plants belonging to the natural order *Anonaceæ*. The only interesting species is *D. quitarensis*, a native of Guiana, which furnishes the strong, elastic wood called lance-wood. This is chiefly used by coachmakers.

DULCAMARA. (*See* SOLANUM.)

DULSE. (*See* RHODOMINIA.)

DUMB. (*See* DEAF AND DUMB.)

DUMB CANE, the popular name of a plant (*Dieffenbachia seguina*) of the natural order *Araceæ*, and a native of the West Indies. The juice produces a most painful swelling of the tongue which renders speech impossible; hence the name given. The juice is sometimes used in the manufacture of sugar; and a decoction of the stem is used as a fomentation to relieve dropsy.

DUNES, *dunes* (Celt., *dun*, a hill, whence Fr., *dunes*; Ger., *dünen*; Du., *duynen*), the name given to low and almost barren hills of sand of great breadth, that extend along the coast of Holland, Belgium, and the northern departments of France, and serve to protect the fertile land within them from the inroads of the ocean. They have been formed by the wind blowing great quantities of sand inland whenever it sets dead on shore. A few kinds of grass, such as the *Carex arenaria* or sea-carex, the *Festuca rubra* or creeping fescue-grass, and the *Arundo arenaria* or sea-reed, grow on these sand-banks, and are of material benefit in binding the loose surface together. These sand-hillocks are to be found on the coasts of Brittany and Gascony and parts of Spain; they also exist on the north coast of Norfolk, where they are called *denes*.

DUNG-BEETLE, *dung-be'-tl* (Ang.-Sax.), the name of certain of the *Scarabæides*, living for the most part on or in the dung of other animals. They are scientifically known as *Coprophagi* (Gr., dung-eaters). For the most part they are black, or black and brown, and some few are adorned with brilliant metallic colours. To this section belongs the sacred beetle of the Egyptians. This species is not only found in Egypt, but is met with in the south of Spain, France, and Italy, and, as well as other species of the group to which it belongs, incloses its eggs in a ball of excrement, which it forms by rolling the substance by means of its hind-legs. The size of the ball, when completed, is much larger than the insect, being sometimes as much as an inch and a half in diameter. The dor, or shard-born beetle (*Geotrupes stercorarius*), belongs to this tribe, and is one of the commonest of British beetles. It is of a stout form; less than an inch long; black, with metallic and blue reflexions on the under surface. This species may often be heard droning through the air of a summer evening. It is almost impossible to over estimate the great good performed by these insects. Not only do they hasten the removal from the ground of what becomes more offensive the longer it stays, but they carry the offensive matter to where plants grow, and, by distributing it in the soil, materially assist their proper growth.

DUODENUM, *do-o-de'-num* (Lat., *duodenus*, consisting of twelve), the first portion of the small intestine, so called by the ancients because it was supposed not to exceed the breadth of twelve fingers; but as they dissected only animals, this does not hold true in the human subject. It is in this intestine that chylification of the food takes place. (*See* DIGESTION.)

DUPLICATION OF THE CUBE. (*See* CUBE.)

DURA MATER. (*See* BRAIN.)

DURAMEN, *du-rai'-men* (from Lat., *durus*, hard), the heart-wood or central portion of an exogenous stem. It is made up of wood cells with thickened sides, and which are impermeable to fluids, hard in texture, coloured, and of a dry nature. (*See* ALBURNUM.)

DURIAN. (*See* DURIO.)

DURIO, *du'-re-o* (from Malay, *dury*, thorny), in Botany, a genus of plants belonging to the natural order *Sterculiaceæ*. The species *D. zibethinus* yields the fruit called the durian, which is highly esteemed in the south-eastern parts of Asia. It is about six inches in diameter, with a thick rind, covered with short spines. It has, however, a strong smell, which renders it disagreeable at first to those unaccustomed to it; but the dislike to this smell is generally soon overcome.

DURRA. (*See* HOLCUS.)

DURRA, OR DAIRA GRASS, *doo'-ra*, also known as Indian Millet, or Sorgho Grass, a genus of grasses, several species of which are cultivated in Asia and Africa as corn-plants. The species are annual, with broad leaves, and a juicy saccharine pith. One species, *Sorghum vulgare*, is cultivated in some of the warmer parts of Europe. Another species, the sugar-grass (*S. saccharum*), is grown in America, and known as the Chinese sugar-cane, and yields large quantities of sugar.

DUSICYON, *du-si'-se-on*, a genus of *Canidæ*, including many species of American dogs, sometimes known as Agerara dogs. They have a fox-like aspect, live in burrows, and feed on birds and smal quadrupeds.

DUST, ATMOSPHERIC, *dust*.—When a ray of sun-light enters a partially-darkened apartment through any small aperture or chink in the shutters, or when a flood of intensely-brilliant light from the same source pours into a room, we can distinctly see small particles of various substances, familiarly called motes, floating about in the track of the sunbeam, and moving with greater or less rapidity according to the extent to which the air is agitated in which they are suspended. Under ordinary circumstances, these motes, or atmospheric dust, are invisible to human sight, being so minute that they can only be seen under the conditions that have been mentioned, through the reflection of strong sunlight from their surface, or by the aid of a powerful microscope. But whether they are visible to us or not, they are always present in the atmosphere that we breathe ; and it is considered that the lower strata of the air immediately in contact with and above the surface of the earth are constantly impregnated with these small particles, of unappreciable weight and size, that are fragments of various organic and inorganic substances that have been worn away from the bodies of which they originally formed a part, by friction and other causes. It has been discovered by Professor Ehrenberg, of Berlin, that the particles carried about by the wind, when submitted to chemical tests, consists of minute fragments of all kinds of mineral substances, mixed with mould and various organic bodies. Professor Tyndall asserts that the atoms frequently contain the germs of infectious diseases.

DYKE, In Geology, a term applied to any wall-like mass of igneous rock filling up a fissure in other rocks. A dyke may come up through any king of previously existing rock, whether igneous or aqueous. When the matter of the dyke is harder than the intersected strata, and these have been subjected to waste and denudation, the igneous wall-like mass may be traced for miles across a country; and, on the other hand, where the rock-matter of the dyke has been softer, its course may also be traced by narrow wall-sided fissures and linear ditch-like depressions.

DYNAMICS, *di-nam'-iks* (Gr., *dunamis*, power), that division of mathematics which treats of force, considered as producing motion in bodies. Force may be defined as any cause which changes, or tends to change, a body's state of rest or motion. The case of force tending to move bodies from rest will be found under the subject of Statics. The case of force actually producing motion, or changing motion, belongs to Dynamics. Some of the most distinguished philosophers have given much time and labour to the investigation of this branch of mathematics. Among these may be mentioned Newton, Huygens, Euler, D'Alembert, Poinsot, and others. The doctrine of dynamics is divided into several distinct heads. First, the names and definitions of the various terms employed; such as force, velocity, accumulating velocity, moving velocity, motion, accumulating motion, &c. The second branch of dynamics treats of the movement of points, and is divided into two classes of problems—direct and inverse. In the first case the path of a point is determined when the forces acting upon it are given ; and in the second case the force or forces acting upon a point are determined when the path of the point is given. In the third branch of dynamics the motion of a rigid system of points or a solid body is treated of. D'Alembert first laid down the general method for treating problems in rigid dynamics. Motions of rotation are treated of in the fourth branch of dynamics. The three laws of motion upon which most of the problems in dynamics depend are as follows :—First, a body under the action of no external force will remain at rest, or move uniformly in a straight line. Second, when any number of forces act upon a body in motion, each produces its whole effect in altering the magnitude and direction of the body's velocity, as if it acted singly on the body at rest. Third, when pressure produces motion in a body, the momentum generated in a unit of time, supposing the pressure constant, or which would be generated supposing the pressure variable, is proportional to the pressure. (*See* CENTRAL FORCES, FORCE, PERCUSSION, PROJECTILES.)

DYSENTERY, *dis'-en-ter-e* (Gr., *dusenteria*, from *dus*, with difficulty, and *enteron*, intestine), is a disease characterized by frequent mucous or bloody discharge, attended with griping pains in the abdomen, straining, and tenesmus. Dysentery consists essentially in inflammation of the mucous membrane of the large intestines, and, in the acute form or stage of the disease, is attended with fever. Dysentery is one of the pests of hot climates, and in all tropical countries, at certain seasons of the year, it is very prevalent and destructive. It is, however, among fleets and armies that this malady most displays its deadly power; so that it has been termed the " scourge of armies and the most fatal of all their diseases." At one time it was very prevalent in this country ; but now it is not a very common nor a very serious disorder here. The forms of this disease and the circumstances under which it prevails are infinitely various, and many speculations have been formed regarding it. It has been ascribed to exposure to wet and cold, to the use of unwholesome food, to the agency of malaria, to contagion. Generally the most violent forms of this disease occur in warm climates and in situations where the body is exposed to extreme alternations of heat and cold ; and hence there is every reason to believe that these influences are largely concerned in its production. The patient passes sleepless or dreamy and disturbed nights, and is low-spirited and desponding. The duration of this disease is very various. In some cases it may prove fatal in a few days, or even hours; in others it may last for weeks or months. Two stages are recognised of this disease—the inflammatory and that of ulceration.

DYSPEPSIA, *dis-pep'-se-a* (Gr., *duspepsia*, from *dus*, bad, and *pepto*, I concoct or digest), a bad or difficult digestion. It is by means of digestion that the food which is taken into the stomach is converted into nutritive matter for supplying the waste that is constantly going on in the system; hence anything that interferes with the due supply of nutritive matter materially affects the system, and may introduce a long series of ill. (*See* DIGESTION.) Among the innumerable disorders in more distant parts that are produced by dyspepsia are palpitations of the heart, irregularities of the pulse, asthma, pain in the head, with the loss of mental energy, and some confusion of thought. One of the worst of the occasional concomitants of dyspepsia is that state of mind which is known as hypochondriasis. There is languor, listlessness, or want of resolution, with an apprehension of some great evil in the future. Such persons are particularly attentive to the state of their own health,

GEOMETRIC ORNAMENTS.

DRAWING.

and, from any unusual feeling, perhaps of the slightest kind, they apprehend great danger, or even death itself. Of the causes that induce dyspepsia, are indigestion, noxious or irritating substances taken into the stomach as food or drink—such as tainted meat, decayed vegetables, unripe fruit, very acid matters, alcoholic liquors, &c.; and even wholesome food taken too frequently, or in too large a quantity, especially when its nature is very nutritious or in a very concentrated form, or rendered too stimulating by being highly seasoned. The abuse of fermented and spirituous liquors is one of the most frequent causes of dyspepsia; and the consumption of large quantities of fluids, particularly during meals, is very injurious. Among the more remote causes of dyspepsia, or those which affect the stomach through other organs, are want of exercise or of pure air, intense study, or too close application to business, strong mental emotion, or exposure to a cold or moist atmosphere. In the treatment of dyspepsia it is to be borne in mind that it is not so much medicines that will remove the present discomfort that are required, as a discontinuance of those habits which have generated the discomfort. Hence one great and indispensable principle in the treatment of dyspepsia is that of restricting the quantity of food taken at any one time. The amount of food introduced into the stomach should be kept within the limits of its capacities and powers. Another very important principle is, that the stomach should have time to perform one task before another is imposed upon it. Animal food, with a moderate portion of thoroughly-cooked vegetables, is, perhaps, the diet best suited for a feeble stomach. As regards the use of spirituous or fermented liquors, in the opinion of Dr. Watson—though some allowance must, no doubt, be made for custom—most dyspeptic persons would be better without any of these drinks. Finally, change of air, change of scene, change of society, usually exert a very beneficial effect in this disorder.

DYSODIL, *dis'-o-dil*, a laminated bituminous mineral, of a yellow or greyish colour, often found in connection with lignite. It burns with a bright flame and gives out a very disagreeable odour.

DYSPNŒA, *disp-ne'-a* (Gr., *dus*, with difficulty, and *pneo*, I breathe), is an embarrassed or laborious breathing. It is owing to a disturbance of the natural and healthy relation that ought to subsist between the quantities of blood and air in the lungs. When the quantity of atmospheric air that reaches the lungs is by any means diminished, or when there is more venous blood sent to the lungs than can be arterialized under the ordinary modes of inspiration, then instinctive efforts are made to increase the quantity of air by increasing the number of acts of inspiration. Hence dyspnœa may arise from a number of causes; as croup or laryngitis, diminishing the only inlet for the air; pressure upon the lung, or any other means by which its size is diminished, or it is rendered less spongy; or by increased action of the heart.

DYTISCUS, *di-tis'-kus*, a genus of aquatic coleopterus insects, or water-beetles, forming the family *Dystiscidæ*. They are generally oval in form, with smooth surfaces. A common British species, *D. marginalis*, is about an inch and a quarter in length, of an olive colour, marked with yellow. All the species are very voracious, and boldly attack creatures larger than themselves. They become very tame in a fresh water aquarium, and will receive food, worms, &c., from the hand. They live in marshes and ditches, but can fly well. The larvæ hide themselves in the earth before changing to the pupæ state.

DZIGGETHAI, or DJIGGETAI, *jig'-ge-ti*, a quadruped (*Egnus Hemoionus*) known also as the Khur or Goor, resembling in appearance both the horse and the ass, and therefore named by the Greeks, *hemionus*, half-ass. It is a native of the steppes of Tartary. It is like the horse in size, gracefulness, and neighing. It lives in herds, and is fleet and shy, so that it is hunted with great difficulty by the Tungûs and Mongols, who consider its flesh a delicacy. The animal has been domesticated, but does not breed except in a wild state.

E.

EAGLE, *e'-gl* (Fr., *aigle;* Lat., *aquila*), a genus of birds of prey, constituting the largest of the *Falconidæ*. In these birds the bill is of moderate length, with the ridge of the upper mandible straight from the base, at least as far as the end of the cere, beyond which it is decurved; the lip is strongly hooked and acute, but is destitute of the strong tooth characteristic of the true falcons; and the lateral margins are more or less festooned. The wings are long and usually pointed, with the third, fourth, and fifth quills longest; and the tail is long, broad, and rounded. The tarsi are rather long, but vary greatly in their clothing, being sometimes covered with scales of various forms, and sometimes completely clothed with feathers. The toes are long and powerful, the inner one being usually stronger than the outer: they are all armed with long, strong, and greatly acute claws. The finest of the species is the well-known golden eagle (*Aquila chrysaëtos*). It is a solitary bird, building its nest on ledges of rock in the wildest part of the country, and far from the habitations of man. It is very common throughout Western Continental Europe, and less common in Scotland, India, North Africa, and North America. The general colour of the plumage is deep brown, mixed with tawny on the head and neck, the feathers on the back being finely shaded with a darker hue. The wings, when closed, reach to the end of the tail; the quill-feathers are chocolate-coloured, with white shafts; the tail brown; feet yellow. It measures in length about three feet, with an expansion of wing of a least seven feet, and weighs about fourteen pounds. The female is rather larger than the male. Its strength is prodigious. It has been seen to carry up to its lofty nest lambs of several weeks old, and even young fawns. The ring-tailed eagle is the one and two-year-old young of the golden eagle. Besides the golden eagle, there is another British species of this family, which feeds on fish, and, for this reason, is always met in the neighbourhood of water. This is the white-tailed sea-eagle (*Haliaëtus albicilla*). It is rather larger than the golden eagle, but exhibits a smaller extent of wing. Despite this bird's large size and strength, it rarely ventures to attack any animal larger than a hare; indeed, it seems to prefer its prey ready killed, and subsists for the greater part on stranded fish and the carrion carcases of such animals as it may find. This bird builds upon ledges of rocks that overhang the sea: the nest is composed of sticks, seaweed, and similar coarse material. The American or white-headed sea-eagle (*Haliaëtus leucocephalus*) is found in every part of the United States of America, preferring the low lands near the sea-shore to mountainous districts. It is this bird that America takes as its symbol. It is about the size of the golden eagle, but of a lighter colour, and the legs are only feathered a little way below the knees. The bill is large, acutely hooked, and of a bluish colour. A row of strong, bristly feathers hangs from its lower mandible, and from this it takes its occasional name of Bearded eagle. Its chief prey is fish. Besides those enumerated, there are the crowned eagle (*Aquila coronata*) found in Africa; the superb eagle (*Falco superbus*) of Guinea; the cheela eagle (*Falco Cheela*) of India; the royal eagle (*Aquila imperialis*) of Northern Africa and some parts of Southern Europe; the spotted eagle (*A. nævia*); the vulturine eagle (*Aquila vulturina*) of Caffraria; and the Australian eagle (*A. fucosus*).

EAGLE-HAWK (*Morphnus*, or *Spizaëtus*), a genus of *Falconidæ* of the Eagle group, but consisting of species of a comparatively small size, and characterized by short wings, long slender legs (tarsi), and comparatively feeble toes and claws. They are natives of warm climates, chiefly of South America, but also of Africa and the East Indies. Some of the species are very beautiful in form and colour.

EAGLE-OWL (*Bubo maximus*), a genus of the Owl family, found in almost all parts of America. (*See* OWL.)

EAGLE-STONE, a variety of argillaceous iron ore, having a concentric structure and occasionally so decomposed as to contain a loose kernel that rattles when shaken. The ancients imagined that this stone was the egg of the eagle, the internal nodule being the embryo eaglet. (*See* also GEODE).

EAR, *eer* (Ang.-Sax.), the organ of hearing, consisting of three parts—the external ear, the middle ear or tympanum, and the internal ear, or labyrinth. The external ear consists of an expanded trumpet-shaped cartilaginous structure, called the pinna or auricle, which collects the sounds, and a tube which conveys these sounds to the internal ear. The pinna or auricle is of an oval form, with the margin folded and the larger end placed upwards. The round rim-like margin is called the helix, and the depression immediately within the groove or fossa of the helix. Within the latter is a large elevation, called the antihelix, which presents at the upper part a well-marked depression—the fossa of the antihelix. In the centre of the pinna is a deep hollow, named the concha, which conducts to the opening of the meatus auditorius. In front of that hollow is a projection of a triangular shape, called the tragus; and on the opposite side of the hollow, rather below the level of the tragus, is another projection—the antitragus. Inferiorly the pinna is terminated by a soft pendulous part, called the lobule. The auditory canal, *meatus auditorius externus*, or the tube by which sound is conveyed from the pinna to the internal ear or tympanum, is about an inch and a quarter in length, and is formed partly by bone and partly by cartilage and membrane. Around the entrance of the meatus are some fine hairs; and there are also ceruminous glands, which secrete the ear-wax, and open on the surface by separate orifices. The middle ear or tympanum is an irregular cavity situated within the petrous bone, and interposed between the meatus auditorius and the labyrinth or inner ear. It is filled with air and communicates with the pharynx by the Eustachian tube. It is traversed by a chain of small movable bones, which connect the membrana tympani with the labyrinth, and serve to convey the vibrations communicated to the *membrana tympani* across the cavity of the tympanum to the internal ear. The outer boundary of the cavity is formed by the membrana tympani, and by a small portion of the surrounding bone. This membrane is a thin semi-transparent substance, nearly oval in form, separating the cavity of the tympanum from the bottom of the auditory canal. It is directed very obliquely towards the auditory canal, its external surface being concave, its internal convex. The inner and fundamental portion of the organ of hearing is called, from its complexity, the labyrinth, and consists of three parts—the vestibule, the semi-circular canals, and the cochlea. It consists of a series of cavities channelled out of the substance of the petrous bone, communicating externally with the cavity of the tympanum and internally with the meatus auditorius internus, which contains the auditory nerve. Within the osseous labyrinth is contained the membranous labyrinth, upon which the ramifications of the auditory nerve are distributed. The sense of hearing is, strictly speaking, only a refinement of the sense of touch. The impressions with which it is conversant arise wholly from peculiar undulations of the particles of ordinary matter, propagated in obedience to its ordinary laws through the medium in which the animal lives, and impinging more or less immediately upon a sensitive part. The trumpet-like pinna or auricle of the external ear serves to collect the sound, which is then conveyed, by means of the meatus auditorius externus, to the membrana tympani. This is thrown into vibration, which is communicated to the malleus, and is carried by the incus and stapes to the membrane of the fenestra ovalis. From this last the motion is communicated to the various parts of the membranous labyrinth, taken up by the fine filaments of the auditory nerve, and conveyed to the brain.

EAR-SHELL (*Halistis*), a genus of univalve mollusca, the shell of which somewhat resembles in shape the human ear. The head of the animal is large, having two long round tentacula, with eyes at the base or footstalks. Foot very large, having the margin fringed all round. It is always found near the surface of the water; and is plentiful in the East Indies.

EARTH, *erth* (Sax., *eorth*; Ger., *erde*), the name given to the globe on which we live, which constitutes one of the larger, or primary, planets of our solar system, revolving round the sun as a centre. The Earth is the fourth planet from the Sun in order of distance (*see* PLANETS), including the planet Vulcan, discovered in 1859 between the Sun and Mercury. Its mean distance from the Sun is nearly 93,000,000 miles, and it performs an annual revolution round that body in 365 days, 6 hours, 9 minutes, 6·9 seconds. The form of the earth, speaking in general terms, is globular, or spherical: and the simplest proof that can be adduced in support of this fact is that the extent of land or water over which we can look is much greater when we are on the top of a mountain or lofty tower, or at the mast-head of a vessel, than when we are on deck, or on the ordinary level of the ground; and that the tops of the masts of a vessel at sea always come into sight before the hull, which would not be the case if the hull of the distant vessel were not hidden from us by the convexity of the surface of the water. The same effect is also visible when we approach a city on land: the tops of the towers and the spires of the churches are seen before buildings of less altitude rise into sight. The earth moves in an elliptical orbit from east to west, and moves through space at the rate of 19 miles in a second, and travels over a distance of 1,641,600 miles per day, or nearly 600,000,000 of miles in the course of the year. It revolves on its axis in 23 hours, 56 minutes, 4 seconds. That period of time forming a day, as the time of revolution around the sun makes a year. The velocity of the rotation about its axis varies from 0 at the poles to about 1,000 miles an hour at the equator. The Earth's axis has an inclination of 23½ degrees to the plane of its orbit: from this arises the phenomena of the seasons, and the variation in the length of dayand night at various periods of the year. (*See* CLIMATE, DAY, NIGHT, SEASONS, &c.)

Shape of the Earth.—The form is nearly spherical, but not exactly so, being slightly flattened at the poles, or points marking the extremities of its axis of rotation. The reason of the variation from the true spherical form is that the velocity of the earth's daily rotation upon its axis being greatest at the equator, the consequent greater action there of the centrifugal force (*see* CENTRIFUGAL FORCE) would produce a bulging out in the equatorial region and a flattening at the poles. The influence of this force in determining the shape of the earth is probably now very slight, but was considerable in the early history of our planet, when it was in a semi-fluid condition.

Size.—The mean equatorial diameter is 7,925 English miles. The polar diameter is 7,898 miles. The mean circumference, 24,869 miles. The area of surface, 196,000,000 square miles. The solid contents, 259,373,000,000 cubic miles.

Weight.—The density or weight of the earth has been ascertained with great precision by the result of many remarkable experiments, conducted over a long series of years by eminent observers from Newton to Baily and Professor Airey. The principle on which these experiments have been conducted is, to ascertain the force of attraction by certain bodies of known dimensions, and then, the size of the earth and its attractive force being known, to work out the problem in this manner:—As the size of the earth is to that of the object tested, so would be its attractive power if the specific densities were the same, attraction being in proportion to density. If the proportion of attraction is not the same, the earth and the other body must be of different densities, and it then remains to be ascertained what specific density of the earth, its size being known, would give the attractive power it is known to possess. Newton made a very near approximation to the true result by abstract reasoning; and between 1774 and 1776 Dr. Maskelyne, the Astronomer Royal, endeavoured to ascertain the attraction exercised by a large mountain in deflecting a plummet from the vertical line. The mountain of Schehallion in Perthshire was selected, but the results of the experiments were not scientifically satisfactory. Henry Cavendish, one of the greatest of English natural philosophers, "the Newton of chemistry," suggested another mode of investigation, which was carried out by Mr. Francis Baily in a series of experiments extending over several years, resulting in ascertaining the exact weight or density of the earth. In these experiments the attraction exercised by large balls of lead on small balls of lighter material was observed and calculated; and then, in accordance with the rule given above, the attractive force of the earth and a mass of lead of the same size was contrasted, and the relative densities of the earth and lead ascertained. The result of these carefully conducted calculations is that the weight is 5,842,000,000,000,000 (5,842 trillions) of tons, or more than 5½ times that of water.

Temperature.—The temperature of the earth varies at the earth's surface at different times from different causes. (*See* DEW, METEOROLOGY, TEMPERATURE.) As we descend below the surface, as in the shaft of a coal-mine, for example, the heat is found to increase to the extent of 1° Fahrenheit for every 15 or 20 yards; but it is not at all certain that this would be found to be a fixed law, and that the heat would increase in this ratio as we approached the centre of the earth, if it were possible to do so.

EARTHQUAKE, *erth'-kwaik* (Sax., *cwacian*, to tremble), a term applied to any shaking or tremor of the outer surface or solid crust of the globe. It is asserted with confidence that the surface of the earth is at no time free from these tremblings, frequently so slight as to be scarcely noticeable, at other times so extensive and terrific as to produce the most appalling catastrophes. Records of more than 7,000 earthquakes, so disastrous as to induce special remembrance, which have occurred between the remotest period known to history and the present time, have been preserved. That earthquake phenomena are connected with volcanic action can scarcely be doubted. The result of observations carefully made and extending over a long period of time show that great volcanic eruptions are almost invariably accompanied by shocks of earthquake; but it is also an ascertained fact that some of the most terrible earthquakes recorded in history have not occurred in volcanic regions. The movements of the ground during an earthquake are vibrations either tremulous, vertical, horizontal, or rotatory. Sometimes these vibrations follow each other rapidly; sometimes they occur singly; and in other cases they appear to take place simultaneously. No previous intimation is given of the approach of the shock—which is thus made more terrible from its suddenness. In Chili and adjacent parts of South America, slight tremblings of the surface of the earth are of almost daily occurrence, and attract very little attention. The vertical movement is similar to that produced by the explosion of a mine—the surface being broken up, and human beings and animals, rocky masses and other matters on the surface being shot perpendicularly into the air. Great earthquakes are marked by horizontal movements, propagated in undulations, like waves upon water, and estimated to travel at the rate of nearly thirty miles in a minute. Rotatory movements have been observed, but are unfrequent. When they take place walls are twisted round without being prostrated, and parallel rows of trees and ridges in fields are deflected. The direction of the shocks is either linear or in circles and ellipses, gradually decreasing in intensity with the distance from the central or focal points. The shocks are accompanied by great noises, in some cases like the rumbling of distant thunder, in others loud detonations like the discharge of cannon; the most remarkable sounds being described as resembling the clanking of chains, as if huge masses of mineral or vitrified matter were struck in caverns underground. Regarding these sounds, a suggestion has been made:—"Sometimes at stations very remote, where no shock whatever has been perceived, the sounds of explosion have been heard the same instant as at the sites of catastrophe. As sound requires a definite time to be transmitted through the air, it could not in these cases have been propagated by that medium. Solid bodies are much better conductors of sound, baked clay transmitting it with ten or twelve times the velocity of the open air; yet the supposition of the sonorous waves being conducted by the surface of the earth is untenable, because time is still demanded for the transport. It is likely, in such instances, that the sounds originated at such an immense depth below the surface as to be nearly equidistant from all the places where they were observed." Careful observations, however, made after the great Neapolitan earthquake of 1857, pointed to the conclusion that the "seismic centre" (Gr., *seismos*, earthquake), or focal depth of the convulsion, was only about six miles below the surface; and similar calculations respecting an earthquake in India in 1857 gave a depth of about thirty miles, which there is reason to suppose is the maximum. The prodigious force exerted in these subterranean convulsions may be partially appreciated by a reference to some of the more remarkable results which have been observed. The shock of the earthquake which produced such terrible results at Lisbon in 1755 was felt with more or less intensity over an area of 7,500,000 square miles; it extended to Finland, in the north of Europe, and some of the West India islands, and produced agitation of the waves of Lake Ontario, in North America. The velocity with which the shock travelled was computed to have been about twenty miles a minute, or 1,760 feet a second, or nearly half as fast again as the average velocity of sound; and the sea rose into a wave sixty feet high, which broke upon the shore. An earthquake at Guadaloupe, in 1842, was felt from the mouths of the Amazon, in South America, to the coast of South Carolina, North America, a distance of 3,000 miles, and over a breadth of 70 miles. In 1692 Port Royal, Jamaica, was destroyed, and "houses engulfed forty fathoms deep." In 1693 an earthquake in Sicily destroyed 54 towns and 300 villages, more than 100,000 lives being lost. In 1797 the whole country between Santa Fé and Panama, Central America, suffered from an appalling convulsion: "40,000 people were buried in one second." In September, 1759, on the lofty table-land about 150 miles south-west of the city of Mexico, an area of four square miles was suddenly raised about 550 feet, and numerous cones appeared, one of which, the volcano of Jorullo, is nearly 1,700 feet high. A contrary effect was produced in Java in 1772, when a lofty mountain entirely disappeared, the area sunk being fifteen miles long and six miles broad. A great earthquake in Chili in 1822 produced a permanent elevation of from two to seven feet of quite 100,000 square miles of land between the Andes and the coast; and distinct traces of lines of sea-beaches at higher levels farther inland indicate previous liftings-up of the same region at different times along the same lines. These are but a few instances of the stupendous force exerted, out of many hundreds which might be quoted; and it is estimated that at least 13,000,000 human beings have perished from earthquakes. The cause of the peculiar agitations of the surface of the earth presents a problem which is not easily solved, although various theories have been propounded. The "Steam explosion" theory has been ingeniously advocated. Mr. Mallet, noticing the fact we referred to, that volcanic eruptions are commonly followed by shocks of earthquake, and assuming that the lines or centres of volcanic action are generally near the sea, supposes that fissures may be formed in the bed of the ocean by submarine eruptions, that water flows in, reaching the central fire, and that, arriving there, it assumes the spheroidal form, until the surface with which it is in contact is cooled, when an explosion takes place, an earthquake being the result. A more satisfactory explanation has been given by the late Professor H. D. Rogers and his brothers, who gave great attention to the subject; they express a very strong opinion that a great "pulsation" of the molten fluid mass in the centre of the earth takes place, and is carried forward in the shape of huge waves, bearing along, or floating, as it were, the rocky crust of the earth above. The structure of certain mountain ranges remarkably confirms this theory.

EARTHS (in Chemistry).—The old chemists regarded as elementary, a class of substances which are insoluble in water. These "earths" are now known to be compound, consisting of a metal in combination with oxygen which do not decompose water. Many of them have been but imperfectly examined, owing to their extreme rarity. Alumina, a constituent of all clays, and glucina, found in the emerald, are the most important. (*See* ALKALINE EARTHS.)

EARTH-WORM (Ang.-Sax.) (*Limbricus*), a genus of *annelida*. Its outward appearance is a body composed of numerous narrow rings (sometimes more than a hundred in number) closely approximated to each other; the colour of the body is reddish, or purplish; of a cylindrical form, somewhat pointed at the anterior extremity, and usually a little flattened at the tail. It is without the organs of sight. The organs of motion consist of a double row of bristles running down the lower surface of the body, and which are capable of being withdrawn within small hollows when not in use. The mouth is unarmed, and the intestine runs straight through the body. The vascular system consists of two longitudinal vessels running along the ventral and dorsal regions of the body, and united by numerous branches. The blood is red. Like the leeches, this worm is furnished with ciliated canals, which have been supposed to serve as organs of respiration; but their real destination appears to be still uncertain. As far as relates to its appearance above the ground, the earth worm may be regarded as a nocturnal animal. In the night and at early morning, hundreds may be seen in localities where, during the daytime, not one is to be seen. They are of immense utility in improving the soil. The organs of the earth-worm's locomotion prevent its moving backwards, whilst the expansion of the rings, as it contracts the anterior segments and draws forward the hinder parts, widens a passage for it through the earth, whose particles were close together before. They are thus, in their multitudes, of incalculable utility in constantly loosening and stirring the soil, and accumulating on the surface those little hillocks of earth known as "worm-casts." On this subject the late Mr. Darwin, who gave it long and careful attention, remarks: "The burrowing of earth-worms is a process exceedingly useful to the gardener and agriculturist; and these animals are far more beneficial to man in this way than they are injurious by devouring the vegetables set in the soil. They give a kind of under-tillage to the land, performing the same below ground that the spade does above the garden, and the plough for arable land; and loosening the earth so as to render it permeable to air and water. It has been shown, too, that they will even add to the depth of soil; covering barren tracts with a layer of productive mould. Thus, in fields which have been overspread with lime, burnt marl, or cinders, these substances are in time covered with finely divided soil well adapted to the support of vegetation. That this result, which is commonly attributed by the farmers to the 'working down' of the materials in question, is really due to the action of the earth-worms, appears from the fact that in the soil thus formed large numbers of worm-casts may be distinguished. These are produced by the digestive process of the worms, which take into their intestinal canal a large quantity of the soil, through which they burrow, extract from it the greater part of the vegetable matter it may contain, and eject the rest in a finely divided condition. In this manner a field manured with marl has been covered in the course of eighty years with a bed of earth averaging thirteen inches in thickness." In his last published work "Vegetable Mould and Earthworms," Mr. Darwin says: "Coins, gold ornaments, stone implements, &c., if dropped on the surface of the ground, will infallibly be buried by the castings of worms in a few years, and will thus be safely preserved until the land is at some future time turned up." The same eminent naturalist was led to the conclusion that "all the vegetable mould over the whole country has passed many times through, and will again pass many times through, the intestinal canals of worms." Besides their usefulness in the manner above described, the earth-worms are of importance as food for birds, fish, &c. Their value as bait for fishes is well known to every angler. The power of reproducing parts after mutilation is very great in this animal, as in the whole of the order. It is generally supposed that the earth-worm may be propagated by division; but this scarcely appears to be the case. It is said, however, that if it be divided across the middle, the part bearing the head will develop a new tail, although the tail will soon die; and that if the head be cut off, the body will form a new head; but it appears that both portions never survive the mutilation.

EARWIG, *eer'-wig* (Sax., *ear* and *wicga*, a worm or grub), a genus of orthopterous insects, forming the family *Forficulidæ*, but by some naturalists considered to be a distinct order, *Dermaptera*, "leather-winged." One of the most striking characters of the earwig is the structure of the hinder wings. The radiating nervures, instead of finding their common centre at the base of the wing, as is the case in most *Orthoptera*, spring from the extremity of a broad leathery piece, which occupies about a third of the anterior margin. Other radiating nervures occupy the space between the principal nervures, but only run from the posterior margin to the middle of the wing; and the whole are united by a transverse nerve, which runs parallel to the posterior margin. By the assistance of these nervures, the wing, which is of very delicate texture, folds up exactly the shape of a closed fan; but as the wing-cases of the earwig are very short, the wings can only be got under them by very complicated transverse folding in two places—namely, at the apex of the leathery basal piece and at a second point about the middle of the wing, where the nervures appear to be thickened. Earwigs are distinguished from some other orthopterous insects by having the posterior legs formed for running. The female has no corneous ovipositor; and a remarkable fact connected with the insect is, that she sits upon her eggs in the manner of the hen, and the young, as soon as hatched, creep under the belly of the mother for protection at the approach of danger. In both sexes the abdomen is furnished with a pair of forceps, apparently of use as an instrument of defence. The antennæ are slender, filiform, and inserted before the eyes, and vary considerably as to the number of their joints. The thorax is generally of a rounded form, and but slightly convex. Ridiculous as is the fancy, there is no doubt that the insect's name, earwig, is furnished by the delusion that it will creep into the ears of sleeping persons. In all European countries the insect's appellation is significant of the belief. Newman, however, in his Introduction to the "History of Insects," says, "The shape of these wings (the hind ones), when fully opened, is nearly that of the human ear; and from this circumstance it seems highly probable that the original name of this insect was ear-*wing*." Earwigs appear to prefer damp situations, and are found under stones and under the bark of trees in great abundance. They subsist chiefly on the leaves and flowers of plants, and on fruits.

EBENACEÆ, *eb-en-ai'-se-e* (Lat., *ebenus*; Sp., *ebano*, ebony), the Ebony family, a natural order of dicotyledonous plants, in the sub-class *Corolliflorœ*, consisting of about 160 species, mostly natives of tropical India. Many of the *Ebenaceœ* are remarkable for the hardness of their timber, which is known under the names of ebony and iron-wood. Many species have edible fruits, and some have astringent barks. (*See* DIOSPYROS.)

EBONY. (*See* DIOSPYROS, EBENACEÆ.)

EBULLITION, *eb-ul-lish'-un* (Lat., *ebullitio*, a bubbling up), the bubbling agitation of liquids after they have been heated to their boiling-points. On gradually heating water in a glass flask by means of a spirit-lamp, we first observe the formation of minute air-bubbles, which dart through the liquid with great rapidity. As the temperature increases, these give place to larger bubbles, consisting of steam, which are formed at the bottom of the vessel, and which rise a little way in the liquid and then contract and disappear, producing a hissing or simmering sound. But as the heating goes on, these steam-bubbles rise higher and higher in the liquid, until at last they reach the surface and escape, when the liquid is said to be in a state of ebullition. The temperature at which the ebullition of a liquid takes place varies with the pressure of the atmosphere. When the barometer stands at 30 inches, water begins to bubble at the temperature of 212° Fah., because at this temperature the elastic force of steam will support thirty inches of mercury, and consequently the bubbles acquire the power of breaking through the surface of the heated liquid.

ECBALIUM, *ek-bai'-le-um* (Gr., *ekballo*, I cast out, expel), a genus of plants belonging to the natural order *Cucurbitaceæ*. The species *E. officinarum* is commonly called the squirting cucumber, from the fruit separating, when ripe, from its stalk, and expelling its seeds and juice with much violence. It is a native of the south of Europe, and is cultivated in England. The feculence deposited from the juice of the fruit, when dried, constitutes the drug called elaterium, or extract of elaterium, which is a powerful hydrogogue cathartic. It owes its properties to a bitter principle, named *elaterin*.

ECCENTRIC CIRCLE.—According to the Ptolemaic system of astronomy, every heavenly body was supposed to move round the earth, as the centre of the universe, in a circular orbit, and at a uniform rate of speed. When it was found, however, that the apparent orbits of the heavenly bodies were not circular, and that they moved through unequal spaces in equal times, they accounted for it by supposing that the earth was situated in a position which did not coincide with the centre of the orbits of the bodies that were revolving round it, and in this manner they attempted to reconcile the discrepancy between the apparent motion of the sun and planets and the theory they had invented with regard to them. The orbit of a revolution of a heavenly body is therefore called an eccentric circle in the Ptolemaic system, because the earth, round which it revolves, must be considered to occupy a position that is out of, or removed from, its centre.

ECCHYMOSIS, *ek-ke-mo'-sis* (Gr., *ek*, out of; *chumos*, juice), a discoloration of the skin, occasioned by the rupture of blood-vessels and extravasation of blood, usually produced by falls, blows, sprains, and the like. The presence of ecchymosis is generally considered as evidence that blows were given during life, or almost immediately after death. One of the most common examples of ecchymosis is a black eye. In general, the discoloration does not take place till some time after the receipt of the injury; and it may usually be much diminished by the speedy and continued application of cold wet cloths to the part.

ECHIDNA, OR PORCUPINE ANT-EATER, *e-kid'-na* (Gr.), a genus of quadrupeds found only in Australasia. There are two species —*Echidna hystrix*, peculiar to New South Wales, and *Echidna setosa*, chiefly found in Van Diemen's Land. They are of the same size, and, in general appearance, resemble the common hedgehog. They affect hilly countries, living in burrows, and feeding on insects, principally ants and termites, which they capture by the protrusion of their long viscous tongues; which latter organ, as in the case of the true ant-eaters, by an arrangement of longitudinal and annular muscles, is capable of being extended and contracted to a considerable extent. The head is small; muzzle elongated, and terminating in a little mouth, destitute of teeth, but furnished with several rows of small spines on the palate, directed backwards. The legs are short and strong, and the feet all furnished with five toes, armed with powerful claws. With the aid of these latter, it can burrow with great rapidity, and when pursued, and not allowed sufficient time to bore a complete hiding in the earth, it enters itself so far as to expose only its prickly back to the threatened assault.

ECHIMYD, a genus of rodent quadrupeds, resembling dormice, but having scaly tails and coarse fur mingled with flattened spines. They are all South American.

ECHINOCACTUS, *e-ki-no-kak'-tus* (Gr., *echinos*, hedgehog; *cactus*, a spiny plant), a genus of plants belonging to the natural order *Cactaceæ*. The stem is nearly globular, and is furrowed with longitudinal grooves, varying in number and depth. The flowers appear on the salient angles of the stem, in the centre of little tufts of bristles and spines. Many species of this genus are in cultivation as stove or greenhouse plants.

ECHINODERMATA, *e-ki-no-der'-ma-ta* (Gr., *echinos*, spine, and *derma*, skin), a class of radiate animals, the highest in organization of that great division. They are characterized by possessing a well-organized skin, under which, or attached to it, are frequently found plates of solid matter constituting a kind of skeleton. They have a digestive and a vascular system, and a circular nervous system has been detected in many of the species. A muscular system is constantly present. The nutritive apparatus of the *Echinodermata* is very simple, presenting in most of the family a single orifice, destitute of teeth, in the centre of the lower surface of the body, performing the functions both of the mouth and anus; but in some presenting a digestive cavity, with an orifice for the evacuation of its contents, distinct from that by which the food is taken in. The muscular motion is generally present in these animals, but the organs of motion in them are various, the principal ones being the membranous tubes, which can be protruded at will through the ambulacral apertures, and which have been termed the feet. Whether or no the highest among the *Echinodermata* possess sight is not a settled matter. They are all marine animals, and are fairly represented by the star-fish, sea-urchin, and sea-cucumber.

ECHO, *ek'-o* (Gr., *echo*, sound), a popular term applied to reflected sound. When sound from any origin is propagated through the elastic medium of the atmosphere, undulations, or waves, are produced in the air. When these waves come in contact with a cliff, or wall, or other opposing surface, they are reflected like light or heat. When the sound is so reflected as to come back to the observer's ear, it is called an echo. In order that the echo may be heard at the place where the sound originated, it is necessary that the reflecting surface should be at right angles to a line drawn to the point where the observer stands. An oblique wall throws off the echo so that it can be heard by others, but not by the originator of the sound. The most perfect echoes come from surfaces that are either even or so curved as to be in the form of a concave mirror. This, however, is not necessary; for a very distinct echo is often returned from the edge of a wood. Sound travels at the rate of 1,125 feet in a second; consequently it is necessary, in order to obtain an echo, to be at least sixty-two feet from the reflecting surface, and about the tenth of a second must be allowed to elapse in order to distinguish the sound from the echo. When nearer than this distance, the echo blends with the original sound, thus making both indistinct. In many churches and public halls, where the principles of acoustics have not been considered, the multitudinous echoes drown the speaker's voice. The distribution of sound in public buildings, so that the echoes may assist in strengthening the original sound, is a subject of great importance. When several objects reflect sound, the number of echoes is multiplied, the sounds growing weaker and weaker till they die away. The number of syllables that an echo will repeat depends upon how many can be uttered in the time that the sound takes to go and return from the reflecting surface.

ECLIPSE, *e-klips'* (Gr., *ekleipsis*), the entire or partial obscuration of a heavenly body; which may be caused in two ways—either by another body passing between it and the sun from which it derives its light, as in the case of an eclipse of the moon, when the earth passes between the sun and moon; or by the passage of a body between that which is eclipsed and the earth, as in an eclipse of the sun, when the moon passes between the sun and the earth. The eclipses which happen most commonly from the first-named cause are those of the moon (*see* LUNAR ECLIPSE), the partial eclipse of Jupiter by the passage of one of its satellites between it and the sun, and the eclipses of the satellites of that planet (*see* JUPITER); while those which are occasioned by the second cause are eclipses of the sun by the moon passing between it and the earth (*see* SOLAR ECLIPSE), or by Venus and Mercury crossing the sun's disc, or the occultation of a fixed star by the moon. (*See* MERCURY, MOON, VENUS.) Eclipses of Jupiter and his satellites can also happen through the second cause as well as through the first. Eclipses of the sun and moon, like the appearance of comets, were generally regarded by the ancients as omens of some terrible public calamity that was about to happen. Within the last few years astronomical expeditions have been arrayed to observe eclipses of the sun from various points of the earth's surface; and by the aid of photography very important records of appearances have been obtained. The theory of eclipses and the various phenomena that attend them are given in the articles to which reference has been made above, and all technical terms used in the description of an eclipse will be found under their proper headings. (*See* EMERSION, IMMERSION, PENUMBRA.)

ECLIPTIC, *e-klip'-tik*, the great circle in which the sun appears to move; so called because the moon is always found to be in or near this circle at the time of an eclipse. The plane of the ecliptic has a mean inclination of 23° 30′ to that of the equator. The angle of inclination varies to the extent of 5″ or 6″ in ten years. It is computed that the obliquity of the ecliptic varies between two extreme limits; namely, from 23° 53′ to 22° 54′, and that it takes about 8,500 years to effect the transition from one limit to another. The change in the angle of inclination arises from the attraction that Jupiter, Mars, and the other planets exercise on the earth. The inclination of the ecliptic to the equator is said to have been first measured by Eratosthenes about 250 B.C. The ecliptic is divided into four quadrants or arcs of 90° each by the equinoctial points and solstices. (*See* EQUINOXES, SOLSTICES.) These quadrants are subdivided into three arcs of 30° each, which are called the signs of the zodiac (*see* SIGNS OF THE ZODIAC), and named from the constellations which happened to be found in each when the division of the ecliptic was first made. These do not now coincide, although the names are still preserved. Astronomical calculations are made from that point of intersection of the equator and the ecliptic, which is the position of the sun in the heavens on March 21st, and which is known as the first point of Aries. (*See* ARIES.)

ECSTASY, *eks'-ta-se* (Gr., *ekstasis*, a standing out, change, or transposition), is a condition of mind in which the soul seems as if it were transported out of the body. The varieties of ecstasy are infinite, but they are all marked by an altered or diminished consciousness. The individual may be either completely passive or violently moved, and may or may not have any knowledge of what is going on around him. Sometimes he assumes the air of inspiration. This mental condition may be induced by fixing the mind too exclusively on one idea or object, so as to overlook all other sensations, as in mesmerism and certain forms of disease. It is also known in connection with certain highly religious states of mind.

ECTOZOA, *ek-to-zo'-a* (Gr., *ektos*, without; *zoos*, living), a term applied to those parasitic animals, such as lice, ticks, &c., which live upon the external parts of other animals. The word is used in contradistinction to *entozoa*.

ECTROPION, *ek-tro'-pe-on* (Greek, *ek*, and *trepo*, I turn out), a condition of the eyelid, in consequence of which it turns away from, and does not cover the globe of the eye. It can generally be remedied by a slight surgical operation.

ECZEMA, *ek'-ze-ma* (Greek, "to boil out"), an eruption of small vesicles on the skin, with a little inflammation around the bases, but not attended by fever.

EDDY, *ed'-de* (Ang.-Sax.), a circular motion of the water, either in rivers or in the sea, but most frequently in the former, caused by the opposition of currents.

EDENTATA, *e-den-tai'-ta* (Lat., toothless), an order of mammalia characterized by the absence of incisive teeth in their jaws, and the length of their claws. With regard to the incisors, however, there is an exception to the rule in the case of the armadillo (*Dasypus setosus*), in which a single tooth is found in each intermaxillary bone, but placed so completely at the sides of these bones, that the front of the mouth is quite destitute of teeth. The number of existing edentata is not nearly so great nor are they so gigantic in size as at a remote period of the world's history, as the remains of the mylodon, megatherium, and the megalonyx testify.

EDIBLE BIRDS' NESTS. (*See* NESTS, EDIBLE.)

EEL, *eel* (Sax., *æl*), a family of fishes (*Anguilla*), belonging to the apodal section of the *Malacopterygii*. Their long and cylindrical bodies are covered by a thick and soft skin, in which the scales are so deeply imbedded as to be scarcely apparent. The gill orifices are very small, and are situated far back; so that there is a long passage from the gill-chamber outwards; and hence, the gills not soon becoming dry, these fishes can remain a long time out of the water, some of them, indeed, leaving it of their own accord. Most of the eels are included in the Linnæan genus *Murænа*, and are divided by some naturalists into the families *Synbranchidæ*, *Murænidæ*, *Anguillidæ*, *Congeridæ*, and *Ophisuridæ*. The

Synbranchidæ have the gill-passages so united under a common integument as to present externally only a single orifice: they are almost destitute of fins. The species are few, and they are chiefly found in tropical seas. The *Murænidæ* are also generally destitute of fins, or nearly so: they are all destitute of scales, and never found in fresh water. The *Anguillidæ* are fresh-water fishes, though some of them occasionally visit the sea. They have mdderately large pectoral fins, anal and dorsal fins extending to and encompassing the tip of the tail, and numerous longish scales embedded in groups in the skin, so as to resemble lattice-work. *Ophisuridæ*, or snake-eels, are distinguished by the tail ending in a conical pointless fin. At least three species of eels are found in this country—the Sharp-nosed, the Broad-nosed, and the Snig. The first-mentioned, which is common in streams and lakes, is distinguished, as its name implies, by its comparatively long and narrow muzzle. Its colours are dark olive-green on the upper surface of the head and body; under surface silvery white. The clearer the stream in which the eel lives, the more vivid are its colours. The broad-nosed eel is not uncommon, and is often found in the same waters with the sharp-nosed, from which, however, it is to be readily distinguished by the comparatively greater breadth of its head and the situation of its eyes, which are placed in advance of the angle of the mouth; the body, moreover, is thicker in proportion to its length, and the teeth more numerous and stronger; and the dorsal and anal fins, which are much deeper and thicker, commence fartherback. In some parts of England this sort is known as the grig-eel. The snig is in many respects intermediate between the broad-nosed and sharp-nosed species; its colour is closely like that of the sharp-nosed eel. The snig is considered superior to other kinds for the table; but the sharp-nosed eel attains the greatest size—sometimes five-and-twenty, and even thirty pounds weight. The eel migrates at the approach of winter to warm estuaries, generally brackish, and at times perfectly salt. Those, however, which live in ponds, and cannot emigrate, bore down into the mud, and there remain during the colder months of the year. They are sometimes dug out of the mud-banks of rivers and lakes in considerable quantities. Eels are taken in the winter by means of *eel-spears*, or forks with several prongs, which are plunged into the mud. They are captured in great quantities by the use of large jar-shaped baskets, with funnel-shaped entrances, and flexible withes coming from the mouth inwards to a point. The eels can enter easily enough, but if they try to return, they find the entrance closed against them. These baskets are placed in weirs across streams. Small baskets of a similar construction, known as *eel-pots*, are sunk in the streams. Night lines, with baited hooks, are stretched across the water. Eels are also caught with lines baited with worms, in which needles are enclosed.

Eels, in paste, vinegar, and vegetable substances in process of decay, are infusoria of the family *Vibrionidæ*. They appear like minute pieces of thread, and some wind themselvés into spirals when they move.

EEL, CONGER. (*See* CONGER EEL.)

EEL, ELECTRICAL. (*See* ELECTRICAL EEL.)

EFFERVESCENCE, *ef-fer-ves'-ens* (Lat., *effervesco*, I boil over), the escape of gas in minute bubbles from a liquid. Thus, when any strong ammonia is uncorked, effervescence takes place, from the relief of pressure. It also happens when a gas is replaced in a solution by some liquid or solid, as where sulphuric acid is added to a solution of carbonate of soda to unite with the alkali, setting free the carbonic acid.

EFFLORESCENCE, *ef-flo-res'-ens* (Lat., *effloresco*, I blossom), the formation of an opaque powder upon the surface of a crystal, from its losing its water of crystallization spontaneously, the action generally continuing until the whole has fallen to powder. Familiar instances take place in common carbonate of soda, and sulphate of soda, or Glauber's salt. It is the reverse of deliquescence.

EFT (Ang.-Sax.), a common name for lizards and newts, but more strictly limited to the latter. (*See* NEWTS.)

EGG, *eg* (Sax., *æg;* Lat., *ovum*), a body produced in the females of birds and certain other animals, containing an embryo or fœtus of the same species, or the substance from which a similar animal is ultimately produced. Those animals in which reproduction takes place by means of eggs are called oviparous. The marsupial quadrupeds and the mono-tremata form the connecting link between the warm-blooded animals which are oviparous and the truly viviparous animals, which only belong to the mammalia. The number of eggs produced varies greatly in different animals; some birds only produce one egg in a year, while others produce as many as twenty. The roe of some fishes contains myriads of eggs. The eggs deposited by some animals are enveloped in a gelatinous substance; others are connected in various ways, sometimes being in the form of a string. The eggs of a large number of birds are used as articles of food, those most generally used belonging to the class of birds called poultry. The common domestic fowl, the turkey, and the pea-hen, are birds whose eggs are most generally used all over the world. In some of the islands of Scotland, the eggs of several species of sea-birds, such as the gull and guillemot, form an important article of food among the inhabitants. Although the eggs of birds are principally eaten, the eggs of the turtle are also considered a luxury; and the eggs of fresh-water tortoises are valuable for the oil which they yield. An ordinary hen's egg has an average weight of 875 grains, of which the shell and its inner membranous coating weigh 93·7 grains; the albumen, or white, 529·8 grains; and the yolk 251·8 grains. The shell contains about two per cent. of animal matter, and one per cent. of the phosphates of lime and magnesia, the rest consisting of carbonate of lime, with a trace of carbonate of magnesia. (*See* ALBUMEN.)

EGG-APPLES. (*See* SOLANUM.)

EGG-BIRD (*Hydrochelidon fuliginosum*, or *Sterna fuliginosa*), a bird of the Gull family, sometimes called the sooty tern, somewhat larger than the other members of the tern family. It abounds in the West-Indian seas, and is chiefly valuable for its eggs, which are about two inches long, cream-colour, sparingly streaked with purple. So highly are these eggs esteemed, that their gathering is a considerable trade. The nest of the egg-bird is made in the sand, and the eggs number from one to three.

EGGAR MOTH, *eg'-gar*, a moth of the

genus *Lasiocampa*, applied to the silkworm moth. The caterpillar of one species (*L. trifolii*) is as thick as a large quill, hairy, and of a yellowish-brown colour. It is common in clover fields.

EGLANTINE, *eg'-lan-tine*. A name given to the sweetbriar, and to other small-flowered species of roses.

EGRET, *e'-gret*, a name often applied to various species of heron, but not to the common heron; most frequently to those which have soft and flowing plumage, generally white. The French form of the name is commonly given to a tuft of feathers. (*See* AIGRETTE.)

EGYPTIAN BEAN. (*See* NELUMBIUM.)

EGYPTIAN VULTURE, one of the smaller *Vulturidæ*, of a genus (*Neophron percnopterus*) differing in some respects, especially in the bill, from a true vulture, and much smaller. The plumage of the male is white, except the great quill feathers, which are black. It is common in Egypt, where it is often known as Pharaoh's chicken.

EHRETIACEÆ, *er-e-ti-ai'-se-e* (in honour of D. G. Ehret, a German botanical draughtsman), *Ehretia* family, a natural order of dicotyledonous plants in the sub-class *Corolliflora* resembling the *Boraginaceæ* in most of their characters. There are 14 genera and 297 species, chiefly tropical trees or shrubs. Some species bear edible fruits. Some have a delicious odour, as *Heliotropium peruvianum*, the Peruvian heliotrope.

EIDER DUCK (*Somateria mollissima*), a species of wild duck inhabiting the frozen regions of the north. It is very abundant in Iceland, Lapland, on the shores of Baffin's Bay, &c., and is met with in the Scottish and the Fern Islands; especially on St. Cuthbert's rocks, from which it is sometimes named St. Cuthbert's Duck. Generally, it is of a size intermediate between the domestic duck and goose. The top of the head is soft velvety black, cleft behind by a narrow streak of white; the feathers from the nape of the neck to the throat are puffed out, and look as though the ends had been clipped. The cheeks, chin, upper part of the neck, the back, and lesser wing-coverts, are white; bastard wings and primary quills brown; the front part of the neck to the breast is dun-colour, and thence to the under part of the tail. The eggs are very fine, and the flesh not unpleasant in flavour. The King Eider, or King Duck (*S. spectabilis*) belongs to higher latitudes than the common eider, and is abundant on the coast of Greenland, Spitzbergen and Nova Zembla. It has been seen in Britain, but very rarely.

Eider Down.—This curious and beautiful down grows on the breast of the bird, and the mode adopted to procure it is somewhat singular. The nest is composed of seaweed, and any hole or ledge is evidently considered an eligible building site. The number of eggs laid is usually five, six, or seven; they are three inches long, two broad, and of a uniform pale green. When first deposited in the nest, they are allowed to go uncovered; but in a few days the mother begins to pluck the down from her breast, and to cover them over; and this process would seem to be indispensable to the growth and hatching of the young birds; for, if the nest be plundered, till the female has left no more down on her breast, the male bird will begin to furnish the comfortable covering from his own body. The common practice is to remove the whole of the eggs with the down, twice, and to leave the third lot of eggs, that the birds may not be thinned in number. The gross weight of the down yielded by one bird in a single season is half a pound; but this, when cleaned, is reduced by one half. The elasticity of eider down is so extreme that three-quarters of an ounce will fill a man's hat. It is capable of great compression, so that the down makes its appearance in balls no larger than a breakfast cup, but weighing about three pounds.

ELÆAGNACEÆ, *el-e-ag-nai'-se-e* (Greek, *elaia*, an olive, and *agnos*, chaste), the Oleaster family, a natural order of dicotyledonous plants in the sub-class *Monochlamydeæ*. There are four genera and thirty species, mostly natives of the northern hemisphere. The fruits of several species of the typical genus *Elæagnus* are eaten in Persia and some parts of India.

ELÆOCARPUS, *el-e-o-kar'-pus* (Gr., *elaia*, an olive, and *karpos*, a fruit), a genus of plants belonging to the natural order *Tiliaceæ*. The Molucca berries, which are frequently made into necklaces in India, are obtained from the species *E. serratus*.

ELÆOCOCCA, *el-e-o-kok'-ka*, a genus of *Euphorbiaceæ*, the seeds of which yield oils. In Japan the oil is used for food; but elsewhere in the East, for burning or in painting.

ELÆODENDRON, *el-e-o-den'-dron*, a genus of trees of the natural order *Celostraceæ*. One species (*E. glaucum*) is sometimes known as Ceylon tea; and the timber of another species (*E. croceum*), growing in South Africa, and much used in building and cabinet-making at the Cape of Good Hope, is known as saffron wood. The fruit of some species is eaten, and from others an oil, similar to olive oil, is extracted.

ELAIS, *el-a'-is* (Gr., *elaion*, oil), a genus of palms. The two species *E. guineenis* and *melanococca* are the Guinea oil-palms, from the fruits of which the vegetable butter called palm oil is extracted. The oil is of a rich orange-yellow colour, and is extensively used in this country in the manufacture of candles and soap. In Africa it is used as food by the natives. Being emollient, it is sometimes used in medicine as an embrocation to spasms and bruises. The hard stony putamen of the same fruits yield a limpid oil. Palm wine may be prepared from the juice which flows from the wounded spathes of the two palms.

ELAND, *e'-land*.—This animal, considerably the largest of all the antelopes, is known by several different names—the impoofoo, eland Cape elk, canna, or bastard eland, are among th many terms applied to it. The ordinary eland is a large heavy animal, weighing, at full growth, from 7 cwt. to 9 cwt; and, contrary to the rule amongst antelopes in general, is prone to be fat. Its usual size is that of a full-grown horse, measuring generally a little more than eight feet in length, and standing full five feet at the shoulder. The horns of the male are thick and heavy, and about a foot and a half in length. They are straight till they arrive at about three inches from the tips, where they bend outwards. They are also surrounded by a thick spiral wreath, which becomes indistinct at the points. The horns of the female eland are longer and smaller, and the spiral wreath is often absent. In both sexes the head is long and pointed, the ears large, the neck thick, and in front of the chest is a loose hanging skin or dewlap, with a border of long hair on its margin. A short erect mane of dark brown hair runs from the centre of the forehead to the root of the tail. This mane is directed backwards along the spine, but is reversed on the neck. The tail is more than two feet long, and terminates in a tuft of long black hair. The flesh of the eland is more prized as food than that of any other wild animal of Southern Africa. Elands were formerly very common in the neighbourhood of Cape Town; but they have been so universally hunted that they are only to be met with in the most retired parts of the colony. The disposition of the eland is very mild and gentle, and it seems predisposed to domesticity. It is gregarious, and lives in large herds upon the low hills and level plains. The scientific name of this animal is *Antilope oreas.*

ELANET, *el'-a-net*, a genus of *Falconidæ*, allied to the Kites. One species is common throughout Africa, and is found also in India. Another species is a native of the southern part of the North American continent, where it is known as the black-shouldered hawk. They feed on insects, small birds, and reptiles.

ELAPS, *e'-laps*, a genus of venomous serpents, of a slender form, and beautiful in colour. They are most common in the islands of the Indian archipelago, Australia, and tropical America.

ELASTICITY, *e-las-tis'-e-te* (from Fr., *élastique*, elastic; primarily from Gr., *elastes*, an impeller forward), that property which certain bodies possess of recovering their former figure or state after internal pressure, tension, or distortion. Elasticity is perfect when the body exactly recovers its primitive form after the force by which its form has been changed is removed. Perfect elasticity is, however, not to be found in nature. Aëriform fluids or gases approach nearer to perfect elasticity than any other substances. In solid bodies, as a general rule, elasticity is destroyed by use: thus a bow loses its elasticity by being kept bent. Iron and steel can have their elasticity increased by being tempered, that is, by contracting their volume suddenly after being expanded by heat.

ELATERIDÆ, *el'-at-e-ri'-de*, a family of coleopterous insects, divided into many genera. They are generally found upon the flowers and leaves of plants, which are their food. If they fall, or are placed on their backs, their legs are too short to permit them to regain their natural position in the ordinary way; but they can fling themselves into the air with a violent jerk, making a "clicking" noise. The names click-beetle and skipjack are, from that peculiarity, often given. Many of the species are British, and the fire-flies of tropical countries belong to this family.

ELATERIUM. (*See* ECBALIUM.)

ELATINACEÆ, *e-lat'-e-nai'-se-e* (Gr., *elate*, a fir; the leaves resembling those of the fir-tree), the Water-pepper family, a natural order of dicotyledonous plants in the sub-class *Thalamifloræ*, consisting of 6 genera and about 22 species—little annual marsh-plants. The plants of this small order are scattered all over the world. They are generally considered acrid.

ELBOW, *el'-bo* (Sax., *elneboga*), the joint of the arm formed by the lower end of the humerus and the upper end of the radius and ulna. (*See* ANATOMY.)

ELDER, *el'-der*, a genus of plants (*Sambucus*) of the natural order *Caprifoliaceæ*, consisting chiefly of shrubs and trees, very widely distributed throughout Europe, the north of Asia, and the north of Africa. The common elder (*S. nigra*) is found in all parts of Britain. It has rather large leaves, and cream-coloured flowers, which are followed by small black berries. Elder-flower water, employed in perfumery and confectionery, is distilled from the flowers, from which, also, boiled in lard, a cooling ointment is made. Elder-wine, made from the berries, is a favourite beverage, especially in winter time, when it is drunk hot, or "mulled." A less legitimate use of the berries is in the adulteration of port wine, and the manufacture of spurious port wine. The wood of the elder is of a yellow colour, hard, and susceptible of a fine polish, and is often used as a substitute for boxwood. There is a great amount of pith, employed, on account of its lightness, to make pith-balls for electric experiments. The scarlet-fruited elder (*S. racemosa*), a native of the south of Europe and of Siberia, is cultivated in this country as an ornamental tree—of great beauty. The juice of the berries is a powerful sudorific. The danewort, or dwarf elder (*S. Ebulus*), is a rather rare British plant, from the inner bark of which is made a decoction, sometimes administered with advantage as a remedy for dropsy.

ELECAMPANE, a genus of plants of the natural order *Compositæ*, nearly allied to asters. (*See* INULA.)

ELECTIVE AFFINITY, OR ELECTIVE ATTRACTION.—At one time chemists employed this phrase to describe the affinity or mutual attraction of certain bodies, and their tendency to combine. The phrase has recently been revived to express the connection between the chemical activity of a body and its combining weight.

ELECTRICITY, *e-lek-tris'-e-te* (Gr., *elektron*, amber), the most stupendous force in nature, apparently active throughout the universe, the cause of the phenomena described as attraction, gravitation, and magnetism, and most probably of heat and light. It is incessantly active, and maintains, it would seem, the physical life of the world. Science can only appreciate some of its results, and apply it on a very limited scale to practical purposes; but knowledge of its adaptability is growing every day, and what a few years since was little more than material for brilliant laboratory experiments, or the production of scientific toys, is now becoming a gigantic motive power available for the service of practical science and the progress of civilization. Already it provides a means of instantaneous communication between portions of the earth's surface most remote from each other; it is gradually superseding all other methods of artificial illumination; and it promises to make steam obsolete as a motive power. What other aid it may give, we know not, and we scarcely dare conjecture, although it would seem that the most vivid imagination must fail to apprehend its possibilities. It is in the earth beneath us, known as terrestrial magnetism; it is in the atmosphere around us, and its energy is seen in the lightning flashes which mark the discharge of force between clouds, each of which is a storage of force; and in the vast, indeed inconceivable, kosmos, electricity maintains the relations of suns and systems moving with enormous velocity and unvarying regularity through space.

It is a force which, so far as human intellect can appreciate it, knows no cessation or diminution or deterioration. It can be summoned but not created by any skill of man; made apparent in the results of friction or chemical action, but made apparent only, not produced. A spark the eighth of an inch long produced by contact with the small electric machine of the lecture-room is precisely similar in character to the terrible flash which splits a tree to fragments, striking it with sudden death, or topples down the most massive tower reared by the skill of man. In Oriental fables we read of lamps the rubbing of which produced an obedient geni ready to minister to every want. We can excite the electric force, and the most stupendous of all the genii of nature—if not, indeed, the one master-spirit, of which all known natural forces are but variations —is at our service; our servant, if we will, our most terrible master if we have not skill to conciliate him. Define the nature of the force, we cannot; to describe some of its aspects as exhibited in the results of experiments and of practical adaptation, we may more safely attempt. In an able paper in *The Nineteenth Century*, Viscount Bury says:—"Electricity being, like heat or light, a mode of motion, its manifestation is usually spoken of conventionally as a current. Probably there is no such thing; the force obeys certain laws, and acts in particular ways, but it does not flow bodily from place to place as a current does. It follows rather the analogy of light-undulations, or sound-waves. Sir William Thomson and others who have devoted themselves to the investigation of electrical phenomena avow themselves at fault; they do not know what electricity is; but, whatever it is, the earth contains a practically inexhaustible supply of it, and portions of it can be separated from the main body. The portion so separated has a tendency to escape and recombine. In doing so, it exerts energy; in other words, it performs work which may be directed, utilized, or measured." In common language, the force is described as the "electric fluid." That is a figurative expression conveniently used, but, as we have just seen, by no means scientifically precise. Throughout the 16th and the earlier part of the 17th centuries, philosophers had been experimenting and noting appearances, but failed to obtain any but the vaguest conception of the nature of the power. In 1733, C. F. Dufay, a distinguished French investigator, announced a theory of two electric fluids, one of which was developed by the rubbing of glass and similar substances, and named by him *vitreous*; and the other by rubbing amber and resinous substances, and named *resinous*. There were, then, he maintained, two kinds of electricity, and two bodies charged with the same kind repelled each other, but two charged with opposite kinds were mutually attractive. In accordance with this double-fluid hypothesis, which met with considerable support, these two fluids are supposed to be present in equal quantities and combined together in a neutral body—that is, a body apparently possessing no electric power. Friction has the effect of separating them, and giving one fluid to the rubbing body, and the other to that rubbed. When a body, possessing electricity of one sort, is brought near to an insulated conductor, the neutral fluid upon it is, as it were, decomposed. The kind of electricity opposite to that in the inducing body is attracted towards that body, while the opposite kind is repelled as far as possible from it. For nearly twenty-five years this hypothesis found acceptance; then Franklin, the great American, who proved that a flash of lightning and an electric spark were identical in nature, suggested the existence of a single homogeneous imponderable fluid of extreme tenuity and elasticity, in a state of equal distribution throughout the material world. This fluid is assumed to be repulsive of its own particles, but attractive of all other matter. When distributed in bodies, in quantities proportionate to their capacities or attraction for it, such bodies are said to be in their natural state. When we increase or diminish the natural quantity of electricity in any substance, excitation is the result, and the substance, if overcharged, is said to be electrified *positively*, or, if undercharged, *negatively*. These terms are retained, although the sense in which they are used is not precisely that given to them by Franklin. The action of the electric force—or rather of the true opposing manifestations of force, by whatever name we call them, *vitreous* and *resinous*, or *positive* and *negative*—may be exhibited by a familiar little experiment. But we must premise that the mysterious force will travel rapidly through some substances, which are therefore known as *conductors*, and very unreadily (practically, not at all) through others, known as *non-conductors*. The metals are conductors, and silk, glass, resin, amber, and various other substances are non-conductors. No electricity will remain in a body connected with a conductor which carries it away as fast as produced, and that is the reason why the well-known metallic rods, lightning conductors, carry off the electricity in the atmosphere, otherwise dangerous, and get rid of it in the earth. Understanding that, we shall the better understand the experiment we have mentioned. A light pith-ball or a feather is suspended by a silk thread, which is a non-conductor, and therefore impervious to electricity. A glass tube smartly rubbed with a silk handkerchief becomes charged with vitreous electricity, and if then brought near to the pith-ball, or feather, that is briskly attracted towards it, but in a moment a contrary action takes place, and it is as smartly repelled. The fact is, it has become charged with the same kind of electricity as the tube itself, and the similarity produces antagonism. If a piece of sealing-wax is then excited by rubbing, and so charged with resinous electricity, and presented to the pith-ball, or feather, attraction and repulsion again take place, as when the glass was used. This may be done over and over again, and we readily arrive at the conclusion that similarly electrified bodies repel each other, and dissimilarly electrified bodies attract each other. If the electrified pith-ball be touched with any conductor in communication with the ground, it will instantly lose its charge of electricity, which will be carried back to the great natural reservoir of the force, on the lightning conductor principle. We may just observe that friction develops both kinds of electricity, the rubber and the rubbed body assuming opposite states. The electric force always seeks to pass from one to the other, and so restore the equilibrium, and the end of one of the wires connected with an electric machine is known as the positive pole, and the end of the other as the negative; and when the two are connected a circuit is established, and when separated by a small space the electric force makes great effort to complete the circuit by passing from one to the other.

The positive electricity so striving to unite with the negative takes the form of a spark, the intense force developing combustion of the intervening atmosphere. Electricity, then, is a force; not a visible fluid, like water, nor an invisible fluid, like gas, but simply a force, undefinable in its nature, and recognisable only by its stupendous results. Electrical action can be produced by friction, by the action of certain acids upon metals, and by the very rapid motion of metals in the immediate vicinity of magnets. The first kind of action is known as *frictional*, the second as *voltaic*, and the third as *magneto-electricity*. Frictional electricity is that exhibited in the experiment we have mentioned, and in the machines constructed with glass cylinders with which most of us are acquainted; voltaic electricity is developed in the galvanic battery, a series of metal plates immersed in various solutions, in extensive use in connection with telegraphic apparatus, and also tolerably well known; and the third, magneto-electricity, is that produced by the Gramme and other electro-dynamic machines so much talked of in connection with the introduction of the electric light. We need but add that the magnetic and electric forces are proved to be identical and that a reciprocal action is established—that is, that a bar of iron around which a wire is coiled becomes a magnet when a current of electricity is passed through the wire, and has positive and negative poles or ends; and, on the other hand, a coil of wire becomes electrified if a powerful magnet is placed in the centre, or revolves with great velocity near it, or if the coil revolves near the magnet. It will be more convenient to reserve more detailed explanations on some of these subjects for special articles under the headings ELECTRIC LIGHTING, ELECTRO-DYNAMIC MACHINES, and MAGNETO-ELECTRICITY.

Frictional Electricity.—This name must be taken as describing one method of exciting electrical energy, not as an energy of a different kind. Some bodies which do not conduct electricity—that is, through which the force does not pass—are capable of electrical excitation from friction, and are in consequence termed *electrics;* other bodies, through which the force passes, are conductors, cannot be excited by friction, and are known as *non-electrics*. If a stick of sealing-wax be rubbed with a dry piece of flannel or cloth, it becomes electrified, in other words, it acquires the power of attracting light bodies, as feathers, wafers, or bits of paper. Many other substances besides sealing-wax can be readily electrified by friction. The kind of electricity resulting from friction appears to depend on some peculiar condition of contact between the rubbed surfaces; thus smooth glass rubbed with silk or wool becomes positive, but when roughened by sand or emery it acquires, under the same circumstances, a negative charge. Again, when silk is rubbed with glass, it becomes negative, but when rubbed with sealing-wax, positive. If a warm and a cold surface be rubbed together, the colder becomes positively electrified, the other, negatively. When two silk ribbons are rubbed across each other, that which is longitudinally rubbed becomes positively electrified; and when a white ribbon is rubbed by a black one, the white ribbon becomes positive. Both kinds of electricity are produced in every case of electrical excitation, the rubber and the rubbed body always assuming opposite states; in fact, both electricities are produced together, and in exactly equal amounts. When the electricity is produced by friction upon glass, it remains where it was produced, *insulated*, and exhibits its effects of attraction and repulsion towards external objects; but if it be produced on such a body as a rod of iron held in the hand, it is transferred through the iron to the hand, thence through the body to the earth. If, however, the iron rod be cemented to a stick of glass and thus supported, it can readily be electrified by friction. The following is a list of various substances, arranged so that if any two of them be rubbed together, the one which stands nearest to the beginning becomes positively electrified, the others negatively:—

Cat's Skin.	Glass.
Flannel.	Cotton.
Ivory.	Silk.
Rock Crystal.	The Hand.
Wood.	Sulphur.
Shellac.	Caoutchouc.
Resin.	Gutta Percha.
Metals.	Gun Cotton.

Before the recent applications of the electric force to the practical arts, and so long as electrical science was limited to the laboratory or lecture-room, friction was one of the chief modes—indeed, the chief mode of producing the exhibition of the phenomena. *Cylinder and Plate Electric Machines* were those chiefly employed. The cylinder machine consists of a glass cylinder supported by means of a horizontal axis on two wooden uprights, and made to revolve rapidly by means of a winch. Two brass cylinders of smaller diameter are placed on each side of, and parallel to, the glass cylinder, and supported on glass pillars. To one of the brass cylinders is attached a cushion as long as the cylinder itself, made of horse hair, and covered with leather, made, by means of a spring or screw, to press against the glass cylinder. To the lower end of the cushion is attached a long flap of silk, which, when the machine is at work, passes between the cushion and the glass cylinder, over which it lies, covering the whole upper half. That portion of the silk which covers the cushion is spread with "electric amalgam," a compound of tin, zinc, and mercury, in the respective proportions of 1, 2, and 6. The other brass cylinder, the "prime conductor" of the machine, is furnished with a horizontal row of pointed wires, like a comb, with intervals of half-an-inch between the teeth, which project towards the glass cylinder, approaching as nearly as possible without touching it. When the glass cylinder is turned, it becomes positively, and the cushion negatively, electrified by friction. The positively electrified glass is carried round till it comes opposite to the points belonging to the prime conductor, which becomes excited by induction (*see* below, INDUCTION), and, in fact, is electrified negatively on the side nearest to the glass, and positively on the side opposite to the glass. But the points have no power to hold a charge, and they discharge towards the glass cylinder, permitting negative electricity to flow from themselves towards it, and thus they neutralize the positive electricity on it, and leave the prime conductor charged with positive electricity. A spark of positive electricity can now be obtained from the prime conductor. But during this time the cushion has, as we have mentioned, been charging with negative electricity, and when it has attained a certain degree of electrification, it is necessary to discharge it before any more positive electricity can be obtained from the prime conductor. It is usual to connect the cushion permanently by means of a chain or wire to the earth, and then, on turning the machine, a continuous discharge of positive electricity can be got from the prime conductor. The *Plate Electric Machine* is the same in principle as the cylinder machine; but, instead of a glass cylinder, a circular glass disc or plate is used. In some of the improved forms the prime conductor is a large brass ball. The friction caused by steam at high pressure issuing from a narrow pipe develops electricities on the steam and pipe which depend on the material of the latter. An accidental injury to a workman directed the attention of Mr. (afterwards Sir William) Armstrong to this fact, and he designed a *Hydro-Electric Machine*, consisting of an ordinary steam boiler, insulated on four glass legs. To the escape-pipe a row of nozzles were attached, constructed so as to give as much friction as possible to the steam rushing out through them. Round the nozzles was a box of cold water, in order that the steam, after passing through it, might issue from the nozzles charged with vesicles of water. The steam was charged with positive electricity, the boiler with negative; and the electricity of the steam was given up to the points and prime conductor.

Voltaic Electricity, or Galvanism.—Electric currents are obtained by chemical action, especially that attending the dissolution of metals. When two plates of

ELECTRICITY.—PLATE MACHINE.

copper and zinc (the surface of which has been rubbed over with mercury) are placed in a vessel containing water, to which a small quantity of sulphuric acid has been added, and the plates are made to touch, bubbles of hydrogen gas are formed in abundance at the copper plate, and their formation continues until the plates are again separated; and if wires of copper or any other conductor of electricity be attached to the plates by solder or binding screws, and be made to touch, the same results occur. The fact is, there is an excitement of electrical power; and the two plates, with the wires, form a cell, and a number of these cells a battery, from which powerful electric currents can be obtained. Such a battery is of great value, and is in constant employment in arts and manufacture. For more extended information on the subject, see GALVANISM.

Other Sources of Electricity.—Besides friction and chemical dissolution of metals, there are other methods of inducing electrical action. After cleavage or pressure, certain laminated minerals, such as mica, arragonite, or calcareous spar, exhibit strong electrical excitement at the surfaces cleft or pressed, one of these surfaces being always positive and the other negative; and many other bodies, not minerals, possess the same property. Thus, if a disc of cork and a disc of caoutchouc be pressed together and then separated, the former is found to be electrified positively and the latter negatively. Change of temperature also produces electric excitement. If a crystal of tourmaline be warmed, it shows positive electricity at one extremity of its principal axis and negative at the other, and if it be broken during the heating, each of the parts is electrified at each end, just as the whole was, showing apparently that the crystal possesses electric polarity analogous to the polarity which a magnet has. Topaz, boracite, and some other minerals exhibit similar action under the influence of heating. Electricity is also obtained by the action of heat to a junction of two dissimilar metals. (*See* THERMO-ELECTRICITY.)

Positive and Negative Electricities.—The absolute inability of the most acute investigators to define the real nature of the electric energy compels them to use terms which to a certain extent have a definite meaning for practical purposes, but which are by no means scientifically correct. It has already been shown that Franklin adopted the words *positive* and *negative* in place of the *vitreous* and *resinous* of the earlier investigators. The fact that electricity developed on glass by friction with silk will attract electricity developed on wax by friction with flannel is indubitable; so also is the fact that electricity of either kind will repel its own kind. But, even so far, the subject is surrounded with difficulty; and we are unable to distinguish the essential difference between the so-called vitreous and resinous electricities; for "we may get from glass the same electricity (that is, electricity acting in the same manner) as we do from wax if the glass be ground and rubbed with flannel instead of silk; or even by holding an ordinary glass tube in an alcohol flame, it becomes negatively electrified." The hypothesis, indeed, is a remainder of the "two-fluid theory." A recent clever writer on the subject, Mr. Thomas Dunman, says, "It must be thoroughly understood that this theory or hypothesis is rather an *expression* than an *explanation* of the phenomena of electricity, and must by no means be regarded as a final and thorough solution of the various features, but rather should be looked upon as an hypothesis which is temporarily made use of until some more comprehensive and trustworthy theory shall take its place." We require, probably, to know something more of the amount of heat generated by friction, of the conversion of such heat into energy, and of the phenomena of polarization before we can hope to arrive at a satisfactory solution of the problem. Modern electricians appear, while adopting Franklin's selection of the terms *positive* and *negative*, to have so far added an acceptance of his views regarding abundant and deficient energy as to indicate *positive* electricity by the plus sign (+), and *negative* by the minor sign (—).

Conductors and Non-Conductors.—It has been already stated that the electric energy passes with great rapidity and ease through some substances and disappears, while other substances retain it. The former are known as *conductors*, the latter as *non-conductors*. When a conducting substance is insulated—that is, separated from the earth (to which electricity is always trying to return) by the interposition of a non-conducting substance, such as glass—it is perforce retained, being unable to escape, but may be "drawn off," as it were, by bringing a conductor into contact, or very near proximity. The electricity developed in a glass cylinder by friction (as explained above), passes readily into the brass conductors, because metals are conductors, but goes no farther, because the brass cylinder is insulated by being mounted on a glass tube. If, however, a person presents his knuckle to the knob of the brass conductor, electricity passes in the form of a spark, because animal substances are conductors. The imprisoned energy seizes the opportunity of regaining the earth through the human body, and what is known as a "circuit" is completed. What that means will be presently explained.

Conductors and Non-Conductors.—Some bodies appear on a cursory examination to offer no obstacle to the passage of electricity through them, and such bodies are known as *conductors*; others seem to be impervious to the transmission of the energy, and are styled *non-conductors* or *insulators*. Strictly, however, no body is a perfect conductor, permitting the electricity to pass without resistance, nor is there any perfect insulator, and there is no line where conductive power can be said to cease, and insulating power to begin. In the article already quoted, Lord Bury says: "It is only a question of degree. Even the best conductor offers a certain amount of retardation; and the worst conductor known is permeable in time, and does not afford perfect insulation. To be sure, the limits of variation in this respect are wide enough. An uncovered wire of copper will allow a current to move along it at the rate of 288,000 miles a second, and it would take minutes, and perhaps hours, to creep over an inch or two of gutta-percha. Still, as a mathematical fact, neither insulators nor conductors are perfect." Conductors have been defined as bodies whose molecules have the power of communicating their electricities to each other with great ease, whilst non-conductors are those whose molecules only acquire this power under great force. Practically, bodies may be classed as conductors through which the electric force is transmitted with great rapidity; semi-conductors, or slow-transmittors, and non-conductors, which are, if not strictly, yet for all practical purposes insulators.

Conductors.—Metals, gas carbon, graphite, acids, aqueous solutions, water, vegetable substances, animal substances, soluble salts, linen, cotton.

Semi-Conductors.—Alcohol, ether, powdered glass, flowers of sulphur, dry wood, ice at freezing point.

Non-Conductors.—Dry oxides, ice at 13 degrees below zero, fatty oils, caoutchouc, air and gases, dry vapours, silk, diamond glass, wax, sulphur, resin, amber, shellac, paraffin, gutta-percha.

Electric Induction.—Free electricity has the power of inducing the bodies in its neighbourhood to assume a peculiar electric condition. To show the inductive action, let an insulated and positively charged conductor be brought into the vicinity of another conductor, likewise insulated, but uncharged. If the latter be furnished with pith-ball indicators at each end, they will be seen to diverge more and more as the charged body approaches; and on examining the ends it will be found that the side of it nearest to the charged body is negatively, and the remote side positively electrified. If the charged conductor be either removed or discharged, the disturbance ceases, and the original neutral condition of the other is restored. Thus it appears that an uncharged conductor, under the influence of an electrified body, assumes an excited state, one side of it being electrified similarly, the other oppositely to the charged body. This propagation of electric force across a non-conducting medium is called *induction*. If, instead of one uncharged insulated conductor, a number are used, the action is carried on from one to the other. The positive electricity at the end of the first row acts by induction on the next, and makes the near end negative, the remote end positive. The action is propagated still farther, and, finally, the last of the row is affected, the side nearest the last but one is electrified negatively, the remote side positively. Nor does the action stop here, for the positive electricity, thus developed at the remote end of the row, acts inductively towards all the surrounding objects—it may be the floor, walls, and ceiling of an enclosing chamber, or it may be the surface of the earth, the trees, the clouds, "perhaps even towards the remotest star," where no conductors intervene. Faraday originated the theory now generally accepted, that induction is not the direct action of one body on another, but an action transmitted through, or possibly residing in, the medium (*dielectric*) between them. It is shown by experiment that the action takes place through air in curved as well as in straight lines, which implies the action of an intervening medium. The relative powers of different substances in facilitating induction are termed their *specific inductive capacities*. The effect of induction on wires in proximity will be noticed under the head TELEGRAPH, ELECTRIC.

Electric Current.—To explain what is meant by an electric current, let us suppose a wire connected with the ground to be applied to the prime conductor of an electric machine while it is being worked. The prime conductor is thus discharged, and, according to common phraseology, the electricity passes through the wire to the ground, the passage of the electricity being called an electric current. The existence of a current can be ascertained and its strength measured by its action on a magnetized needle suspended in its vicinity. When a magnetized needle is capable of turning about an axis perpendicular to its length, as is the case with a common compass needle, and is brought near to a wire through which a current is passing, the needle tends to turn its length at right angles to the direction of the current. It is upon this principle that the *galvanometer*, or current measurer, is founded.

Electric Circuit.—The whole system over which a current passes is called a circuit. A *closed* circuit is when the way is continuous throughout, however many interpolations of extraneous resistances it may contain; an *open* circuit is when, either by design or accident, the continuity of the conductor is destroyed.

Electrical Resistance.—The opposition offered by every constituent part of a circuit to the passage of a current and by work to be performed.

Measurement of Electric Force.—There are four electrical elements capable of measurement—strength of the current, electro-motive force, resistance and quantity. Electricians have fixed as a *unit* of measurement the force capable of raising one gramme in weight through one metre of height in one second of time. A committee of the British Association established the series of standards now in general use, and gave to the new measures the names of eminent electricians. The unit of electro-motive force is known as a *volt*, from Volta, the great discoverer of voltaic electricity. The standard of resistance is an *ohm*, from the discoverer of the law known as Ohm's law, that "the intensity of a given current is equal to the electro-motive force of the battery, or generating machine, divided by the total resistance of the circuit." An ohm corresponds to the resistance of an iron wire four millemetres in diameter and about a hundred metres in length—the French decimal system of measures being adopted for the convenience of electricians of various nations. *Resistance coils* of platinum silver wire are prepared by which the number of ohms of resistance can be ascertained. Each coil opposes one or some definite number of ohms resistance to the passage of a current, and is marked with the proper number. All electrical resistances are now habitually measured in ohms. The intensity of a current is measured by *ampères*, named after M. Ampère, the French electrician. The quantity of electricity forced through the resistance of one ohm by a current with the intensity of one ampère is known as a *coulomb*. The name *weber* was, until very recently, given to the measure of intensity and quantity combined, but is now disused.

History of Electrical Discovery.—The ancients were well acquainted with the fact that certain bodies, when rubbed, acquire the power of attracting light particles of matter. Thales of Miletus, the founder of the Ionic philosophy, who flourished some 600 years before the Christian era, developed this attractive property in amber by friction, and concluded that the substance was animated by an unknown spirit or element. Theophrastus, some centuries later, observed the same attractive property in a crystal termed the lyncurium, now supposed to be the tourmaline. Pliny and other naturalists refer to the attractive power of amber as something well known, but say nothing to lead us to suppose that their knowledge of electrical phenomena went beyond the discoveries of the old philosophers. The first attempt towards a generalization of electrical phenomena was made near the close of the 16th century, by Dr. William Gilbert, in a treatise on the Magnet. In the following century, Dr. Wall, Boyle, Newton, and others, accumulated many new facts; but these were not of a nature to lead to the discovery of general principles. The electric spark was first noticed by Dr. Wall. In the early part of the last century, Dr. Hauksbee made many electrical experiments, from which he ascertained that glass was a substance which could be readily electrified by friction; and that some other bodies, especially metals, treated in the same manner, manifested no electrical power whatever. In 1728, Mr. Stephen Grey, a pensioner at the Charterhouse, performed a number of experiments which led to the discovery of electrical conduction, and to the classification of bodies into conductors and non-conductors. The conclusions arrived at by Grey were firmly established by the brilliant researches by Du Fay. In 1745 and 1746, numerous attempts were made to confine electricity in glass vessels containing water or mercury; and, almost simultaneously, Von Kleist, in Germany, and Cunæus, in Holland, became acquainted with the disagreeable effects of the electric shock. Muschenbroek, of Leyden, repeated the experiments of Cunæus, and published a wonderful report of the effects of the shock received from the apparatus, which is still known as the Leyden jar or phial. The discoveries of Franklin followed soon after, and greatly advanced the science of electricity. By a series of experiments with a common kite, he ascertained what had been before conjectured, that lightning was an electrical phenomenon. Cavendish afterwards entered with great spirit into the field of electrical research, and thoroughly investigated the conditions of bodies charged with electricity. In 1787, Coulon, by means of his torsion balance, investigated the laws of electric attraction and repulsion. About the year 1789, Galvani, of Bologna, discovered that the mere contact of metals with the muscles and nerves of a frog recently killed produced convulsive motions; and, by repeating Galvani's experiments, the celebrated Volta, a professor of natural philosophy at Pavia, was led to the discovery of the apparatus now known as the Voltaic pile, a discovery which gave rise to a new branch of electrical science, which is termed galvanism, or, more correctly, Voltaic electricity. Davy's researches proved that the Voltaic current was a most potent agent in chemical analysis. Oersted discovered, in 1820, that the current exerted a peculiar influence on the magnetic needle, and founded the science of electro-magnetism, which was soon afterwards fully developed by Ampère. Faraday, in his "Experimental Researches in Electricity," published between 1830 and 1840, described the phenomena of Volta-electric and magneto-electric induction, and thus established the beautiful science of magneto-electricity. Seebeck, of Berlin, found that an electric current may be generated by the unequal effects of heat on different metals in contact, and gave the name of thermo-electricity to the new branch of science which sprung from this observation. Among the more eminent modern electricians are Wheatstone, Grove, Becquerel, Jacobi, Daniell, Smee, Bunsen, Ruhmkorff, Siemens, Sir William Thomson, Tyndall, Gramme, and Edison.

ELECTRICITY, ANIMAL.—Various kinds of fishes possess organs capable of developing electric force. The species which has been longest known, and to which the popular name of torpedo has been given is the *Raia torpedo*, or electric ray. (*See* TORPEDO.) The *Gymnotus electricus*, or electric eel, is an extraordinary fish, an inhabitant of the fresh-water lakes and rivers of the warmer regions of America, Africa, and Asia. A specimen more than three feet in length was preserved alive in London between the years 1838 and 1842, and was examined by a great many electricians. It has the power of giving electrical shocks, which power it exerts for killing or stunning the fishes upon which it feeds. Its body is smooth and without scales. A long ventral fin extends from behind the head to the extremity of the tail; the mouth is armed with sharp teeth, and projecting into it are numerous fringes, that, from their nature, appear to serve a purpose in respiration. The gullet is short, terminating in a capacious stomach. The electrical organs are situated on each side, and consist of flat partitions or septa, and cross divisions between them. The outer edges of these septa appear, when the skin of the body is turned over, in parallel lines, nearly in the direction of the longitudinal axis of the body. They are thin membranes nearly parallel to one another, their breadth being nearly the semi-diameter of the body. A powerful shock is felt when one hand is placed near the head and the other near the tail. By the electricity generated by the specimen exhibited in England, Faraday magnetized steel needles, and decomposed iodide of potassium with the greatest ease. A single medium discharge from the animal is calculated to be equal to the electricity of a Leyden battery of fifteen jars, containing 3,500 square inches of coated glass, charged to the highest degree. The *Malapterurus electricus*, found in the Nile, called by the Arabs, "the thunder-fish," averaging about ten or twelve inches in length, and a smaller fish of the same genus, the *M. Beninensis*, of the Old Calabar river, West Africa, possess considerable power of developing electricity. The late Professor George Wilson, in a paper in the *Edinburgh Philosophical Journal* for October, 1857, expressed the opinion that in ancient times it was a common practice to use electrical fishes as remedial agents. Between 1786 and 1794, Galvani made important discoveries referring to the electric properties of the muscles and nerves of animals (*see* GALVANISM); and Matteuci, an Italian investigator, and Dubois Reymond, a German, have demonstrated that there is a "muscular current" in living animals.

ELECTRICITY, ATMOSPHERIC, the term applied to electricity as a natural agent existing and acting in the atmosphere. Electricity is called into action upon a grand scale in the thunderstorm. The beautiful phenomena of the aurora borealis is connected with, or dependent upon, atmospheric electricity. (*See* AURORA BOREALIS.) All meteors were at one time considered as derived from electricity; but the showers of stones by which many of them are accompanied show that they must be ascribed to other sources. (*See* METEOR, METEORIC STONES.) It may be almost certainly assumed that the magnetism of the earth acts on the electricity of the atmosphere. At present it would appear that between the atmosphere (itself affected by solar influences) and the earth, there is a continual interchange of magnetic and electrical action, and that light and heat are important factors in the solution of the great problem. (*See* TERRESTRIAL MAGNETISM.)

ELECTROLYSIS, *e-lek-trol'-e-sis* (Gr., *elektron*, amber; *luo*, I loose), a term applied by Faraday to the process of electro-chemical decomposition. The voltaic current has the power of loosening and separating the elements of certain compounds when these are interposed in the circuit. The substances which are thus susceptible of decomposition are termed *electrolytes*. The amount of electrical power required to effect decomposition varies greatly with different electrolytes: solution of iodide of potassium, melted chloride of lead, hydrochloric acid, water mixed with a little sulphuric acid, and pure water, demand very different degrees of decomposing force, the resistance increasing from the first-mentioned substance to the last. One of the indispensable conditions of electrolysis is fluidity; for bodies which, when reduced to the liquid state by fusion or solution, freely conduct electricity and readily suffer decomposition, are frequently absolute insulators when solid. The decomposition of water by the voltaic current was first observed by Messrs. Nicholson and Carlisle, and their discovery caused a great sensation in the scientific world. The researches of Davy on the chemical effects of the current led soon after to the great discovery that the alkalies, soda and potassa, and the earths, which had hitherto been regarded as elementary bodies, contained metals. This discovery, which was announced in 1807, proved that the voltaic pile was an instrument of immense importance in chemical investigations. To Davy's great pupil and successor, Faraday, the world is indebted for the elucidation of beautiful phenomena attendant on electrolysis. From a very extended series of experiments he was enabled to draw the general inference that the effects of chemical decomposition were always proportionate to the quantity of circulating electricity, and might be taken as an accurate and trustworthy measure of the latter. Guided by this important principle, he constructed his *voltameter*, an instrument which has rendered the greatest service to electrical science. This is merely an arrangement by which a little acidulated wate, is decomposed by the current, the gas evolved being collected and measured. By placing such an instrument in any part of the circuit, the quantity of electrical force necessary to produce any given effect can be at once estimated; or, on the other hand, any required amount of the latter can be, as it were, measured out and adapted to the object in view.

ELECTRO-MAGNETISM, *e-lek'-tro-mag'-ne-tizm*, an important branch of electrical science, which may be said to have sprung from a discovery made by Professor Oersted, of Copenhagen, in the year 1820. The discovery of the Danish philosopher was thus simply stated:—When a properly-balanced magnetic needle is placed in its natural position in the magnetic meridian, immediately under and parallel to a wire along which a current of voltaic electricity is passing, that end of the needle which is situated next to the negative side of the battery immediately moves to the *west*; if the needle is placed parallel to and over the wire, the same pole moves to the *east*. When the uniting wire is situated in the same horizontal plane as that in which the needle moves, no declination takes place; but the needle is inclined, so that the pole next to the negative end of the wire is depressed when the wire is situated on the west side, and elevated when situated on the east side. By this discovery the relation of magnetism to electricity, which had long been suspected, was satisfactorily established, and a new and boundless field of research was opened. A consideration of the influence exerted by electrical currents on magnets naturally led to the conclusion that the neutral condition of bodies susceptible of magnetism would be disturbed by an electrical current, and this conclusion was quickly verified by experiments. When an electrical current is passed at right angles to a piece of iron or steel, the latter acquires magnetic polarity, either temporary or permanent, as the case may be, the direction of the current determining the position of the poles. This effect is prodigiously increased by causing the current to circulate a number of times round the bar, which then acquires extraordinary magnetic power. A steel bar may be permanently magnetized in this way, but a bar of pure and soft iron retains the magnetic force only so long as the electrical current is circulating round it. Bars of iron thus temporarily magnetized are called *electro-magnets*. (*See* MAGNETISM and TELEGRAPH.)

ELECTROPHORUS, *e-lek-trof'-o-rus* (Gr., *elektron*, and *phoreo*, I bear), a valuable instrument for exciting electricity, devised by Volta. In the chemical laboratory it is generally used instead of an ordinary electrical machine for charging small Leyden jars, when mixtures of gases have to be exploded by the electric spark. To construct it, a plate of tin is made into a circle of about twelve inches diameter; a raised border is then turned up for about half an inch, and the extreme edge is turned outwards over a wire, so as to avoid a sharp border. A mixture of equal weights of shellac, Venice turpentine, and resin, is made by gently heating them together until well fused, stirring during the time with a stick, so as to thoroughly incorporate the ingredients. The composition should, when perfectly homogeneous, be poured into the plate with the raised edges until it is quite full, and the composition is to be kept melted, but not too hot, until the bubbles have entirely disappeared. The second portion of the instrument, or that which serves the place of a conductor, consists of a flat circle of wood, rounded at the edge, and neatly covered with tin-foil: it is rather smaller than the resinous plate. An insulating handle, formed of a piece of stout glass rod, is cemented into the centre of the wooden disc.

ELECTRUM, *e-lek'-trum* (Gr., *elektron*, amber), a term used by the Greeks to denote amber, and applied by the Romans to this substance and to an alloy of gold and silver containing three or four parts of the former to one of the latter. At the present day the term is often used to denote native gold associated with silver.

ELECTUARY, *e-lek'-tu-a-re* (Lat., *eligo*, I make choice), a form of preparing certain remedies, such as dry powders, by forming them into a soft mass by means of syrup or honey.

ELEMENTS, *el'-e-ments* (Lat., *elementum*), in Chemistry.—An element may be defined as a substance which cannot be resolved into others. The ancient philosophers imagined earth, air, fire, and water to be elements, by the combination of which all other substances were formed. Modern chemistry has, however, proved that air, earth, and water are compound bodies, and that fire is an effect, and not a substance. The number of substances which cannot be further resolved by chemists are provisionally termed by them elements, it being by no means improbable that many of them are compound bodies. In the present state of knowledge, they are 64 in number, and are divided broadly into the non-metallic and metallic elements; these two divisions somewhat running into each other. The following is a list of the elements divided in this manner:—

Non-Metallic, or Metalloid.

Boron.	Hydrogen.	Selenium.
Bromine.	Iodine.	Silicon.
Carbon.	Nitrogen.	Sulphur.
Chlorine.	Oxygen.	Tellurium.
Fluorine.	Phosphorus.	

Metallic.

Aluminium.	Gold.	Rubidium.
Antimony.	Indium.	Ruthenium.
Arsenic.	Iridium.	Silver.
Barium.	Iron.	Sodium.
Bismuth.	Lanthanum.	Strontium.
Cadmium.	Lead.	Tantalum.
Cæsium.	Lithium.	Terbium.
Calcium.	Magnesium.	Thallium.
Cerium.	Manganese.	Thorinum.
Chromium.	Mercury.	Tin.
Cobalt.	Molybdenum.	Titanium.
Columbium (or Niobum).	Nickel.	Tungsten.
Copper.	Osmium.	Uranium.
Didymium.	Palladium.	Vanadium.
Erbium.	Platinum.	Yttrium.
Glucinum.	Potassium.	Zinc.
	Rhodium.	Zirconium.

The metallic elements are generally, but not invariably recognised by the power of reflecting light and conducting heat and electricity. At ordinary temperatures, oxygen, hydrogen, nitrogen, chlorine, and fluorine, are gaseous; bromine and mercury are fluid; the others are all solid.

In **Astronomy**, elements are those numerical quantities, obtained by observation and calculation, which are used in compiling tables that exhibit the ephemeris of a planet's motions. The principal are its greatest, mean, and least distance from the sun; its mean daily motion; its mean annual motion; the eccentricity of its orbit and its inclination to the ecliptic; the longitude of its ascending node and perihelion; and its mass and density.

ELEMI, *el'-e-mi*, a fragrant resinous substance obtained from different species of the natural order *Amyridaceæ*. It was formerly obtained from Egypt, but now chiefly from the tropical parts of America. It is soluble in alcohol, except a white, crystalline, inodorus residue known as *elemine*. Elemi is used in the preparation of medicinal plasters and ointments, and a volatile oil is obtained from it.

ELEPHANT, *el'-e-fant* (*Elephas*).—This is the largest of existing *Pachydermata*, and of quadrupeds classified in the section *Proboscidea*. In ancient times the most curious notions were entertained concerning it, not the least quaint being that it had no joints. Aristotle and Pliny were firm adherents to this doctrine. There can be little doubt that this delusion sprung from the fact that the elephant seldom lies down either in a wild or captive state. They have been surprised by hunters standing and yet fast asleep. Were the elephant's legs formed like those of other quadrupeds, the labour of raising his immense carcass from the ground might account for his dislike to a recumbent position; but his structure is such that lying down and rising are matters of but little difficulty. Instead of bringing his hind legs *under* him when he lies down, he extends them behind him, in the position of a kneeling human being; when he wishes to rise, he simply draws his hind feet gradually under him, and his enormous weight is levered up with perfect ease. This mobility of limb is of vast service to the elephant in the performance of his duty as a beast of burden; and with a *howdah* on his back containing eight or ten persons, and the driver on his neck, he can descend steep hills with perfect safety. He manages in this way: kneeling down at the commencement of the declivity, he puts out one fore-leg and feels cautiously for a safe footing; if he does not find it, he hammers at the soft soil with his heavy foot until he has made an indentation sufficient to secure firm footing. One foot thus accommodated, the other is drawn out with equal care, and provided for in the same manner as the first. Then one of the hind legs is cautiously drawn forward and one of the fore feet being released from the foot-hole, it is inserted in its place: and all this is performed so rapidly that it might be repeated at least three times in as little time as it takes to write this explanation. It is almost needless to observe that the elephant is distinguished by the possession of a long trunk or proboscis, which serves him in place of a hand, and enables him to perform many extraordinary feats. Without this curious appendage, he would find existence difficult, if not impossible. Elephants sometimes go blind while in a state of freedom, but, guided by this exquisite organ of touch, they are still enabled to make their way through dense forests, to gather food, and to avoid ditches and hollows. The elephant's trunk is not composed of a mere series of muscular rings, as its appearance would lead one to suspect. It has three perfect and distinct uses. As an organ of smell, it is an elongated and curiously elastic nose. Within it two canals are continued from the nostrils, which are reflected round the nasal bones and then proceed straight to its end. These canals are separated by, and imbedded in, a fatty elastic membrane containing thousands of minute muscles. Of these there are three sets—an outer longitudinal, composed of four layers; an oblique set, which are variously directed; and a third set, which radiate from the tubes to the circumference. They are very small, and supposed to number as many as forty or fifty thousand. Besides as an organ of smell, the elephant's trunk serves as a sucker, by which the great animal may quench his thirst at the shallowest pools. There is no passage from the trunk to the mouth; but the former may be filled, and then, the mouth of it being turned under and into the proper mouth of the elephant, the operation of drinking is accomplished. The elephant is very tenacious lest harm should come to this valuable organ. The dentition of the elephant is of a very remarkable nature. From the upper jaw extend two enormous teeth fixed in sockets in the front of the mouth, but which, in fact, are neither incisors nor tusks, although by the latter term they are generally known. They spring, however, from the intermaxillary bones, and must be regarded as the representatives of the incisors. They grow from a permanent pulp, and continue to increase in size during the life of the animal. The incisors are wanting in the lower jaw, as are also the canines in both jaws; and the only other teeth possessed by this immense quadruped consists of two molars of a most remarkable structure on each side of each jaw. These teeth are of a very large size, and a quadrangular form. They consist of a series of plates of the ordinary substance of teeth (*dentine*), each coated with a layer of enamel, and united together into a mass by a material called the *cement*. The form of these transverse plates of dentine and enamel varies greatly in the different species. The formation of the molar teeth, like that of the tusks, is going on as long as the elephant lives; but with this difference, that whilst after shedding the first or milk tusks, the pulp of each tusk continues adding matter to its base without any change, in the case of the molars it is a succession of separate teeth that is produced, the hindermost pressing gradually forward to take the place of those which have been abraded by use, and cast off as unserviceable. Elephants rarely breed in a state of domestication. The period of gestation of the elephant is a few days over twenty months. The breasts of the female are placed under the chest, and the young one sucks not with the trunk but with the mouth. The strongest proof of the elephant's antipathy to a recumbent position may be drawn from the fact that although the new-born calf is much too short to reach the teat, the mother, rather than lie down, will extend her legs so as to bring her breast nearer the earth. In a state of domesticity, the elephant-keeper will, under such circumstances, build a little platform of earth for the elephant-calf to stand on while it sucks. At its birth, the calf is about thirty-six inches in height. There are two living species of the genus Elephas—the Indian (*Indicus*) and the African (*Africanus*). The latter is confined to the central and southern parts of Africa, and is distinguished from the former by the convexity of its forehead, the enormous size of its ears, and the lozenge-shaped arrangement of the dentine and ivory in its molar teeth. The Indian or Asiatic elephant has the forehead concave, the ears of moderate size, and the dentine and enamel of the teeth arranged in transverse bands. It differs likewise from the African species by the paler brown of the skin, and in having four nails on the hind feet, instead of three; and its tusks are smaller, although in size and weight the Indian elephant exceeds the other. The tusks are valuable. (*See* IVORY.) It is conjectured that elephants attain their full growth at about their twentieth year. Their size has been greatly exaggerated. It is now pretty certain that 10 feet is tall, and 13 feet an extraordinary height for one of these animals. It is a tolerably well-ascertained fact that the ordinary duration of life in these animals is from seventy to eighty years; but there are records of the elephant living to a much greater age. In the East, elephants are used to carry distinguished personages, in tiger-hunting, as beasts of burden, and to carry military stores. In the latter capacity they did good service in the Abyssinian wars. In ancient times they were employed in war.

Fossil Elephants. (*See* MAMMOTH.)

ELEPHANT, SEA. (*See* PHOCIDÆ.)

ELEPHANT'S FOOT, OR HOTTENTOT'S BREAD, a plant (*Testudinaria elephantipes*) of the natural order *Dioscoreaceæ*, growing in South Africa. The Hottentots eat the root stock, a large mass, somewhat resembling an elephant's foot in shape, covered with a soft cork-like bark. The name is also given for the same reason of resemblance to a genus of plants (*Elephantopus*) of the natural order *Corymbiferæ*, one species of which is used medicinally in India in affections of the urinary organs.

ELEPHANTIASIS, OR BARBADOES LEG, *el-e-fan-ti'-a-sis* (Gr., from *elephas*, an elephant), is the name of a disease common in the East and West Indies, and so called from the skin of the afflicted limb becoming rough, scaly, and enormously thickened, so as to resemble the leg of an elephant. It generally comes on with great heat of the skin, alternating with profuse perspiration and ardent thirst. The part becomes red, hot, swelled, and painful, increases to great size, and becomes a burden to the patient. Though it is the leg that is generally affected by this disorder, other parts of the body are liable to its attack; but it is not usual for more than one part to be morbidly enlarged in the same individual. In the treatment of this disease in its earlier stages the use of laxatives and diaphoretics is recommended, together with the application of iodine ointment to the part, and firm bandaging.

ELEUSINE, *e-loo'-sine*, a genus of grasses, some of which are cultivated as grain in India and other hot countries. In Tibet a weak kind of beer is made from the *E. corocana;* and in Egypt a medicinal decoction of *E. Egyptica* is used as a remedy for diseases of the kidneys and bladder.

ELEVATION, *el-e-va'-shun.*—In Astronomy, the height above the horizon of an object on the sphere, measured by the arc of a vertical circle through it and the zenith.

ELEVATOR, *el-e-vai'-tor* (Lat.), in Anatomy, is a term applied to various muscles of the body, whose action is to lift up or elevate the parts to which they are attached; as the elevator muscles of the eye, mouth, &c. It is also the name given to an instrument in surgery, employed for raising depressed portions of the bones of the skull.

ELK, OR MOOSE DEER, *elk* (Sax., *elch*) (*Alces malchis*, or *Cervus alcos*), the largest of all the *Cervidæ*, or deer family, and common to the northern parts of both hemispheres. The antlers of this animal are comparatively short, but broadly dilated, and terminated by a numerous series of long points. When fully grown, these organs weigh from fifty to sixty pounds. The moose does not reach its full development till its fourteenth year, and then may be met with measuring six or even seven feet at the shoulders. Its legs are very long; its neck thick and short; its head elongated, and terminated by a broad muzzle. The coat of the moose is composed of long bristly hair, of a light ash-colour, and of a dark russet-brown on the surface. In the winter the coat of the bull moose changes to a glossy black. From behind the ears (which are large) down the neck and part of the back extends a mane, harsh and thick, and nearly a foot in length. The hair on the belly and inside the legs is sandy colour. Pendant from the spot where the junction of the head and neck occurs is a baggy pouch covered with long black hair, and known as the "bell." The ordinary food of the moose consists during the summer months of such leaves and tender branches as abound in its native forests. In the winter season it subsists on the tops of young shoots, pulling them into its mouth by its prehensile upper lip (or mouffle), and biting them off. Its flesh is highly esteemed as an article of food, especially when smoked or dried bacon-fashion. It is a swift and enduring animal, although its gait is clumsy and awkward in the extreme. The only pace of the elk is a long swinging trot; but its legs are so long and its paces so considerable, that its speed is much greater than it appears to be. The moose is a very wary animal, with an acute sense of smell, and is with difficulty approached by the hunter. The most successful way of hunting it is by "calling;" that is, imitating the trumpeting noise made by the female at the pairing season to attract the bull. Shy as the gazelle at other times, the bull moose swiftly obeys the invitation, and is thus brought within range of the rifle of the hunter, who is concealed in the thicket. The elk is easily domesticated, and at one time was employed in drawing sledges in Sweden, travelling at the rate of more than 200 miles in a day.

Fossil Irish Elks.—The bones of a large deer, *Megaceros Hibernicus* are found in the Pleistocene strata, in Ireland, and also in some parts of England, Scotland, the Isle of Man, and on the continent of Europe. The antlers were of enormous size, some skeletons having been found in which a straight line drawn between the extreme tips measured very nearly 11 feet. The weight of the antlers was in some cases over 80 lbs. The vertebræ of the neck and the limbs were necessarily very strong, to enable the animal to support so great a weight.

ELLAGIC ACID, *el-lai'-jik*, an insoluble acid found as a grey crystalline powder during the preparation of gallic acid from gall-nuts. It also occurs, in the intestinal concretions called bezoar-stones, found in the stomachs of the wild goats, antelopes, and deer of central Asia.

ELLIPSE, *el-lips'* (Gr., *elleipsis*), an oval curve, one of the conic sections. (*See* CONIC SECTIONS.) The section of a cone formed by a plane passing through it at right angles to its axis is a circle. If the plane cuts the cone in a direction parallel to its surface, the conic section so formed is a parabola; but any section formed by the passage of a plane through the cone at any angle to its axis between a right angle and the angle at which the surface of the cone is inclined to the base, is an ellipse.

ELM. (*See* ULMUS.)

ELMO'S FIRE, SAINT, *el'-moze*, a luminous appearance or fiery meteor frequently seen playing about the masts and rigging of vessels at sea, during dark stormy nights. The phenomenon is due to atmospheric electricity. The phenomenon gave rise to the Greek myth of Castor and Pollux. It is a common superstition now among sailors that the appearance of such lights at the masthead are a presage of safety in a storm.

ELONGATION, *e-lon-gai'-shun* (from low Lat., *elongo*, I lengthen). In Astronomy, this name is sometimes applied to the angular distance between the sun and any other heavenly body, viewed from the earth's surface.

EMBERIZA, *em-ber-i'-za*. (*See* BUNTING.)

EMBLICA, *em'-bli-ka*, a genus of plants of the natural order *Euphorbiaceæ*, having a fleshy fruit. An Indian species, *E. officinalis*, or, more commonly, *Emblic Myrobalans*, is used in India as a febrifuge for tanning leather and making ink.

EMBROCATION, *em-bro-kai'-shun* (Gr., *embroche*, a moistening), a term originally applied to those external applications used for softening or dissipating swellings. The word has, however, extended beyond its primary meaning, and is applied to oleaginous and spirituous compounds which incite the surface of the skin to increased action, and produce all the effects of counter irritants, or which, by their influence on the extremities of the nerves, assist in resolving spasms, thus acting as antispasmodics.

EMBRYO, *em'-bre-o* (Gr., *embruon*, from *embruo*, I bud forth), is the rudimentary state of any organized body. In Physiology, it is applied to the fœtus *in utero* befor the fifth month of pregnancy, from its growth resembling the budding of a plant. Hence we have *embryology*, a description of the embryo; *embryotomy*, or the extraction of the embryo piecemeal in delivery. In Botany, the embryo is the rudimentary plant existing in the seed. The presence of a true embryo is the essential characteristic of the seed of flowering plants; for a *spore*, as the reproductive body of a flowerless plant is called, has no true embryo, the rudimentary plant being only developed from it after its separation from the parent. Three parts, corresponding to the root, stem, and leaves of the perfect plant, are distinguished in the embryo, and are termed respectively, the *radicle*, the *plumule*, and the *cotyledons*.

EMERALD, *em'-er-ald* (Fr., *émeraude*), one of the precious stones, of a rich deep green colour, occurring in hexagonal prisms in granite, gneiss, and mica rocks. The finest emeralds, however, are found in South America, Bavaria, India, and Siberia. Some specimens from the latter country measure 4½ inches in breadth and 12 in length; but they are worthless as gems, being full of striæ, and not transparent. Emerald consists of silica, alumina, glucina and a little peroxide of iron, lime and oxide of chromium. It is distinguished from beryl by its more brilliant colour, being coloured with oxide of iron instead of oxide of chromium.

EMERSION, *e-mer'-shun* (Lat., *e* from, and *mergere*, to plunge), the term applied to the reappearance of a heavenly body from behind another, after the former has been hidden from view by the passage of the latter across its disc, as in an eclipse.

EMERY, *em'-e-re* (from Cape Emeri, in the island of Naxos), a variety of corundum, consisting mainly of alumina, combined with a small quantity of silica, peroxide of iron, and a little water. Emery occurs in Spain, Asia Minor, in the Greek islands, and in the island whence it takes its name. Ground to powder of different degrees of fineness, it is much used in the arts as a polishing powder, frequently employed attached to cloth or paper.

EMETICS, *e-met'-iks* (Gr., *emetika*), those medicines which influence the stomach in a peculiar manner, so as to invert its action and produce vomiting. This effect is caused not by the quantity of the matter introduced, but by the nature of the emetic itself. Emetics are administered in many cases of illness. They are useful when it is found necessary to relieve the stomach of some hurtful or indigestible substance. Lives that have been endangered either by poisons or excess of food have frequently been saved by means of emetics. In cases of fever, emetics are used: it is supposed that the copious secretion which they produce from the glands of the stomach and intestines has a direct curative action. In all cases of fever, emetics should be administered at as early a stage of the disease as possible. They invariably render the disease milder, and may be advantageously repeated even at a more advanced stage, as they induce sleep and a moist state of the skin. The emetics generally used consist of preparations of antimony, zinc, and copper. Squills, lobelia, ipecacuanha, and other substances, are also employed. Mustard and water diluted is one of the mildest and most generally used emetics. Emetics should never be administered to a patient who is disposed to apoplexy, or a tendency of blood to the head, or where the patient is liable to hemorrhage from any organ, or is subject to hernia. During pregnancy, also, emetics must be avoided.

EMETINE, *em'-e-tine*, the alkaloid which forms the active principal of ipecacuanha root.

EMEU. (*See* EMU.)

EMOLLIENTS, *e-mol'-yents* (Lat., *mollis*, soft), a term employed to denote those substances which are used externally, in medicine, for the purpose of softening the part of the body to which they are applied. They are mostly used in the form of poultices, fomentations, &c.

EMPEROR MOTH (*Saturnia pavonia minor*), one of the most beautiful of the British species of moths. The expanse of its wings is about three inches. The colour is a greyish brown, tinged with purple; the back part of the wings has a band of pale brown and purple, the last band being much waved. In the centre of each wing is a large spot consisting of a black pupil with a yellow or grey iris, partly surrounded by a light blue crescent. The larva is of a green colour, with a black band on each segment, ornamented with pink tubercles, bearing a whorl of six hairs, diverging like a star. The cocoon of the emperor moth is very curiously constructed, the extremity not being closed, but terminated by a converging circle of stiff hairs, which enables the insect to make its escape, but entirely prevents the entrance of all intruders. This moth is of the same family as the silkworm moth (*Bombycidæ*).

EMPETRACEÆ, *em-pe-trai'-se-e* (Gr., *en*, upon; *petros*, a rock), the Crowberry family, a small natural order of dicotyledonous plants in the sub-class *Monochlamydeæ*. They are small heath-like evergreen shrubs, mostly natives of northern Europe and North America. Their leaves and fruit are generally slightly acid. The berries of *Empetrum nigrum*, the crowberry, are eaten in the very cold parts of Europe, and are also employed in Greenland to prepare a fermented liquor.

EMPHYSEMA, *em-fi-se'-ma*, in Physiology, an unnatural distension of a part with air. In case of wounds near the air-passages of the lungs, the cellular tissue is sometimes inflated; and occasionally arises from the decomposition of fluids in the stomach giving out gases, which distend the textures with which they are in contact.

EMPYEMA, *em-pi-e'-ma*. (*See* PLEURISY.)

EMU, *e'-mu* (*Dromaius Novæ Hollandiæ*, or *Dromaius ater*).—This bird is widely diffused over the southern part of Australia, and is closely allied to the cassowary. When fully grown, it measures seven feet in length. The plumage is, for the most part, a mixture of grey and brown, paler below than above; head covered with feathers, which, together with those about the neck, are of a hairy texture. The long feathers observable in the wings of the cassowary are wanting in the emu; but instead of them it has real wings, though of so small a size as to be useless for flight. The legs are short and stout; there are three toes to each foot, and these are furnished with nearly equal claws. It is very swift, and when attacked kicks, as does the ostrich, but not forwards, as does the latter bird, but more as a cow kicks, sideways or backwards. The nest of the emu is made by scooping a shallow hole in the ground in some scrubby spot; concerning the formation of the nest, however, there are various opinions. Its eggs are dark green, and the number laid varies from seven to thirteen, always an odd number. Emus are monogamous, and the males perform the duties of incubation. The eggs are eagerly sought after by the natives as an article of food, as is also the bird itself for the sake of its flesh, which, particularly that about the hind quarters, is said to be of good flavour. The skin contains a large quantity of oil.

EMU WREN, a passerine bird of Australia (*Stipiturus malacharus*), nearly allied to the wren of Europe and America. The genus includes about a dozen species. The bird is found in marshy districts, where it runs rapidly along the grass, with its six tail feathers erect. The resemblance of these feathers to those of the emu is the origin of the name.

EMYS, *e'-mis*, a genus of marsh tortoises, of considerable size, natives of hot climates. They are particularly abundant in North America, especially the painted tortoise, *Emyspiata* and the alligator tortoise, *Emysaina serpentina*. They feed chiefly on animal food. Some of the smaller European species are kept in ponds, fed on vegetable matter, and fattened for the table.

ENCEPHALARTOS, *en-sef-al-ar'-tos* (Gr., *enkephalos*, that which is in the head; *artos*, bread), a genus of the natural order *Cycadaceæ*, composed of elegant palm-like trees and shrubs, mostly natives of South Africa and Australia. From the stems of various species a kind of sago, called Caffre bread, is obtained.

ENCEPHALOCELE, *en-sef-a-lo-sele'* (Gr., *encephalon*, the brain; *kele*, a tumour), the term applied to a tumour projecting through the skull, at a part where the bones were incomplete in infancy, and consisting of a protrusion of the membranes containing a portion of the brain.

ENCHONDROMA, *en-kon-dro'-ma*, an abnormal growth of the cartilage, generally in connection with the bones.

ENCKÉ'S COMET, *eng'-kes*, a comet of periodic recurrence, to which the attention of astronomers was first especially directed when it was discovered by M. Pons at Marseilles, November 26, 1818. The similarity of its elements to those of comets which had been observed in 1786, 1795, and 1805, led M. Encké to calculate its orbit. The comet reappeared in 1882, and on comparing its elements, and the time of revolution, with those of the comets of the years above mentioned, it was found that they were only successive apparitions of the same comet, and that it regularly appeared at its perihelion at intervals of rather more than 1,211 days. It was also found that its period of revolution was gradually growing shorter, at the rate of nearly three hours per revolution, which caused M. Encké to imagine that it was occasioned by some very slight resisting medium spreading throughout the whole of our solar system. It was named after M. Encké, instead of M. Pons, its discoverer, on account of the success of the former in determining its orbit and period of revolution, and predicting its reappearance in 1825.

ENCRINITE, *en'-krin-ite* (Gr., *en*, and *krinon*, a lily), in Geology, any fossil crinoid, or lily-like echinoderm. (*See* CRINOIDEA and ECHINODERMATA.) The encrinites, which form a most important class of fossils, are characterised by their long many-jointed stalks, surmounted by flower-shaped bodies, which were furnished with numerous finger-like rays, capable of closing and expanding. Their internal calcareous skeletons in scattered joints and fragments are so abundant in some carboniferous limestones as to compose the greater portion of the mass; hence the term *encrinal* or *encrinital limestone*. The minuter joints of the fingers and rays are usually termed *entrochi*, or wheelstones, and the limestones in which they abound, *entrochal limestone*. Geologically the encrinites range from the Silurian up to the present epoch. They occur most abundantly in palæozoic and mesozoic strata, rarely in cainozoic, and are now only represented by the comatula or feather-star, and the all but extinct pentacrinus of the West Indies. Like the corals, their function seems to have been, to a great extent, the secretion of lime from the ocean—whole strata of limestone, silurian and carboniferous, being almost entirely made up of their remains.

ENDEMIC, *en-dem'-ik* (Gr., *endemikos*, from *en*, among, and *demos*, the people), a term employed to designate diseases peculiar to a certain class of persons, or to a particular district. Thus ague is an endemic disease in low marshy countries; the goitre in the Alps. They differ from epidemic diseases, which, without reference to locality or class, attack many persons at the same time in the same place, and are contagious: as influenza, scarlet fever, &c.

ENDERMIC, *en-der'-mik*, a method of making the skin the medium for the reception of medicines. (*See* HYPODERMIC.)

ENDIVE. (*See* CICHORIUM.)

ENDOCARDITES, *en-do-kar-di'-tes*. (*See* HEART, DISEASE OF THE.)

ENDOCARP, *en'-do-karp* (Gr., *endon*, within; *karpos*, a fruit), the inner layer of the pericarp of a fruit. In certain fruits it is remarkably hard, and is termed the *stone* or *putamen*. (*See* FRUIT.)

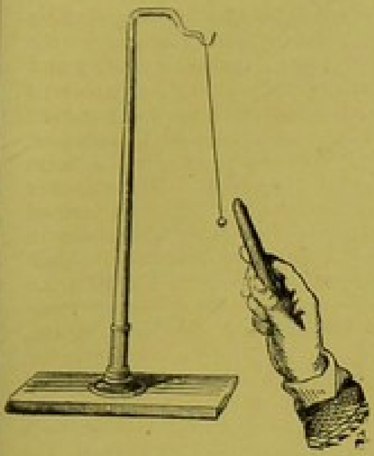
ENDOGENOUS PLANTS, OR ENDOGENS, *en-doj'-e-nus* (Gr., *endon*, within; *ginomai*, I am formed), plants having stems which increase by the addition of new matter within. (*See* MONOCOTYLEDONES.)

ENDOSMOSE, *en-dos'-mose* (Gr., *endon*, within; *osmose*, impulsion), a term originally applied by Dutrochet to the transfusion of gaseous bodies or liquids through membranous substances either of an animal or vegetable origin. (*See* OSMOSE.)

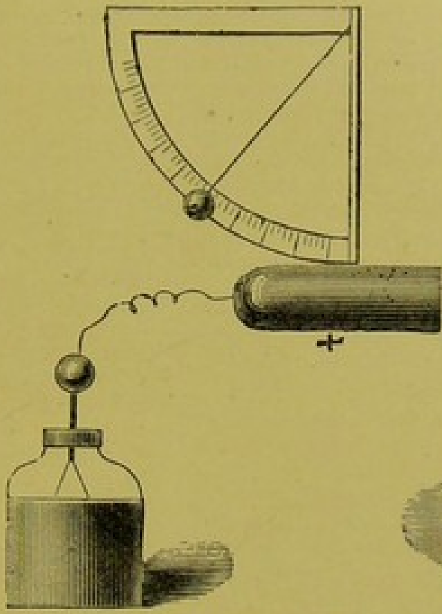
ENDYMION, *en-dim'-e-on*, the Blue-bell, a genus of plants of the natural order *Liliaceæ*. *E. nutans* is the species which adorns the woods and thickets of this country. Its flowers are usually blue, rarely white.

ENERGY, *en'-er-je* (Gr., *en*, within, and *ergon*, work), the inherent power to perform work. Energy is either visible or molecular, and both kinds are divided into *kinetic*, the actual amount of work a moving body is capable of doing at any instant during its motion; and *potential*, or derived from advantage of position.

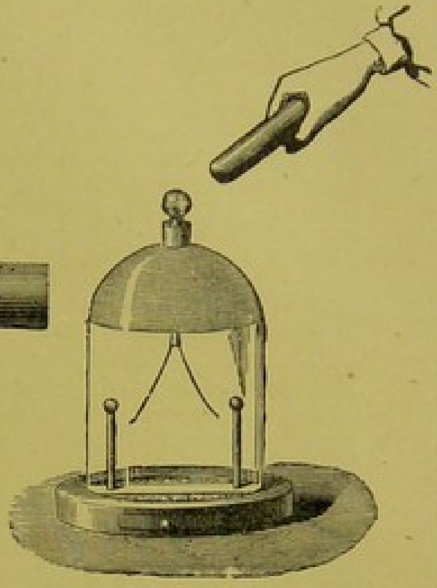
ENTADA, *en-ta'-da*, a genus of climbing shrubs, of the natural order *Leguminosæ*, and sub-order *Mimoseæ*. The seeds lie embedded in a glutinous substance, in pods of a great size,



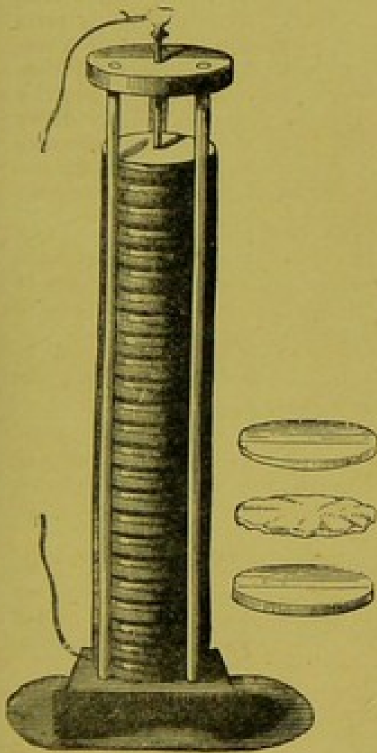
AN ELECTRIC PENDULUM.



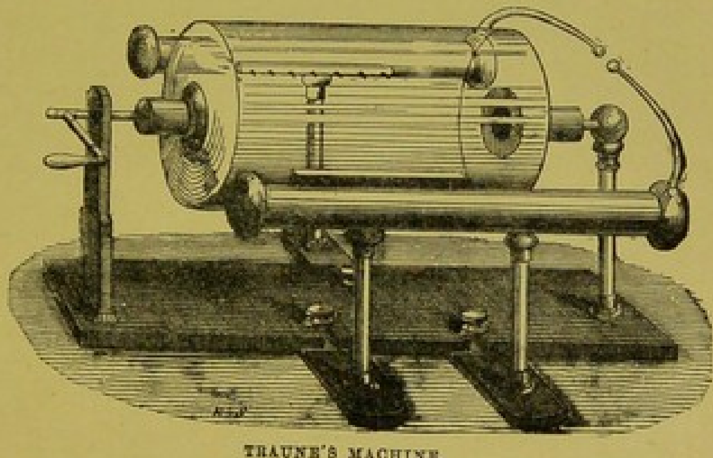
PITH-BALL ELECTROMETER.



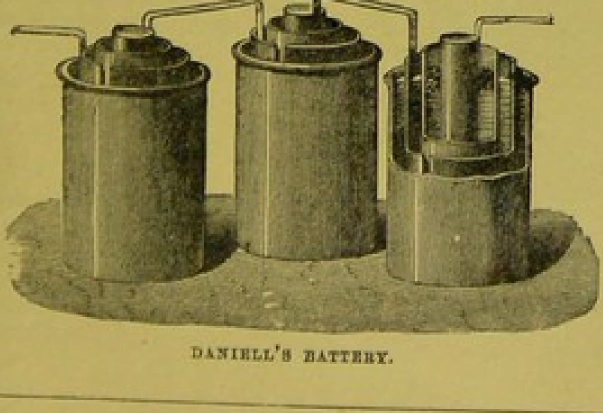
ELECTROSCOPE.



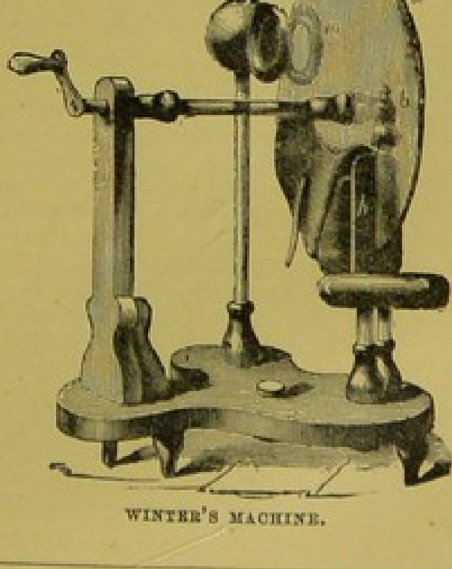
VOLTA'S PILE.



TRAUNE'S MACHINE.



DANIELL'S BATTERY.



WINTER'S MACHINE.

sometimes five feet long and six inches broad. The seeds, of a brown colour, are so large that in Ceylon they are hollowed out and used as boxes. The seeds of an East Indian species (*E. Pursætha*) are saponaceous.

ENTELLUS MONKEY, OR HONUMAN, *en-tel'-lus ho-noom'-an*, a native of the East Indies, with a bluish face surrounded with hair of a light yellow colour, presenting a remarkable appearance resembling the light, bushy, hair and whiskers of a human being. The limbs are long and powerful, and the tail is long, but not prehensile. It is the sacred monkey of the Hindoos, and lives in the villages, and so great is the reverence that the Hindoo laws inflict a greater punishment for killing one of these monkeys than for killing a man.

ENTERITIS, *en-te-ri'-tis* (Gr., *enteron*, the intestines), an acute inflammation of the peritoneal or external coat of the intestines. It is characterised by pain in the bowels (increased on pressure), vomiting, constipation, fever, and great prostration of strength. The brain is generally unaffected, and the intellect remains clear; but sometimes delirium occurs late in the disease. Enteritis may arise from various causes, particularly from cold and wet, more especially applied to the feet or legs, or cold drinks when the body has been previously overheated. Hardened fæcal matters, arising from indigestible substances taken into the stomach, may also produce this disease. Strangulated hernia, or the involution of one fold of the intestine within another, may induce this disease, by causing a complete obstruction to the passage of the contents of the bowels. Various diseases bear a considerable resemblance to enteritis; but that which most closely resembles it is colic, which, indeed, often passes into enteritis. Colic, however, is distinguished from enteritis by the absence of fever, the difference in the state of the pulse, the pain occurring more in paroxysms, and by being usually mitigated by pressure; whereas, in enteritis, it is increased. The ordinary remedies employed in inflammatiom must be resorted to in this disease. Horses and cattle are subject to similar attacks, arising generally from improper feeding, wet pastures, or over driving.

ENTOMOLOGY, *en-to-mol'-o-je* (Gr., *entomon* an insect; *logos*, a discourse), that branch of science which treats of the habits, properties, and organization of insects. The name insect implies an animal insected or divided into segments. This term is applicable to the principal part of the articulate sub-kingdom, and was formerly applied to it; at present the word insect is only used in reference to those articulated animals which are distinguished by antennæ and breathing organs composed of ramified tracheæ, with or without air-sacs. Entomology was not studied as an absolute science till the 17th century, when progress began to be made. The chief naturalists of that period were Goedart, Swammerdam, Malpighi, Leeuwenhoeck, and Ray. The science, however, was very backward, as Ray estimated the whole number of insect species in the world at 10,000. At the present day, it has been ascertained that a larger number than this exists in this country alone. During the 18th century, the great Swedish naturalist, Linnæus, gave his attention to the study of entomology, and his classification, as far as the orders are concerned, has served as the basis of all that have been since promulgated. It is founded on the presence or absence of the wings, their number, consistence, surface, position in repose, and also on the presence or absence of a sting. By this classification, insects were at first divided into seven classes; but additions and alterations have been made since that time. Eleven different orders of insects are generally enumerated. 1, Coleoptera; 2, Orthoptera; 3, Hemiptera; 4, Newroptera; 5, Hymenoptera; 6, Lepidoptera; 7, Shepsitera; 8, Diptera; 9, Suctoria; 10, Thysanoura; 11, Parasita. (*See* various headings.) The Entomological Society of London was instituted in 1833.

ENTOMOSTRACA, *en-to-mos-tra'-ka* (Gr., shells of insects), a term frequently applied to the second of the two great divisions of crustacea. They are of small size, some very minute, and exist in great numbers in stagnant, or nearly stagnant, fresh water, and in sea water. They differ very much in form, some having a large number of organs of locomotion, and some have mouths fitted for mastication, and some for suction. The name has been given because most of the species have shells of one or two pieces, very thin, and of a horny consistence. Many fossil species are met with, especially in the Silurian trilobite, and the old red sandstone.

ENTOPHYTES, *en'-to-fites* (Gr., *entos*, within, *phyton*, a plant), parasitic plants growing on living animals, including all those which have their seat on animal living tissues. Some are *algæ* and some *fungi*, and they occur both in man and in the lower animals, more being peculiar to fishes than to any other class of animals.

ENTOZOA, *en-to-zo'-a* (Gr., *entos*, within; *zoon*, an animal), a term applied to those animals which live within others. They are of low organization, and generally vermiform in structure. In most cases the blood is colourless, and circulates, in the higher organized species, in a closed system of vessels. They have no respiratory organs, no articulated members for locomotion, and no organs of sense. In the higher organized entozoa, a filamentary nervous system has been recognised. Several species of entozoa infest the human body. (*See* INTESTINAL WORMS.) Some of the entozoa only have a parasitic existence during part of the life, the larvæ developing in the intestines, and then, having been discharged, undergo further changes externally.

EOCENE, *e'-o-sene* (Gr., *eos*, the dawn; *kainos*, recent), in Geology, a term designating the lower tertiary strata, from the idea that the very small per centage of still existing species among the fossils of these strata indicates what may be regarded as the *dawn* or commencement of the present condition of creation. (*See* TERTIARY SYSTEM.)

EOZOON CANADENSE, *e-o-zo'-on kan'-a-dense*, a species of foraminifera found in the Laurentian limestone, near Montreal, in 1858, and supposed to be the earliest known form of life.

EPACRIDACEÆ, *ep-a-krid-ai'-se-e* (Gr., *epi*, upon; *akros*, the top), the Epacris family, a natural order of dicotyledonous plants in the subclass *Corolliflorœ*, having a considerable resemblance to the *Ericeæ*, or Heath family. The species are shrubs or small trees, natives of Australia, the Indian archipelago, and the South-Sea Islands, where they are very numerous. About 400 species are known. They are of little importance, except for the beauty of their flowers, on which account they are much cultivated.

EPACT, *e'-pakt* (Gr., *epaktos*, additional), the excess of the solar month above the lunar month, amounting to 1 day, 11 hours, 15 minutes, 57 seconds; and also the excess of the solar year above the lunar year, nearly 11 days. (*See* GOLDEN NUMBER.)

EPEIRA, *e-pe-i'-ra*, a genus of spiders, which construct webs with regular meshes, formed by concentric circles and straight radii. They are well known in gardens, and are among the largest British species; but attain the greatest size and beauty of colours in tropical climates, where there webs are of great strength.

EPHEMERA, *e-fem'-e-ra* (Gr., *epi*, on; *emera*, a day), a genus of neuropterous insects, forming the family *Ephemeridæ*. They have long, soft, tapering bodies, terminating in two or three long setæ. Their wings are placed nearly, or quite, perpendicularly; their antennæ are three-pointed, and very small. In the larva state they live in wet places, or under water, and enjoy an existence of two or three years; but when they attain their final stage of metamorphosis and perfect form, they are among the most fleeting of living creatures, existing often only a few hours, and propagating their species before they die. In this state they sometimes appear suddenly in myriads during fine summer evenings by the water-side, when they may be seen flitting about, and balancing themselves in the air, in the manner of gadflies. They are known also as day-flies and May-flies.

EPICALYX, *ep'-e-kai-liks*, the term applied by many botanists to a circle of bracts appearing immediately below the calyx or outer covering of the flower. It is seen in the mallow tribe, and in many plants of the pink and rose tribes.

EPICARP, *ep'-e-karp* (Gr., *epi*, upon; *karpos*, fruit), the external layer or region of the pericarp or shell of a fruit. (*See* FRUIT.)

EPICYCLE, *ep-i-si'-kl*, the term applied by the ancient astronomers to the supposed movements of the planets round centres, which were describing a large circle round the earth, which was supposed to be the great centre of the planetary system. These imaginary smaller circles were imagined in order to reconcile the different periods of the planets' rotation with the theory of uniform velocity of the heavenly bodies.

EPICYCLOID, *ep-i-si'-kloid*, a peculiar curve, described by every point in the plane of a circle moving in the convex circumference of another circle. The epicycloid has properties useful in the mechanical arts; for instance, the teeth of wheels must have an epicycloidal form in order to secure uniformity of movement.

EPIDEMIC, *ep-e-dem'-ik* (Gr., from *epi*, upon, and *demos*, the people), is a general term applied to diseases which prevail among a large portion of the people of a country or place for a certain time, and then gradually disappear. The most generally assigned causes are a peculiar state of the atmosphere or climate, the seasons, &c. Defective ventilation or drainage, and unwholesome food or drink, are also among the causes that induce epidemics. Most epidemic diseases are likewise contagious, and thus, when once induced, spread with great rapidity. There are epidemic mental diseases, such as the dancing madness, convulsions, and panic, which spread from one person to another, and may involve whole nations.

EPIDERMAL APPENDAGES, *ep-e-der'-mal ap-pen'-daj-es* (Gr., *epidermis*, the cuticle; Lat., *appendo*, I hang or attach to), the general term for certain structures, consisting of cells, variously combined, found upon the surface of the epidermis of plants, or in the sub-epidermal tissue. They may be divided into *hairs* and *glands*. The former are thread-like elongations, externally, of the epidermal cells, covered by cuticle. When a hair is formed of a single cell, it is said to be *simple;* and when composed of several cells, *compound*. Hairs occur upon various parts of plants, and, according to their abundance and nature, give varying appearances to them.

EPIDERMAL TISSUE, the term applied to the external layer of cells in flowering and the higher flowerless plants. This layer may commonly be readily separated as a distinct membrane or skin, as its component cells differ in shape and in the nature of their contents from those cells placed beneath them. This tissue consists of two parts—namely, of an inner portion, usually called the *epidermis*, and of an outer thin pellicle, to which the name *cuticle* is given; but Carpenter, and some other authors, make use of these terms in precisely the reverse sense, calling the external pellicle the epidermis. The *stomata*, or *stomates*, are orifices situated between some of the epidermal cells leading into the intercellular cavities beneath, so as to allow a free communication between the internal tissues and the external air. They are commonly called *breathing-pores*. They vary in form and position in different plants and different parts of the same plant; but they are always the same in any particular part of a plant. The most common form is oval, but they are sometimes seen round or square. We give the numbers counted in a square inch upon the upper and under surfaces of the leaves of a few plants, to show the extent of this variation:—Mistletoe, upper surface 200, under surface 200; pæony, upper surface *none*, lower surface 13,790; house-leek, upper surface 10,710, lower surface 6,000; lilac, upper surface *none*, lower surface 160,000. Stomata exists more or less upon all flowering plants, but are absent from the lower orders of flowerless plants. On floating leaves they are only found on the upper surface.

EPIDERMIS. (*See* SKIN.)

EPIDOTE, *ep'-i-dote*, a mineral composed of silica and alumina, with lime, and peroxide of iron or manganese, and nearly allied to garnet. The colour is green, yellow, or grey; less frequently, red or black.

EPIGASTRIUM, *ep-i-gas'-tri-um* (Greek, *epi*, over; *gaster*, the stomach), is that part of the abdomen which extends from the sternum to the navel, and is commonly known as the pit of the stomach.

EPIGENESIS, *ep-i-gen'-e-sis* (Greek, *epi*, and *genesis*, a formation), a term applied in physiology to the theory which supposes new formations in organized beings to spring from superadded centres of vital activity as opposed to the theory which supposes that the new structure is formed by a development or modification of the old.

EPIGLOTTIS, *ep-e-glot'-tis* (Gr., *epi*, upon, and *glotta*, the tongue), the cartilage at the root of the tongue that falls upon the glottis, or superior opening of the larynx. It is somewhat oval, rather convex above and concave below, and covered by mucous membrane. It adheres inferiorly to the interior part of the thyroid cartilage by a strong elastic membrane. Its apex is loose, and always elevated upwards by its own elasticity. When the back of the tongue is drawn backwards in swallowing, the epiglottis is put over the aperture of the larynx, and thus shuts up the passage from the mouth into the larynx.

EPIGYNOUS, *e-pij'-e-nus* (Gr., *epi*, upon; *gune*, female), a term applied to the stamens and corolla of a plant when they appear to arise from the summit of the ovary, in consequence of the adherence of the calyx to that organ. Examples may be seen in the campanula, carrot, and ivy.

EPILEPSY, *ep'-e-lep-se* (Gr., *epilepsis*, from *epi*, and *lambano*, I seize), is a form of disease which receives its name from the suddenness of its attack. It is also called the "falling sickness," from the patient, if standing, suddenly falling to the ground. By the ancients it was called the sacred disease, from being supposed to be due to the influence of the gods or evil spirits. The attack is usually sudden, without any warning. The patient may be in his ordinary health, engaged, perhaps, in his usual occupation, when all at once he utters a piercing scream, and falls to the ground. Immediately thereafter the face becomes violently distorted, the head is usually drawn to one side, the eyes are set and staring, or roll wildly about, the colour of the skin becomes dark and livid, and the veins swollen and turgid; there is frothing at the mouth; the muscles of the lower jaw act violently, producing gnashing of teeth, and frequently the tongue is thereby grievously injured; the arms are sometimes thrown violently about, and the lower limbs may be agitated in a similar manner, while the fingers with greater power clutch at whatever comes in their way. The breathing is at first heavy and difficult, but afterwards it becomes short, quick, and stertorious, and is often accompanied with sighing and moaning. One side of the body is commonly more agitated than another. After a longer or shorter period, the convulsive movements gradually diminish, and the patient seems to recover a faint glimmering of consciousness; but the look which he casts around is stupid and heavy, and he goes off into a lethargic sleep, from which he does not awake for some hours. Commonly there is no consciousness of anything that occurred during the paroxysm. On coming out of the fit, there is generally headache,, and always languor, and it may be days before he fully recovers from the attack. The duration of the paroxysm is usually from five to ten minutes; but sometimes several attacks follow each other, and it may be protracted for several hours. This is a severe form of epilepsy; but frequently it is less severe, consisting merely of loss of consciousness, slight rigidity, and the convulsion of a few muscles, and lasting only for a minute or two. Occasionally death takes place during the paroxysm; but generally it is attended with little danger, unless the patient may injure himself by falling in some dangerous position. During the attack, the principal thing is to see that the patient do not injure himself. The dress should be loosened about the neck and chest; the head, if possible, a little raised, and a free circulation of air maintained. The return of the fit is exceedingly various in different individuals; several years, in some cases, intervening between the attacks, while in others they may occur every month, week, or day. When neglected, they usually become more and more severe, or recur at shorter intervals. Repeated attacks of this disease, in general, soon produce a marked change in the mental and physical character of the individual. There is a gradual diminution of the active powers, purpose becomes irresolute, the spirits are depressed, and the memory fails; the features become coarse, heavy, and inexpressive, and the look vacant. The most frequent perhaps, of the consequences of confirmed epilepsy is insanity, either in the form of acute mania or monomania following the attacks, or of gradual imbecility, without any acute seizure. Though the fit, as we have said, usually comes on suddenly, yet there is sometimes distinct warning of its approach. These vary in different individuals, and may be lowness of spirits, irritability, dizziness, noises in the ear, floating specks before the eyes. There is, however, a particular sensation which is said to be felt by some immediately before the attack, and which is known as the *aura epileptica*. It is variously described as resembling a current of air, a stream of water, or a slight convulsive tremor, commencing in one of the limbs, and proceeding upwards to the head, when the patient is deprived of all consciousness. Epilepsy is commonly divided into idiopathic, when it is a primary disease, depending on some affection of the brain, and sympathetic, when produced by an affection in some other part of the body—as the stomach, bowels, liver, circulating system, &c. Among the causes which give rise to epilepsy are external injuries done to the brain by blows, wounds, fractures, and the like, or internal injuries by water in the brain, tumours, concretions, and polypi. Violent affections of the nervous system, sudden frights, strong mental emotions, acute pains in any part, worms in the stomach or intestines, teething, suppression of accustomed evacuations, &c., are causes which also produce epilepsy. Sometimes it is hereditary, at other times it arises from a predisposition, occasioned either by plethora, or a state of debility. When it arises from hereditary predisposition, or comes on after the age of puberty, or when the attacks are frequent and of long duration, it is usually difficult to effect a cure; but occurring in early life, and occasioned by worms or any other accidental cause, it may, in general be remedied with ease. Where the disease can be traced to any special exciting cause—as injuries of the head, worms, teething, &c., the treatment should be first directed to its removal. Where, as is often the case, a plethoric state appears to occasion the disease, the patient is to be restricted to a low diet, frequent purgatives are to be exhibited, and everything avoided that may determine the blood to the head; and to counteract such a tendency, occasional cupping, blisters, issues, &c., may be useful. If, on the contrary, there are marks of inanition and debility, a generous diet, with tonic medicines and other means of strengthening the system, will be proper. In this disease great care is necessary in the matter of diet, and moderation in quantity and simplicity in character are material points.

EPILOBIUM, *ep-i-lo'-bi-um*, a genus of plants of the natural order *Onagraceæ;* herbaceous perennials, natives of temperate and cold climates. Some of them bear beautiful flowers. One species, *E. angustifolium*, is sometimes known as the French willow. In Kamschatka, the pith yields a quantity of sugar, which is used for making a kind of ale, and also vinegar.

EPIPETALOUS, *ep-e-pet'-a-lus* (Gr., *epi*, upon; *petalon*, a petal), a term applied to the stamens of a flower when they are attached to the corolla, as in the primrose.

EPIPHEGUS, *ep-e-fe'-gus* (Gr., *epi*, upon; *phago*, I devour), a genus of plants belonging to the natural order *Orobanchaceæ*. The root of *E. Virginiana* is called cancer-root, from having been formerly used as an application to cancers.

EPIPHYTES. (*See* AIR-PLANTS.)

EPITHELIUM, *ep-e-the'-le-um*, the cell tissue which invests the outer surface and the mucous and other membranes of the human body.

EPIZOA, *ep-e-zo'-a* (Gr., *epi*, on; *zoon*, an animal), a term applied to those parasitic animals which live upon the bodies of other animals. They may be divided into two classes—those which live on the surface of the skin, and those which live in the skin. In the first class may be mentioned fleas, lice, bugs, ticks, &c.; and in the second, the itch-insect or *sarcoptes*, the pimple-mite, together with other species of the Acaridæ.

EPIZÖOTICS, *ep-e-zo-ot'-ikz* (Greek, *epi*, upon, and *zoon*, an animal), diseases of animals which prevail at the same time over considerable tracts of country and partake of a common character.

EPOCH, *e'-pok* (Lat., *epocha*, point of time). —In Astronomy, the longitude or right ascension of a planet, at any particular moment of time, is simply called the epoch of that planet, for the sake of brevity. In order to determine the future position of a planet in the heavens at any particular period, it is necessary to reckon from its epoch, or known longitude at a certain point of past time.

EQUATION, *e-kwai'-shun* (Lat., *æquare*, to make even or equal), the rate of motion of the heavenly bodies revolving in elliptic orbits is variable, and they are, from different causes, sometimes in advance of, and sometimes behind, the position in which they would be if they travelled at a uniform rate of motion. In calculating the position of a heavenly body from any epoch, a small amount, by way of correction, must consequently be added to or taken from its longitude at the time required, as it would be if it moved at a uniform rate; and this correction is termed an equation. There are various equations required in astronomical calculations of the longitude of heavenly bodies at given periods, arising from the attraction exercised on the planets by the sun, and that which they exercise on one another and their satellites. The moon's annual equation, the equation of time, and the equation of precession of the equinoxes, will be noticed elsewhere. (*See* MOON, SUN, PRECESSION.)

Equation of Light.—The allowance to be made for the time occupied by the light in traversing a variable space. It is to be considered in conjunction with aberration. (*See* ABERRATION.)

Equation of the Centre.—The orbit of the earth being slightly elliptical and the motion quicker at perihelion (when nearest the sun) than at aphelion (when furthest away), the "mean" longitude and the true longitude differ in a slight degree, and the quantity by which they differ is called the equation of the centre.

Equation of Time.—The want of uniformity in the sun's apparent motion, and the obliquity of the ecliptic to the equinoctial, produce an inequality in the time of the sun's appearance on the meridian, and the correction of this is the equation of time. The mean noon is sometimes 16½ minutes before the apparent noon, and sometimes 14½ minutes behind. Four times in the year, about the 15th of April, the 15th of June, the 31st of August, and the 24th of December, the mean and the apparent motions agree.

EQUATIONS, a term applied in Algebra to those propositions which assert the *equality* of two quantities. The sign $=$ placed between the two quantities signifies that they are equal. Thus $5x+10=25$, is an equation expressing the equality of the quantities $5x+10$ and 25. A simple equation is that which contains only the first *power* of the unknown quantity or quantities. Pure equations of the higher degrees are those which contain the square or any higher power of the unknown quantity, and are divided in two classes—*pure* and *affected*. A pure equation is that in which only one power of the unknown quantity is involved, and an affected equation is that in which different powers of the unknown quantity are involved. Thus, $ax^2=b$ is a pure equation, and $ax^2+bx=c$ is an affected equation. An affected quadratic equation is that which contains the square of the unknown quantity and also the unknown quantity itself.

EQUATOR, *e-kwai'-tor* (Lat., *æquus*, equal), the name given to the imaginary great circles that surround the heavens and the earth midway between the poles, so that every point in them is equidistant from each polar point. The plane of the terrestrial and celestial equator is at right angles to the axis of either sphere. The equator is so called because day and night are equal when the sun crosses it at the vernal and autumnal equinoxes in his passage along the ecliptic.

EQUIDÆ, *e-kwi'-de*, a family of mammalia, of the order *Pachydermata*, containing only a small number of species, comprising the horse and its allies. The name *Solid ungula* (solid hoofed) is sometimes applied. Their most striking character consists in the structure of the feet, which are composed of but a single finger or toe terminating each extremity, and encased in a horny sheath or shoe. Besides this well-developed toe, however, the Equidæ possess on each side of the metacarpus and metatarsus two small rudimentary processes, which represent two lateral toes. (*See* HORSE.)

EQUILATERAL, *e-kwe-lat'-e-ral* (Lat., *æquus*, equal; *lateralis*, side), having all the sides equal; as an equilateral triangle. All the regular polygons are equilateral.

EQUILIBRIUM, *e-kwe-lib'-re-um* (Lat., *æquus*, equal; *libra*, balance), a state of rest produced by the mutual counteraction of several forces. (*See* MECHANICS, STATICS.)

EQUINOCTIAL, *e-kwe-nok'-shal* (Lat., *æquus*, equal; *nox*, night).—The celestial equator is sometimes called by this name, because day and night are of equal length all over the world when the sun crosses the equator.

EQUINOXES, *ek'-we-noks-ez*, the points in which the great circles known as the ecliptic and equator cut each other. They are distinguished as the vernal and autumnal equinox. The sun is at the former on the 21st of March, when he enters the first point of Aries; and at the latter on the 22nd of September, when he enters the first point of Libra. In the southern hemisphere, the names of the equinoxes are transposed; the vernal equinox to those who are north of the equator becoming the autumnal equinox to those in countries lying to the south of it; and the autumnal, the vernal equinox.

EQUISETACEÆ, *ek-we-se-tai'-se-e* (Lat., *equus*, a horse; *seta*, a hair, or bristle), the Horsetail family, a natural order of *Acotyledones*, sub-class *Acrogenæ;* consisting of herbaceous plants, with striated, hollow, jointed, simple or verticillately-branched, aerial, silicious stems, arising from slender creeping rhizomes, or underground stems. The joints are surrounded by membranous toothed sheaths, which are regarded as modified leaves; but, in general, the plants of the order are considered leafless. These plants are found in marshy or watery places in most parts of the world. There is but one genus, *Equisetum*, which includes about ten species, the greater number of which are indigenous. The silex, or flint, contained in the tissue of the rough horsetail, *Equisetum hyemale*, renders it a useful plant. Its stems are largely imported from Holland under the name of Dutch rushes, and employed by cabinetmakers, whitesmiths, and ivory-turners for smoothing the surface of their work.

EQUISETITES, *ek-we-se-ti'-tes* (Lat., *equisetum*, the plant horsetail), the name given to fossil plants which resemble the equisetum of our pools and marshes. They are found in all formations, from the Devonian upwards.

EQUISETUM. (*See* EQUISETACEÆ.)

EQUIVALENTS. (*See* ATOMIC WEIGHTS.)

EQUULEUS, *e-kyu-ul'-e-us* (Lat., the little horse), one of the old Greek constellations named by Ptolemy, and situated between Aquila and Capricornus. Its brightest stars are of the fourth magnitude only. There is another constellation, named by Lacaille *Equuleus pictoris*, the easel, or painter's horse, which is situated near the constellation Argo.

ERBIUM, *er'-be-um*, an exceedingly rare metal, found with yttrium and terbium in gadolinite. The oxide erbia is similar in its characteristics to alumina. It has a dark yellow colour, but forms colourless salts.

EREMACAUSIS, *e-re-ma-kaw'-sis* (Gr., *erema*, slow; *kausis*, burning), a term applied by Liebeg to the slow decay of moist organic bodies by the absorption of oxygen without the production of heat. The slow decay of wood, under the combined influence of air and moisture, is an instance of this action.

ERGOT OF RYE. (*See* SECALE.)

ERICACEÆ, *e-ri-kai'-se-e* (Lat., *erica*, heath), the Heath family, a natural order of dicotyledonous plants in the sub-class *Corolliflore*, consisting of 42 genera and about 850 species. They are very abundant at the Cape of Good Hope, and are more or less generally diffused throughout Europe, North and South America, and Asia; and there are a few species in Australia. Many of the *Ericaceæ*, particularly species of the genera *Erica*, *Rhododendron*, *Kalmia*, and *Azalea*, are largely cultivated in this country on account of the beauty of their flowers. The three latter genera are commonly called American plants by florists; but they are not confined to America, as the name would imply. Medicinally, the plants of this order are chiefly remarkable for astringent properties. Some, however, are narcotic, and a few even poisonous. The fruits of many are edible.

ERIDANUS, *e-rid'-a-nus*, a constellation formed and named by Aratus after the river Eridanus. It stretches along the heavens from Phœnix to Orion, in the shape of a winding river; it has one star of the first magnitude, and many of the third and fourth.

ERIGERON, *e-rij'-e-ron*, a genus of plants of the natural order *Compositæ*, sub-order *Corymbiferæ*, having heads of many florets. A British species, *E. acris*, commonly known as the Flea-bane, is about eighteen inches high.

ERIOCAULACEÆ, *er-e-o-kaw-lai'-se-e* (Gr., *erion*, wool; *kaulon*, a stem), the Eriocaulon, or Pipe-wort family, a natural order of *monocotyledones*, consisting of aquatic or marsh plants, mostly natives of tropical America and the north of Australia. One species is found in Britain—namely, *Eriocaulon septangulare*, the pipe-wort.

ERIODENDRON, *er-e-o-den'-dron* (Gr., *erion*, wool; *dendron*, a tree), a genus of the natural order *Sterculiaceæ*. The most remarkable species is *E. Samauma*, a native of South America. Its trunk frequently overtops all the surrounding trees before it gives off a single branch. The flowers are large and beautiful. The hairy covering of the seeds of various species of this genus forms a kind of vegetable silk much used for stuffing cushions and similar purposes.

ERIOPHORUM, *er-e-of'-o-rum* (Gr., *erion*, wool; *phoreo*, I bear), a genus of the natural order *Cyperaceæ*, or Sedge family, consisting of numerous species, commonly known as cotton-grasses, from their fruits being surrounded by cottony or downy hairs. These hairs are sometimes used for stuffing cushions. The leaves are reputed to possess astringent properties.

ERMINE, *er'-min* (Fr., *hermine*), *Mustela ermina*.—This little digitigrade animal is found generally in temperate Europe, but is common only in the north. It is not generally known that the ermine and the stoat are the same animal: the confusion arises from the change that takes place in the colour of the animal's fur at the different seasons. In the winter it is yellowish-white, the yellow hardly showing about the head, but gradually appearing more and more on the body, and increasing in intensity, so that some are of a pale yellow colour on their hind parts: then it is known as the ermine. About the end of March, however, the upper parts change to reddish-brown of rather a dull tint, the lower parts continuing white: the tail remains black at the tip through all the changes. It is in the extreme northern regions that this change in the animal's colour takes place with greatest distinctness. Like many other species of this genus, the ermine has the faculty of ejecting a fluid of a strong musky odour. Its fur is in great request; at one time it was one of the insignia of royalty, and it is still worn by the judges.

ERNE, a genus of birds (*Haliæëtus*), of the Falcon family, differing from the true eagles in the greater length of the bill, in the toes, and the lower part of the tarsi being destitute of feathers, in feeding on fish and carrion, and in inferior courage. The only British species is sometimes known as the sea-eagle. (*See* EAGLE.) It seldom measures more than 33 inches in total length.

EROSION, *e-ro'-zhun* (Lat., *erosus*, gnawed or worn away), the act of gradually wearing away; the state of being gradually worn away. In Geology, this term is employed to distinguish those features which are the results of the slow destructive action of running water, glaciers, the waves, and other agents; thus, *valleys of erosion* are those valleys which have been gradually cut out of the solid strata. Most of the ravines and glens and river-channels in the British isles are the results of erosion. Just as actual sea-cliffs are proofs of the erosive action now in operation, so in almost all cases, inland cliffs, crags, scars, and precipices, as well as valleys, ravines, gorges, and mountain-passes, are proofs of the erosive action of the sea in times when the land stood at a lower level with respect to it. A still more wonderful example of erosion is frequently afforded in a low and gently undulating district, from which the very mountains themselves, that geologists can prove once covered it, have been removed. (*See* RIVER, GLACIER, ICEBERG.)

ERRATIC-BLOCK GROUP, *er-rat'-ik* (Lat., *erraticus*, wandering), a synonym of the boulder clay, from the large transported blocks of stone which occur in it. The blocks, or boulders, are sometimes briefly designated erratics. (*See* BOULDERS, PLEISTOCENE.)

ERRHINES, *er'-rines* (Gr., *errinon*, from *en*, in; *rin*, the nose), those medicines which are applied to the mucous membrane of the nostrils. The term *sternutatories* is restricted to those which cause sneezing. The aromatic errhines most commonly applied are powdered herbs—as mint, lavender, and rosemary; also tobacco as snuff. Ammonia and its carbonates are much employed. Acrid vegetables and poisons, and preparations of mercury, are applied in rare cases.

ERVUM, *er'-vum* (Lat., *eruo*, I pull up by the roots), the Tare, a genus of the natural order *Leguminosæ*, sub-order *Papilionaceæ*, consisting of herbs with weak and slender stems, small papilionaceous flowers, and pods containing from two to four seeds. The species are common fodder plants in many parts of the world. The seeds of the *E. Lens* are called *lentils*. (*See* LENTILS.)

ERYNGO, *e-rin'-go*, a genus of plants of the natural order *Umbelliferæ*. There are many species, mostly natives of the warmer temperate parts of the world. The Sea Eryngo, or Sea Holly (*E. maritimum*) is frequent on sandy sea shores. The root was formerly used as a tonic; and at Colchester especially was sold in a candied state. An American species, *E. aquaticum*, is known as Rattlesnake Weed, from its supposed value as a remedy for snake-bite.

ERYSIMUM, *e-ris'-i-mum*, a genus of plants of the natural order *Cruciferæ*, tribe *Sisymbrieæ*. The best known species is a branching annual about 18 inches high, with small yellow flowers. It is a native of the north of Europe and North America. It is commonly known as worm-seed, having been used as a remedy for those parasites. It is also known as Treacle-Mustard.

ERYSIPELAS, *er-e-sip'-e-las* (Gr., from *eruo*, I draw; and *pelas*, near or adjoining), is the name given to a peculiar kind of inflammation of the skin, so called from its tendency to spread to adjoining parts. It is known also as St. Anthony's fire or *ignis sacer*, and in common language as the Rose. It most commonly attacks the head and face; but it also sometimes occurs on other parts of the body. The local inflammation is preceded and accompanied with fever, and there are also usually certain premonitory symptoms that precede the outbreak of the disease; the patient feels ill—shivery, feeble, languid, and often drowsy. After these symptoms have continued for some time, a red spot appears on some part of the body, accompanied with a burning heat and tingling. When attacking the face, it usually makes its appearance on the bridge of the nose, and rapidly extends itself to the eyelids, cheeks, and forehead. Sometimes the inflammation and swelling extend to the neck and throat, and may produce suffocation. In very bad cases, delirium and coma come on, and death ensues from effusion on the brain. No remission of the fever takes place on the appearance of the inflammation; but, on the contrary, it generally increases with the progress of the inflammation, and only ceases when it goes away. When the complaint is mild, the inflammation and fever generally cease gradually without any evident crisis. Among frequent causes of this disease, are exposure to a cold and moist atmosphere, sudden changes of temperature, intemperance, and unwholesome articles of food. It is sometimes also induced by wounds or sores, or even a slight puncture or scratch of the skin in persons predisposed to it. It is likewise contagious, and has to be strictly guarded against by means of ventilation and cleanliness in hospitals. Though the proper seat of the inflammation is the skin, it frequently extends to the parts underneath.

ERYTHEMA, *er-e-the'-ma* (Gr., *eruthros*, red), a lesser kind of erysipelas, being characterised in like manner by some degree of redness of the skin and disorder of the constitution, but with little swelling, and little tendency to suppuration or vesication. It is not infectious, and usually arises from some local irritation, or from a disordered state of the digestive organs.

ERYTHRÆA, *er-e-thre'-a*. (*See* CENTAURY.)

ERYTHRINA, *er-ith-ri'-na*. (*See* CORAL TREE.)

ERYTHRONIUM, *er-ith-ro'-ne-um*, a genus of plants of the natural order *Liliaceæ*, with bulbous roots and drooping flowers. The familiar *Dog-tooth Violet* (*E. dens canis*) is a native of the central parts of Europe and the south of Siberia. The bulbs are sometimes used medicinally as emetics and as a cure for worms.

ERYTHROPHLÆUM, *er-ith-rof'-le-um*, a genus of the natural order *Leguminosæ*, sub-order *Mimoseæ*. *E. Guineense* is the sassy-tree of Western Africa, the bark of which, under the name of "ordeal bark," or "doom bark," is used by certain tribes as an ordeal to which persons suspected of witchcraft or secret poisoning are subjected, from the superstition that their innocence or guilt will be indicated by the effects produced by the bark on the system.

ERYTHROXYLACEÆ, *er-e-throks-e-lai'-*

se-e, the Erythroxylon family, a natural order of dicotyledonous plants, in the sub-class *Thalamifloræ*; consisting of but one genus, *Erythroxylon*, which includes seventy-five species, natives of the warmer regions of the globe, and especially abundant in Brazil. This order is closely allied to *Malpighiaceæ*, and in fact scarcely presents characters sufficient to warrant its separation from that order. Some of the plants are tonic, others purgative, and others stimulant and sedative. The wood of *E. hypericifolium*, and the bark of *E. suberosum*, are red, and are used for the preparation of dyes of that colour. The most important species is *E. Coca*, the leaves of which are much used by the Peruvians and other peoples of South America to form a masticatory, which is prepared by adding to them a very small quantity of an alkaline paste, made from the ashes of different plants, or even a little common quick-lime. The Indians of Peru have always ascribed to the coca marvellous virtues, believing that it will lessen the desire and necessity for ordinary food. No Quitchoan Indian would dream of crossing the snow-clad passes without a sufficient store of coca leaves. It is certain that these men, who cross the Andes by almost impassable tracks, heavily laden with baggage, and without any strengthening food but coca, arouse the admiration of every traveller by their wonderful feats of great endurance. The Indians of Peru have a singular habit of measuring distances by so many mouthfuls of coca. To understand this we must remember that the stimulating effect produced by the chewing of a few leaves continues for a definite period, and if the coca globule held in the mouth is not refreshed by the addition of new leaves, its effects pass off, and a reaction of physical weakness sets in. "As a result of the observations made during my journey," says Bastion, "it may be concluded that the excitement begins after the coca has been held in the mouth for about eight to ten minutes, and that if no fresh leaves are added it will last for thirty-five to forty minutes." Its excessive use is stated to be most injurious, producing analogous effects to those occasioned by the immoderate consumption of opium and fermented liquors.

ERYTHROXYLON. (*See* ERYTHROXYLACEÆ.)

ESCALLONIACEÆ, *es-kal-lo-ne-a'-se-e* (in honour of Escallon, a Spanish traveller), the *Escallonia* family, a small natural order, subclass *Calycifloræ*, consisting of evergreen shrubs, with alternate exstipulate leaves and axillary showy flowers. They are chiefly natives of the mountains of South America.

ESCALOP, OR ESCALLOP, *es-kal'-lup* (Du., *schalp*, a shell), a family of bivalve molluscs the shells of which are deeply indented. In the centre of the top of the shell is a trigonal sinus, with a hinge consisting of elastic cartilage.

ESCASS, *es'-kass*, long narrow ridges of carboniferous limestone, accumulated during the Pleistocene period. They are known in Scotland as *kames*, and in Sweden as *äsar*.

ESCHALLOT, *es-shal-lot'* or *shal-lot'* (Fr., *échalote*), *Allium ascalonicum*, a species of small onion or garlic. It is said to have come originally from Palestine.

ESCHAR, *es'-kar* (Gr., *eschara*), the crust of a scar produced by burning substances of a caustic nature which have the power of searing or destroying the flesh. (*See* CAUTERY, CAUSTIC.)

ESCHSCHOLTZIA, *esh-kolt'-zhe-a*, a genus of plants of the natural order *Papaveraceæ*. The calyx separates from the dilated apex of the flower-stalk, being thrown off by the expanding flower. Some of the Californian species have large yellow flowers, and are cultivated in our gardens.

ESENBECKIA, *es-en-bek'-e-a*, a genus of trees of the natural order *Diosmaceæ*. One species, a native of Brazil (*E. febrifuga*), furnishes a bark reported to be of equal medicinal value with Peruvian bark.

ESOCIDÆ, *es-os'-ci-de*, a family of malacopterous fishes, now regarded as including only the pikes. Flying-fishes were until recently considered to belong to this family.

ESOTERIC, *es-o-te'-rik*, a term applied by the Greeks to these doctrines designed only for those who had been initiated in the ancient mysteries, and not to be imparted to others. The teaching considered to be different from the initiated was styled *exoteric*.

ESPARTO, OR SPANISH GRASS, *es-par'-to* (Spanish), a species of grass, the *stipa*, or *Macrochloa tenacissima*, obtained from Africa and Spain. In Spain it is plaited and used in many ways, and a great deal of the cordage employed in the navy of that country is made from it. Within the last few years esparto has been largely imported into this country for making paper. It grows in bunches or tufts from two to four feet in height.

ESQUIMAUX DOG, *es'-kwe-mo.*—This animal is rather larger than the English pointer, but appears less, on account of the shortness of its legs. It has oblique eyes, an elongated muzzle, and a bushy tail, which curls over the body. The colour is generally a deep dun, obscurely barred and patched with darker colour. In the northern parts of America and the neighbouring islands, this animal is the only beast of burden. With a team of dogs harnessed to his sledge, the Esquimaux may scud over the snow at a rate of sixty miles a day, and this for several days in succession.

ETHMOID BONE, *eth'-moid* (Gr., *ethmoides*, from *ethmos*, a sieve, and *eidos*, because it is perforated like a sieve), one of the bones of the head, which is exceedingly light and spongy, consisting of many convoluted plates, which form a network like a honeycomb. It is somewhat cubical in form and is situated between the two orbitary processes of the frontal bone, at the root of the nose. The olfactory nerves shoot down through the numerous small perforations of this bone to the organ of smell.

ETHNOLOGY, *eth-nol'-o-je* (Gr., *ethnos*, nation, and *logos*, discourse), is that science which treats of the varieties of the human race, their history and distribution, their languages, physical and mental characteristics; arranging and classifying them, noting their points of similarity or dissemblance, and having in view the difficult problem of the unity or non-unity of the human race. Ethnology differs from anthropology in that the latter deals with the relations of man to the other members of the animal kingdom, whereas the former regards the differences that exists among the different varieties of the human race. It partakes of history, but, unlike ordinary history, which deals with actions, it treats of the effects of physical agencies upon man—soil, climate, nutrition, and the like; going back to a period long anterior to the existence of written records, and, unlike history, arguing from effects to causes, from the known to the unknown. In this way ethnology is, as Prichard says, the general archæology of the human race. Language, too, forms an important element in the study of ethnology as well as physical geography, which teaches the relations that subsist between the inhabitants of a given area, and its physical configuration, climate, &c. (*See* PHYSICAL GEOGRAPHY.) The ethnologist should thus not only be a naturalist, but should also have a knowledge of archæology, or the study of human monuments and remains; philology, or the science of languages; and physical geography, so far as it relates to the effects of physical influences upon different races. The science of ethnology is of recent origin, and is as yet almost limited to the accumulation and record of observations, which may perhaps, in time, lead to the discovery of the basis of a systematic ethnological philosophy. The evolutionists are busy with theories on the subject, and many are disposed to argue that the human being is a development from inferior organizations; but, if so, there must have been a remarkable cessation of the development process after man had attained his present form. In no other family of animals is there such uniformity of size and structure. The equine, the canine, the feline, or the bovine families—not to refer to innumerable others—all nearly allied by the possession of some common attributes, exhibit an almost infinite variety of detail; but in the human race the variations are almost insignificant. The general organization of man in all countries is absolutely the same, the only difference being in the greater activity of some of the organs induced by civilization or the necessities of existence. Geology has revealed to us the existence in prehistoric times of animals allied to those which now exist, but with great variation in organization, and differing very considerably in size. Among the fossils are the skeletons of creatures far exceeding in size any now living, and, on the other hand, bones of a small animal scarcely larger than a dog of one of the breeds of medium size, which geologists assert was the progenitor of the modern horse. But so far as science has been able to discover, the human being has ever been of the same average dimensions. Individuals of all races vary in height; the average bulk of the inhabitants of tropical climates is generally less than that of the people who dwell in the regions of temperate climate; and stunted men and women occupy the colder parts of the earth; but so it has been apparently in all ages. The skeletons found in old barrows, representatives of the men of the prehistoric period, the bones found imbedded in strata of great antiquity, are of about the same dimensions as those of the men of to-day. No necessity of existence has lengthened the arms or neck, changed toes into thumbs, or added a finger to the hand. The general type of all men in all regions, from the equator to the poles, is that they are two-handed, walk erect, have the power of speech more or less developed, and that between even those of lowest organization and the most intelligent of quadrupeds there is a very marked distinction. Human idiots there are, as there are human monstrosities of form; but they are exceptions which prove the permanence of the typical characteristics. While, however, the general agreement in organization appears to be ineradicable, there are certain external differences, in complexion, hair, facial contour, and other minor matters, which seem to indicate separate groups or families of the human race, and have suggested the theories advocated by some ethnologists of distinct centres of creation, in opposition to the more generally accepted belief in the derivation of all human beings from the same stock. In discussing this question, we may fairly take into consideration that, in the respect of the means by which the human race might have spread over the earth, we are not encountered by the difficulties which present themselves when we are examining the history of the movements of other members of animated nature. The will to travel, inspired by many motives, is added to the power to travel, given by natural adaptability to endure atmospheric and other variations, and by the exercise of the reasoning power; and in cases of accidental drifting to unknown islands or continental coasts, there is a power to make the best of adverse conditions. It is quite possible that the intelligent and active descendants of a small family located in south-western Asia should in the course of thousands of years have made their way east and west, north and south, making at intervals settlements which became centres of new dispersions. From Asia to Western Europe was a comparatively easy journey, allowing many centuries for its accomplishment. Africa could be peopled not only by passing across the neck of land which divides it from Asia, but by settlements on the coast made by adventurous mariners, or by parties drifted to the shores. The straits which separate north-eastern Asia from north-western America could be crossed by canoes, visiting the chain of islands on their way. We know that adventurous Northmen of Europe reached the North American coast from Greenland centuries before Columbus crossed the Atlantic; and the Chinese have traditions of discoveries and settlements on the western coast of North America, nearly as far south as California. The islands of the Pacific offer more difficult, but not insoluble problems. The island groups are so numerous, that it is not beyond the possibility of belief to suppose that, either by intention or accident, the inhabitants of one might reach and settle on another. In the course of this long travel, however, geographical considerations would cause variations of colour, features, and habits, which might appear to indicate separate origins. Long residence in hot climates affects the colour of the skin, and it becomes hereditary. The necessity of constant physical exertion to maintain existence, and the absence of intellectual training, develop the muscles and bony framework, and induce a dwindling of the brain. The facial angle becomes more acute, the jaw-bone more prominent, and the figure more lithe and active. In very hot climates less animal food can be eaten, even by recent settlers, and in the course of ages is dispensed with altogether—sometimes from religious considerations, as among the natives of the Indian peninsula and other parts of Asia—and the resulting difference of physique is very noticeable. Other causes, such as the effects of the chemical constituents of the atmosphere and of water, it may be the effects of terrestrial magnetism, are in continual operation, and the results, aided by hereditary transmission, produce the differences which mark what are popularly called the races of mankind.

Ethnological Classifications.—Peter Camper, a distinguished Dutch anatomist of the last century, was the first who attempted to lay down on scientific principles a method of distinguishing between the different races of mankind, from the form and size of the skull, by what is known as the facial angle. The head being viewed in profile, a line is drawn through the *meatus auditorius* of the ear to the base of the nose, meeting another touching the most prominent part of the centre of the forehead, and falling down to the most advanced portion of the upper jaw. The nearer the angle thus formed approaches a right angle the greater, as a general rule, is the intellectual development of the individual; and this is found to be generally the case, not only as regards man, but also among the lower animals—the smaller the facial angle the lower are they in the scale of intelligence. One great deficiency in this method was its taking into account only one feature of the skull, instead of the general capacity and shape, and, to remedy this, Blumenbach fixed upon a number of characteristic peculiarities; and he suggested the division of mankind into the five following classes:—(1) the Caucasian, (2) Mongolian (3) Ethiopian, (4) American, (5) Malay. Cuvier reduced the five classes of Blumenbach into three—the Caucasian, Mongolian, and Ethiopian, treating the Malay and American as subdivisions of the Mongolian. He referred the original seats of the human race to the mountain-chains—the Caucasians to Mount Caucasus, the Mongolian to the Altai mountains, and the Negro to the chain of the Atlas. Dr. Prichard, who was the first to bring to the study of this subject a large knowledge of languages as well as of physiology, regards the banks of the great rivers, and not the mountains, as the primary seats of the different races. The arrangement which he adopts is—(1) The Syro-Arabian or Semitic race (including the Syrians, Jews, and Arabs). This race is intellectual, energetic, and restless. The second group are the Egyptians or Hamitic race, which he regards as indolent and superstitious, reposing ever in luxurious ease and wealth on their own rich soil. The third group is the Indo-European, Japetic, or Arian race, comprising the Hindoos, Persians, Afghans, Koords, Armenians, and the nations of Europe, with their American colonies. The great central region of High Asia is inhabited by five nomadic races, belonging to the Mongolian division of authors, and characterized by pyramidal heads and broad faces. These are—(1) the Ugrian, in the N.W., from whom the Magyars are believed to have descended, and of which the Finns, Laps, Ostaks of the Obi, and other Siberian tribes, are varieties; (2) the Turkish, with their nomadic tribes, and the Ottoman branch; (3) the Mongolian, including the Calmucks; (4) the Tungusian, in the mountainous region between Lake Baikal and the river Okhotsk; (5) and the Bhotiya race (often termed Tartars), inhabiting a great part of Thibet and the Himalayan chain. Beyond the central region occupied by the five nomadic races are various tribes of people, spread over the lower countries of northern Asia, and over the cold plains which are traversed by the Siberian rivers and border of the Icy Sea. They belong to the same great division of mankind as the Tartars, whom they resemble in some of their leading characteristics, particularly in the form of the skull. Prichard termed them Ichthyophagi or fishing tribes. To the same type of the human species as the nations of High Asia belong the Chinese, Koreans, Japanese, the races of the Indo-Chinese peninsula and the aborigines of India, distinct from the Hindoos (who belong to the Indo-European stock). Prichard believed that in the regions afterwards occupied by the Indo-European and Syro-Arabian races there existed a more ancient stock of inhabitants, also of eastern origin, but who had migrated westward at an earlier date, and to whom he gives the name of Allophylians. These, when displaced by the invaders, took refuge in the mountainous parts; and to them belong the Caucasians, the Iberians of the Pyrenees, the Berbers of the Atlas chain, and the Guanches of the Canary Islands. Of the black races of the interior of Africa, the principal are the Senegambian, including the Mandingoes and the Foolahs. The true negro characters are most strongly marked on that portion of the coast which encircles the projecting region of Western Africa to the inmost angle of the Bight of Benin, the centre of the slave trade. The Hottentots and Bushmen of South Africa in many respects resemble the nomadic Mongolians of Asia; the warlike Caffres are said to combine the prominent forehead and nose of the European, the thick lips of the Negro, and the high cheekbones of the Hottentot. Among the African races is the Abyssinian, a fine dark, but not negro race. The Oceanic races Prichard divides into Malayo-Polynesian, Pelagian Negroes, and the Alfoorians of the New Guinea group of islands (which include the Australians). The American races are distinguished from those of the old world by their moral and social traits and by the structure of their languages. The Mexican tribes, which, according to him, arrived on the central plain of Anahuac, from the north, in the 7th century, found this region inhabited by the nations which have left the splendid ruins of Palenque; among whom were the Othomi, remarkable for their monosyllabic idiom. The Esquimaux and the Athabascas, with a Mongolian cast of countenance, extend across the northern portion of the continent from ocean to ocean; south of these, east of the Mississippi, were the Algonquins and the Iroquois, with their numerous tribes, almost always at war with each other, and the Alleghanian nations toward the south; west of the Mississippi were the Sioux and Pawnees; on the Pacific coast the dark Californians and the tribes of the north-west coast; and in South America the Andean nations, the Brazilio-Guarani, and the Mediterranean or central groups. Dr. Latham, one of the latest writers on the subject, finds only three distinctive groups (each with many sub-divisions), and names them Mongolidæ, Atlantidæ, and Japetidæ. The first inhabit Asia, Polynesia, and America; the second Africa; and the third Europe. A convenient arrangement, now very generally adopted, is one which professes to be only descriptive of what exists, and does not attempt to explain the origin of diversities of human being. This arrangement is into six groups:—Iranians, of western Asia; Turanians, including the Mongolian and Malayan races; Negroes; Hottentots and Bushmen of South Africa; Ocean Negroes, including Papuans or natives of the archipelago of the South Pacific, and Alfourons or natives of some parts of New Guinea and Australia; and Americans, including the Esquimaux.

Unity or Diversity of Origin.—We have referred above to some arguments in favour of the theory of a common origin of the whole human race which claim to be taken into consideration, but it is necessary to explain the views of some eminent investigators, mostly American, who have arrived at conclusions in favour of the theory of various centres of origin. Dr. Morton of Philadelphia, who for many years gave great attention to the subject of comparative craniology, arrived at conclusions "in favour of the doctrine of primeval diversities among men, and an original adaptation of the several races to their varied circumstances of climate and locality, which, while congenial to the one, are destructive to the other." In reply to this theory of creative adaptation, it may be urged that no part of the vast surface of the globe, except the frozen poles, or a very few small volcanic or coral islands, is untrodden by the foot of man. The limit on land of the absolute possibility of sustaining animal life is the only limit to the residence or the wanderings of the human race. Members of any of the races, white or black, Semitic, Mongolian, or Negro, can live together in almost any part of the world. Whether there was one act of creation in south-western Asia, or whether there were many acts of creation taking place in different places and at different times, one fact is not affected: that fact is, that man, wherever originating, possesses faculties which make him very independent of geographical conditions. Mountains or seas cannot shut him in; and familiar as we are with his peculiar powers of body and mind, there is no reason why, in the course of ages, the progeny of a single pair dwelling near the Euphrates, or indeed almost any other spot on the earth's surface, should not spread over the entire habitable surface of the globe. Dr. Morton to the last remained firmly convinced that "our species had its origin, not in one, but in several or in many creations, and that these, diverging from their primitive centres, met and amalgamated in the progress of time, and have thus given rise to these intermediate links of organisation which now connect the extremes together." Other advocates of the theory were Mr. G. R. Gliddon and Dr. Nott; and a supporter of even greater scientific eminence was Professor Agassiz, who, in contributions to "Types of Mankind," an elaborate work, edited by Messrs. Nott and Gliddon (1845), holds "that what are called human races, down to their specialization as nations, are distinct primordial forms of the type of man; believing that the boundaries within which the different natural combinations of animals are known to be circumscribed upon the surface of our earth coincide with the natural range of distinct types of man." He gives a sketch of the natural provinces of the animal kingdom and their relation to the different types of man. He classes them according to the following realms:—1, Arctic, inhabited by Hyperboreans; 2, Asiatic, by Mongols; 3, European, by white men; 4, American, by American Indians; 5, African, by Nubians, Abyssinians, Foolahs, Negroes, Hottentots, and Bosjesmen; 6, East-Indian or Malayan, by Telingans, Malays, and Negrillos; 7, Australian, by Papuans and Australians; and 8, Polynesian, by South-Sea Islanders. In the "Indigenous Races of the Earth" (1857), Messrs. Nott and Gliddon give an ethnographic tableau, in which the races are divided zoologically, according to the eight realms of Agassiz; they are also grouped physiologically (after Desmoulins, Achille Compte, and O. d'Halloy) into sixty-five families—seven belonging to realm 1 of Agassiz, twelve to realm 2, sixteen to realm 3, fourteen to realm 4, eight to realm 5, three to realm 6, two to realm 7, and three to realm 8. The same realms have also their corresponding classes, arranged linguistically, after Alfred Maury, Crawfurd, Logan, &c. (In the full-page illustrations, plates 24 and 25, are depicted individuals of some of the various races.)

ETIOLATION, *e-te-o-lai'-shun* (Gr., *aitho*, I shine).—When all the green colour of a plant is absent, it is described as etiolated. This condition is produced by the want of light.

EUCALYPTUS, *u-ka-lip'-tus* (Gr., *eu*, well; *kalupto*, I cover), a genus of the natural order *Myrtaceæ*, consisting of trees having hard wood, alternate, entire, coriaceous leaves, and yellow flowers, growing in corymbs. They are mostly natives of Australia and Tasmania, but are met with also in the Malayan archipelago. The most important species is *E. resinifera*, the iron-bark, which yields on incision an astringent substance called *Botany Bay kino*. This contains a peculiar substance, to which the name *Eucalyptin* has been given. It has been employed as a remedy in diarrhœa and as a surgical dressing. The leaves of *E. mannifera* and other species spontaneously exude a saccharine substance resembling manna, and hence termed *Australian manna*. It is said to drop from the trees in pieces sometimes as large as an almond. The secretions of the *Eucalypti* are commonly of a gummy nature, and on this account the trees are commonly known in Australia as Gum-trees. The bark of some of them separates in fibrous layers; and this peculiarity has also obtained for them the name of stringy-bark trees. They frequently attain a prodigious height—200 feet or more, the trunks being destitute of branches to a height of from 100 to 200 feet. Recently trees have been seen which far surpass in height the renowned Mammoth trees of California, being 480 feet high.

EUGENIA, *u-je'-ne-a* (in honour of Prince Eugene, of Savoy), a genus of the natural order *Myrtaceæ*, composed of tree and shrubs with opposite entire leaves, axillary white flowers, and black or red berries. *E. pimenta* is the most important species. Its dried unripe fruit constitutes pimento, or Jamaica pepper, or, in more familiar language, allspice. The latter name is given to it because it is thought to have combined the flavours of cinnamon, clove, and nutmeg. It is used as a spice, and in medicine as an aromatic stimulant. Its properties are dependent on the presence of a volatile oil. The rose-apples of the East, which are much esteemed as dessert fruits, are the produce of *E. Malaccensis*, *E. aquea*, *E. Jambos*, and other species of this genus. In Brazil, the fruit of *E. cauliflora*, the *Jabuticaba*, is also much esteemed. The leaves of *E. Ugni* are used in Chili as a substitute for Paraguay tea.

EULOPHIA, *u-lo'-fe-a* (Gr., *eulophos*, a handsome crest), a genus of Orchids. The tubercular roots of *E. vera* and *E. campestris* are much used in India for the preparation of the nutritious substance known by the names of salep, salop, and saloop.

EUONYMUS, *u-on'-e-mus* (Gr., *eu*, well; *onoma*, a name), a genus of the natural order *Celastraceæ*. The species *E. europæus* is the common spindle-tree of our hedges. In France, charcoal prepared from the wood is largely used in the manufacture of gunpowder; while the young shoots, in a charred condition, are employed as rough crayons for sketching. The seeds are stated to be purgative and emetic, and also to be poisonous to sheep. The bark of *E. tingens* can be used as a yellow dye-stuff.

EUPATORIUM, *u-pa-to'-re-um* (derived by Linnæus from Mithridates Eupator, who first used it as a counter-poison), a genus of the natural order *Compositæ*, sub-order *Tubulifloræ*. *E. ayapana* and *perfoliatum* are employed as antidotes to the bite of venomous reptiles. Only one species, the common hemp-agrimony (*E. cannabinum*) is British. It is a perennial plant with a slightly aromatic flavour, growing generally in damp soils. It was formerly used as a purgative and diuretic.

EUPHORBIA, *u-for'-be-a* (named after Euphorbus, physician to Juba, king of Mauritania), the typical genus of the natural order *Euphorbiaceæ*, consisting of about 300 species, many of which have valuable properties. The acrid resin commonly known as gum Euphorbium is the produce of certain undetermined species, the principal of which are probably *E. antiquorum*, *canariensis*, and *officinarum*. It is a dangerous emetic, cathartic, and rubefacient, and produces severe inflammation of the nostrils if those who powder it do not guard themselves from the dust. It is produced from the wounded stems, and collected in leather bags. The juice of the species *E. cereiformis*, *heptagona*, and *virosa*, African plants, furnish the Ethiopians with a mortal poison for their arrows; whilst that of *E. cotinifolia* serves a like purpose for the Brazilian Indians. The species *E. Hibernica* is extensively used by the peasantry of Kerry for the purpose of stupefying fish; and so powerful are its properties said to be, that a small creel or basket filled with the bruised herb suffices to stupefy the fish for several miles down a river. *E. hypericifolia*, a plant of tropical America, is astringent and somewhat narcotic, and is employed in the diarrhœa of children and as a vermifuge; and *E. thymifolia* is employed for a like purpose in India. The root of *E. ipecacuanha* is said to be equal to the true ipecacuanha, and is commonly used in the states of North America. Another species, *E. corollata*, the milk-weed, is also used as an emetic in the

States. The fruits of *E. Lathyris*, or caper-spurge, are sometimes pickled and eaten, instead of ordinary capers; but although the process of pickling appears to destroy in a great measure the acrid purgative properties which the fruits possess in a fresh state, their use is by no means free from danger. A very active cathartic oil may be expressed from the seeds of the caper-spurge. Many species are purgative. *E. Tirucalli*, a native of India, is common in the Madras presidency, and makes an excellent hedge, as no cattle will touch its leaves. The sap of *E. phosphorea* is said to shine with a phosphorescent light in the forests of Brazil on warm nights.

EUPHORBIACEÆ, *u-for-be-ai'-se-e*, in Botany, the Spurge-wort family, a natural order of *Dicotyledones*, in the sub-class *Monochlamydeæ*, consisting of trees, shrubs, and herbaceous plants, generally with an acrid milky juice. There are about 2,500 known species, mostly natives of tropical countries. The few species found in the temperate regions are nearly all herbaceous, but the common Box is shrubby.

EUPIONE, *u'-pe-on-e* (Gr., very fat).—A limpid fluid, first discovered by Reichenbach in wood tar. It is found in the tar produced by the destructive distillation of several vegetable and animal substances, its properties being found to agree with those hydrocarbons found in Boghead mineral. It evaporates at 340°; its specific gravity is 0·74, being the lightest liquid known. It is soluble in alcohol and ether, but does not dissolve in water. It has no smell, is tasteless, and is highly inflammable.

EUPODA, *u'-po-da* (Greek, web-footed), a family of coleopterous insects, so named from the great size of the thighs of many of the species. They feed on the stems and leaves of plants. In the tropics they are of great size and beauty. Many of the smaller species are British.

EURYATE, *u-ri'-a-te*, a genus of plants of the natural order *Nymphæaceæ*, or water-lilies. *E. ferox* has small red or violet-coloured flowers. The seeds of the fruit are roasted and eaten in China and India.

EUSTACHIAN TUBE. (*See* EAR.)

EUSTACHIAN VALVE, *u-stai'-ke-an*, a membranous semilunar valve separating the right auricle of the heart from the inferior vena cava. (*See* HEART.)

EUTERPE, *u-ter'-pe*, a genus of palms. The species *E. montana* is one of the cabbage-palms, so called because the young leaf-buds are boiled and eaten like cabbage.

EVAPORATION, *e-vap-o-rai'-shun* (Lat., *evaporatio*, an evaporation), the conversion of liquid or solid bodies into elastic vapours or gases by means of heat. Evaporation goes on slowly or rapidly according to circumstances. Water evaporates gradually at ordinary temperatures all over the surface of the globe. It rises in the air as vapour, and when condensed by change of temperature, forms rain or dew, and descends again to the earth. When, however, evaporation takes place rapidly, as in the case of ebullition, it is generally called *vaporization*. The quantity of vapour which rises from the surface of a liquid in the open air not only depends upon the quantity of surface exposed, but also on the state of the atmosphere at the time. In warm and dry weather, both in winter and summer, evaporation is greatest. It was found by Dr. Dalton that water raised to 212° evaporated at the rate of 4·244 grains per minute. Mercury does not evaporate till it is raised to 60° or 80°.

EVECTION, *e-vek'-shun*, a lunar inequality resulting from the combined effect of the irregularity of the motion of the perigee and the alternate increase and decrease of the eccentricity of the moon's orbit. (*See* MOON.)

EVERGREENS, *ev'-er-greens*.—Trees and shrubs which do not shed their leaves in autumn, but retain their verdure throughout the winter. Firs, heaths, laurels, rhododendrons, bay, holly, myrtle, and ivy are very familiar examples. The leaves of evergreens are generally of firmer texture than those of deciduous trees and shrubs.

EVERLASTING FLOWERS.—A popular name given to some plants of the order *Compositæ*, the flowers of which may be dried and kept for a long period without losing much of their beauty. The name is sometimes applied to various species of cudweed; but the plants mostly belong to the genus *Helichrysum*, which contains a great number of species, none natives of Britain. The *Immortelles* woven into circular wreaths and placed on graves are forms of the everlasting flowers.

EVIL, KING'S. (*See* KING'S EVIL.)

EVOLUTE AND INVOLUTE, *ev'-o-lute, in'-vo-lute*.—Terms applied relatively to particular curves, the nature of which has been thus simply described. If a string be closely wrapped on a curve, fastened at one end and free at the other, the curve described by a pencil attached to the free end as the string is unwound, is called the involute of the first curve, which is known as the evolute.

EVOLUTION AND INVOLUTION.—In Algebra, the former term is applied to the extraction of roots, and the latter to the raising to powers. (*See* EXTRACTION OF ROOTS.)

EVOLUTION OF SPECIES.—The theory of development elaborated by Darwin, but partially anticipated by Lanarck and others, which asserts that the various species of plants and animals, instead of being each specially created and immutable, are continually experiencing change through a process of adaptation, by which these varieties of a species that are in any way better adapted for their conditions of life survive and multiply at the expense of others. This theory is sometimes expressed in the phrase, "survival of the fittest." Darwin considered that all existing species may have descended from one—or, at any rate, a very few low forms of life. (*See* SPECIES.) Evolution of more complex from more simple organisms does not necessarily form a linear series; and, with regard to the theory of the origin of many animal and vegetable forms from a common stock, some members of a group commonly manifest such modifications as render them permanently unlike their kindred, of whom the majority retain for a longer or a shorter time their original characters. Evolution does not mean change of matter as well as of the relation of its parts; fresh matter not being essential to it, since the phenomena are, as a matter of fact, re-arrangements of that which exists.

In Astronomy, the nebular theory includes the evolution of planetary bodies from incoherent fragments, which not only come into relation with each other, but in the process become grouped together so that the mass comes to consist of parts.

In Geology, evolution means not merely change in obedience to constant laws, but change under the influence of laws, the operation of which varies with the conditions under which they act.

EWE, *yu*, the female of the sheep. (*See* SHEEP.)

EXANTHEMATA, *ex-an-the'-ma-ta* (Gr., to come out in a rash). A class of febrile diseases attended by eruptions on the skin, small-pox, measles, and scarlet-fever are well-known examples.

EXCRETION, *ecks-kre'-shun*, the throwing off by means of the skin, the kidneys, and bowels of the human body, such matters as if retained would be injurious to health.

EXHAUSTIONS, METHOD OF, *egz-hawst'-yuns.*—A mode of proving mathematical propositions regarding quantities by continually taking away parts of them. The method was frequently employed by the ancient geometers.

EXIDIA, *ek-sid'-e-a*, a genus of Fungi. The species *E. Auricula Judæ*, Jew's ear, is reputed to possess astringent and discutient properties, when applied externally as a decoction or poultice. *E. hispidula* is used in China as a styptic, and as food mixed in soups and hashes. It is known there under the name of *Moghi*, which signifies "ears of trees."

EXOGENS, *eks'-o-jens* (Gr., *exo*, without; *ginomai*, I am formed), plants with stems that increase by external concentric layers—as the beech, ash, and oak. The class *Exogenæ* of some botanists corresponds with the class *Dicotyledones* (which *see*).

EXOGONIUM, *ex-o-go'-ne-um* (Gr., *exo*, without; *gonia*, angle), a genus of *Convolvulaceæ*. The species *E. purga* is a native of Mexico, near Chincanquiaco. Its tubercular roots constitute the true jalap of the Materia Medica, so well known as a purgative.

EXOSMOSE, *eks-os'-mose* (Gr., *ex*, out of; *osmos*, impulsion), the passage from within outwards of fluids or gases through a membranous separation. (*See* ENDOSMOSE.)

EXOSTEMMA, *exks-os'-tem-ma*, a genus of trees and shrubs of the order *Cinchonaceæ*, natives of America. Caribbee bark and St. Lucas bark, valuable febrifuges, are obtained from trees of this genus.

EXOSTOSIS, *eks-os-to'-sis* (Gr., from *ex*, out of, and *osteon*, a bone), is a term applied to a morbid enlargement or hard tumour of a bone. This term is applied properly only to osseous tumours on the bones, though it is also sometimes applied to other morbid growths. Exostoses are easily distinguished from other swellings by their being fixed and immovable, and at first unattended with any pain or inconvenience. There are three varieties—the solid, the hollow, and the foliated. There is no bone that may not become the seat of this disease, though some are much more subject to it than others. No external treatment is of any benefit in this disease; and when it is necessary that they be removed, and can be done with safety, it is effected by sawing or cutting.

EXPANSION, *eks-pan'-shun* (Latin, *expansio*), a term applied to the enlargement or increase of bulk in bodies, generally produced by heat. This effect is one of the most common and obvious results of the raising of temperature in all bodies, solid and liquid. Among the solids, the metals are the most expansible by heat. In most cases all bodies contract when the temperature is lowered; but there is a remarkable exception to this rule in the case of water, which begins to expand when lowered to 40° Fah. (*See* WATER.) Aëriform bodies are the most expansible forms of matter.

EXPECTATION OF LIFE, *ex-pek-ta'-shun.* (*See* PROBABILITY.)

EXPECTORANTS, *eks-pek'-to-rants* (Lat., *ex*, out of, and *pectus*, the chest), substances which promote the expulsion of mucus, or other matters, from the air-passages of the throat and chest. Vapours are the only agents that can act directly upon the organs affected; those that are taken into the stomach being only capable of acting in an indirect manner. The inhaling of the vapour of warm water simply, or mixed with certain medicinal substances, as vinegar, is very useful in this way. Most medicines which, taken in large doses, act as emetics, are used as expectorants. The expectorant most commonly used in ordinary cases is the syrup of squills. All substances, also, which excite irritation at the upper part of the windpipe, and produce coughing, act as expectorants. When there is decided inflammation, the best expectorants are such as lessen the inflammatory state.

EXTRACTION OF ROOTS.—(*See* CUBE and SQUARE ROOTS.)

EXTRAVASATION, *eks-trav-a-sai'-shun* (Lat., from *extra*, without; and *vas*, a vessel), a term applied to fluids which are out of their proper vessels or receptacles. Thus, an extravasation of blood takes place when an artery or vein is injured, and the blood escapes into the cellular membrane; and an extravasation of urine, when, in consequence of a wound or ulceration, that fluid makes its way into the cellular substance, or among the abdominal viscera. Extravasation is distinguished from exudation, in that, in the latter case, the walls of the vessels remain entire, and the fluids escape by secretion. The discolouration that follows contusions is occasioned by the extravasation of blood into the cellular tissue under the skin, from the rupture of small blood-vessels.

EXUVIÆ, *egs-u'-ve-e* (Lat.), a word applied to the cast-off skin of any animal, reptile or shell-fish, which is "shed." In the more warm-blooded classes, the moulted feathers of birds and the hairs of various species of *mammalia* may be looked upon as *exuviæ*, or exuvial deposits; as also the small scales of what is termed scarf-skin, which are continually cast off from our own bodies.

EYE, *i* (Ang.-Sax.), the organ of vision is one of the most wonderful and delicate portions of the animal body. It is placed within a bony cavity, termed the orbit, pyramidal in form, with the base anteriorly, and directed a little outwards, and the apex backwards and inwards. The orbit contains the globe of the eye, with numerous muscles, nerves, vessels, fat, &c. The external appendages of the eye are the eyebrows, eyelids, and lachrymal apparatus. The eyebrows, or *supercilia*, are arches of hair covering the supra-orbital ridge of the frontal bone on each side, and extending from near the root of the nose to a little beyond the outer canthus of the eye. They serve to prevent the sweat from falling into the eyes, and to protect them against a strong light The eyelids, or *palpebræ*, are two thin curtains which cover the eye, the one being inferior, the other superior. Where they join outwardly is called the *external*, and inwardly towards the nose the *internal canthus*. The margin of the eyelids, which is cartilaginous, is called *tarsus*. Along the margin of each eyelid is a row of stiff hairs, termed *cilia*, or eyelashes and which serve to keep external bodies out of the eyes, and moderate the influx of light. Within the lids, near their edges, are numerous glandular bodies, named after their discoverer, the *Meibomian* glands, and secrete an oily or mucilaginous fluid, which lubricates the eyes and lids, and facilitates their movements. The lachrymal gland is situated in a small depression of the frontal bone near the external canthus, and from it seven or eight canals issue, called the lachrymal ducts, and open on the internal surface of the upper eyelid; it secretes the tears, which then pass along the surface of the eye to the *puncta lachrymalia*, which are two callous orifices or openings, one in each lid, at the internal angle of the tarsus. From the lachrymal points the tears are conveyed by the lachrymal canals into the lachrymal sac, which is a membranous receptacle situated in the internal canthus of the eye. The nasal duct is a membranous canal, extending from the inferior part of the lachrymal sac downwards, backwards, and outwards, into the cavity of the nose. The lachrymal caruncle (*caruncula lacrymalis*) is a small fleshy body, of a red colour, composed chiefly of mucous follicles, and situated in the internal canthus of the eye. The globe or ball of the eye is composed of membranes or coats, humours, vessels, and nerves. The *membrana conjunctiva*, or conjunctive membrane, is a delicate mucous membrane, lining the internal parts of the eyelids, and covers the whole of the anterior part of the globe of the eye. The outermost coat of the eye is the sclerotic (Gr., *skleros*, hard), so called from its hardness. It is a strong, dense, white, fibrous structure, covering about four-fifths of the ball, and leaving a circular deficiency in front, which is occupied by the cornea. The latter, so named from its horny appearance, is the transparent covering in front of the eye, its edges being slightly over-lapped by the sclerotic coat. Externally it is covered by the membrana conjunctiva, and internally it is in contact with the membrane of the aqueous humour. It is convex anteriorly and concave posteriorly, and is composed of several laminæ, or layers. The choroid membrane is of a black colour, and covers the internal surface of the sclerotic coat, with which it is loosely connected by connective tissue. Near its anterior margin it is thrown into numerous folds or processes, alternately long and short, and which lie upon the edge of the lens and anterior portion of the vitreous humour: they are called ciliary *striæ* or processes and conjointly the *corpus ciliare*. On the outer surface of the choroid are seen the ciliary nerves and long arteries; next come the veins called, from the peculiar manner of their arrangement, *venæ vorticosæ*): next is the *tunica Ruyschiana*, composed chiefly of ramifications of minute arteries, forming a beautiful network; and next to this is the *tunica pigmenti*, composed of pigment-cells, usually of a hexagonal form, and secreting on its inner surface the *pigmentum nigrum*. The retina, or inner coat of the eye, consists of three layers of membranes, the outermost of which, in apposition with the choroid, is an extremely delicate membrane, termed the *tunica Jacobi*. The middle one, *tunica nervosa*, is in reality the expansion of the optic nerve, and terminates at the edge of the ciliary processes. The inner coat is the *tunica vasculosa retinæ*, which is vascular in texture, and contains several minute branches of the central artery of the retina. On the inner surface of the retina, at the back of the eye, and in a line with the axis of the globe, is a circular yellow spot, called the *limbus luteus*, in the centre of which is an apparent orifice, named, after its discoverer, the *foramen* of Sömmering. The *iris* (Lat., a rainbow), so called from its variety of colour in different individuals, may be regarded as a process of the choroid, with which it is continuous, although the two membranes differ in structure. It is a thin, flat, circular, membranous curtain, hanging vertically in the aqueous humour in front of the lens, and having a central orifice, termed the pupil, for the transmission of light. Its anterior surface is coloured variously in different individuals, and its inner surface is lined with a substance resembling the pigmentum nigrum, called the *uvea*. It divides the space between the cornea and the lens into two chambers, communicating freely with each other through the pupil. The anterior chamber is about a fifth larger than the posterior, and is lined with a membrane, which secretes the aqueous humour. The external edge of the iris, by uniting with the choroid and sclerotic coats, forms a greyish circle, termed the ciliary circle or ligament. The iris is muscular in structure, and has great power of contracting or expanding the pupil, so as to admit more or less light into the interior of the eyeball. In the anterior and posterior chambers is the aqueous humour of the eye, which serves to distend the cornea to allow the free motion of the iris, and to direct the rays of light as they pass through it. The crystalline lens is a transparent body situated behind and opposite to the pupil, while its posterior surface is received into a corresponding depression on the fore-part of the vitreous humour. In form it is double convex, the posterior surface being more convex than the anterior; and it is invested by a transparent membrane called the *capsule*, which contains also a small quantity of fluid, called the *liquor Morgagni*. The lens consists of concentric laminæ, formed upon a hard, firm nucleus, and becoming softer as they tend to the outer surface. The vitreous humour, or *corpus vitreum*, lies in the concavity of the retina, occupying about four-fifths of the eye posteriorly, and being perfectly transparent. It is inclosed in the hyaloid membrane, which also sends numerous processes inwards, so as to divide it into a number of cells, and to equalise the pressure exerted on the different parts. It is penetrated by branches of the central artery of the retina. The eyeball is moved about in its orbit by six muscles, four of which are straight (*recti*) and two oblique—the superior and inferior. The four recti muscles have their origin at the apex of the orbit, and are inserted into the sclerotic coat near the cornea, above, below, and on either side. When acting together, they tend to fix and retract the eye; when separately, to raise, depress, or turn it to one side or the other. The superior oblique rises with the straight muscles, proceeds forwards to the upper edge of the orbit, where it passes through a small pulley of bone or cartilage, by which its direction is changed; and its course is then backwards, outwards, and downwards, to be inserted into the sclerotic coat. It serves to draw the eye downwards and outwards. The inferior oblique arises from a minute depression in the orbital plate of the superior maxillary bone, just within the margin of the orbit, at its lower part, whence it passes backwards, outwards, and upwards, to be inserted into the sclerotic, at its posterior part. Its action is to direct the eye upwards and inwards. The optic nerves, or second pair, after uniting to form the optic commissure, in which some of the fibres of each nerve cross to the opposite side, separate, and enter the optic foramen at the apex of the orbit. They pass through the sclerotic coat on the inner side of and below the axis of the eye, then through the choroid, and spread themselves out, and are lost or terminate in the retina. Branches of the third, fourth, fifth, and sixth pairs of nerves also proceed to the eye, for regulating the movements, &c., of the different parts. In sight, then, the rays of light in passing through the cornea are converged, so as to pass through the relatively small pupil, and impinge upon the lens, which, by the convexity of its surface and its greater density towards the centre, serves to converge the rays, and to correct the aberration. They then traverse the vitreous humour, and strike upon the retina. (*See* OPTICS.) The human eyeball (the head being fixed) is capable of a movement of 55 degrees sideways, upwards, and downwards. The greatest distance at which objects can be discerned by the human eye varies greatly, and it is not possible to speak with precision on the subject. The smallest square magnitude discernible by the ordinary eye is about 1-400th of an inch, but smaller bodies may be seen if they reflect light.

Comparative Anatomy of the Eye.—The eyes of animals of the class mammalia differ considerably from those of birds, insects, and fishes. In *mammals* the structure of the eye is almost identical with that of man; but there are occasional modifications suitable to the peculiar requirements of the animal. The eyes of *birds* are not spherical as in the mammalia, but flattened anteriorly. The cornea is very prominent, and there is a much larger proportional amount of aqueous humour, and a greater distance between the lens and the posterior part of the retina. A series of bony plates extend backwards from the margin of the cornea, and are embedded in the sclerotic. These plates, acted upon by the muscles of the ball of the eye, cause a protrusion of the aqueous humour and of the cornea, adopting the eye for near vision; and relaxation of the muscles causes a recession of the humour and flattening of the cornea, fitting the eye for distant vision. This power of varying the focal distance is of great use to birds, especially birds of prey. Birds have also a lower as well as an upper eyelid, and an elastic fold, which in a state of repose lies in the inner angle of the eye, termed the *membrana nictitans*. The chief peculiarity of the eye of a *fish* is the size, extreme density, and spherical shape of the lens, which magnifies objects so considerably that it has been used as a simple microscope. The pupil is large, but generally motionless, and there is no lachrymal apparatus, none being necessary as the eye is constantly washed by the water in which fishes live. *Insects* have simple and compound eyes usually associated in the same individual. The simple eyes have a general resemblance to those of animals of the higher order. The compound eyes are wonderful structures, consisting of an extraordinary number of hexagonal facets or corneæ. Some beetles have more than 25,000 of these facets—each a perfect organ with lens, iris, pupil, and a nervous apparatus—in each compound eye. Many of the *crustaceans* also have compound eyes.

EYE, DISEASE OF THE.—This organ, from its delicacy and the numerous parts of which it is composed, is subject to a great variety of diseases, most of which will be noticed under their own names in different parts of this work. (*See* AMAUROSIS, LACHRYMAL ORGANS, OPHTHALMIA, SQUINTING, &c.) We shall here, therefore, only give an account of *cataract*, which has been referred to this place. It is derived from the Greek verb *katarasso*, I disturb or confound, and is usually defined to be a weakness or interruption of sight, produced by opacity of the crystalline lens or its capsule. Sometimes it is applied to every perceptible obstacle to vision situated in the posterior chamber between the vitreous humour and the uvea. When the disease is situated in the lens or its capsule, it is called a true cataract; but when it consists of opaque matter deposited in front of the lens, it is termed spurious. The latter arises from inflammation, and is to be treated by the usual means employed for allaying inflammation; but no operation can be of use in such a case. Of true cataract three kinds are distinguished;—*lenticular*, affecting the lens alone; *capsular*, affecting the capsule; and *capsulo-lenticular*, affecting both lens and capulse. Lenticular cataracts are of two kinds—*hard* and *soft*; the former being the more common, especially among elderly persons, and is usually of an amber-colour or brownish tint, and generally deep in proportion to its firmness. Soft cataract prevails in childhood and middle life, and occurs more frequently single than the other. A cataract may be occasioned by active inflammation or external violence, or it may arise from internal or unknown causes. Frequently it proceeds from an hereditary disposition which has existed for several successive generations, and sometimes it attacks several members of the same family, without any evidence of its being hereditary. The habitual examination of minute objects in a depending position of the head, by which an undue proportion of blood is thrown upon the organ, is said frequently to bring on cataract. It may make its appearance at any age, but is most frequently in elderly persons, though children are by no means exempt from it, and may be even born with it. It comes on without pain, and the symptom first perceived is a dim haziness of sight, as if a mist or thin film were interposed between the object and the eye. The obscurity is greatest in direct vision, the opacity being almost always first noticed in the centre of the pupil. Hence the sight is better in a weak than in a strong light, because in the former case the pupil is enlarged, and admits the passage of the rays through the less opaque edge of the lens. Hence, too, the remarkable effect produced by the application of belladonna to the eye, which has the power of dilating the pupil and producing a temporary improvement in the sight—a means sometimes had recourse to by quacks, who profess to be able to cure this disease. There is no medicinal remedy that is known to have any effect upon this disease, nor is it at all likely, from the structure of the parts, that any such remedy exists. All palliative measures, therefore, are confined to attention to the general health of the patient and the removal of any inflammatory symptoms that may exist along with it. The only mode of cure is actual removal by an operation; but so long as one eye remains unaffected, the operation may be delayed. There are three modes of operation employed for the removal of cataract, each of which has its advocates, and any one of which may be best, according to circumstances. The first is by *extraction*, or the removal of the lens, and is effected by making an incision through the cornea as near the iris as possible, and then, by means of a needle, opening the front of the capsule, and gently removing the lens. The second method is the displacement of the lens from the axis of vision by what is called *couching* (Fr., *coucher*, to lie down) or *depression*. A needle is inserted through the fore part of the white of the eye, and is brought to bear upon the lens, pressing it back and down into the vitreous humour; and the opaque body being thus removed, sight is restored. The third method, by *absorption*, is effected by puncturing the front of the capsule, and thus admitting the aqueous humour to act upon the cataract; by which means it is absorbed. All these operations require great care and skill in the operator, and the setting in of inflammation has to be specially guarded against.

EYEBRIGHT, *i'-brite*, a genus of plants (*Euphrasia*) of the natural order *Scrophulariaceæ*. Some are root parasites. The common eyebright (*E. officinalis*) is the only British specimen. It is a little plant, six or seven inches high, with white or reddish flowers, streaked with purple, appearing singly in the oxits of the leaves. In mountainous regions the plant is very minute. It is in great repute in rustic domestic medicine as a cure for diseases of the eye. Milton refers to it as "euphrasy."

F.

FAAM, OR FAHAM, an orchid (*Angræcum fragrans*), native of India and the Mascarene Isles. The fragrance of its leaves makes it much valued in the east; and in some parts an infusion of the leaves is considered to be a cure for pulmonary consumption and some affections of the stomach. The leaves are sold in France, under the name of Isle of Bourbon Tea, as an expectorant and anti-spasmodic.

FABA, *fai'-ba* (from Gr., *phago*, I eat), the Bean, a genus of the natural order *Leguminosæ*, sub-order, *Papilionaceæ*. From the species *F. vulgaris*, formerly regarded as *Vicia faba*, all the cultivated varieties of the broad bean have been produced. The earliest garden variety is named the Mazagan, and the largest the Windsor. Of the field bean there are two sorts, the smaller being called *ticks*. Beans are largely used in feeding cattle, and are very nutritious. The garden beans form an important article of human food.

FABACEÆ, *fai-bai'-se-e*, a synonym for the natural order *Leguminosæ* (which *see*).

FACE, *fais* (Fr., *face*; Lat., *facies*; Ital., *faccia*), in Crystals, the terminal planes of a regular solid: thus, the cube has six faces, or flat surfaces.

FACIAL ANGLE. (*See* ETHNOLOGY.)

FACTOR, *fak'-tor* (Lat., *facere*, to form), in Mathematics, a term applied to each of the quantities which are multiplied into one another; in other words, to the multiplicand and the multiplier, in order to form a product. The term factor is also used in the same sense as divisor; so that any quantity that will divide another is a factor of it. The entire factors of 12 are 1, 2, 3, 4, and 6. Taken in pairs, the factors are 1×12, 2×6, 3×4, &c. The prime factors of a quantity are those factors which cannot be exactly divided by any other quantity except 1. Every number has 1 for a prime factor.

FACULÆ, *fak'-u-le* (Lat., *facula*, a torch). Spots brighter than the rest of the surface sometimes seen on the sun's disc.

FÆCES, *fe'-ses*.—The solid excrement ejected by animals from the intestinal canal, consisting mainly of such portions of food as are worthless in the office of nutrition.

FAGOPYRUM, *fai-go-pi'-rum*, the Buckwheat, a genus of *Polygonaceæ*. The fruits of *F. esculentum* and *tataricum* are used as a substitute for corn in the north of Asia and eastern Europe. The former species is cultivated in Britain as food for pheasants.

FAGUS, *fai'-gus*, the Beech, a genus of trees of the natural order *Cupulifera*. There are not many species, but all are forest trees of great beauty. The common beech (*F. sylvatica*) grows to a height of more than 100 feet, and has a trunk frequently four feet in diameter. It is a noble looking tree, with very long branches which often droop almost to the ground. In many parts of Europe there are large forests of beeches. The bark is smooth, often of a whitish colour, and the tree is remarkable for the number of hard wooden knobs, abortive branches, which occur in the bark. The leaves are thin and ovate with fine bristles on the margin. The male catkins are almost globular in shape; and the female flowers grow on the same tree. When the flowering is over, a sort of capsule is formed, which when ripe contains one or two nuts of a triangular shape, known as beechmasts. Light soils are best adapted to the beech, the roots of which do not go deeply into the ground, but spread horizontally under the surface. The timber is hard, but best adapted for weirs, sluices, &c., as it is very durable under water, but it is very liable to rot and the ravages of insects in dry situations. Cabinet-makers and turners use it for the framework of chairs and couches and for ornamental work; and in France the *sabots*, or wooden shoes, worn by the peasantry are almost invariably made of beechwood, because it does not absorb damp. The ashes yield large quantities of excellent potash; and raspings of the wood are used in the preparation of vinegar. The beech is a native of Europe, except in the coldest parts, and of the temperate parts of Asia and North-America. In Tasmania and Terra del Fuego, the beech (*F. betuloides*) is an evergreen. The beech of North America (*F. ferruginea*) forms extensive forests, and the timber is more valuable than that of the white beech.

Fagine.—A volatile, narcotic, poisonous principle found in the beechmast, chiefly in the rind. When the rind has been removed, the beechmast affords wholesome food for swine and poultry. It has a sweet taste, and contains a fixed oil, a starchy farina, sugar and an astringent substance. The oil, obtained by pressure, and well clarified, is sometimes used in cookery, but more commonly for lamps and in some manufactures.

FAINTING, OR SYNCOPE, *faint'-ing, sin'-kope* (Gr., from *sun*, with, and *kopto*, I fall down).—A sudden and total or partial unconsciousness, resulting from impaired circulation of the blood through the brain, occasioned commonly by diminished action of the heart. The functions of the nervous system, respiration, and the action of the heart, are either suspended or very much diminished in force. The causes of fainting are various; as any strong mental emotion, loss of blood, severe pain, or anything which tends to diminish the vital energy of the system. Usually the patient is first conscious of a singing in the ears, then the sight becomes confused and all the senses deadened; the countenance becomes deadly pale, and the limbs are unable to support the weight of the body, which sinks to the earth. Fainting, if occasioned by a diseased state of the brain or heart, or, if prolonged, may result in death; but if arising from any trivial cause, the patient in general speedily recovers. The patient should be laid on the back, with the head low, and the dress loosened about the neck; abundance of fresh air should be admitted, and cold water may be sprinkled on the face and neck, or ammonia applied to the nostrils. (*See* HEART, DISEASES OF THE.)

FALCON. (*See* FALCONIDÆ.)

FALCONIDÆ, *fal-kon'-i-de.*—Birds of this genus are distinguished from all other members of the family by the existence of a slight festoon on the lateral margin of the upper mandible, and also of an acute tooth on each side towards the apex. The wings are very long and pointed, the second and third quills being the longest; the tail is long and rounded: the tarsi is of moderate length, stout and reticulated; the toes usually elongated, and terminated by long curved and acute claws. The tongue is fleshy, sloped, and canaliculated. The falcons proper are distinguished from the ger-falcon by a tooth more strongly defined on each side of the upper mandible, which, among the others, is a mere festoon; the lower mandible is also much more sloped at its point than in the true falcon. The falcons are found in all parts of the world, and the number of species is very large. Their flight is very swift, and their courage certainly greater than that of other rapacious birds. Their flight is performed by regular continuous beats, with little or none of that sailing motion which characterises the kites. In capturing their prey, whether in the air or on the ground, they descend perpendicularly upon it. Their food consists, for the most part, of small quadrupeds and birds; but many of them also feed partly on reptiles and insects. The nests of these birds are rough and bulky, composed of sticks and twigs placed in the hollows of rocks or in trees. The eggs are usually laid at the close of winter or very early in spring: they vary in number from three to six, and are generally speckled with red or brown. (*See* GER-FALCON, GOSHAWKS, &c.)

FALL OF BODIES, *fawl* (Ang.-Sax.).—When a body is allowed to drop through the air from a great height, or is thrown upwards, or through the air in any direction, the course which it takes, and the rapidity of its motion from or towards the earth, is regulated in all cases by certain laws. The motion of a body projected through the air in a horizontal or oblique direction, and the path which it describes, are considered elsewhere (*see* PROJECTILES, THEORY OF); and it will be sufficient here to examine the rate of motion of a body moving towards or from the earth in a vertical line. If a person were to stand on the top of a very high tower, and drop a ball from his hand, it would fall to the earth, moving much more rapidly as it approached the ground than it did when it was first dropped from the hand at the top of the tower. Its motion downwards is found to be what is termed an uniformly accelerated motion; that is to say, a motion continually increasing at a certain rate; or, in other words, if a body be moving at a certain velocity at the expiration of one second from the point of time at which it was allowed to fall, it will be moving twice as fast at the expiration of two seconds, three times as fast at the end of three, and so on. Experiments have shown that the rate per second at which bodies acquire velocity if moving downwards through the air, or lose velocity if moving upwards, is $32\frac{1}{6}$ feet. (*See* GRAVITATION, PENDULUM.) This velocity acquired by a falling body in a second of time is called the measure of the accelerating force, which force is produced by the attraction of the earth. The velocity of a body at any period of its fall may be ascertained by multiplying the rate of motion at the end of the first second, or, as it is generally called, the measure of the accelerating force, by the number of seconds during which it has been falling. The velocity of a body at any period of its fall being known, the space or length through which it has fallen may be ascertained by multiplying the velocity at that period by the number of seconds during which it has been falling, and dividing the result by 2. Thus, if a body has been falling from a state of rest for 5 seconds, its velocity at the end of the fifth second will be $32\frac{1}{6} \times 5 = 160\frac{5}{6}$ feet per second; and the space through which it has fallen will be $160\frac{5}{6} \times 5 \div 2 = 402\frac{1}{12}$ feet. If a body be thrown from the hand with considerable force, instead of being dropped in the direction of the ground, its velocity at any period of its course will be found by adding the rate of motion that it would have attained at the end of any number of seconds, if allowed to fall from a state of rest to the initial velocity imparted to the body at the moment when it was launched from the hand. If a ball be thrown upwards into the air at a certain velocity, by a person standing on the earth's surface, its motion will become slower and slower, at the rate of $32\frac{1}{6}$ feet per second, until the force with which it has been propelled upwards is entirely counteracted and destroyed by the attraction of the earth, which now acts as a retarding force; and when its initial velocity has been thus exhausted, the ball will seem to be stationary for a very small fraction of time, and then descend, acquiring rapidity of motion at the same rate as a ball allowed to fall from the same height from a state of rest.

FALLING SICKNESS. (*See* EPILEPSY.)

FALLING STARS, *fawl'-ing*, meteoric bodies, supposed to be of a similar nature to aërolites. (*See* AËROLITE.) They appear to the observer to resemble stars suddenly falling from their position in the heavens, and vanishing after a flight of short duration, during which they seem to draw a brilliant train of light behind them. The diameter of these bodies is supposed to vary from 80 to 120 feet, and their rate of motion to

be between 20 and 40 miles per second; their distance from the earth, when visible to the beholder as falling stars, is considered to range between 20 and 150 miles, beyond which limit they become invisible. They generally appear singly, but sometimes in great numbers, almost resembling a shower of fire. It is also supposed that they occur with greater brilliancy at intervals of about thirty-four years. The last extraordinary display took place in November, 1866.

FALLOPIAN TUBES, *fal-lo'-pe-an*, so called after the anatomist by whom they were first described, are slender tortuous canals, about four inches in length, proceeding from the upper angle of the uterus. Their inner, or attached extremity, is narrow and cordlike; but they soon begin to enlarge as they proceed outwards, and at length they bend backwards and downwards towards the ovary, about an inch beyond which they terminate in an expanded extremity, the margin of which presents a number of irregular processes, named *fimbriæ*, one of which, somewhat larger than the rest, is attached to the outer end of the corresponding ovary. They serve as ducts of the ovaries.

FALLOW DEER (*Cervus Dama*).—This animal may be distinguished from the stag by the spotted coat, the spread and palmated horns, and the smaller size. It seldom measures more than three feet high at the shoulder. Its colour is reddish brown, spotted with white; but there is a variety which is of a nearly uniform dark brown. It attains full growth at the age of three years, and is said to live twenty years. The fallow deer's native country is the south of Europe and the south-western part of Asia. (*See* DEER.)

FAMILY, in Botany, a synonym for Order (which *see*).

FAN PALM.—A common name for palms which have fan-shaped leaves.

FARCEY, *far'-se*, a disease of horses, generally accompanying glanders, appearing in the form of ulcers.

FARINA. (*See* FLOUR.) Also sometimes applied to the pollen of flowers collected by bees.

FASCINATION BY SERPENTS, *fas-se-nai'-shun*.—A power possessed by some serpents, of exercising a kind of mesmeric influence over small animals, which appear to render them incapable of motion, and so an easy prey. The possession of such a power was long doubted by naturalists; but recent observers consider it as established.

FAST, *fast* (Ang.-Sax., *fæstan*), a partial or total abstinence from food, a due supply of which is necessary to maintain the body in a healthy and vigorous condition. The length of time during which a person may subsist without food is very various, even though we give no credence to those remarkable instances, some of which seem to be well authenticated, that are given of life being maintained in the circumstances for a number of weeks. In 1880, a Dr. Tanner, in America, voluntarily fasted for forty days, as an experiment. (*See* HUNGER.)

FATA MORGANA, *fa'-ta mor-ga'-na* (Ital.), a singular phenomenon of unusual refraction, seen in the Straits of Messina. It is sometimes called "the castles of the fairy Morgana."

FATHER LASHER.—The *Cottus bubalis*, the most spiny of the British species of *Cottus*. When touched, it distends its gill-covers, and sets out strong spines on the back of the head. It is of a brown colour above, and white underneath, and is marked and spotted in a singular manner.

FATS, *fats* (Sax., *fæt*, fat).—In Chemistry, these important compounds are so nearly connected with the fixed oils, that it will be necessary to consider the properties of both under one head. The fats and fixed oils form a well-defined natural group of organic compounds, occurring abundantly both in the animal and vegetable kingdoms. Although, in common language, we speak of coal oils and essential oils, neither of these must be confounded, chemically, with the true fixed oils. (*See* OILS.) The vegetable fats and oils are found in various parts of the plant, but they are most abundant in the seeds. In animals, fat is found distributed through most parts of the body in warm-blooded animals, while in fish, and cold-blooded animals generally, its place is taken by oils.

Fat on the Human Body.—The quantity varies considerably at different periods of life, being least at the growing time, and generally most at middle age. Some persons, however, appear to accumulate very little fat, no matter what food they eat; while others grow enormously fat without any special reason being obvious. The chief chemical use of the fat on the body is its power of exciting and supporting the animal heat.

FATUITY, *fat-u'-e-te* (Lat., *fatuitas*, from *fatuus*, foolish), denotes foolishness or weakness of mind. The fatuous are distinguished from the imbecile, or idiots, in that the mental powers which they once possessed have been impaired or extinguished, whereas, in the case of the latter, the mental powers have been deficient from birth. There are various degrees and kinds of fatuity. It may amount only to some incoherence of ideas and words, or the patient may be deprived of all consciousness; it may merely enfeeble the intelligence or memory, or it may pervert the moral nature. (*See* INSANITY.)

FAUCES, *faw'-seez* (Lat., plural of *faux*), the gorge or back part of the mouth, terminated by the gullet.

FAULTS, *fawlts* (Fr., *faute*, defect), in Mineralogy, a miner's term for any fissure accompanied by a displacement of the strata. Slip, slide, heave, pitch, and throw are also common miners' terms for the same thing.

FAUNA, *fawn'-na*, a term employed by naturalists to express the whole of the members of the animal kingdom living in a particular district, or at a particular time. Thus all the animals living in Great Britain constitute the British fauna. Those inhabiting the land form the terrestrial fauna, and those inhabiting the seas, the marine fauna. It is often applied, collectively, to all the animals of the world, the extinct species constituting the fossil fauna, and the living species the recent fauna. The word is derived from the Fauni, who were supposed to be the patrons of wild animals.

FAUVETTE, *fo-vet'* (Fr.), a name partially adopted in the English language for some of the little song birds of the warbler family (*Sylviadæ*).

FAVOSITES, *fai'-vo-sites*, a genus of lamelliferous corals found in Silurian, Devonian, and carboniferous strata.

FAVUS, *fai'-vus* (Lat., honey-comb), a disease of the skin, most commonly appearing on the scalp, of a fungoid character, and marked by incrustations of a yellowish character. It destroys the bulbs of the hair, and baldness generally follows. Unless cleanliness is strictly attended to it is contagious.

FAWN, an appellation given to a buck or doe of the first year. (*See* DEER.)

FEATHERS, *feth'-ers* (Ang.-Sax.), the general name for the exterior covering of birds. They consist of the *quill*, the *shaft*, and the *vanes*. The quill is a hollow semi-transparent horny cylinder, by which the feather is attached to the skin. It combines strength with lightness in a very extraordinary manner. The cavity of the quill contains a series of conical capsules united together by a central pedicle, forming the membranous remains of the original formation-pulp. The *shaft* is quadrilateral, with a smooth convex surface; it contains a white, dry, and very light pith. The *vanes* are subdivided into two parts—the barbs and the barbules. The sides of the shaft are covered with the barbs, and each barb forms of itself a small shaft, which is covered in a similar manner with little barbs on each edge. Those barbules are so firmly bound to each other, that although, in reality separate, they seem to adhere. The feathers of birds are changed at periodical intervals. This is called "moulting." Feathers vary in their size, form, and function, and in most cases are accompanied by an accessory plume, which is usually in the form of a small downy tuft.

FEATHER GRASS.—A genus of grasses (*Stipa*), remarkable for the long awns which have a very graceful appearance. The common feather-grass (*S. pennata*), is a perennial and is cultivated as an ornament in gardens.

FEBRICULA, *feb-rik'-u-la* (Lat., a little fever), a fever of short duration and mild character, known also as Ephemera, or "fever of a day."

FEBRIFUGE, *feb'-re-fuje* (Lat., *febris*, fever, and *fugo*, I drive away), a medicine administered as a remedy for fever.

FECUNDATION OF PLANTS. (*See* REPRODUCTION.)

FEELERS, in Entomology. (*See* ANTENNÆ.)

FEIGNED DISEASES, *fained* (Fr., *feindre*, to feign), are diseases which certain persons pretend to be afflicted with in order to avoid some duty, or in the hope of gain. The soldier, to escape the performance of duty; the mendicant, to impose on public or private beneficence; the criminal, to avoid the infliction of punishment, most frequently have recourse to these pretences. They are sometimes, however, had recourse to when no adequate motive can be assigned, and are difficult of detection in proportion to the skill with which they are simulated; and Fodère has observed that during the conscription in France the imposture had been "brought to such perfection as to render it as difficult to detect a feigned disease as to cure a real one." The diseases most commonly feigned are epilepsy, catalepsy, convulsions, blindness, deafness, palsy, insanity, indigestion, neuralgia, rheumatism, palpitation of the heart, ulcers, &c. Vomiting, spitting of blood, diarrhœa, and ophthalmia, are also often simulated. It frequently demands very considerable ingenuity on the part of the physician to detect the knavery of such persons. Perhaps the strongest light is thrown upon these cases by an examination of the involuntary functions. In diseases in which the pulse ought to be affected (and there are few which do not affect it), its condition will often lead at once to a detection of the imposture. There is generally, also, an aversion in persons feigning disease to take the proper remedies.

FELIDÆ, OR FELINA, *fe'-le-de* (Lat., *felis*, a cat), a family of the Cat kind, of the order *Carnivora*, in which the destructive organs reach the highest perfection, including the cats, lions, tigers, leopards, and lynxes. In these animals the head is short and almost rounded in its form. The principal instruments of the destructive energy of these animals are the teeth and claws. The canines are long, sharp, compressed, and cutting; the præmolars are furnished with two roots, compressed, pointed, and serrated; the flesh-teeth, or true molars, are very large, sharp-edged, and terminated by two or three points; and behind the flesh-tooth in the upper jaw there is a small tubercular tooth, which is wanting in the lower. In addition to this formidable apparatus of cutting-teeth, the tongue in these animals is covered with small recurved prickles, by which they can detach from the bones of their prey every particle of flesh. The palate is soft, and that part of the tongue which corresponds with it is smooth; as it advances forward, it is covered with large soft papillæ directed backwards; then there are four large fessulate papillæ, anterior to which the simple conical papillæ continue increasing in size to near the tip of the tongue. These papillæ are armed with the strong cuticular spines before mentioned. The five toes of the anterior and four toes of the posterior extremities of the cats are armed with very strong, hooked, sub-compressed, sharp claws, which are preserved from being blunted by a peculiar arrangement of the phalanges. For this purpose the claw-joint of each toe is drawn back by ligaments attached to the penultimate joint, until it assumes a perpendicular position, when the claw which it supports is completely retracted within a sort of sheath, and is entirely concealed by the fur. When, however, the animal springs upon its prey, the tendons of the flexor muscles of the toes implanted into the opposite surface of the phalanx overcoming the elasticity of the retractile ligaments, push forward the claws, and they are ready to be buried in the flesh of a victim. The lower surface of the foot is furnished with thick ball-like pads of the epidermis, upon which the animal walks; and these are the cause of the peculiarly noiseless tread which is characteristic of all the members of this family. It will be seen, on reference to any members of the cat tribe, that the mode of walking adopted by these creatures is different from that of man, monkeys, or bats. The weight of the body rests only on the toes, and not on the entire foot. The manner of walking is termed "digitigrade," from the Latin words *digitus*, a finger, and *gradus*, a step. Cats hunt in the gloom, and consequently, while escaping observation, require every ray of light that can be made available. The pupil is a long vertica lfissure; but this only obtains among the smaller genera; for in all the *Felina* that surpass the ocelot in size, the pupil again assumes a round form. "On the top of the skull there runs a tolerably high bony crest, which reaches its greatest elevation at the very back of the head.

This bone-ridge is intended for the attachment of the powerful muscles which raise the head and enable the animal to perform its prodigious feats of strength. The first two vertebræ partake of a similar enlargement to that which has already been observed on the back of the skull. The vertebra which is nearest to the head, and is called the 'atlas,' is broad and strong, and spreads laterally; while the second, or 'axis,' is long, and is developed upwards into a very powerful crest. The ribs are beautifully formed, and placed rather widely apart, giving plenty of room for the heart and lungs to perform their duties effectually. The vertebræ that fill the space between the ribs and the hip-bones are very large, and so exquisitely jointed together that they unite a graceful flexibility of movement with great muscular power." The senses of sight and hearing are extremely acute. The bulbs from which the long hairs, popularly known as "whiskers," arise are very sensitive to touch, and the whiskers in consequence are very useful to the animal when making its way through thickets, or other obstructions. The *Felidæ* are distributed in all parts of the world, with the exception of Australia, but principally in the warmer regions, where alone the larger species are met with. (*See* various headings.)

FELSPAR, *fel'-spar*, an important mineral, and common constituent of rocks. It is the representative of a family, and consists essentially of a double silicate of alumina and some alkali, or alkaline earth. It forms a principal constituent of granite. Potash felspar is the orthose of the mineralogist, and gives rise to kaolin, or china-clay, by disintegration. Soda felspar is albite, lithia felspar petalite, and lime felspar labradorite. The term is derived from the German, and means *field-spar*.

FEMALE, *fe'-mail*, the offspring-bearing sex of animals. Females are generally smaller and weaker, and, especially in the case of birds, of less attractive appearance than the males. The last remark very obviously does not apply to human beings; neither is it generally applicable to the higher classes of domestic animals. The mare, for instance, is quite equal in appearance to the horse.

FEMALE FLOWER, (Lat., *femella;* Fr., *femelle*, female; *fleur*, flower), a term used to distinguish those flowers which are furnished with pistils, or female organs, but which have no stamens, or male organs of production.

FEMORAL, *fem'-o-ral* (Lat., *femur*, the thigh). A term applied to parts of or connected with the thigh; as, the femoral bone, or *os femoris*, the femoral artery, &c. (*See* THIGH.)

FENNEC, *fen'-nek* (*Vulpes zaarensis; Canis Zerda* of Zimmermann), belonging to the carnivora, and chiefly found in Nubia and Egypt. This animal, which has given rise to much controversy, is generally placed by the French zoologists among the foxes; but the observations of Mr. Yarrell led him to pronounce decidedly that the fennec appears to him to belong to the genus *Canis*, the osteological part of its structure closely resembling that of the dog, and the pupil of the eye being circular. The fennec is of slight build, and seldom measures more than a foot in length, exclusive of the tail, which is fox-like and bushy, and measures eight inches in length. Its colour is very pale fawn, with a slight touch of jetty black at the base and the extremity of the tail. Although without doubt a carnivorous animal, the fennec is especially fond of the fruit of the date-palm, and is said to be able, and frequently to exercise his ability, to climb the lofty trees, and gather the dates. Bruce, who claims the honour of introducing the fennec to zoological science, asserts that it builds its nest in trees. In later times, however, it has been certainly ascertained that it burrows like the foxes. It is of nocturnal habit.

FENNEL. (*See* FŒNICULUM.)

FENUGREEK, *fen'-u-greek*, a genus of plants (*Trigonella*) of the natural order *Papilionaceæ*, sub-order *Leguminosæ*, and allied clover. The common fenugreek (*T. fœnum Græcum*, "Greek hay") is a native of the south of Europe, and of some parts of Asia. It is used as fodder for cattle.

FEOFFMENT, *fef'-ment* (Lat., *feoffamentum*, from the verb *feoffare* or *infeudare*, to enfeoff, or give one a feud), in Law, is applied to the most ancient and solemn method of conveyance. It is defined to be "the conveyance of any corporeal hereditaments from one person to another by delivery of the possession of the hereditaments conveyed, and evidenced by an instrument in writing;" for since the Statute of Frauds, 29 Car. II. c. 3, no valid feoffment can be made without a written instrument. The person that so gives or enfeoffs is called the *feoffor*, and the person so enfeoffed is termed the *feoffee*. This mode of conveyance included a very material ceremony, called livery of seisin, without which the feoffee had but an estate at will. This was the actual delivery of a portion of the land or real hereditaments conveyed, as a twig or a turf, to testify to the reality of the act; or, the parties being within view of the land, the feoffer, referring to it, gave it to the feoffee. This latter mode of delivery was ineffectual unless the feoffee entered into possession during the life of the feoffor. (*See* CONVEYANCE.) Feoffments are now little used, and actual or symbolical livery of seisin is rendered unnecessary by 8 and 9 Vic. c. 106, by which corporeal hereditaments are made to be in grant as well as in livery, and which declares that a feoffment shall not have a tortuous or wrongful effect.

FERÆ, *fe'-re* (Lat., *ferus*, wild), a term employed by Linnæus to distinguish the order of mammalia which subsist more or less exclusively upon the flesh of other animals. (*See* CARNIVORA.

FERMATA, *fair-mai'-ta*, in Music, a pause or resting point, generally marked by a dot within a curve placed over notes, which are then prolonged.

FERNS, an order (*Filices*) of acrogenous or cryptogamous plants. (*See* ACROGENÆ and CRYPTOGAMOUS PLANTS.) It consists of herbs with rhizomatous stems, and of arborescent plants. The leaves, or *fronds*, as they are generally called, arise irregularly from the rhizome, or are placed in tufts upon the apex of the stem; they are almost always circinate in vernation, and are simple or compound. The fructification consists of little somewhat rounded cases inclosing *spores*. These cases are called *sporangia*, and are collected in heaps, usually on the under surface or at the margin of the fronds, or rarely on the upper surface, or occasionally in a spiked manner upon a simple or branched rachis. The order is commonly divided into three sub-orders; namely, *Polypodieæ*, *Danæaæ*, and *Ophioglosseæ*. Ferns are found in greater or less abundance in every part of the globe. In the northern hemisphere, they are herbaceous plants of small size; but in the southern hemisphere, and in the tropics, they are sometimes aborescent, having stems occasionally fifty feet or more in height, and with the general habit of palms. There are upwards of 2,500 species, and are divided by botanists into *Danæaæ*, *Gleicheneæ*, *Hymenophylleæ*, *Ophioglosseæ*, *Osmundeæ*, *Schizææ*, and *Polypodieæ*. The last-named includes the great majority of all ferns, including many British species. The Hymenophilleæ, Osmundeæ, and Ophioglosseæ are exclusively British. Ferns are much cultivated in greenhouses and closed glass cases (*see* WARDIAN CASE), and their graceful and tender green fronds form a charming ornament. Several ferns have farinaceous rhizomes or stems, which, in certain parts of the world, are roasted or boiled, and eaten in times of scarcity. The fronds of several species possess slightly bitter, astringent, and aromatic properties, and those of others are mucilaginous, as those of the Maidenhair fern, which is used for making capillaire. The rhizomes of some are astringent and tonic, and occasionally possess well-marked anthelmintic properties. The silky hairs found on the rhizomes and stalks of some species have been used for stuffing cushions and as mechanical styptics.

FERONIA, *fer-on'-i-a*, a genus of the natural order *Aurantiaceæ*. The species *F. elephantum* is a large tree, growing in India. A kind of gum, closely resembling gum-Arabic, exudes from its stem. The young leaves have an anise-like odour, and are used in India for their stomachic and carminative effects. The fruit is known as the elephant or wood-apple.

FERRET, *fer'-ret* (Du., *vret;* Fr., *furet*).—This well-known animal, *Mustela furo*, is a native of Africa, but domesticated in Europe. Its habits are similar to those of the weasel, but it is more blood-thirsty. Its length is about fourteen inches, exclusive of the tail, which measures about five and a half inches; snout sharp; eyes red and fiery; colour commonly pale yellow, but sometimes partaking of all the colours usual in the weasel kind. In slightness of body and shortness of leg it likewise resembles the weasels. Ferrets are chiefly used to drive rabbits out of their burrows. In the pursuit of this latter sport, it was the custom in olden time to *sew* the lips of the ferret together before it was turned into the right burrow, and so prevent it doing anything but scare them out of the hole and into the hands of the watcher at the mouth of it. The modern system, however, is to muzzle or "cope" the ferret. This is accomplished by the use of two pieces of soft string, one of which is passed round the neck, and the other under the jaws, the four ends meeting at the back of the neck, and being there tied. The ferret is always to a certain extent a dangerous animal, and even when supposed to be domesticated, is likely to attack young children. Poultry should be strictly guarded from them. Cold is fatal to the domesticated ferret. It breeds twice a year, the production ranging from six to nine young ones at a litter. Sometimes the female will eat up her young, and in that case she is likely to litter three times in the year. The period of gestation is six weeks. The young are born and continue blind during an entire month, and at three months old are considered fit for "work."

FERRUGINOUS, *fer-rugé-e-nus*.—A term denoting the presence of iron in mineral water. (*See* CHALYBEATE.)

FESCUE, *fes'-kew*, a genus of grasses (*festuca*), nearly allied to brome-grass, with many flowered spikelets. There are many species found in nearly all parts of the world, including many valuable pasture and fodder grasses.

FETID LIMESTONE.—A variety of limestone (popularly known as stinkstone or swinestone) which, on being violently rubbed, or struck with a hammer, gives out an odour like that of sulphuretted hydrogen gas.

FETLOCK, *fet'-lok* (Ang.-Sax., from *foot-lock*), a tuft of hair which grows behind the pastern-joint of most horses; horses of diminutive size, however, have hardly any tuft. The term is now more generally applied to the joint on which the tuft in question grows.

FEVER, *fe'-ver* (Lat., *febris*, from, *ferveo*, I am hot), is the name given to a very numerous and important class of maladies. Among the features that are almost always present are spontaneous and painful lassitude, weakness of the corporeal and mental faculties, alterations of the secretions, altered animal heat, quickened circulation, and increased thirst. One of the earliest and most constant symptoms of fever is lassitude, and is usually attended by a painful or irksome sensation in the back and limbs. It is manifestly referable to a depressed state of the nervous energy, more particularly as regards the organic nervous system. Some of the mental powers are more affected than others; as attention and the reasoning faculties, than the imagination. Alterations of the secreting and excreting functions are among the earliest and most constant, and most important phenomena of fever. The exhalations from the lungs and skin are the earliest and most affected; but, besides these, the salivary, gastric, hepatic, intestinal, and urinary secretions, are more or less altered as respects either quantity or quality; the alterations being somewhat different types and states of fever. The temperature of the body is also variously affected in the different stages. At first it is usually below, but it soon after rises above, the normal condition, and is generally accompanied with a certain morbid sensation which it is difficult to describe. Thirst is seldom wanting in fever, except occasionally in its advanced state; and the appetite for food is also diminished, or entirely abolished. Medical men distinguish various stages or periods in the course of fever which are characterized by features more or less marked; as (1) the formative or precursory stage, the earliest stage of the disease, being characterized by those early changes which are productive of those which constitute the developed disease; (2) the stage of invasion, when the earlier symptoms of the disease itself manifest themselves; (3) the period of excitement or reaction, when fever in its more literal sense begins, and manifests its specific form; (4) the period of crisis, when a sudden change takes place in the course of the disease, known as the crisis; (5) the period of decline which succeeds the crisis, and which passes into the (6) last stage—that of convalescence. Fever presents itself in a great variety of forms, the simplest of which is what is termed ephemera, or one day's fever. (*See* EPHEMERA.) If such an affection be supposed to recur several times every other day, with an interval of comparative health in the intervening days, a clear notion will be formed of *intermittent* fever in its most frequent and characteristic form—the tertian; and from the tertian may be derived all the other forms of intermittent fever. If, in the next place, the febrile state be conceived to be reinforced twice a day, or oftener, by a fresh attack of rigor or chilliness, with subsequent reaction before the pre-existing pyrexia had materially subsided, a distinct conception may be formed of remittent fever. From the remittent fever most nosologists deduce the only remaining primary type—continued fever, by supposing the remissions to become gradually less and less distinct; but others, with perhaps more reason, regard them as ephemera, merely prolonged to such a duration as that its several stages occupy between four and nine or eleven days. In accordance with these remarks, what are known as primary fevers may be divided into the three classes—continued, intermittent, and remittent fevers. The first class comprises synocha, or inflammatory fever; synochus, mixed, or nervous fever; and typhus, or adynamic fever. Intermittent fevers are divided into tertian, quotidan, and quartan; while remittent fevers comprise the marsh remittents, and probably also the yellow fever. Besides primary fevers, there are the irruptive class of fevers, comprising the small-pox, measles, and scarlet fever; and the irritative fevers, comprising gastric fever and gastro-intestinal, remittent, and hectic fever. (*See* various headings.)

FIBRE, *fi'-br* (Lat., *fibra*).—Animal, vegetable, or mineral substances which have a stringy or thread-like structure. In a general sense, it includes the hair and wool of quadrupeds, the threads enwrapping the cocoons of silkworms, &c., the fibres of the leaves of plants and of their inner bark, the elongated cells or hairs connected with the seeds of plants, and the ordinary materials used in making cordage and textile fabrics. Mineral substances are called fibrous in structure, even when it is impossible to detach the apparent fibres. The only fibrous mineral which has been used for textile fabrics is *Amianthus*, a variety of asbestos; but that only to a very limited extent. The animal substances used are divided into two classes; the first including hair and wool, and the second the silk of cocoons. Nearly all textile fabrics are made from the first, and the wool of the sheep is the most important division of the class. The hair of the goat, alpaca, camel, bison, and other animals, is also used. The hair of most animals is, however, in general, too short to allow of its being used for textile manufacture. The vegetable kingdom yields the largest number of useful fibres, which are obtained from natural orders very different from each other. The acrogenous or cryptogamous plants do not, however, afford any. From exogenous plants, fibres are obtained from the inner bark, as in the case of flax, hemp, &c., and from the hairs of the fruit, as in cotton. In endogenous plants, the fibre is sometimes obtained from the fruit, as in cocoa-nut fibre. The spathe of some palms is also used. Some of the slender palms called rattans, and the bulrush, &c., are much used, on account of their fibrous nature, for wicker-work, chair-bottoms, and similar purposes. The most valuable fibres obtained from endogenous plants come from the leaf or leaf-stalk. The fibres of the bark of exogens are readily separated, usually by steeping or continually moistening with water. As this process injures the colour of endogenous substances, the fibres are generally separated by heating or passing between rollers. Fibres obtained from fruits, as cotton fibre, like the wool and hair of animals, exist naturally in a separate state, and only require to be collected and cleaned. Amongst the useful vegetable fibres, those of flax, hemp, and cotton have long held the first place. The principal additions, of late years, have been New Zealand flax, jute, Sunn or Sunn hemp, coir, Pita flax, Abaca or Manilla hemp, China grass, and some others. One of the most important uses of vegetable fibre is in the manufacture of paper. Among exogenous plants whose fibres are used for economical purposes, are a species of gossypium which produces cotton; the *Bombax villosum*, which produces silk-cotton, or vegetable silk; and the *Asclepias syriaca*, producing the silk-like down of Virginian silk. These three substances are obtained from the fibres of the fruit. Those obtained from the inner bark include the following:—several species of Hibiscus, producing Deckanee hemp; the *Corchorus olitorius*, from which jute is obtained; the *Linum usitatissimum*, producing flax; several species of the Crotolaria; together with other leguminous plants, producing Sunn, Jubbulpore hemp, &c.; several species of Bœhmeria, one of which produces China-grass fibre; the *Cannabis sativa* producing hemp; and the inner bark and roots of some species of pine and fir. Among the endogenous plants from which fibres are obtained, are the *Phormium tenax*, yielding New Zealand flax; *Agave americana*, yielding Pita flax; some species of Musa, from the leaves of which are obtained Abaca or Manilla hemp, and plantain fibre; several species of Bromelia, from which are obtained pine-apple fibre, &c.; the husk of the cocoa-nut and the fibre of the stem yield coir; and mats, chair-bottoms, and other important articles in general use, are obtained from the fibre yielded by the leaves of the cotton-grass and other species of the natural order Cyperaceæ (which *see*).

FIBRIN, *fi'-brin* (from Lat., *fibra*, a thread), one of the constituents of the blood, and of muscular tissue. It occurs in two states—liquid in the animal organism, and solid by spontaneous coagulation, as soon as it is removed from the living body. It is contained in blood in a liquid state, in the proportion of 2·5 parts to 1,000, and coagulates in a very short time after the exposure of blood to the air. It constitutes a large portion of muscle, arranged in bundles of fibres; whence its name. According to Liebig, it is found in the juices of plants and in the gluten of wheat.

FIBULA. (*See* LEG.)

FICUS, *fi'-kus* (Lat., a fig), a genus of the natural order *Moraceæ*, consisting of trees and shrubs abounding in a milky juice. The most important species is *F. Carica*, the common fig, supposed to be a native of Asia Minor, but now found in all the southern countries in Europe. The fruit is termed a *cyconus* (which *see*), and is eaten green, and dried as a luxury in some countries, and as a common article of food in others. The finest dried figs are imported from Turkey, the best being known as Elemi figs.

In consequence of their nutritive, emollient, demulcent, and laxative properties, they are frequently employed in medicine. The fig-tree is cultivated in Britain, but not extensively. It is only in very warm situations that it will ripen its fruit in the open air, even though trained against a wall. When grown in houses built on purpose for it, the fig-tree is remarkably prolific. This fruit-tree is the *jennah* of the Bible. *F. Indica*, the banyan or banian tree, is another interesting species. (*See* BANYAN.) Its branches produce long shoots, or aëriel roots, which descend to the ground and penetrate the soil; so that, in course of time, a single tree becomes a vast umbrageous tent, supported by numerous columns. No fewer than 350 stems, each equalling in bulk the trunk of a large oak, and more than 3,000 smaller ones, have been counted in one example. The fruit of the banyan is of a rich scarlet colour, and about the size of a cherry; it is eaten by the monkeys, which live with birds and enormous bats in the thick forest of branches. The bark is a powerful tonic, and is much used by the Hindoo physicians. The white glutinous juice of the tree is used to relieve toothache, as an application to the soles of the feet when inflamed, and for making bird-lime. *F. elastica*, also a native of India, yields an inferior kind of caoutchouc. *F. Sycamorus*, the sycamore fig, is said to have yielded the wood from which mummy-cases were made.

FIELDFARE, *feeld'-fair* (*field* and *fair*, from Saxon, *faran*, to go) (*Turdus piralis*), a migratory bird, appearing among us about the beginning of November and departing at the end of April. It seldom breeds in this country. It is about the size of a blackbird, and of the following colours:—head, hind neck, and wings, grey; fore part of the back, chestnut; space before the eyes, brownish black; fore-neck and breast, reddish yellow; over each eye a whitish line; feathers tipped with a brownish triangular spot; those of the sides with large dusky spots, and margined with white; lower wing-coverts and axillary feathers, pure white. In Poland, Russia, and Austria, it is found throughout the year. It builds its nest in lofty trees, and feeds on worms and various berries.

FIG. (*See* FICUS.)

FIGHTING FISH, a small fresh-water fish (*Macropodus pugnax*) of the family *Anabasidæ*, a native of Siam and other parts of south-eastern Asia. It is remarkable for its love of fighting, and the Siamese find one of their favourite amusements in watching and betting on the fights of two of these fishes, kept in tanks for the purpose. The Siamese government licenses these fights, and derives a good amount of revenue therefrom.

FIGULINE, *fig'-u-line*. (*See* POTTER'S CLAY.)

FIGURE OF THE EARTH. (*See* EARTH.)

FILARIA, *fe-lai'-re-a* (Lat., *filum*, a thread), a genus of parasitic entozoa, common to large and small animals, and infesting even certain of the mollusca. Of this family the most inimical to the comfort of man is the Guinea-worm (*Filaria medinensis*), which, in hot climates, insinuates itself under the skin of the lower members, causing excruciating pain. It has a slender and thread-like body, and sometimes attains a length of six feet. It is met only in certain portions of the torrid and temperate zones in Africa and Asia, and is especially frequent on the African coast. At the meeting of the British Association for the advancement of science, in 1862, Dr. Cobbold stated that it was possible for one human body to contain 37,000,000 very minute organisms of this character.

FILBERT. (*See* CORYLUS.)

FILE-FISH. (*See* BALISTES and MONACANTHUS.)

FILICÆS. (*See* FERNS.)

FIN, *fin* (Sax., *finn*), a flat expanded organ, projecting from the bodies of fishes, and used as an instrument of locomotion in the water. The fins of fishes are supported by elongated filamentary bones or rays, by the number and nature of which the naturalist is able to distinguish the various groups. Many species of the whale tribe possess an immovable fin upon the back, composed merely of a reflexion of integument over a mass of dense and ligamentous cellular membrane. The tail fin has the same structure, but is moved by the action of muscles upon the caudal vertebræ, which are continued through the middle part.

FINCHES, *fin'-tshes* (Sax., *finc*), a family of birds belonging to the order *Passeres*, and the division *Conirostres*, and known by the general name of *finches*. This family embraces, in addition to the *Alaudinæ*, or larks, to which the buntings, or *Emberizinæ*, seem nearly allied, the greater part of the Linnæan *Fringillidæ*, with the Linnæan *Tanagrinæ* (tanagers), which approach these in their external characters and in their habits. None of the finches are of large size, and in their habits and general appearance there is a strong likeness. For the most part they are hardy birds. Their food chiefly consists of grain, worms, and insects. The characteristics of this family of birds are—beak straight, longer than deep, conic and pointed; mandibles nearly equal, cutting edges entire, forming a straight commissure; nostrils basal, lateral, oval, partly hidden by the frontal plumes; wings with the first quill-feather longer than the fifth, but a little shorter than the second or third, which are equal, and the longest in the wing; legs with the tarsi of moderate length; toes divided, and adapted for hopping and perching; claws curved and sharp.

FINSCALE, *fins'-kale*. (*See* RED-EYE.)

FIORIN, *fi'-o-rin*. (*See* BENT GRASS.)

FIR.—A name frequently applied to all trees of the natural order *Pinus*; but also, and in a more restricted signification, for the genus *Abies*. (*See* ABIES, CONIFERÆ, PINE, SPRUCE, FIR, &c.)

FIRE, *fire* (Sax., *fyr*), heat and light emanating visibly, perceptibly, and simultaneously, from any body.

FIRE-BALL, in Meteorology, globular masses of fire moving through the atmosphere. (*See* METEORS, and SHOOTING-STARS.)

FIRE-CLAY, a variety of clay capable of bearing a great heat without melting or vitrifying. This arises from the absence of any alkaline earth to act as a flux. Stourbridge clay is one of the most famous, and is used largely in the manufacture of glass pots. It contains 64 per cent. of silica, 24 of alumina; the rest being oxide of iron, water, and traces of carbonaceous matter.

FIRE-DAMP, a miner's term for the light carburetted hydrogen of the coal-mines, from its inflammability, in contradistinction to *choke-damp*, which chokes or extinguishes flame.

FIREFLY, a name commonly applied to those insects which have the power of emitting a luminous appearance from their bodies. (*See* GLOWWORM, &c.) They are all, except the lantern-fly (which *see*), coleopterous, and belong to the two nearly allied tribes, *Lampyrides* and *Elaterides*. Insects of this kind are very common in Mexico, where ladies use them as ornaments for head-dresses. The light emitted is so intense that one of them is sufficient to enable a person to read in the dark at a short distance from it. Examined in the spectroscope, the light gives a continuous spectrum, but without lines.

FIRE, ST. ANTHONY'S. (*See* ERYSIPELAS.)

FIROLA, *fi-ro'-la*, a genus of gasteropodus molluscs, of the order *Heteropoda* destitute of shell. They are very elongated, and the mouth is situated at the extremity of a proboscis. They are almost transparent, and have sometimes golden spots.

FISH, *fish* (Sax., *fisc*) (*Pisces*), a name applied to animals exclusively aquatic, and occupying the fourth and lowest station of the section *Vertebrata*. The head is large, and set upon the neck without the intervention of any distinct neck; the body is usually of a spindle shape, tapering gradually towards the extremity; and the surface is usually smooth, without any irregularities which might impede the motion of the creature in its native element. In its general form, the body is usually rounded, or slightly compressed at the sides; sometimes this flattening proceeds to a much greater extent, so that the animal presents the appearance of a broad band, or oval disc, of which the edges correspond with the dorsal and ventral surfaces; in other cases, the flattening takes place from above downwards, producing a disc-like body, of which the upper and lower surfaces are dorsal and ventral. A fish may be shortly defined as an animal breathing through the medium of water, by means of gills; and in giving it our consideration, this latter apparatus is the most important feature presented. It is situated on each side of the neck, and consists of numerous laminæ fixed on arches. These laminæ are covered with innumerable blood-vessels, and are so constructed as to present a considerable surface to the water, so that the blood may receive a sufficient portion of the oxygen contained in that element. As the water in contact with the gills becomes deteriorated, it is necessary that a constant current be caused to flow over them. In most fishes this is effected by their taking water in at the mouth and expelling it at the gill-covers. The blood, which is constantly sent from the gills to the heart, is distributed by means of the arteries to every part of the body, whence it returns to the heart by means of the veins. Animals of this order are for the most part furnished with an air-bladder in the interior of the body, which, as it is often connected with the œsophagus by a tube, must be regarded to a certain extent analogous to the lungs of the air-breathing vertebrata. This sac or air-bladder, however, has nothing to do with respiration; it receives blood from the arteries, and returns it into the veins, and the air which it incloses is probably derived from this fluid. By the dilation or compression of this sac, the specific gravity of the fish is governed, and, acted on by a curious muscular apparatus, renders its possessor lighter or heavier than the surrounding element. The limbs of the fish are formed into fins; the fore-legs constituting what are termed the pectoral fins, and the posterior extremities, the ventral. Besides these, ordinary fishes are furnished with one or two dorsal fins, an anal fin, and a caudal fin, or tail. In some fishes, the dorsal or median fins are continuous round the whole posterior portion of the body; and this is the condition in which these organs first make their appearance, during the development of the embryo in all fishes, the subsequent changes which take place in the arrangement of the parts being due to the unequal development of the bony rays, which support and stretch the membrane of which the fins are composed. The pectoral fin in all fishes consists of the same parts as the anterior limbs of any other vertebrated animal. Concealed within the skin, immediately behind the branchial openings, is found a bony circle, composed of several pieces, representing the shoulder-blade, with the coracoid bone and clavicle. This supports the bones of the arm, which are usually very short, and bear a series of carpal bones at their extremity; the latter supporting a number of short cylindrical joints, whence the rays of the fin take their rise. The internal supports of the ventral fins never present such a close resemblance to the pelvis of the higher vertebrata as do those of the pectorals to the scapular arch. When situated in their normal position in the abdomen, they always consist of cartilaginous or bony pieces, lying freely in the muscles, and quite unconnected with the vertebral column; but when the fins are advanced from this position to the neighbourhood of the pectorals, their internal supports are attached to the scapular arch of the latter members. The principal organ of motion is the caudal fin, or tail: by this it is propelled. The dorsal and ventral fins serve to balance it, and the pectorals to arrest its progress when required. The bones of fishes are of a less dense and compact nature than in the higher orders of animals, and always remain in an isolated state similar to that of the embryo of the mammalia. The skeleton may be divided into four chief parts—the vertebral column, the head, the respiratory apparatus, and the limbs. The vertebral column consists of vertebræ which are concave at each end and pierced in the middle; and, when joined together, the hollow space between each two is occupied by a gelatinous substance, which passes from one space to the next, through the hole in each bone. This hole is usually very small; but in some instances, it is so large that the bodies of the vertebræ are mere rings. To the vertebræ are attached the ribs: in fact the ribs are the main support of all the other bones. The head varies more in form than in any other class of vertebrate animals. The same bones as those found in other oviparous animals are almost always traceable. The upper jaw consists of maxillary and intermaxillary bones. In the greater number of fishes, the intermaxillary bones constitute the chief portion of the upper jaw, the maxillary bones being placed behind and parallel to them. The lower jaw is composed, generally, of two bones on each side, the dental portion in front and the articular portion behind. The form of the body is for the most part such as mechanical principles teach to be best adapted for moving with least resistance through a liquid medium. The surface of the body is either smooth and lubricous, or is covered by closely-imbricated scales, rarely defended by bony plates or roughened by hard tubercles, still more rarely armed with spines. The central axis of the nervous system presents but one partial enlargement, and that of comparatively small size, at its interior extremity, forming the brain, which consists of a succession of ganglionic masses, most of them exclusively appropriated to the function of a nerve of special sense. The power of touch can be but feebly developed in fishes. The organ of taste is a very inconspicuous one; the chief function of the framework, supporting it, or the hyoidan apparatus, relating to the mechanism of swallowing and breathing. Of the organ of hearing there is no outward sign; but the essential part, the acoustic labyrinth, is present, and the semicircular canal, largely developed within the labyrinth, is without cochlea, and is rarely provided with a special chamber, but is lodged in common with the brain, in the cranial cavity. The eyes are usually large, but are seldom defended by eyelids, and never served by a lachrymal organ. The alimentary canal is commonly short and simple, with its divisions not always clearly marked, the short and wide gullet being hardly distinguishable from the stomach. The pancreas, for the most part, retains its primitive condition of separate cæcal appendages to the duodenum. The heart consists essentially of one auricle and one ventricle, receiving the venous blood and propelling it to the gills; whence the circulation is continued over the entire body, in vessels only, which are aided by the contraction of the surrounding muscular fibres. The blood of fishes is red but cold, and is rarely elevated above the temperature of the surrounding element. The sexes of fishes, excepting the sharks and rays, offer no very decided external characters by which they may be distinguished. The respiratory organs, however, occupy more space in the males than in the females; and, on the other hand, the abdomen is larger in the females than in the males. Fish are oviparous, or egg-producing; but in some cases the eggs are hatched within the body, and the young produced alive. The chief reproductive organs are generally two elongated lobes, known as "milt" in the male, and "roe" (consisting of rudimentary eggs) in the female. Impregnation usually takes place after the roe or spawn is deposited. Many fishes are gregarious, swimming in enormous shoals; and some make periodic migrations. The fecundity of fish is very wonderful. The number of eggs in the spawn of a cod has been found to be about 91,000,000, and of a flounder, 14,000,000; of a mackerel, 540,000: and the salmon is far more productive still, the ovarium of one female salmon having been known to produce 20,000,000 eggs.

Fishes, Royal, or those which at common law are the property of the crown—are the whale and the sturgeon—when either thrown on shore or caught near the coast. In olden times, these fishes were considered too precious for a subject; and the right was strictly claimed by the sovereign, and is expressly mentioned in a statute referring to the royal prerogatives passed in the reign of Edward II. In the case of a whale, the head only was claimed by the king, the tail being reserved for the queen-consort.

FISH-HAWK. (*See* OSPREY.)

FISSIROSTRES, *fis-se-ros'-treez* (Lat., *findo*, I cleave; *rostrum*, a beak), the name of a tribe of birds, consisting of the swallows, swifts, and goatsuckers, distinguished by having the bill short, broad, depressed, slightly curved, without any tooth, and so deeply cleft as to give peculiar wideness to the gape; a structure of great use to birds which prey so exclusively on insects taken on the wing. On account of the food on which they subsist, all the fissirostres migrate from northern countries towards the close of autumn, and return again in spring.

FISSURELLIDÆ, *fis-sure-el'-i-de.*—A family of gasteropodus molluscs of the order *Scutibranchiata*. The shell generally resembles that of the limpet, but has either a hole at the apex or a slit at the front margin.

FISTULA, *fis'-tu-la* (Lat., a pipe or reed), a long and sinuous ulcer, having a narrow opening, sometimes leading to a larger cavity, and which has no disposition to heal. The most common form of this disease is the *fistula in ano*, the sinus extending into the cellular substance about the anus, or into the rectum itself. It is the result of abscesses formed in the cellular tissue around the rectum, and which, having burst or been opened, are prevented from healing by the action and irritation of the sphincter ani. They are divided into two kinds—complete and incomplete, or blind; the former having two openings or outlets, the one externally, the other into the rectum; the latter having only one, and being divided into blind external and blind internal, according as the opening is external or internal. This disease is commonly attended with intense pain, especially when passing the fæces, and there is an irregular discharge of purulent matter, which is sometimes mixed with blood. The treatment consists in making a complete division with the knife of the whole of the parts between the fistula and the bowel, and the edges of the wound are kept apart by lint, in order to allow the cavity to fill up by granulation. A *fistula lacrymalis* is a disease of the lachrymal sac, caused by an obstruction to the flow of tears along the nasal duct. The symptoms of this disease are a watering of the eye, with a dryness of the corresponding nostril, a distension of the lachrymal sac, and a discharge of muco-purulent fluid mixed with tears, from the puncta lachrymalia, when the sac is compressed. *Salivary fistula* is a fistulous aperture in one of the salivary ducts, opening externally, and through which the saliva escapes. It is generally caused by a wound, which, if recent, a cure may be effected by merely bringing together and uniting the edges of the wound; but if of some standing, a free canal ought to be formed for the discharge of the saliva into the mouth. In *fistula in perinæo*, which is almost always accompanied with a stricture of the urinary passage, the fluid passing out of the external opening of the sinus, an operation is necessary, which will require the aid of a competent surgeon. Fistulas generally require very skilful treatment and are often extremely difficult to close; and though not in themselves dangerous, they are not unfrequently attended with fatal results, arising out of the constitutional depression, which they occasion by the long-continued wearing pains, and the drain upon the system, in consequence of the protracted discharge. Fistula in ano is often observed in consumptive patients.

FISTULARIDÆ, *fis-tu-la'-ri-de*, known also as Flutemouth, a family of acanthopterous fishes, remarkable for the elongation of the skull into a tube, at the extremity of which are the mouth and jaws. One species (*Centriscus Scolopax*) is commonly named the Snipe-fish, the Sea-Snipe, or the Trumpet-fish.

FISTULINA, *fis-tu-lee'-na.*—A genus of Fungi, the under surface of which is at first covered with small tubercles, which afterwards become tubes. F. *hepatica* (so named from its resemblance, when decaying, to a mass of liver) is common on all trees, especially oak, walnut, and chestnut. It is of a red colour, semi-circular in form, and the substance resembles beet-root in appearance. Specimens weighing eight pounds have been found. It is esculent, wholesome, and nutritious, and in some parts of Europe is greatly liked. The taste resembles that of the mushroom. The best mode of cooking it is by broiling. (*See* FUNGI.)

FITCHET. (*See* POLECAT.)

FITS, the popular name of convulsions, or syncope, or sudden attacks of paralysis. Some etymologists suggest that the word is derived from "fights," or conflicts between disease and nature.

FIXED AIR, *fiksd* (Fr., *fixer*, to fix), an old term for carbonic acid applied by Dr. Black, who first observed the evolution, by the action of heat, of carbonic acid from the solid substance carbonate of magnesia.

FIXED OILS. (*See* OILS.)

FIXED STARS, the common name given to all stars in the heavens, with the exception of the planets. They are so called because they appear to us to be stationary in the broad field of the heavens, having no apparent motion, and always preserving the same relative position with regard to each other. They are supposed to be the centres or suns of other systems, similar to our own. Sirius, the dog-star, in the constellation Canis Major, which is the brightest of all the stars, is considered to be nearer the earth than any other; and the distance of this from our planet is computed to be not less than nineteen millions of millions of miles. The fixed stars have been grouped into separate clusters called constellations, and divided into six classes according to their respective apparent magnitudes, the largest and brightest being called stars of the first magnitude, those that are next in size and lustre stars of the second magnitude, and so on. Stars of the sixth magnitude are the smallest that are visible without the aid of a telescope.

FLACOURTIACEÆ, *fla-koor-te-ai'-se-e*, named after M. de Flacourt, a director of the French East-India Company. (*See* BIXACEÆ.)

FLAG, a general term for a number of endogenous plants, the leaves of which are sword-shaped. (*See* ACORUS and IRIS.)

FLAG-STONE, the name given to a rock, generally of sandstone, mixed with argillaceous or calcareous matter, which splits into tabular masses, or "flags," suitable for paving, the construction of cisterns, and similar purposes. The best flags come from North Wales, Yorkshire, and Caithness in Scotland.

FLAKES, *flaiks* (Ang.-Sax.), a layer or stratum in carnations with large stripes of colour. (*See* DIANTHUS.)

FLAME, *flaim* (Fr., *flamme*).—Flame may be defined as a shell of incandescent matter surrounding a mass of combustible vapour. To produce flame it is therefore necessary that the burning body should be capable of volatilization just below the temperature at which it undergoes combustion. A piece of wood or paper burns with a large luminous flame, in consequence of the combustible matter of which it is composed rising in vapour or becoming converted into mixed gases at the temperature required for kindling the substance. Flame is, in fact, produced whenever a continuous supply of inflammable vapour or gas is made to combine with a supporter of combustion, such as the atmosphere, at a sufficiently elevated temperature to cause ignition. The heating power of a flame is in direct proportion to the energy of the chemical action that takes place, those flames being hottest and least luminous which proceed from gases containing no solid particles, as in the case of a mixture of oxygen and hydrogen in the proportion necessary to form water, which is one of the hottest flames we have at our command. The most luminous flames are from gases which contain just sufficient solid matter to give the maximum of incandescence without any of its particles passing away unburnt. The flames used for illuminating purposes are all produced by the combustion of compounds containing carbon and hydrogen. The flame of an ordinary candle is a good illustration of the phenomena of flame. At the lower, or blue portion, the hydrocarbon contained in the gases resulting from the decomposition of the tallow by heat, mixed with so much atmospheric air that the whole of the carbon unites with hydrogen, none being left to give incandescence. Passing higher up, we see a dark part, which consists entirely of the gaseous matter formed by the decomposed tallow. This, on being heated by the blue portion of the flame, rises in luminous vapour until it comes in contact with the oxygen of the atmosphere, when it unites with it, forming a bright but not luminous envelope to the incandescent carbon—the products of the combustion being water and carbonic acid.

FLAMINGO, *fla-min'-go* (Sp.-Port., *flamenco*), a genus of birds (*Phœnicopterus*), generally ranked among the *Palmipedes*. This bird inhabits the warm climates of Asia, Africa, and America, and is one of the most remarkable of aquatic birds. Its height is about four feet. In its first year it is of one colour—greyish white; in its second year, the white is purer and the wings are tinted rose-colour; in the third year it attains its full plumage—wings roseate, back deep scarlet, and quill-feathers jet black; and as the bird grows older, these colours increase in tone. The neck is slender and of great length, equalling that of the legs, which are about two feet. The head is small and round, and furnished with a bill nearly seven inches long, which is higher than it is wide, light, and hollow, having a membrane at the base, and suddenly curved downwards from the middle, as if broken. The lower mandible, which is the larger, is so adjusted as to fit the angle with its edges, its under surface being greatly arched downwards. The edges of both mandibles are serrated. In operation, these mandibles act like a strainer, allowing the water to escape, but retaining any sort of prey the flamingo may capture. Its food consists of small fish and water insects, which it fishes up by means of its long neck, turning its head in such a manner as to take advantage of the crook in its beak. In searching among the mud at the bottom of the water for food, the upper, not the under, mandible is applied to the ground. In that situation the inferior mandible is uppermost, and by its motion works the disturbed water through the two. The flamingo's mode of incubation is peculiar. The great length of its legs, combined with the fact that the bird never sits down, but rests standing on one leg, renders a nest of the ordinary construction altogether unsuitable; so the flamingo constructs a tallish cone of mud, with a cavity at the top, and in this cavity the eggs are laid, and straddles across the whole, so that her feet rest on the ground and the under part of her body on her eggs. The latter are white, and rather larger than those of the goose.

FLATULENCY, *flat'-u-len-se* (Lat., *flatus*, a blast), a morbid collection of gases in the stomach and bowels, commonly arising from indigestion, or from indulgence in certain kinds of vegetable food. For its cure, carminatives, tonics, and aperients are resorted to; and strict attention to diet is necessary, taking only such food as is light and easy of digestion, and avoiding certain vegetables, as peas, beans, and flatulent fruits. Weak brandy-and-water, as a beverage at dinner, is also very beneficial. When the pain is excessive, hot applications to the stomach and friction will frequently afford considerable relief.

FLAX, *flaks* (Sax., *fleax, flex*), the fibre of the *Linum usitatissimum*, separated from the woody portion of the plant, and ridded of any impurities, after which it is spun into thread, from which state it is woven into linen. (*See* LINEN.) It is supposed to be the fruit of Egyptian discovery, as the coverings of the mummies found in the pyramids all attest to their being composed of what is generally termed flax. The flax-plant is of slender form and of annual growth. It reaches generally the height of from two to three feet, and has small lanceolate leaves, which terminate at the extremities in delicate blue flowers, which are afterwards replaced by seed vessels, containing each ten seeds. (*See* LINSEED.) The plant itself grows over the whole extent of Europe, Asia, and America.

FLAX, NEW ZEALAND.—A fibre yielded by *Phormium tenax*, a perennial plant growing in New Zealand and Norfolk Island. The leaves from which the flax are obtained are, in some instances, from five to six feet in length, and about three inches wide. The fibre is very fine and strong.

FLEA, *fle* (Anglo-Sax.).—The proper position of this insect in entomological classification has been the subject of much dispute; but naturalists now generally consider it as belonging to a distinct order, known as *Suctoria, Siphonaptera*, or *Aphaniptera*. The most familiar species is the common flea (*Pulex irritans*), which is very unpleasantly numerous in this country. The body of the flea is protected by a horny covering, composed of segments, which are very well defined—those of the thorax are always disunited. Its mouth is suctorial, formed of three pieces, inclosed by two articulated laminæ, which, when united, form a cylindrical or conical proboscis, the base of which is protected by two scales. Although, to all appearance, apterous, the flea possesses the rudiments of wings, which are four in number, in the form of horny plates on the sides of the meso- and meta-thoracic segments, the hindmost pair being somewhat larger than the other. Its head is small and compressed, on each side of which is a small round eye. The most singular organs of the flea are the two fine-pointed mandibles of the mouth, which, in combination with another sharp organ, constitute the powerful attacking instrument of the insect. The *antennæ* are very minute, and concealed beneath a rake-like plate on the sides of the head behind the eyes. The legs are very strong, more particularly the hinder ones, which are used by the flea in its extraordinary leaps. This insect undergoes a complete metamorphosis; the larva is an elongated footless grub. On arriving at the pupa state, which occupies about twelve days, it incloses itself in a silken cover, and in a few days assumes its mature condition. Besides *Pulex irritans*, there are several other species peculiar to different animals. The dog possesses such a parasite (*P. Canis*); also the martin (*P. Hirundinis*); the mouse (*P. Musculi*); and the mole-flea, a large variety (*P. Talpæ*). They are very intelligent, and, minute as they are, have been trained to perform tricks. There have been several exhibitions of "industrious fleas."

FLEABANE.—A genus of plants (*Pulicariæ*), belonging to the natural order *Corymbiferæ*. Two species are known in England, in moist places, standing about a foot high. The flowers are yellow. The peculiar odour is said to be efficacious in driving away fleas. One of the species, *P. dysenterica*, is reputed to be of great value as a cure for diarrhœa and dysentery. The name fleabane is also given to the Conyza. (*See* CONYZA.)

FLESH, *flesh* (Sax., *flæc*), a compound substance, constituting a large portion of every animal; consisting of the softer solids, as distinguished from the bones and fluids. As a general appellation, it may be taken to include the blood-vessels, nerves, cellular tissue, &c. (*See* MUSCLE, TISSUE.) Chemically considered, flesh consists of fibrin in a coagulated form, permeated by at least three times its weight of water and fluid, consisting partly of blood and partly of substances secreted from it. The soluble matters consist chiefly of albumen, the soluble salts of the blood, two animal principles, called kreatine and urorite, and phosphoric, lactic, butyric, acetic, and formic acids. The salts consist of the phosphate of potash, magnesia, and lime, and a small quantity of chloride of sodium.

FLESH-FLY, belongs to the general order of *Diptera* in the classification of the insect tribe, and the name by which it is distinguished in this order is *Musca vomitoria*, in contrast to the common house-fly, or *Musca domestica*. The insect is termed *flesh-fly*, from the fact of its depositing its eggs in fleshy viands, in which the larvæ are hatched. It is also commonly known as the Blue-bottle. It is generally larger than the common house-fly, and its wings indeed are sometimes nearly three-quarters of an inch in expanse. A nearly-allied species (*M. Cæsar*) is of a golden green colour, and is common in this country. Another species (*M. lardaria*), most common at the end of autumn, and frequenting ivy bushes and late flowers, has black stripes on the crown and thorax.

FLEXIBILITY, *fleks-e-bil'-e-te* (Lat., *flectere*, to bend), a property which all bodies possess to a greater or less degree, which is evinced in their disposition to yield or change their form in a direction at right angles to their length, through their own weight or by means of any pressure or strain applied to them. There is no material that will not exhibit flexibility in some degree, because there is no substance in nature that is perfectly rigid and inflexible; but the degree of flexibility possessed by any material is denoted by the extent to which it will bend, or by the weight which it will support without breaking. This property must not be confounded with that of elasticity; elastic bodies will return to their former shape when they have been bent or altered by pressure in any way; but bodies which possess flexibility without elasticity do not return to their original form in all cases. (*See* MATERIALS, STRENGTH OF.)

FLEXOR, *flek'-sor* (Lat., *flecto*, I bend), the name of certain muscles the office of which is to bend the parts into which they are inserted. The antagonistic muscles are termed extensors.

FLIES, SPANISH. (*See* CANTHARIS.)

FLINT, *flint* (Ang.-Sax.), a mineral composed almost entirely of silica, with traces of iron, clay, and lime. The formation of flint has long been a disputed question amongst geologists: the dialytic discoveries of Graham and Church throw great light on the matter. If a solution of silica be prepared by dialysis, and poured into a vessel containing a very minute quantity of carbonate of lime, the whole becomes rapidly pectised, assuming the gelatinous form in a few minutes. From this it will be easily seen what would happen if a lake or river, containing a notable quantity of silica in solution, were to suddenly flood a chalk plateau. Some writers suppose that the silex was secreted from the sea-water by diatoms and sponges, and their remains most probably supplied the material of the flint. Flint is of great importance as an economic product, being largely used, when calcined and ground, in the manufacture of china, porcelain, and glass. In parts of the country where flints are plentiful, it is much used as a building material, with excellent artistic effect.

FLINTY STATE.—An impure quartz, assuming a slaty structure, and containing about 75 per cent. of silica, the remainder being lime, magnesia, and oxide of iron. There are beds in many parts of Scotland.

FLOAT-STONE, *flote'-stone*, a porous, soft, and friable mineral, consisting of silica, alumina, and carbonate of lime. From containing numerous pores, it holds a large quantity of air, and swims on water until it is saturated; hence its name.

FLORA, *flo'-ra*.—A collective name for vegetable productions. Scientific writers speak of the Flora of a particular country when describing its trees, flowers, and productions of the vegetable kingdom.

FLOUNDER, *flown'-der* (Swed., *flundra*), (*Pleuronectes flexus*), a flat fish very similar to the plaice, but smaller, and of more obscure colour. It is very common about the British coast, and is found in the Northern, Baltic, and Mediterranean seas. Its body is covered with very small scales, and along its back runs a row of sharp spines.

FLOWER, *flow'-er* (Fr., *fleur*), that portion of a plant which is formed by the union of all the organs which contribute to the formation of the seed. In common language, the word is used to convey the idea of the portion in which the gayest colours are found. A complete flower consists of the essential organs of reproduction, inclosed in two particular envelopes which protect them. These essential organs are called the *pistils* and *stamens*. The floral envelopes are termed *calyx* and *corolla*. The extremity of the peduncle, or pedicel upon which the parts of the flower are placed, is called the *thalamus* or *receptacle*. (*See* various headings.)

FLOWERING PLANTS. (*See* PHANEROGAMIA.)

FLOWERLESS PLANTS. (*See* CRYPTOGAMIA.)

FLUID, *flu'-id* (Lat., *fluidus*, from *fluo*, I flow), is defined to be that whose component parts or particles yield to the slightest pressure, and are moved or disseminated amongst each other without any apparent sensible resistance. Some writers on scientific subjects distinguish between fluids and liquids. All liquids are fluids; but it does not necessarily follow that all fluids are liquids; for air, ether, mercury, water, and alcohol, are all fluids; but water and alcohol are also liquids, because they wet, or create moisture on bodies, which mercury and air do not do. Fluids are of two distinctive kinds—elastic and non-elastic; the former are comprised under the general term Pneumatics, and include all airs and gases; while the latter, which only include water and other aqueous fluids, are comprised under the general head of Hydrostatics and Hydraulics. (*See* those headings.) The terms *elastic* and *non-elastic* are only used here in a relative sense, and not absolutely, as all fluids are elastic more or less, water being compressible, although offering resistance.

FLUKE, OR FLUKEWORM.—An entozoom (*Distoma hepaticum*) common in the liver and filiary ducts of ruminant animals, especially sheep, producing the disease known as "rot." It is generally about an inch in length and of an oval form. Instances have been known of the appearance of the fluke in the human liver.

FLUORESCENCE, *fluo-res'-sens*.—A blue appearance exhibited by certain substances, especially solutions of sulphate of quinine, when exposed to sunlight.

FLUORESCENT RAYS, *flu-o-res'-ent raiz*, certain rays which exist beyond the blue end of the spectrum, invisible under certain circumstances. (*See* SPECTRUM.)

FLUORIC ACID, *flu-or'-ik*. (*See* HYDROFLUORIC ACID.)

FLUORINE, *flu'-or-ine*.—An elementary substance allied to chlorine. Many unsuccessful attempts have been made to isolate this body. Several chemists have succeeded in obtaining an impure form of it by using vessels of fluor spar, but its properties have never been satisfactorily determined. Its principal compounds are fluoride of calcium, or fluor spar, and hydrofluoric acid. It also combines with most of the metals; also with boron, silicon, sulphur, silenium, and phosphorus. It exhibits no tendency to unite with oxygen. It is found somewhat sparingly in the mineral kingdom, in fluor spar, epatite, topaz, and a few other minerals. It also exists in the ashes of sea-plants, in sea-water, and in blood, milk, and the human teeth. With boron and silicon it forms two compounds, which are absorbed by water, giving rise, respectively, to fluoboric and fluosilicic acids.

FLUOR SPAR, *flu'-or spar*, a mineral of great beauty, found in different parts of the world, but principally at Castleton, in Derbyshire, Aston Moor, in Cumberland, and in Cornwall. It occurs in cubes and octahedra and concretionary masses, being most commonly of a violet-blue colour, but also yellow, green, purplish-red, and red. In its rougher forms it is often used as a flux, and the finer specimens are fashioned into cups and vases, under the name of Derbyshire spar, or, locally, Blue John. It consists, chemically, of fluoride of calcium.

FLUSTRA, *flus'-tra* (Sax., *flustrian*, to weave).—A genus of Zoophytes, of the class *Polyzoa*, some species of which are common on the shores of the British Isles. They have a mat-like structure, and are commonly mistaken for vegetable productions, some resembling a branching frond; but they are, when disturbed, active in their movements. A single specimen has been found to contain about 18,000 polyp heads.

FLUX, *fluks* (Lat., *fluxus*, from *fluo*, I flow), any preternatural fluid evacuation from the body, but more especially those that proceed from the bowels. It is frequently applied to diarrhœa, and dysentery was long known as the bloody flux. (*See* DIARRHŒA, DYSENTERY.)

FLUXIONS, *fluk'-shuns* (from Lat., *fluo*, I flow).—The more common appellations by which the theory of fluxions is known to the general reader or mathematical student, are the differential or integral calculus. The calculus of fluxions, which is one of the most important additions ever made to the abstract mathematical sciences, was invented about the middle of the 17th century. The theory of fluxions, or calculation of the velocity in uniform or variable motion, necessarily depends on that higher system of trigonometry which treats on drawing tangents to curves. The facility which this new motion of velocity gave to the extension of geometry, induced various foreign mathematicians, as Descartes, Roberval, and Fermat, to employ it in their researches. So very near did the last-mentioned approach to the true theory of the fluxional or differential calculus, that Laplace says he ought to be reputed its inventor. To find the real discoverer, however, we must look to two men, Newton and Leibnitz, for each of whom the honour of its invention is claimed. Newton certainly promulgated and published his method the first, in the year 1665. The principles of his theory may be thus described:—1. Supposing two quantities to have a given relation to each other (for example, the one to be always equal to the square of the other), and the rate of increase of one of them at any instant of time to be known: to find the rate of increase of the other at the same instant. These rates of increase were called the *fluxions* of its quantities; and the rules for their determination constituted the *direct method of fluxions*, or *differential calculus*. 2. The second part of this theory was exactly the reverse of the first; it is a problem in which the relations between the rates of increase of two quantities, which depended the one on the other, being given, it was required to discover the relation of the quantities. This was the inverse method, or *integral calculus*. According to Newton's theory, a plane, curve, or line, may be conceived as generated by a point moving uniformly in the direction of some fixed line, and having at the same time a lateral motion with respect to this line, which is governed by some law dependent upon the nature of the curve generated. The part of the curve which is generated at any instant of time is called the *fluent*, and that infinitely small element generated during the next infinitely small and constant period of time is called its *fluxion*. If, in addition to the two motions already explained, we conceive the point to have a third motion at right angles to the plane of the other two, and also regulated by a law which must depend upon the nature of the curve, the generating point will describe a curve in space, which may be either a plane-curve, or one of double curvature. It may be thus easily surmised that by suitably regulating the laws of motion of the generating point, any curve whatever may be described; it is also obvious from the theorem laid down, that, by the law of relation between the fluxions of the elements, the nature of the curve may be easily discovered. In the general deductions of mathematical science, if we suppose any line, which may vary according to some law, to move according to any fixed law, it will generate a surface, and the portion generated during any infinitely small portion of time will be the fluxion of the surface, while the whole portion generated will be the fluent. In a consequent manner, if a plain area move in any direction, the area being supposed to vary by a fixed law, then will the infinitely small volume generated in an infinitely small portion of time be the fluxion of the solid, and the portion generated will be the fluent. In this system, any magnitude may be regarded as flowing ultimately from a point; a point in its motion may generate any line; a line in its motion may be made to generate any surface; and, lastly, a surface may generate any volume. The notation of fluxions has been found to be their drawback, and the main superiority of differentials and integrals over them is due to that.

FLY, *fli* (Sax., *fleoge*), a name applied almost indiscriminately to all insects possessing wings; by many, however, restricted to the various species of dipterous insects. The legs of this class of insects are long and slender; and the feet, it is well-known, are furnished with skinny palms, to enable them to stick on glass and other smooth bodies by means of the pressure of the atmosphere.

FLY-CATCHERS, *fli-katsh'-erz* (*Muscicapidæ*).—This very numerous family of birds is widely diffused throughout both the eastern and western continents. As their name implies, they prey on insects, which they seize in mid-air. They have the beak horizontally depressed, and armed with bristles at its base, with the point more or less decurved and emarginated. One of the best types of fly-catchers is that presented by the tyrant fly-catcher (*Muscicapa Tyrannus*). A bird peculiar to America. It is eight inches in length, and fourteen in extent of wing. The general colour of the upper parts is dark bluish-grey, inclining to dull slate-black on the head, of which the central feathers along the crown form a gorgeous orange patch. It builds its nest on branches of trees; it is a rather bulky structure, composed of twigs and wool, or tow and cotton, and is very thick and snug. No matter the species of bird, on matter its size or strength, it is sufficient that it approaches any way near the tyrant's nest to excite his jealous rage, and out he sallies bent on instant satisfaction. It is said that eagles and hawks may not with impunity approach this bird's nest, made sacred by his fledglings, and that, darting up into the air, it will launch down on to the back of its enemy, and there anchor in such a way as to make it a difficult matter to dislodge him. Only two small species of this tribe are found in this country. The spotted and the pied fly-catchers, about the size of sparrows. The European species are distinguished from any other by having much more slender bills, with shorter bristles at the gape.

FLY, DRAGON. (*See* DRAGON FLY.)

FLYING, *fli'-ing* (Sax., *fleogan*, to fly), the power which many animals possess of raising themselves in the air, and in moving through it in various directions, supported by the atmosphere alone. (*See* WING.)

FLYING DRAGON. (*See* DRAGON.)

FLYING-FISH (*Exocœtus*), a genus of fishes that, on account of the extraordinary length and size of their pectoral fins, are enabled to spring from the water and support a kind of temporary flight through the air. They belong to the *Scombersocidæ* family. Their distinguishing features are—pectoral fins nearly equal to the body in length; head flattened above and on the sides; the lower part of the body furnished with a longitudinal series of carinated scales on each side; dorsal fin placed above the anal; eyes large; jaws furnished with small pointed teeth. Although some few naturalists have supposed that these fish possess the true power of flying, that is, by beating the air with their members, it is generally agreed that their large fins sustain them, parachute-wise, when they have leaped from the water. They will rise sometimes to the height of twenty feet from the water, and not unfrequently fall on the decks of ships. They swim in shoals, and large numbers will rise at the same time. Several instances are on record of the appearance of flying-fishes off the British coast, but the species is doubtful. It is probable that both the oceanic flying-fish (*Exocœtus volitans*) and the Mediterranean flying-fish (*Exocœtus exiliens*) may have made their appearance in our seas. In the Gulf of Mexico are found some species with curious appendages or filaments attached to the lower jaw. The natives of the South Sea Islands catch them for food. The *Flying Gurnard*, a member of the family *Sclerogenidæ*, has also the power of taking long leaps and supporting itself for a time in the air. It differs from the fish described above in the appearance of the pectoral fins.

FLYING FOX. (*See* BAT and KALONG.)

FLYING LEMUR, OR COLUGO (*Galeopithecus volans*).—This is another curious species of mammalia which possesses the power of flying or leaping considerable distances, by means of a membrane connecting its limbs with each other. The flying lemur forms the connecting link between the *Quadrumana* and the *Cheiroptera*; to the latter, indeed, it has a great resemblance, insomuch as many naturalists of eminence have placed it in that order. It differs, however, from the bats in many respects, not the least important deviation of which is the absence of opposable thumbs on all the feet, which are composed of five fingers united by a membrane. Notwithstanding this, it certainly bears, in its appearance and habits, a remarkable similarity to the flying-fox. In its diet, it is both carnivorous and frugivorous; feeding on birds and their eggs, insects, and fruits. It is found in the Indian Archipelago, living in the forests; seeking by night for its food, and remaining in a dormant state during the day.

FLYING SQUID.—A genus of cephalopodous molluscs, differing from the true squid in the construction of the fins and the tail. They have the power of leaping out of the water to a height of 15 or 20 feet. They are used in Newfoundland as bait for cod.

FLYING SQUIRREL.—By this name are known several species of squirrels, the more important being the Taguan flying squirrel (*Pteromys alpinus*), which is a native of India, where it is tolerably abundant. It has derived its name from a parachute-like appendage, consisting of a broad fold of skin, stretching along each side of the animal, from the fore to the hind legs; and when it intends making a leap, it expands this curious membrane to the fullest extent, and is thereby enabled to jump a considerable distance, although always downwards, which, in fact, its so-called "flying" properties are limited to. It measures about three feet in length, of which its tail occupies more than half. Its general colour is chestnut, deepening into brown on the back and red on the sides; the abdomen, throat, and breast are covered with silvery greyish-white fur. The tail is greyish-black, becoming much darker towards its extremity. The assapan, or flying squirrel of America (*Sciuropterus volucella*) is another variety, agreeing with the above in its leading characteristics. The name is also commonly given to the Flying Phalanger (*Petaurus Taguanoides*), a marsupial quadped, native of Australia and New Guinea. One of the Australian species is scarcely larger than a mouse.

FOCUS, *fo-kus'* (Lat., *focus*, a hearth).—When light is reflected from regular curved concave surfaces so that all the rays converge to one point, that point is called the focus. The same term is applied to that point towards which rays of light converge after passing through a refracting medium, such as a lens. A telescope, or other optical instrument, is said to be in focus when the arrangement of lenses is such that the object examined falls clearly and distinctly upon the retina of the observer. In the reflection of heat, the point to which the rays converge is also called the focus. In Geometry and conic sections, the term focus is applied to certain points in the parabola, ellipsis, and hyperbola, where the rays reflected from all these curves converge and meet.

FŒTUS, *fe'-tus* (Lat., from *feo*, I bring forth), a term applied to the child in the uterus from the fifth month of pregnancy to the time of birth. Previous to that time, it is commonly called the *embryo*; but these terms are rather arbitrary, and the one is frequently used for the other. (*See* PHYSIOLOGY.)

FŒNICULUM, *fe-nik'-u-lum* (from Lat., *fœnus*), the Fennel, a genus of the natural order *Umbelliferæ*, formerly placed under *Anethum*. Two species, namely, *F. vulgare*, the common fennel, and *F. dulce*, the sweet fennel, are much used in this country as pot-herbs, and for garnishing dishes. The former grows wild on rocks and walls, particularly near the sea: the latter is frequently regarded as a cultivated variety of the same plant. *F. Capensis* is a common esculent at the Cape of Good Hope. The term is derived from the Latin word for usury, because the seed yields, or is returned with, great increase.

FOG. (*See* MIST.)

FOLIATION, *fo-li-a'-shun.*—A term applied by geologists to the alternating layers or plates of different mineralogical nature, of which gneiss and metamorphic schists are composed.

FOLLICLE, *fol'-le-kl* (Lat., *folliculus*), a superior one-celled, one or many-seeded fruit, and one-valved. By the latter character it is known at once from the legume, which opens by two sutures, and is two-valved. The columbine, larkspur, hellebore, and aconite are examples.

FOMENTATION, *fo-men-tai'-shun* (Lat., *fomentatio*, from *foveo*, I bathe), the application of heat and moisture to a part, by means of flannel or other substance wrung out of hot water, in order to relieve pain or to stimulate the surface.

FOOD AND DRINK, *food* (Sax., *foda*, food and drink).—Those solid and liquid substances which are used either for sustaining animal life or for the purpose of reproducing the ever-wasting tissues and fluids of animal bodies. Of the elementary bodies, only a small proportion enter into the constitution of animals; and the substances included in this small proportion are the only ones required to be present in food and drink. Out of about sixty elements, only oxygen, hydrogen, nitrogen, carbon, sulphur, phosphorus, chlorine, sodium, potassium, calcium, magnesium, iron, and fluorine, are absolutely necessary. Albumen, fibrine, and caseine, which occur both in animals and vegetables, together with vegetable gluten, furnish oxygen, hydrogen, nitrogen, and carbon. Animal flesh, eggs, milk, corn, and various other vegetable productions, contain one or more of these principles. Food containing a large proportion either of sugar, starch, or organic acids, introduces carbon, hydrogen, and oxygen largely into the system. Oleaginous alimentary substances contain carbon with a little oxygen and hydrogen: this class of substances includes fat, suet, butter; oily seeds, such as nuts; and fatty foods, such as liver, &c. Flesh, blood, and bones, used as food, supply phosphorus to the system; the flesh of fishes is particularly rich in phosphorus; and in the shape of phosphates, it exists in the juices of many edible vegetables. Sulphur is introduced into the system from the fibrine of flesh, from albumen, from the caseine of milk, gluten, &c. Chlorine and sodium exist in nearly every variety of animal food, and, in the shape of common salt, are taken separately with nearly all kinds of food. Potassium is found in various kinds of food, both animal and vegetable; in milk, in the juice of flesh, and in nearly all inland plants. Calcium is not only obtained from animal and vegetable food, but also from drinking-water, which usually contains sulphate and carbonate of lime in solution. Magnesium is generally found along with calcium, and traces of fluorine have been observed in milk, blood, &c. These simple bodies are, however, not capable of being directly assimilated and converted into tissue; they must be previously in combination; and their assimilation depends upon certain chemical decompositions and physiological processes. Baron Liebig, who has given much attention to this subject, has divided all kinds of food into two classes—those substances which do contain nitrogen and those which do not. The first class, which is sometimes called nitrogenous or albuminous, is useful in forming blood, flesh, &c.; it is, in fact, nutritious food. The second, or non-nitrogenous class, assists the respiratory organs. Thus, in very cold climates, where more exercise is required in order to sustain the vital heat, more oxygen is consumed, and consequently more carbon is required in the food. In the temperate zone, a moderate mixture of nitrogenous and non-nitrogenous food is used; while, in the tropics, where the system requires oxygen in particular, fruits and vegetables form the principal food. All kinds of flesh are not equal with regard to their nutritive value. Veal, for instance, is totally different from beef. It contains a smaller quantity of the alkalies, and there is 15 per cent. more phosphoric acid than is necessary for the formation of salts; it contains, also, little of the fibrine of flesh, and proportionately more of the fibrine of blood, which is less digestible than the former. Veal is rich in gelatine, which is not nutritious, and seldom contains any quantity of fat: it also contains very little iron. In all these points it is the reverse of beef. Hard-boiled eggs have little or no nutritive power, and the same may be said of boiled fish, the soup of which is generally thrown away. In order to make up the necessary deficiency of nutritive matter in veal, eggs, and fish, vegetables should be taken with them. Celery contains 18 per cent., salad 24 per cent., and cabbage-sprouts 10 per cent., of their dry weight of salts, alkalies, and alkaline earths. Vegetable food in general contains a large proportion of iron. In the human body, iron is present in the blood, the bile, and other places. Prolonged absence from fruits and succulent vegetables brings on scurvy. The absence of the acids which they contain produces this effect: thus lime-juice is used by sailors with good effect on long journeys. Amongst the condiments used for flavouring food, are mustard, cayenne pepper, black pepper, and various spices. They owe their action to the presence of a volatile oil. The volatile oils of fennel, thyme, parsley, anise, caraway, horseradish, mustard, and water-cress stimulate the system, but do not not incorporate themselves. Condiments and sauces (which are usually fluid mixtures of condiments), in time, generally weaken the organs, which they at first stimulate. The only exceptions are salt and vinegar. Drinks for the most part are simply liquid food. They may be divided into the following classes:—1. Mucilaginous, farinaceous, or saccharine drinks; such as barley-water, *eau sucré*, &c. They are a little more nutritive than drinking-water. 2. Aromatic or stringent drinks; such as tea, coffee, chocolate, cocoa, &c. They all contain principles which act with a slightly exhilarating action upon the nervous system: chocolate and cocoa contain oil and starch. 3. Acidulous drinks; such as lemonade, ginger beer, raspberry vinegar, &c. They allay thirst, and form cooling antiscorbutic drinks. 4. Drinks containing gelatine and ozmazome, including broths and soups. These, when properly made, ought to contain all the soluble constituents of the substance from which they are prepared. 5. Emulsive or milky drinks; such as animal milk, cocoa-nut milk, almond milk, &c. Animal milk contains all the essential ingredients of food; the others are slightly nutritive. 6. Alcoholic and other intoxicating drinks, including malt liquor or beer, wines and spirits.

FONTINALIS, *fon-ti-nai'-lis*, a genus of mosses, in many respects similar to *Hypnum*, but having the fruit enveloped in the leaves, and almost without stalk. The water-moss (*F. antipyretica*) is a well-known British specimen, which takes its name from its ability to resist fire, on which account it is used in some parts of the North of England as a lining for chimneys. The shoots are about a foot high. It grows upon rocks and the roots of trees in moist situations.

FOOLS' PARSLEY. (*See* ÆTHUSA.)

FOOT, *foot* (Ger., *fuss;* Lat., *pes*), that part of the lower extremity below the leg with which we stand and walk. It is composed of three series or groups of bones—the tarsal, or hindermost; the metatarsal, which occupy the middle portion; and the phalanges, which go to form the toes. The movements of the foot, which are permitted by the connecting ligaments, are effected by a variety of muscles. (*See* ANATOMY.) The foot, naturally a beautiful structure, is usually so much interfered with in civilized life as to be deprived of much of its beauty, and even of its utility. Its movements are impeded by its being confined in tight-fitting boots; while, in place of the boots being conformed to the shape of the feet, the feet are made to conform to the shape of the boots; the consequences of which are corns, bunions, cold feet, and a number of other evils, from which so many suffer in the present day.

FORAMEN, *for'-a-men* (Lat., an orifice), a term applied to certain holes or openings of the human body, more particularly of the skeleton; as the various foramina of the skull. The *foramen ovale* is a passage or communication between the two auricles of the heart in the fœtus.

FORAMINIFERA, *fo-ra-me-nif'-e-ra*, a group of minute organisms having calcareous shells, which are pierced with numerous holes or foramina. They are now looked upon as protozoa. The pores are for the protrusion of delicate filaments, by the aid of which locomotion and perhaps nutrition are performed. Recent *Foraminifera* are beautiful microscopic objects; they are procured by dredging, or sometimes from the sand of the sea-shore. In the fossil state these tiny shells occur in rocks of all formations; they constitute the greater bulk of the chalk and the tertiary limestones.

FORBIDDEN FRUIT. (*See* CITRUS.)

FORCE, FORCES, *fors* (Fr.).—In Mechanics, force is a term applied to any cause which is capable of producing motion in matter, or of stopping or altering its direction when produced. Every visible particle of matter is under the influence of several forces, exerted upon it both by distant and by adjacent particles, and upon which it acts in return; for the action of one body on another is always accompanied by a re-action of the latter upon the former, of the same intensity, in an opposite direction. The motions observed in some bodies are owing to these forces, and upon their balance the apparent state of rest in others is dependent. Force having its proximate seat in the muscles of man and other animals, it is called muscular or animal force. This force can be communicated to inanimate matter, as when a stone is projected from the hand. Muscular force may also be concentrated in the same mass by continued action, as when a stone, by means of a sling, is continuously acted upon by the same arm, it will at length be projected with an intensity of action capable of producing very violent effects. Force transferred to moving masses of matter is called mechanical force, and by multiplying the quantity of matter in a body by its velocity we arrive at its *momentum*, or the quantity of force which it is capable of exerting upon other bodies opposed to it. The investigation of the laws of motion constitutes the province of Dynamics. In mechanics, the term decomposition of forces signifies the same thing as resolution of forces. Any force may be decomposed or resolved into a number of forces, and the original force will be equal to the resultant of those forces. Some forces cause masses of matter to approach and others to recede from each other, retaining them in their second position against an opposing force: the former are called *forces of attraction*, and the latter of *repulsion;* thus, gravity is a force of attraction, and elasticity a force of repulsion. In electricity and magnetism the forces of attraction and repulsion are also shown. (*See* ELECTRICITY.) Polar forces are those which are conceived to act in opposite directions at the extremities of the axes of molecules or of masses of matter. The forces mentioned above are usually termed *external* forces, for they act upon matter at sensible distances; but there are others which act only upon its constituent molecules at insensible distances: these are frequently called *internal* or *molecular* forces; they include homogeneous attraction or cohesion, the universal antagonist of which is the repulsive force of heat (which *see*). Another attractive force is that of heterogeneous affinity, by which a piece of metal or glass is *wetted* when dipped into water. Heterogeneous attraction is seen in its highest degree in chemical affinity, an inquiry into the laws of which force constitutes the chemist's peculiar province. (*See* AFFINITY.) The correlation of the physical forces is a very important principle in natural philosophy, which has of late years been particularly enunciated by Mr. W. R. Grove. Many philosophers had previously asserted that all the forces of nature were intimately connected, and dependent upon one common principle; but the correlation, or necessary mutual dependence and commutability of each of the physical forces upon and into any other, or into all, and of all, reciprocally into each other, was at its original enunciation the particular theory of Mr. Grove. His doctrine is, "that the various affections of matter which constitute the main objects of experimental physics—namely, heat, light, electricity, magnetism, chemical affinity, and motion, are all correlative, or have a reciprocal dependence; that neither, taken abstractedly, can be said to be the essential cause of the others, but that either may produce or be convertible into any of the others: thus, heat may, mediately or immediately, produce electricity; electricity may produce heat; and so of the rest, each merging itself, as the force it produces becomes developed; and that the same must hold good of other forces, it being an irresistible inference from observed phenomena, that a force cannot originate otherwise than by devolution from some pre-existing force of forces."

FOREST, *for'-est*, a large expanse of ground covered with trees. The word is derived from the Low Lat., *foresta*, which is itself originated by the Ger., *forst*, signifying the same thing. Forests are interesting in many ways, as they may be said to mark the track of civilization, besides being of the utmost utility to man, both from local as well as atmospherical influences. Forests were greatly venerated by the Romans and other ancient peoples, temples being often erected and sacrifices ordained in their honour. This may be considered one of the greatest reasons for the Druids living in them, as it was thought much more sacred to dwell under trees than *en plein champ*—in the open field. Forests abroad are mostly composed of (in Europe) oak, elm, beech, poplar, ash, alder, plane, willow, lime, and birch; not to speak of the numbers of wild apple, pear, and other fruit-trees; besides pine, fir, and cypress in profusion, with all species of bush-wood and vines. In Norway, the forest-land extends up to Drontheim, which is in latitude 63° north. Switzerland is well wooded, and oaks and firs are found at a level over 4,000 feet above the sea. France has some fine examples, her variety of climate being favourable to the growth of all species of trees, some of which, indeed, belong to a much warmer climate: the forest of Ardennes and the Bois de Boulogne may be mentioned as instances of the expanses she has covered with trees. In Italy, the plains of Ravenna afford a wide scope for the luxuriance of forest life, and the pine grows there very extensively; most of the oak, too, used in our navy for shipbuilding purposes, comes from Italy. Russia, however, bears away the palm for her abundance of forests, and some of the finest timber in the world comes from her ports in the Baltic. The districts of Twer and Novgorod are regularly covered with wood and the forest of Volkonsky is thought the largest in Europe. For the largest forests, the reader must look to the New World, where, in both the north and south of America, the vegetation appears to possess no limits. In North America, the forests are gradually disappearing, through the immigration into the country and the diffusion of settlers; but in South America, the whole of the valley of the Amazon, which embraces one-third of the entire area of that country, is one vast forest. It would be impossible to give an account of the various descriptions of trees which are to be found there; for they are apparently without limit, and the size of the individual trees is generally stupendous, and nowhere in the world is there such an abundance of vegetation and of animal life as in the South American forests. The direct influence of forests on climate is a diminution of temperature, which is affected either by screening the soil from the heat of the sun's rays; by the evaporation of moisture from the leaves; or, thirdly, by the uneven surface which the leaves offer to the cooling process of radiation. Cutting down of forests is always followed by a diminution in the rainfall of the district. (*See* RAINFALL.)

Fossil Forests.—The remains of trees are found in the coal measures, and also in the Lower Purbeck and Devonian formations.

FORGET-ME-NOT. (*See* MYOSOTIS.)

FORM, *form* (Lat., *forma*; Fr., *forme*), is the manner and mode in which anything is presented to our ideas of conception. In Physics, the shape and external appearance of a body, the figure of the same as defined by angles or lines, or that manner of presenting itself to the eye peculiar to different bodies, is termed *form*; as, form of a circle; form of a square; the form of the human body; and other instances. Form is likewise to be distinguished from the real apparent nature of things; and if we take it in this light, the idea of form is used in a practical manner in our daily speech and scientific pursuits.

FORMATION, *form-a'-shun*, in Geology, a term applied to a group of strata united by some character which they have in common.

FORMICA, *for-mi'-ka* (Lat.). (*See* ANT.)

FORMULA, *form'-u-la*, in Chemistry, is an expression of the composition of a substance by means of symbols. The formulæ of bodies may be either *empirical* or *rational*. An empirical formula is one giving the elements contained in a body, without reference to their arrangement. For instance, the empirical formula of crystallised sulphate of copper would be CuO_9SH_5, but the rational formula, showing its composition, would be $CuO.SO_3 5aq$.

FORNAX, *for'-naks* (Lat., a small furnace), a constellation of the southern hemisphere, named by Lacaille, and situated in close proximity to Cetus. It contains no stars of the first or second magnitude.

FOSSE, in Anatomy, the term is applied to a large cavity in the bone, with no exit or perforation.

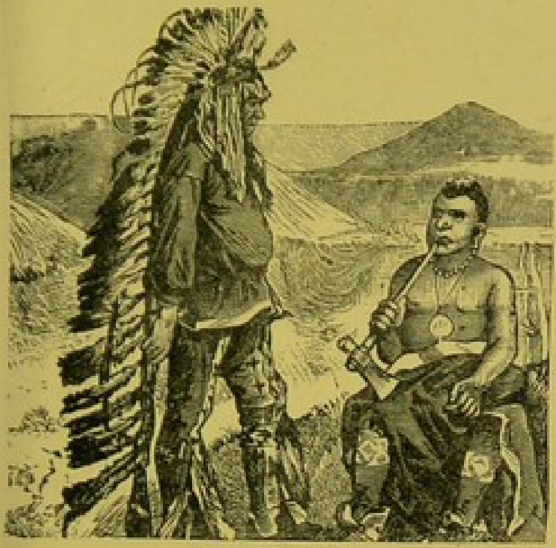
FOSSIL, *fos'-sil* (Lat., *fossilis*, dug up), in Geology, the body, or any portion of the body, of an animal or plant buried in the earth by natural causes, or any recognizable impression or trace of such a body or part of a body. The old geologists used to include minerals, or any other distinct bodies that were found in rocks, under the term of fossils. According to modern views, fossils are simply organic remains, allowing the word "remains" to apply even to foot-prints and other transient impressions. A fossil is not necessarily a petrifaction. Some fossil shells found in comparatively old rocks, such as the soft compact clays of the oolitic series, are less altered from their living state than many shells included in recent coral reefs. Wood, again, may be found in such rocks still soft and but little altered; while in much more recent formations it is entirely mineralized, and converted either into flint or into coal. That department of geology which relates to fossils is termed *Palæontology* (which *see*).

Fossiliferous Rocks, are those which contain organic remains. No fossils have yet been found in the metamorphic rocks.

FOUSIL OIL, *fou'-sil* a substance found in brandies distilled from fermented potatoes, rye, barley, and the marc of grapes. Its chemical name is amylic alcohol, under which heading its properties are described.

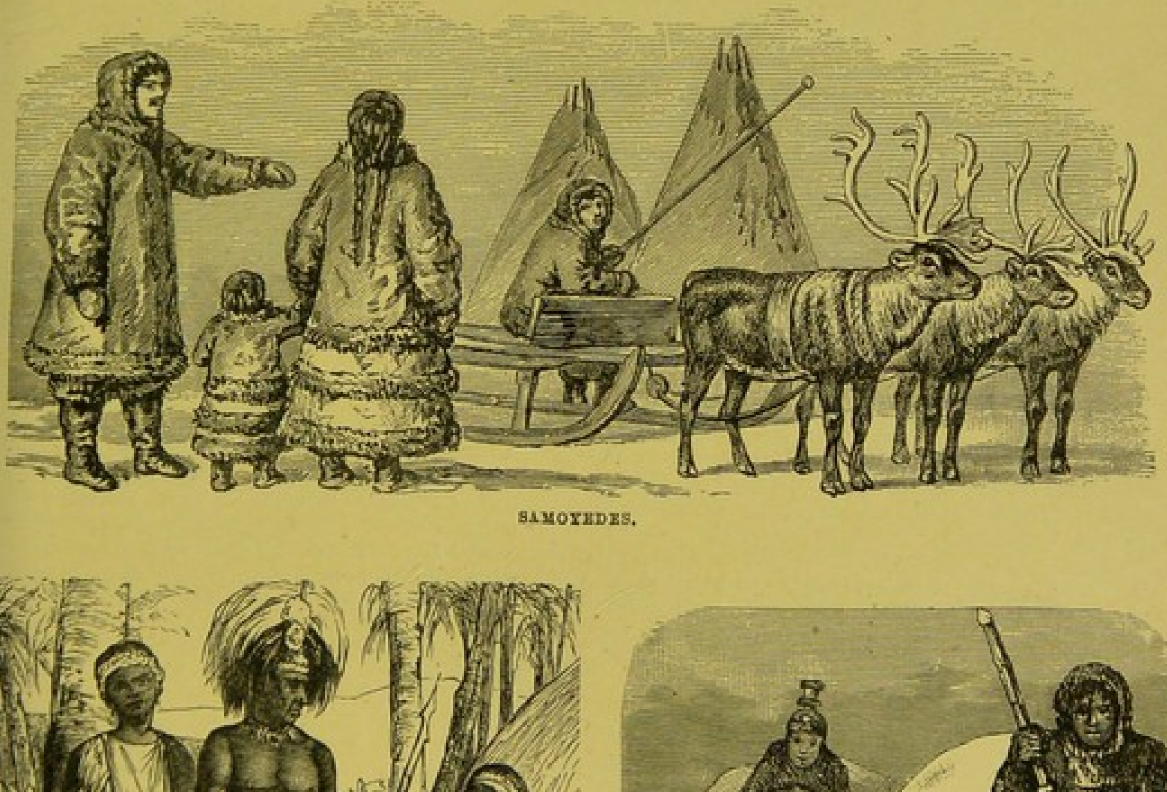
FOVILLA, *fo-vil'-la* (Lat., *foveo*), the matter contained within the membranes of the pollen-grains. It is a semi-fluid granular protoplasm, in which are suspended very minute starch granules, and what appear to be oil globules. It is, without doubt, the essential part of the pollen-grain. (*See* POLLEN.)

FOWL, *fowl* (Sax., *fugel*).—In its general sense, this term is nearly synonymous with *birds*; but in a more restricted sense it means those domestic birds brought up in a farmyard for the table. Fowls originally came from

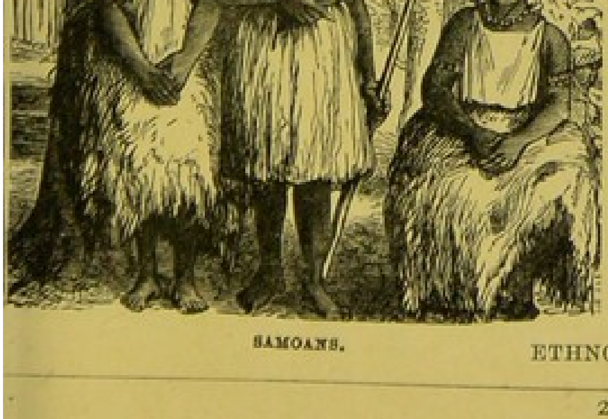


PAWNEE INDIANS.

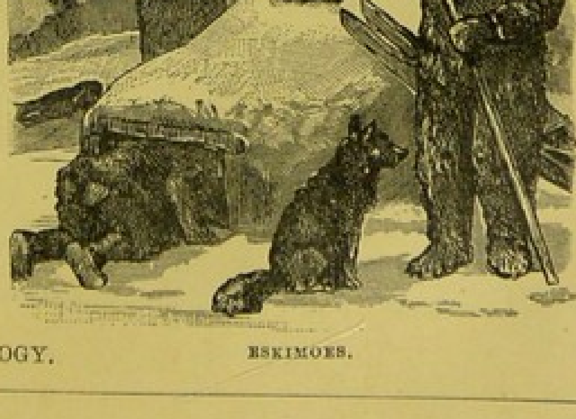
HOVAS.



SAMOYEDES.



SAMOANS.



ESKIMOES.

ETHNOLOGY.

Persia and India, and they are valuable to the breeder in many ways, yielding profit as they do in eggs, in broods, and in feathers. The different kinds of this useful domestic creature are the Cochin-China, the Hambro', the Spangled, the Spanish, the Bantam, the Malay, the Poland, the Brahmapootra, and the Dorking. Besides these there are several other scarce specimens; as the Japanese Bantam or Silky Fowl, the Emu or Silky Cochin, the Andalusian, the Rangoon, and the Ancona fowls, all of which are bred more for exhibition than for real utility. The Cochin-China is one of the largest of the different kinds, and the colours of its plumage are buff, lemon, cinnamon, grouse, partridge, white, and black. They are capital layers, and in a short time a pair will stock a yard. The Hambro' fowl is one of the prettiest varieties and has gold and silver plumage; they are also prodigious layers, but rarely have patience to bring up a brood. The Spanish fowl and the Dorking are more commonly seen than the other varieties, and are certainly of more use to the breeder, being good sitters as well as layers. The Bantams are the greatest favourites, being remarkably small birds, and having delicate plumage. It would be impossible to give a description of all the different varieties here.

The Guinea-Fowl, or Pintado, is sometimes classed among the common order of fowls. These birds are very wild and restless in their nature, and, unlike the ordinary fowls, they give no notice to any one of their laying or sitting; they have consequently to be closely watched. As the Guinea-fowl rarely watches over her nest and rears a brood, its eggs are generally put under a common hen. It is very delicate eating.

FOWLER'S SOLUTION. (*See* ARSENIC.)

FOX, *foks* (Ang.-Sax.).—A genus (*vulpes*) of the *Canidæ*, but differing from others of the family in the shape of the pupil of the eye (which is elongated), the bullet head, the bushy tail, the long body, supported on short limbs. The common fox (*Vulpes vulgaris*) is the only species found in this country. Its colour is reddish fawn, intermixed with black and white hairs; its tail, or "brush," is of the same colour, except at the tip, which is white. It measures about two feet and a half in length, and twelve inches in height. Its coat is much heavier and thicker during the winter months, when its fur is of greater value than in warmer weather. The fox emits a most unpleasant scent, which proceeds from certain glands situated at the root of the tail. This powerful odour is rendered more disagreeable from the remarkable tenacity with which it clings to any object which it has once touched. The common fox lives on rabbits, hares, partridges; and, when occasion offers it a chance of obtaining entrance into the farmyard, it often commits great havoc among the poultry. It burrows in the ground like the rabbit; and, indeed, often turns out that animal from its domicile to take up its own abode there. Besides the above species, there are several others: the Persian fox (*V. flavescens*), the American fox (*V. fulvus* and *V. Virginianus*), the South-African fox, or Caama (*V. Caama*), the Senegal fox (*V. dorsalis*), the Kit fox (*V. cenereo-argentatus*), the Kokree (*V. Bengalensis*), the Salora (*V. Niloticus*), and the Arctic fox (*V. lagopus*), white in colour, densely clothed with a woollen fur, gregarious in habits, and without the offensive odour of other foxes.

FOXGLOVE. (*See* DIGITALIS.)

FOX-GRAPES. (*See* VITIS.)

FOXHOUND, *foks'-hownd* (Ang.-Sax.), a species of dog used in the sport of fox-hunting. In the true foxhound, nearly all the individual good qualities which distinguish other varieties of dogs are combined; and, for fleetness, strength, fine scent, spirit, perseverance, and subordination, it has no equal. The foxhound is not a very large animal, its height averaging from twenty to twenty-two inches. The colour is generally pied, such as yellow, black, dun, fallow, and brown intermixed.

FOX SHARK, OR THRESHER.—A genus of sharks (*Alupias*). The only known species, the *A. vulpis*, is found in the Mediterranean and the Atlantic. The upper lobe of the tail fin is nearly equal in length to the whole body, and is used as a weapon of great power. The fox shark is very bold and voracious. The average length, tail included, is about 13 feet.

FOXTAIL GRASS.—A genus of grasses (*Alopecarus*), of which about six species are British. The meadow Foxtail grows nearly two feet high, and is one of the best meadow and pasture grasses, and good for lawns.

FRACTIONS, *frak'-shuns* (from Lat., *frango*, I break), a term applied to designate a part of any magnitude, integer (whole number), or unit. For example, "two and a fraction" means two units and that part of a unit which can be distinguished as one-half, two-fifths, and so on. In the fraction $\frac{1}{3}$ in arithmetic, or $\frac{a}{b}$ in algebra, the figure 1 or a is the *numerator*, and 3 or b is the *denominator*; and they represent that, if a whole number is divided into *three* or b parts, only *one* or a parts are taken. In the addition of fractions, the fractions must be brought down to the same denominator, and their numerators (as expressed in the value of their new denominator) must then be added, when we have one whole fraction. The true definition of a *fraction* may be thus summed up:—It is the division of its numerator by its denominator; as *seven-eighths* are equivalent to the whole number 7 *divided* by 8—whence a fraction is obtained. Decimal fractions simplify calculations greatly, as they are constructed on the principle of having one common denominator—a multiple of ten; and thus fractions can be added, subtracted, and divided without repeating over and over the tedious process of bringing them down to a common denominator.

FRACTURE, *frak'-tshur* (Lat., from *frango*, I break), the term applied to broken bones. Fractures are divided into simple, compound, comminuted, and complicated. Simple fractures are those in which the fracture does not communicate with the external air. These are by far the most common, and usually affect the shaft of long bones, this part being the most subject to injuries of this description. Compound fractures are those in which one or more bones are broken, and the fracture communicates with the external air by means of a wound in the soft parts. Comminuted fractures are those in which the bones are broken into several portions; while complicated fractures are such as are complicated with some other injury; as a wound of the principal artery of the limb. Fractures are also distinguished as transverse, oblique, or longitudinal, according to their direction. The treatment of fractures consists in restoring the broken fragments, as nearly as possible, to their former positions, and securing them in that state. When the limb has been reduced, or set, it is to be placed in *splints*, which are thin pieces of wood, or other material of the requisite firmness and length, shaped and hollowed out, so as to fit evenly without making undue pressure upon any part. The period taken for the healing of a fracture varies according to the bone broken, the age, constitution, &c., of the patient. It is quicker in children than in adults, and in adults it is slowest in old age. The treatment of compound fracture consists in placing the broken bones in opposition, and healing the external wound, so as to convert the compound into a simple fracture.

FRAGARIA, *frag-ai'-re-a* (from Lat., *fragrans*, fragrant). (*See* STRAWBERRY.)

FRAMBOESIA, OR YAWS, *fram-bo-e'-ze-a* (Fr., from *framboise*, a raspberry), a disease of the skin, indigenous to the Antilles as well as Africa. It consists of imperfectly suppurating tumours, which gradually increase in size until they become as large as, and somewhat resemble, a raspberry. It seldom proves dangerous, and is propagated solely by the contagion of the matter discharged from the eruption when applied to the broken skin of another person who has not previously had the disease; for it only affects the same person once.

FRANCOACEÆ, *fran-ko-ai'-se-e*, the *Francoa* family, a natural order of *Dicotyledones*, sub-class *Calyciflorœ*, consisting of stemless herbs. There are but two genera—*Francoa* and *Tetilla*, and five species, all natives of Chilli. The *Francoas* are reputed to be cooling and sedative; *Tetilla* is astringent, and is employed as a remedy for dysentery.

FRANCOLIN, *fran'-ko-lin.*—A genus of birds of the family *Tetraonidœ*, having a great resemblance to partridges, natives of Europe, Asia, and Africa.

FRANKENIACEÆ, *frank-e-ne-ai'-se-e* (after John Frankenius, professor of botany at Upsal), the *Frankenia* family, a natural order of *Dicotyledones*, sub-class *Thalamiflorœ*, consisting of herbs and under-shrubs. The plants of the order chiefly occur in the South of Europe and North of Africa, but are found in other parts. They are mucilaginous and slightly aromatic. The leaves of a species of Beatsonia are used at St. Helena as a substitute for tea.

FRANKINCENSE, *frank-in'-sense* (Ang.-Nor.), a name given to a species of gum-resin derived from the *Boswellia serrata*, and imported from the Levant. By melting it in water, and straining it through coarse cloths, it is cleaned from a good deal of the oil which is one of its component parts—the oil which is extracted being termed Burgundy pitch, or white resin. If frankincense is sprinkled on coals, it emits a peculiar aromatic odour; whence its name. It is now used in the services of the Roman Catholic Church; and in ancient times by the Jews, Greeks, and Romans.

FRASERA, *fra-se'-ra* (named after John Fraser, a collector of North-American plants), a genus of herbs belonging to the natural order *Gentianaceœ*. The root of the species *F. carolinensis*, or *Walteri*, has properties similar to gentian-root, but is less powerful. It is known as American columba.

FRAXINUS, *fraks'-e-nus*. (*See* ASH.)

FRECKLES, *frek'-ls* (Lat., *lentigines*), small yellow or brownish spots which appear on the face, especially of fair persons much exposed to the weather. Various applications have been proposed for their removal; one of the best is a liniment composed of lime-water and oil, with the addition of a little ammonia.

FREESTONE, *free'-stone* (Sax., *stan*, stone), the name generally given to any soft stone that can be readily sawn and worked with the mallet and chisel. The various kinds of stone that come from the quarries near Bath, and those near Portland, and in the Isle of Purbeck, are freestones; and some kinds of limestone are also included under this term, as well as soft sandstones and oolites.

FREEZING, *freez'-ing* (Ang.-Sax.), the solidification or congelation of water or atmospheric vapour by cold. Water begins to freeze when the temperature of the atmosphere is 32° Fah., at which point ice begins to appear, and continues to be formed, unless some circumstance, such as the disturbance of the water, interferes. As the cold increases, other liquids, which are able to resist the temperature at which water congeals, begin to freeze, and pass into the solid form.

FRENCH BERRIES. (*See* RHAMNUS.)

FRENCH CHALK, *frentsh tchawk*, a kind of soap-stone of a soft and greasy nature, known by that name, and sometimes called Briançon chalk, because it is obtained in great quantities near that town, and in other parts of France. It forms a white pigment when properly prepared, and is much used by tailors in marking the pattern of garments on cloth, before cutting them out, as the marks made can be easily obliterated, and cause no injury to the material. It is used also by bootmakers, in the form of powder, as a small portion shaken into a new boot makes it more easily drawn on.

FRESH-WATER HERRING. (*See* COREGONUS.)

FRESH-WATER MUSCLE, *mus'-sel.*—The popular name of a family of lamellibranchiate molluscs, *Unionidœ*, allied to muscles. All the species are inhabitants of fresh water, and they are more abundant in North America than in Europe. The inside of the shell has a brilliantly coloured lining, which is sometimes used as a substitute for mother-of-pearl, and pearls are sometimes produced, especially in the molluscs found in the Welsh and Scotch rivers. One pearl from the Conway, presented to Queen Catherine, wife of Charles II., by Sir Richard Wynn, is preserved among the crown jewels. There are four British species; one, *Unio margaretifera*, found in the streams of mountainous districts, furnishes most pearls.

FRESH-WATER STRATA. (*See* GEOLOGY.)

FRICTION, *frik'-shun* (Lat., *frictio*), the resistance which a moving body meets with from the surface of the body on which it moves. As no surfaces are perfectly smooth, the imperceptible asperities, which may be supposed to exist on all surfaces, however highly polished, become to some extent interlocked, and a certain amount of force is requisite to overcome the mutual resistance to motion of the two surfaces, and to maintain the sliding motion even when it has been effected. By increasing the pressure, the resisting power of friction is increased; while, on the other hand, by rendering the surfaces more smooth, and by lubrication, the resistance to motion is diminished, although it cannot entirely be avoided. Friction is essentially a passive resistance, a negative force, produced by pressure, to which it bears such relation that its amount may be measured by the same unit, and be enunciated in the same terms. It is always found that the friction is greater between substances composed of the same material than between the surfaces of heterogeneous bodies.

FRIGATE BIRD (*Fregata Aquilus*, Ray), a bird common on the intertropical American coasts, and in the Atlantic and Pacific oceans. It is allied to the cormorants, but differs from them by having a forked tail, short feet, the membranes of which are very deeply notched, an extraordinary spread of wing, and a beak, both mandibles of which are curved at the tip. The plumage is, on the upper parts purple black, the throat and belly white, and the beak red. The frigate-bird is incapable of either swimming or diving; but it seizes fish when they appear at the surface, or, as in the case of flying-fish, above it; and it attacks such gannets and sea swallows as may be returning with full pouches to their nests in the rocks. The frigate-bird soars above its victim, and then, plunging down, strikes it on the head with its beak; the result is an instant disgorging of the day's fishing, which, as it falls, is followed by the robber, who invariably overtakes and secures it before it reaches the water.

FRIGID ZONE. (*See* ZONE.)

FRINGE, *frinj*, in Optics, fringes are coloured bands of diffraction, appearing when a beam of light is transmitted through a small orifice.

FRINGE TREE, a genus of plants (*Chionanthus*), of the natural order *Oleaceæ*, natives of America, the West Indies, Ceylon, and Australia. They are either small trees or large shrubs. The snow-flower (*C. Virginica*), the common fringe tree is found throughout the United States. It is from 10 to 20 feet in height, and the corolla is divided into four large linear segments, whence it takes its name. It is cultivated as an ornamental plant.

FRINGILLIDÆ, *frin-jil'-le-de* (Lat., *fringilla*, a chaffinch), a term applied to a class of birds belonging to the order *Insessores* and its division *Conirostres*. They are characterised by a broad-based, sharp-pointed conical beak, the size of which, in comparison with their head, is something enormous. It is well known that the *Fringillidæ* feed almost entirely upon different seeds of plants and nuts; consequently their beak is required to be strong in order to enable them to obtain their food. The class includes all buntings, crossbills, grosbeaks, linnets, canary-birds, finches, and many other conirostral birds. The *Fringillidæ* are frequently known under the general term of Finches. (*See* FINCHES.)

FRIT.—A very small insect of the same family as the house-fly, which, in some parts of the north of Europe commits great ravages on the barley crops.

FRITILLARY, *frit'-il-la-re.*—A genus of plants, of the natural order *Liliaceæ*, bulbous rooted with bell-shaped pessarid of six sigments. About 20 species are known, natives of the northern temperate regions. They have drooping flowers, and some of the species are very beautiful. The common Fritillary (*F. meleagris*), is found in pastures in the southern and eastern parts of England. It is about a foot high, and the flowers are marked with dark spots.

FROG, *frog* (Sax., *froga*).—A genus (*Rana*) of the order *Batrachia*. Frogs are chiefly distinguished from toads by the unusual length of the hind feet, which are strong and well-palmated; hence, their great power both of jumping and of swimming; their skin also is smooth; and there is not only a row of fine teeth round the upper jaw, but the palate also is furnished with another row placed transversely. It is one of the many singularities of these animals, that while in the young or tadpole state, they are herbivorous, living only upon aquatic plants, yet no sooner do they effect their metamorphosis, than they become carnivorous, pursuing slugs, insects, &c., and consuming them alive or dead. The frog deposits its ova or spawn some time in March, in a clustered gelatinous mass. This lives for a month or five weeks, and at the end of that time, there issues from each little black globule a living tadpole. In this their first stage the young frogs have elongated bodies, laterally-compressed tails, and external branchiæ; their small mouths are furnished with small hooks or teeth, for the separation of vegetable matter, and they have small tubes on the lower lips, by which they attach themselves to aquatic plants, &c. The external branchiæ next disappear, and become covered with a membrane, being placed in a sort of sac under the throat; and the animal then breathes after the manner of the fishes. Furnished with eyes and nostrils, the body of the animal is distended with the great extent of the digestive canal, and it has a large tail for swimming. Soon, however, the posterior limbs are gradually put forth near the origin of the tail, and are developed first; the anterior feet then begin to show themselves; the tail gradually becomes less and less, shortens, shrinks, and seems at last to be absorbed; the mouth widens, and loses its horny processes or jaws; the eyes are guarded by eyelids; the belly lengthens and diminishes in comparative size; the intestines become short; the true lungs are developed, and the internal branchiæ are obliterated; the circulation undergoes an entire change; and the animal, hitherto entirely aquatic and herbivorous, becomes carnivorous, and for the most part terrestrial. In the frog the muscular system, especially the muscles of the abdomen, are more developed than in the other reptiles; offering in this particular some analogy to the abdominal structure of the mammifers. But it is in the disposition of the muscles of the thigh and leg in the frogs and other anurous batrachians, that the greatest singularity is manifested. These, whether taken conjointly or singly, present the greatest analogy with the muscular arrangement in the same parts in man. We find the rounded, elongated, conical thigh, the knee extending itself in the same direction with the thigh-bone, and a well-fashioned calf to the leg, formed by the gastrocnemii muscles. It is impossible to watch the horizontal motions of a frog in the water, as it is impelled by these muscles and its webbed feet, without being struck by the complete resemblance in this portion of its frame to human conformation, and the almost perfect identity of the movements of its lower extremities with those of a man making the same efforts in the same situation. By the aid of these well-developed lower limbs and the prodigious power of their muscular and bony levers, a frog can raise itself in the air to twenty times its own height, and traverse in a single bound a space nearly fifty times the length of its own body. There are several species of frogs. The red frog (*R. temporaria*) abounds in most parts of England and Scotland. The green, or edible frog (*R. esculenta*) is found in central and southern Europe, where it is cultivated and fattened as an article of food. Among the most peculiar may be mentioned the bull-frog of North America (*Rana pipiens*) and the tree-frog (*Hyla leucomystax*, Graves). The former is a very large species, measuring eight inches in length and four in width. Its colour is olive on the upper part, and greenish-white darkly spotted on the belly. It is said that this frog frequents springs only, and, although it is a great destroyer of young goslings, it is tolerated from the benefits derived from its scavenger habits. Its chief peculiarity is its voice, which resembles the distant bellowing of a bull. Of the tree-frog there are several species. They are found in France, Germany, and Italy, as well as in America and Asia. Africa also produces a singular race of frogs, which, from having some of their toes enveloped by a conical horny claw or cap, have been termed *Dactylethræ*, or thimble-toed.

FROG-FISH. (*See* ANGLER-FISH.)

FROND, *frond* (Lat., *frons*), the leaf of a fern or other acotyledonous plant. Fronds are seldom articulated; they are either sessile or stalked; are frequently toothed or incised in various ways, and are often highly compound.

FRONTAL, *front'-al* (Lat., *frons*, the forehead), denotes of or belonging to the forehead: as the frontal bone, arteries, nerves, &c.

FROST. (*See* FREEZING.)

FROST-BITE. (*See* CHILBLAIN, GANGRENE.)

FRUCTOSE, OR FRUIT-SUGAR, *fruk'-toze* (Lat., *fructus*, fruit), found in most ripe fruits, and producible from starch and ligneous bodies by acting on them with dilute sulphuric acid. (*See* SUGARS.)

FRUIT, *frute* (Lat., *fructus*), that part of the plant which is formed by the ripening of the ovary and its contents, after the process of fertilization. The fruit consists essentially of the mature ovary, with its seeds or ripened ovules; but other parts of the flower may enter into its composition. Thus in cases where the calyx is adherent to the ovary, as in the apple, melon, and gooseberry, that organ necessarily forms part of the fruit; in the rose, the concave thalamus, which bears the carpels on the inner surface, becomes a portion of the fruit; in the strawberry, again, the fruit consists of a succulent hemispherical thalamus, bearing the carpels on its convex surface; in the acorn, hazel-nut, and filbert, it consists of pistil, calyx, and bracts, combined together; while in the pineapple, it is composed of the ovaries, floral envelopes, and bracts of several flowers. As the ovary ripens into the fruit, it frequently undergoes important alterations, from the addition or the obliteration of certain parts. The fruit is *simple* when it is formed of a single carpel, and when it is the only one produced by the single flower. The legume and the drupe are examples. The *apocarpous* fruits are formed of single carpels, but several are produced by a single flower. Those fruits are *syncarpous* which are formed by the more or less complete combination of two or more carpels, and of which only one is produced by a single flower. Fruits formed by the combination of several flowers form a distinct class. They are sometimes called *anthocarpous* fruits. In the majority of fruits, the pericarp or shell consists simply of the walls of the ovary in a modified state; but where the calyx is adherent, it necessarily presents a more complicated structure. It is divided into three layers or regions—the external, called *epicarp*, or *exocarp*; the middle, called *mesocarp*, or sometimes, in allusion to its fleshy or succulent nature, the *sarcocarp*; and the inner, called the *endocarp*, or, when very hard, the *stone* or *putamen*. The pericarp either opens to allow the seeds to escape, or it remains closed, and the seeds can only become free by its decay. In the former case, the fruit is said to be *dehiscent;* in the latter, *indehiscent*. Dehiscent fruits open in various ways. When a fruit separates more or less completely into two or more pieces, called *valves*, or even when it opens by a single longitudinal slit, it affords an example of *valvular* dehiscence. When the opening takes place by a transverse line through the fruit, so that the upper part is separated from the lower, like the lid of a pill-box, the dehiscence is said to be *transverse* or *circumscissile*. A third kind of dehiscence, called *porous*, is distinguished. The seeds escape through little pores or slits, formed irregularly in the substance of the fruits, by a process called rupturing. (*See* OVARY, SEED.)

FRUSTUM, *frus'-tum* (Lat., *frustum*, a morsel or gobbet), in Geometry and Mathematics, the name applied to any piece cut from any solid figure, but more particularly to the bottom of a cone or pyramid, from which the upper part, which contains the apex, has been cut away.

FUCACEÆ, *fu-kai'-se-a* (Gr., *phukos*, sea-wrack), a sub-order of *Algæ*, distinguished by their organs of reproduction. Some species attain a great size, having fronds 1,000 feet long, the stem being in no part more than an inch in diameter. *F. vesiculosus*, commonly known as the sea-wrack, is much used during the winter months in some of the islands of Scotland for feeding horses and cattle. The expressed juice of its vesicles has been used medicinally as an internal remedy, and frictions of the plant have been employed externally in glandular and scrofulous affections. It was formerly extensively employed for making kelp.

FUCHSIA, *fu'-she-a* (so named in honour of Fuchs, a famous German botanist of the 16th century), a genus of shrubs belonging to the natural order *Onagraceæ*. The species *F. coccinea*, a native of South America, was introduced into this country at the close of the last century, and is now one of our commonest greenhouse and window shrubs. It is a very elegant plant: the young wood and nerves of the leaves are tinged with purplish-red; the flowers are produced from the axils of the leaves, and hang in a most graceful manner by thread-like peduncles. Many species have been introduced into Britain, and an immense number of beautiful varieties have been developed by cultivation. The fruits of several fuchsias are somewhat acid, and may be eaten.

FULGORA, *ful-go'-ra* (Lat., *fulgur*, lightning). (*See* LANTERN-FLY.)

FULGARITES, *ful'-ga-rites.*—Small tubes, seldom exceeding an inch and a half in diameter, with an internal surface of a hard glassy character, supposed to be formed by the action of lightning melting and vitrifying the sand in sand-banks.

FULLER'S EARTH, *ful'-lerz erth*, a porous soft silicate of alumina, having a strong attraction for greasy matters. If made into a paste with water, and laid upon a greasy spot, it removes the fatty or oily matter by capillary attraction. It is largely used to cleanse woollen fabrics from the grease contained in the wool from which they are made. It is found abundantly near Reigate, in Surrey.

FULMAR, *ful'-mar* (Gaelic, *fulmaire*).—One of the largest of the petrels of the northern hemisphere, abundant in Europe and North America. The fulmar (*Fulmaris glacialis*), known to seafarers as the "Motley Mawk," breeds extensively in St. Kilda and Skye. In the former island, the young are only permitted to be taken in the first week of August, and then it is not unusual for nearly 20,000 to be killed. After the oil (which possesses nearly all the qualities of cod-liver oil) has been extracted, the birds are stored as winter food for the islanders.

FULMINIC ACID, *ful-min'-ik* (Lat., *fulmen*, a thunderbolt, from the noise produced by the explosion of its compounds), an acid possessing the same composition as cyanic and cyanuric acids, but having totally different properties. It is not known in an isolated state, but it forms compounds with the metals possessed of powerfully explosive properties.

FUMARIACEÆ, *fu-ma-re-ai'-se-e*, the Fumitory family, a natural order of *Dicotyledones*, sub-class *Thalamifloræ*, consisting of 15 genera and about 110 species, principally occurring in thickets and waste places in the temperate latitudes of the nothern hemisphere. They are smooth herbs, with a watery juice. The *Fumariaceæ* possess slightly bitter, acrid, astringent, diaphoretic, and aperient properties. Some species are cultivated in our gardens and greenhouses. Of these the most important is *Dicentra spectabilis*, which has very showy, but scentless flowers. The order is named from *Fumaria*, one of the genera.

FUNCTIONS, *funk'-shuns.*—In Mathematics, when, in an equation, two or more variables are combined with constants, and a change of the value of one variable implies a corresponding change in the other, such variables are said to be functions of each other.

FUNDI, OR FUNDUNGI. (*See* RASPALUM.)

FUNGI, *fun'-ji* (Lat.), the Mushroom family, a natural order of *Acotyledones*, sub-class *Thallogenæ*, consisting of parenchymatous cellular plants, growing in or upon damp mould; in or upon the wood and the herbaceous parts of living or dead plants; upon living or decaying animal substances, and in solutions of organic materials. A great number of species are microscopic plants. Fungi have been divided into six sub-orders, which respectively include the mushrooms and their allies, the puff-balls, the smuts, the mildews, the truffles and morels, and the moulds. (*See* AGARICUS, AMANITA, LYCOPERDON, CORDYCEPS, UREDO, PUCCINIA, TUBEE, MORCHELLA, PENICILLIUM.)

FURZE. (*See* ULEX.)

FUSANUS, *fu-zai'-nus*, a genus of the natural order *Santalaceæ*. The species *F. acuminatus* yields the quadrung nut of Australia, an edible fruit resembling the almond in flavour.

FUSUS, *fuse'-us* (Lat., a spindle), a genus of gasteropodus molluscs, nearly allied to *Murœ*. The shell is about six inches long. One species is known in the South of England as the red whelk. It is often used as a bait for cod and other fish.

G.

GAD-FLY. (*See* BOT FLY.)

GADIDÆ, *gai'-de-de* (Lat., *gadus*, a cod-fish), a family of fishes of the soft-finned order; as the Cod. They are easily known by the position of the ventral fins under the throat and the pointed character of those fins. The body is long, rather compressed, and covered with small soft scales. The greater number of the species live in cold or temperate seas, and furnish the greater portion of the fish obtained in England and America.

GALACTODENDRON, *gal-ak-to-den'-dron* (Gr., *gala*, milk; *dendron*, a tree). (*See* BROSIMUM.)

GALAGO, *gai-la'-go.*—A genus of mammalia of the Lemur family, remarkable for the length of the hind-legs and the ears. They are natives of Africa and Madagascar. They are very active, and make rapid jumps to catch insects. In Senegal they are prized as food.

GALANGLE, *ga-lan'-gle.*—A genus of plants of the natural order *Zingiberaceæ*. The root-stocks possess stimulating properties similar to those of ginger, in the eastern archipelago.

GALANTHUS, *gal-an'-thus* (Gr., *gala*, milk; *anthos*, flower).—The Snowdrop, a genus of the natural order *Amaryllidaceæ*. The species *G. nivalis* is found growing wild in our thickets, and is much cultivated in borders for the sake of its early and pretty blossoms. It is a bulbous plant; the flower is solitary, white, and drooping, the inner segments being greenish.

GALAXY. (*See* MILKY WAY.)

GALBANUM, *gal'-ba-num* (Lat.), a fetid gum-resin used in medicine internally as an antispasmodic, and externally as a stimulant and discutient application to indolent tumours and chronic swellings. It is imported from India and the Levant; but botanists have, as yet, been unable to determine the plant yielding this resin.

Galbanum is officinal in our Pharmacopœias, and is supposed to be the same substance as the *chelbenah* of Scripture.

GALBULUS, *gal'-bu-lus* (Lat., the nut of the cypress-tree), a kind of fruit generally regarded as a modification of the cone.

GALENA, *ga-le'-na* (Gr., *galene*, tranquillity, on account of its supposed effect in mitigating disease), an important mineral, forming the principal ore of lead. It is a protosulphide of the metal, and is found crystallized more or less distinctly in cubes of a deep leaden colour and strong metallic lustre. It is found in veins in crystalline rocks, and most abundantly in carboniferous limestone.

GALERITIES, *ga-le-ri'-teez* (Lat., *galea*, a helmet), a genus of fossil sea-urchins, abounding in the Chalk formation, and from their shape popularly known in Kent and Sussex as "sugar-loaves."

GALIACEÆ, *gal-e-ai'-se-e* (from *galium*), the Madder family, a natural order of *Dicotyledones*, sub-class *Corolliflorœ;* common weeds in the northern parts of the northern hemisphere, and also in the high mountainous districts of Peru, Chili, and Australia. The *Galiaceœ* are chiefly remarkable for the presence of a colouring matter in their roots. (*See* RUBIA.) Some have valuable medicinal properties. (*See* GALIUM.)

GALIPEA, *ga-le-pe'-a*, a genus of the natural order *Rutaceœ*. The species *G. officinalis* and *cusparia* yield the drug known as Angustura or Cusparia bark. They are natives of South America. (*See* ANGUSTURA BARK.)

GALLA OX. (*See* SANGA.)

GALL-BLADDER, *gawl* (Sax., *gealla*, gall; Lat., *vesicula fellis*), an oblong membranous receptacle, situated on the concave side of the liver, under the right lobe. It is about the size of a small hen's egg, and resembles a pear in shape. It has three coats—an external or peritoneal, a middle or fibrous, and an internal or villous. The inner coat has a reticulated honeycomb appearance, but does not possess any follicles for the purpose of secretion. It serves as a reservoir for the bile, which, when digestion is not going on, regurgitates through the cystic duct, and is retained for future use. The cystic duct connects the gall-bladder with the hepatic duct, which proceeds from the liver, and the two, when united, form the *ductus communis choledochus*, by which the bile is conveyed to the duodenum.

GALL FLY.—A genus of insects (*Cynips*) forming the family *Gallicolœ*. The females deposit their eggs in a puncture made in a leaf. This puncture produces a tumour, which develops into the excrescence known as "gall," within which the eggs undergo this transformation, the perfect insects eating their way out.

GALLIC ACID, *gal'-lik* (from *galls*).—This important vegetable acid exists ready formed in the gall-nut, in sumach, in valonia, and in a large number of other astringent vegetables. It is readily obtained by allowing an infusion of gall-nuts, or powdered gall-nuts freely moistened with water, to stand in a warm place for some weeks. A species of fermentation is set up, during which the gallic acid is formed in large quantities by the decomposition of the gallotannic acid or tannin contained in the galls. Gallic acid crystallizes in silky needles or brilliant rhomboidal prisms, which dissolve in 100 parts of cold water and three parts of boiling water. It is freely soluble in alcohol, but sparingly so in ether. Heated to a temperature of from 410° to 420°, gallic acid sublimes, and is wholly converted into pyrogallic and carbonic acids. If the temperature passes 480°, melagallic acid is formed. Gallic acid is extensively used as a source of pyrogallic acid, so largely employed in photographs.

GALLINACEOUS BIRDS, *gal-lin-ai'-she-us* (Lat., *gallus*, a cock), the name applied to such birds as, in common with the domestic cock, have the upper mandible vaulted, the nostrils pierced in a large membranous space at the base of the beak, and covered by a cartilaginous scale; wings short, flight laborious, and carriage heavy. Birds of this order have extremely powerful gizzards, and generally large globular crops.

GALLINULE, *gal'-li-nule*, a genus of birds, of the family *Rallidœ*, nearly allied to the coots. Only one species, the Water-hen, or Moor-hen, is found in Britain.

GALLIUM, *gal'-le-um*, a new elementary metal discovered by M. Lecoq de Boisbaudran, in 1875.

GALLITANNIC ACID. (*See* TANNIC ACID.)

GALLS, *gawlz* (Ssx., *gealla*, a gall), excrescences produced on the branches and leaves of trees by the attacks of insects. (*See* GALL FLY.) Oak-trees are especially liable to be thus attacked. Galls are extensively employed in tanning, for making ink, and for other purposes in the arts. (*See* QUERCUS.)

GALL-STONES. (*See* CALCULUS.)

GALVANISM, *gal'-van-izm*.—The science which relates to the phenomena connected with a peculiar form of electrical force obtained by certain arrangements of metals and liquids. Galvani, a professor of anatomy at Bologna, in 1789, made the discovery that the transmission of electricity through the nerves of a frog, recently killed, would excite muscular contractions; and he afterwards found that similar convulsions could be produced by merely touching the nerves and muscles with two different metals and then bringing the metals into contact. Upon these and similar phenomena, observed in an extended series of experiments with different animals, Galvani based his theory of "animal electricity," which was received with enthusiasm by the Italian physiologists of his day. According to this theory, every animal is endowed with an inherent constitutional electricity, generated in the brain and distributed through the nervous system, the principal reservoirs being the muscles. Volta, a professor of natural philosophy at Pavia, repeated Galvani's experiments, and proved that the contractions in the muscular fibre depended, not on any peculiar electrical condition of the animal frame, but on a feeble action derived from the metals with which the nerves and muscles were brought into contact. To determine the exact conditions under which electrical disturbance is produced, he commenced a course of experimental researches on the energies of different metals, which eventually led him to the discovery of the *pile*, an apparatus which must be regarded as the source of all the great discoveries relating to electricity made in modern times. Two theories have been offered in explanation of the action of the voltaic pile or battery. The *contact theory* of Volta assumes that different metals have different electrical capacities, and that electrical disturbance results from simple contact. A *galvanic pair* is an arrangement consisting of two plates (copper and amalgamated zinc), dissimilar in conducting power, immersed in a liquid which acts chemically on one of them, and capable of being placed in conducting connection. The liquid employed is water, with a small quantity of sulphuric acid, and the connection between the plates is by wires of copper or other conductor of electricity. Faraday and others have proved that chemical action does give rise to electrical force; that when the chemical action of a battery diminishes or ceases, the voltaic current also diminishes or ceases; and that powerful currents may be generated without bringing dissimilar metals into contact. (*See* ELECTRICITY.) The current force of the voltaic battery has been practically applied to many useful purposes. It is employed in telegraphy to deflect magnetic needles at a distance of thousands of miles. Its power of causing chemical decomposition has been turned to account by the metal-worker, the engraver, and the calico-printer. (*See* ELECTROTYPE; ELECTRO-PLATING AND GILDING; ELECTRO CALICO-PRINTING.) The current is also much used as a remedial agent in the treatment of many forms of disease of the human body; decided relief has been obtained in paralysis, lockjaw, St. Vitus's dance, tic-doloreux, and deafness. Though the term *galvanism* is still commonly applied to the science relating to the current force, it is certainly less appropriate than either *voltaic electricity* or *voltaism*, for the observations of Galvani were unimportant compared with those of his great follower, Volta.

GAMA GRASS, a genus of grasses (*Tripsacum*). Only two species are known, the *T. Dactyloides* of Mexico, very valuable as a fodder grass, and the *T. Monostachyan* of Carolina. The name Gama is supposed to be derived from that of a Spaniard who first collected it in Mexico.

GAMBOGE. (*See* CAMBOGE, GARCINIA.)

GAMMARUS, *gam'-ma-rus*.—A genus of *Crustacea*, including one species, the Fresh-water Shrimp (*G. pulex*), well known in this country. It is very small.

GANGLION, *gang'-le-on*.—A small rounded or elongated nervous mass, of a reddish-grey colour situated in the course of the nerves. Ganglions are of two kinds, one forming part of the cranial system of nerves, and situated near the origins of many of the cranial and all of the vertebral nerves; the other forming part of the sympathetic system, extending in a series along each side of the vertebral column, and occurring numerously in other parts. They differ widely from each other in figure and size, some of them being large and conspicuous, while others may be almost termed microscopic.

In Surgery, a small indolent fluctuating tumour, developed in the course of the tendons, and containing a semi-fluid secretion inclosed in a cyst, generally communicating with the tendonous sheath. Ganglions sometimes form without any apparent cause, but generally they arise from some wrench or tension of the tendon. They are most frequently situated about the wrist, and the swelling is usually globular; but when much enlarged, it is rendered irregular by the pressure of the tendons.

GANGRENE, *gang'-green* (Gr., from *grao*, I feed upon), a term applied to the first stage of mortification, so called from its eating away the flesh. It is divided into two kinds—the moist and the dry; the former, called also inflammatory or acute gangrene, is that which is preceded by inflammation; while the latter, called also chronic or idiopathic gangrene, is that which takes place without any visible inflammatory action having preceded it. The most frequent causes of grangrene are violent inflammation, erysipelas, contusions, burns, cold, deficient circulation of the blood or nervous energy. Gangrene may also arise from a diseased state of the blood-vessels, attended with debility of the constitution, a form of the disease commonly known as *gangrena senilis*. It rarely occurs except in advanced life, and usually attacks the lower extremities, proceeding from the toes upwards. Hospital gangrene, or *phagedæna gangrenosa*, is a form of this disease which attacks open wounds or ulcers, and is so called from its appearing most frequently in crowded hospitals, and causing a fearful mortality among the patients. Its symptoms and treatment are similar to those already mentioned.

GANNET, OR SOLAN GOOSE, *gan'-net* (Sax., *ganot*).—A genus (*Sula*) of web-footed birds of the family *Pelecanidæ*. In the North of Scotland, the Hebrides, and in Norway, this bird is very abundant. It is almost the size of the tame goose. The bill is about six inches long, jagged at the sides, and straight nearly to the point, where it inclines downwards. A loose skin, bare, and capable of considerable distension, hung from the blade of the lower bill, and extended over the throat, serves as a pouch in which to convey food to its young. The neck of the gannet is long; body flat, and very full of feathers. The crown of the head and a small space on the hind part of the neck are buff-colour, and, with the exception of the quill and the bastard wing-feathers, the remainder of the plumage is white. The legs and toes are black, but the forepart of each is marked with a bright green stripe. The food of the gannet consists of salt-water fish, the herring and pilchard being the staple. It takes its prey by darting down on it from a considerable height. It makes its nests, which are composed chiefly of turf and sea-weeds, in the caverns and fissures of rocks or on their ledges, as well as on the plain surface of the ground. The female lays three white eggs, somewhat smaller than those of the goose. It is stated, however, that the three eggs are only laid in the event of the first and second being removed; and that if left to its own devices, the bird will lay but one egg. These birds are found in great abundance on the island of Kilda, a little spot standing remotely westward in the Atlantic Ocean; on the Bass Rock in the Firth of Forth, and on some parts of the coast of Ireland.

GANOID FISHES, *gai'-noid* (Gr., *ganos*, "splendour."—Fishes with shining scales, as the sturgeon. There are not many living species; but fossil species are numerous.

GAPES, a disease to which fowls are subject, caused by the presence of small worms in the windpipe. Twenty of these worms have been found in one chicken, and partridges and pheasants are also subject to them. Sometimes they can be removed by an oiled feather, or destroyed by putting a little *Epsom salts* into the food. If undisturbed, inflammation and death frequently result.

GARCINIA, *gar-sin'-e-a.* (*See* MANGOSTEEN.)

GARDENIA, *gar-de'-ne-a.*—A genus of the natural order *Cinchonaceæ*. From the fruits of *G. grandiflora*, *florida*, and *radicans*, beautiful yellow dyes are prepared, which are extensively used in China and Japan. The genus was named after Dr. Garden, of Charleston, South Carolina.

GARFISH, *gar'-fish* (*Esox Belone*, Linn.), a fish of the Pike family, common on the English, Irish, and Scotch coasts. It is about two feet in length, body tapering towards the tail, and of small circumference; beak-like snout; teeth minute and numerous; tail considerably forked. It possesses many names besides that here applied to it, and among the rest, "mackerel guide," because of its supposed habit of preceding the shoals of mackerel in their annual visits to shallow waters for the purpose of Spawning. It is sold in the London market. The flavour somewhat resembles that of mackerel.

GARGANEY. (*See* TEAL.)

GARLIC. (*See* ALLIUM.)

GARNET, *gar'-net* (Fr., *grenat*).—One of the precious stones or gems. It is found in rhombic dodecahedra, and consists chemically of the double silicate of lime and alumina, coloured by iron and manganese. When cut *en cabochon*, garnets are known as carbuncles (from *carbunculus*, a little coal). The Noble Garnet, or *Alamandine*, is of a crimson red colour. The finest garnets come from Pega. The pryrope is a species of garnet found in Bohemia, coloured with sesquioxide of chromium. Powdered garnets, commonly known as "red emery" are used for polishing and cutting other stones.

GARROT, *gar'-rot.*—A genus (*Clangula*), of the oceanic section of ducks. The Golden-eye (*C. vulgaris*) is well known in this country in the winter months.

GARRYACEÆ, *gar-re-ai'-se-e* (after N. Garry, of the Hudson's Bay Company), the *Garrya* family, small natural order of *Dicotyledones*, subclass *Monochlamydeæ*. There are but two genera, which include six species, all shrubs found in the temperate parts of North America, or in the West Indies.

GAS, *gas* (probably from Ger., *geist*, a spirit).—This word was first applied by Van Helmont to denote any permanent vapour produced from solid or liquid substances by chemical action. The elementary gases are—hydrogen, oxygen, nitrogen, and chlorine. The principal compound gases are—hydrochloric, hydrobromic, and hydriodic acids; sulphurous acid, nitrous acid, peroxide of chlorine, chlorous acid, hypochlorous acid, carbonic acid, sulphuretted, phosphoretted, seleniuretted, and telluretted hydrogen; cyanogen, protoxide of nitrogen, deutoxide of nitrogen, carburretted hydrogen, olefiant gas, carbonic oxide, and ammonia. One of the most important properties of gas is its perfect elasticity. There is an entire absence of cohesion among the particles, constituting an essential difference between a gas and a liquid. A liquid in a vessel has a definite surface or limit, but a gas will fill any vessel that contains it. (*See* DIFFUSION OF GASES.

GASES, LIQUEFACTION OF.—Many gases which are aëriform at ordinary pressures and temperatures, may be condensed into liquids, and even solids, by the combined action of pressure and cold. Faraday proved that the difference between gases and vapours is only one of degree, gaseous carbonic acid bearing the same relation to the solid gas that steam does to ice. He employed a very strong tube closed at both ends and bent at an angle. One end contained the substances necessary for the production of the gas, while the other was immersed in a freezing mixture. Some of the gases are liquefied with greater facility than others; thus a mere reduction of temperature to 0° is sufficient to reduce sulphurous acid to a liquid state.

GAS-TAR. (*See* TAR.)

GASTEROPODA, *gas-ter-op'-o-da* (Gr., *gaster*, stomach; *pous*, foot), a class of molluscous animals, whose means of locomotion consist of a fleshy disc or foot situated under the abdomen. They are both terrestrial and aquatic, and naked and possessed of a shell. Of the naked Gasteropoda the common slug will serve as an example. Among the terrestrial of the genus is found the snail; and among the aquatic, the whelk, winkle, &c.

GASTRALGIA, OR GASTRODYNA, *gas-tral'-je-a, gas-tro-di'-ne-a.* (*See* CARDIALGIA.)

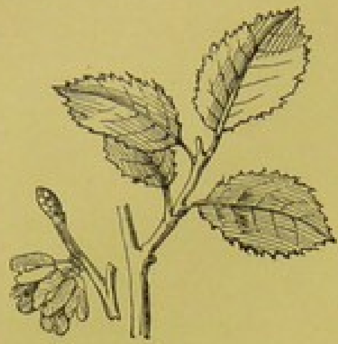
GASTRIC JUICE, *gas'-trik* (from *gaster*, the stomach), is the name given to the digestive fluid contained in the stomach, and which is secreted by the gastric glands on the introduction of food or other foreign substance. It is a clear transparent fluid, inodorous, a little saltish, and very perceptibly acid. Its most singular component is a peculiar organic substance called pepsine, to which its special properties are chiefly owing. The use of the gastric juice is to dissolve the various kinds of food in the stomach, reducing the albuminous and gelatinous portions of it to a state fit for absorption into the system.

GASTRITIS, *gas-tri'-tis* (Lat.), in Surgery, denotes inflammation of the stomach. It is known by pain in the epigastric region, increased when anything is taken into the stomach, vomiting, and hiccough; the pulse small and hard; and general prostration of strength, attended by fever and anxiety. It is produced by poisons of various kinds taken into the stomach, as arsenic or corrosive sublimate; by food of an improper nature; by draughts of any cold liquid when the body is much heated. It is a rapid and very dangerous disease, and requires prompt measures to be adopted.

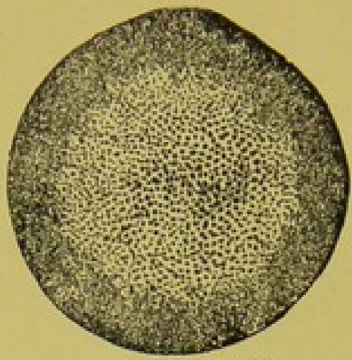
GASTROCHÆNA, *gas-trok-e'-na.*—A genus of lamellibranchiate molluscs, having a delicate shell of two valves. It often takes possession of an existing cavity, which it lines with a calcareous matter, so as to form a tube to which the valves of its cell are cemented. One of these molluscs (*G. modiolina*), common in the Mediterranean, perforates shells and limestones, and have been known to bore through an oyster into the ground below.

GASTRODIA, *gas-tro'-de-a.*—A genus of orchids. The best known species is a native of Tasmania, and is sometimes known as the native potato.

GASTRONEMIUS, *gos-tro-ne'-me-us*, is the

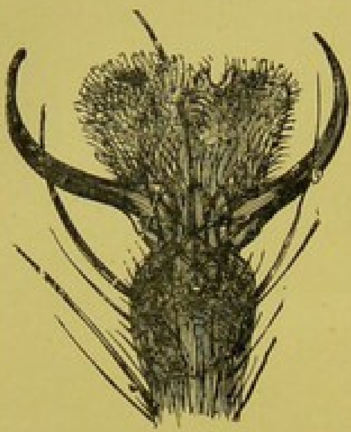


ELM.

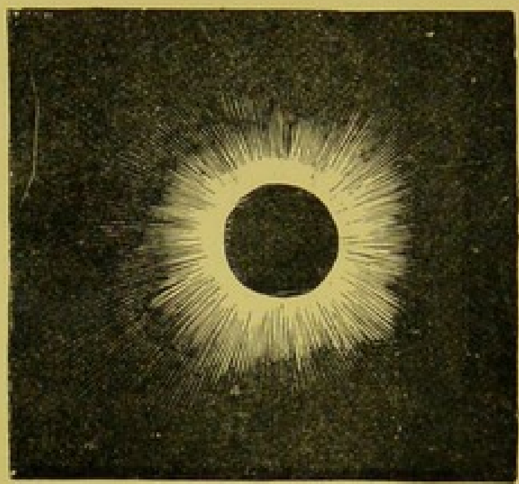


ENDOGENOUS WOOD (TRANSVERSE SECTION).

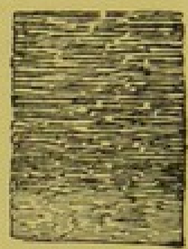
FIG-TREE.



FOOT OF FLY, MAGNIFIED.



SOLAR ECLIPSE WITH CORONA.



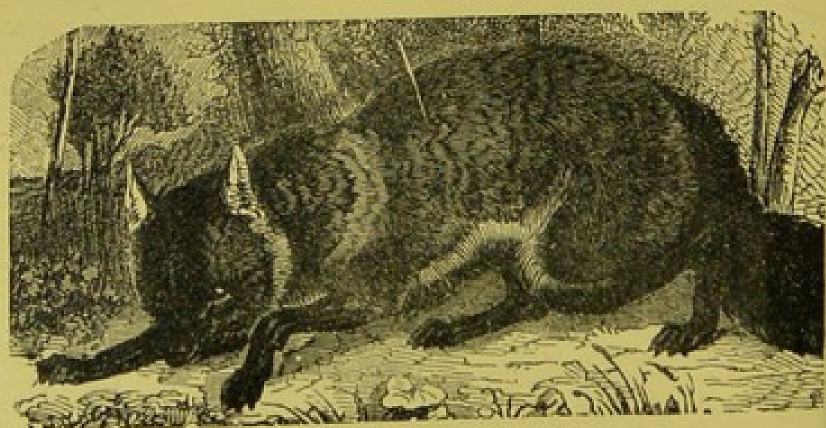
ENDOGENOUS WOOD (PERPENDICULAR SECTION).

TREE FROG.

FLY-CATCHER.

FLAMINGO.

FOSSIL FERN.



FOX.

name given to the muscles of the calf of the leg. The use of these muscles is to raise the heel and extend the foot.

GASTROTOMY, *gas-trot'-o-me* (Gr., *gaster*, and *tome*, an incision), an incision into the cavity of the abdomen, an operation sometimes resorted to in desperate cases; as where, in consequence of a rupture of the uterus, the child escapes into the peritoneal cavity. A somewhat similar operation, occasionally performed for the purpose of introducing food into the stomach, in the case of stricture of the gullet, and known as *gastrotomy*.

GAULT, *gawlt*, the term which is applied to a series of dark blue marls or calcareous clays, which occur between the upper and lower greensand of the chalk formation. The word "gault" is a provincial term for the clay itself, which is much used for brickmaking. When decomposed, it forms a very fertile soil, and is the main repository of the phosphatic nodules which are now so highly prized by the agriculturist.

GAULTHERIA, *gawl-the'-re-a.*—A genus of evergreen shrubs o fthe natural order *Ericeæ*, natives of temperate regions. *G. procumbene*, a native of North America, is known as Partridge Berry, Mountain Tea, and by other names. It is about five inches high, and has whitish flowers and red berries, which contain a pungent volatile oil, used as a stimulant and as a flavouring oil in perfumery. An infusion of the leaves is used as tea. A large species (*G. Shallon*) has purple berries eaten by the North American Indians. It has been transferred from America to this country as food for pheasants and other game. There are other species in Australia, Tasmania, on the Himalayas, and on the mountains of South America.

GAUR, *goor.*—A species of ox (*Bos Gaurus*), a native of the mountain jungles of India. It is of very large size, and has no dewlap. It is gregarious, being found in small herds, and is a bold and formidable animal, being respected, it is said, even by the tiger. It is supposed to be incapable of domestication.

GAVIAL, *gai'-ve-al.*—A genus of reptiles (*Gavialis*) of the crocodile family, but differing from true crocodiles and from alligators in the length and slenderness of the jaws. The only known species inhabits the Ganges. It is of great size, many specimens being 25 feet long.

GAYAL, *gai'-al.*—A species of ox (*Bos Gavæus*) found wild in the mountain regions of Central Asia, and domesticated in Aracan, Chillogory, the eastern part of Bengal, and other places. It is about the same size as the Indian buffalo. The milk of the cow is very rich, but not abundant.

GAZELLE, *ga-zel'* (Fr.) (*Antilope Dorcas*, Pallas), one of the most beautiful and graceful of the antelopes, chiefly inhabiting Arabia and Syria. It is about three feet six inches in length, and in height measures less than two feet at the shoulder. The horns of the adult male rise nearly perpendicularly above the orbits, are black, almost cylindrical, bending at first gently backwards, and finally forwards. The ears are long, narrow, and pointed; eyes large, mild, and black. The size of the gazelle about equals that of the roebuck; but the legs of the former are considerably longer, and the entire form more graceful. (*See* ANTELOPE.)

GEBANG PALM, *ge'-bang.*—A fan-leaved palm (*Corypha Gebanga*), native of the East Indies, and one of the most useful of palm-trees.

GECKO, *gek'-ko.*—A genus of reptiles of the lizard kind, of small size, natives of warm climates, and nocturnal in their habits. The name is taken from the peculiar cry of some of the species. The Gecko is credited with being venomous, and is known in Egypt as "the father of leprosy," but the character does not appear to be deserved. Insects are the chief food. From the formation of the feet, geckos can climb smooth surfaces, or walk inverted on ceilings. Two species are found in the South of Europe.

GELIDIUM, *je-lid'-e-um*, a genus of *Algæ*. From the species *G. corneum*, commonly known as *Algue de Java* in France, M. Payen first obtained the principle to which he has given the name of *gelose*. According to the researches of this chemist, one part of gelose dissolved in 500 parts of boiling water will afford, upon cooling, a colourless transparent jelly. Jellies made from this seaweed are much employed for food in Japan. Some of the species of Gelidium are supposed to afford the material used by a certain species of swallow in building the edible nests of China.

GELOSE. (*See* GELIDIUM.)

GEMINI, *jem'-e-ni* (Lat., the twins), the third constellation, or sign of the zodiac. The name of the Twins is given to the constellation from two remarkable stars of the first and second magnitude, to which the names of Castor (or α Geminorum) and Pollux (or β Geminorum) are given.

GEMMATION. (*See* REPRODUCTION.)

GEMS-BOK. (*See* ANTELOPES.)

GENERATION. (*See* PHYSIOLOGY.)

GENERATIONS, ALTERNATION OF, *jen-e-rai'-shunz* (Lat., *generatio*).—A term applied to a series of phenomena connected with the reproduction of the lower animals. In their development from the ovum to the adult state, a large number not only pass through various stages, but also possess the power of multiplying themselves at certain periods of their growth. The greatest incompleteness and the highest degree of mutual dependence is to be observed in Campanulariæ and similar polypes, in which the generations representing the unity of the species are very unlike each other, and in which all the individuals are fused into an outward unity, or into a set of polypes. The development of animals which do not belong to the water, but to the air, also presents similar phenomena, but in a still higher and more free stage. The propagation of the Aphides through a series of generations has been long known. In the spring, a generation is produced from the ova, which grows and is metamorphosed, and, without a previous fertilization, gives birth to a new generation, and this again to a third; and so on for ten or twelve weeks; so that, in certain species which have been observed, nine such changes have been noted. At last, there occurs a generation consisting of males and females, the former of which, after their metamorphosis, are usually winged; fertilization and the deposition of eggs take place, and the long series of generations recommences in the next year and in the same order.

GENET, *je'-net.*—A genus of quadrupeds (*Genetta*) nearly allied to the Civets, but in claws and eyes more nearly resembling the cats. They are smaller and more slender than the civets, and have only a rudimentary scent-pouch. Most of the species are natives of the warmer parts of Asia and of Africa; but one (*G. vulgaris*) extends into Southern Europe. The colour is grey, with dark spots, and the fur is valuable. Being easily domesticated, it often occupies the position of a domestic cat in Constantinople.

GENIPA, *jen'-i-pa*, a genus of the natural order *Cinchonaceæ*. Some species have edible fruit; thus the *G. Americana*, the lana-tree of South America, produces a delicious fruit called the *genipap*. In British Guiana a bluish-black dye is prepared from the juice of this fruit.

GENISTA, *jen-is'-ta* (Lat., *genu*, knee, in allusion to the angular or jointed appearance of its twigs), a genus of leguminous plants, three species of which are found wild in Britain. *G. tinctoria*, the dyer's broom, yields a good yellow dye, or, when mixed with woad (*Isatis tinctoria*), a green.

GENTIANA, *jen-she-ai'-na*, the typical genus of the natural order *Gentianaceæ*. The gentian, so well known for its tonic properties, is the root of *G. lutea*, a native of the mountains of central and southern Europe. In medicine, gentian is administered as a compound mixture, as an extract, in the form of powder, and as an infusion. From gentian the Swiss prepare a spirit much prized by them as a stomachic. The genus is stated to have been named after Gentius, a king of Sclavonia, who discovered it. The plants included in the order *Gentianaceæ* are found in nearly all parts of the world, even in the coldest and the hottest regions. There are 64 genera and about 450 species.

GENUS, *je'-nus* (Lat.), in Zoology, a distinct group of species, allied by common characters and subordinate to an order, family, tribe, or tub-tribe. In Botany, the term *genus* is applied so a collection of species of plants which resemble one another in general structure and appearance, more than they resemble any other species. The characters of a genus are taken exclusively from the organs of reproduction, while those of a species are derived generally from all parts of the plant. It does not necessarily happen that a genus should contain a number of species; for if a single one presents peculiarities of a marked kind, it may of itself constitute a genus. The plural form of the word is *genera*.

GEOCENTRIC, *je-o-sen'-trik* (Gr., *ge*, the earth, and *kentron*, a point, centre).—An expression meaning having the earth for a centre, and applied to the position of a planet as it would appear to an observer stationed at the centre of the earth. It is opposite to the term *heliocentric*, which is used to denote a planet's position as it would be seen by an observer at the centre of the sun. *Geocentric latitude and longitude.*—The former is the inclination of the plane of the ecliptic of a line connecting a planet and the earth; the latter the distance on the ecliptic from the point of Aries to the point where the planet appears to be as seen from the earth.

GEODE, *je'-ode* (Gr., *gaiodes*, earthy, from *ge*, the earth), a term applied to a round lump of mineral, or to a mere incrustation of the same. Its interior is sometimes empty, and in that case the sides of its cavity are lined with crystals, as in agate balls. Sometimes it contains a solid movable nucleus, and sometimes it is discovered to be filled with an earthy matter different from the external envelope. Ruskin describes a geode as a "potato-stone."

GEODESY, *je-od'-e-se* (Gr., *ge*, the earth; *daio*, I divide).—That science which enables us by measurement and direct observation, to determine approximately the shape or figure of the earth, and ascertain the area of its entire surface, or any part of it, as well as the variations in the force of gravitation at different parts of the earth. (*See* EARTH.) If the latitudes and longitudes of places on the earth's surface, deduced from geodetic measurements, coincided with those obtained from astronomical observations, the form of the earth would be that of a regular spheroid of rotation; but there is such a difference in the results obtained by the two methods, that no regular shape can be assigned to the earth by which these results can be reconciled. (*See* ARC and MERIDIAN.)

GEOGNOSY. (*See* GEOLOGY.)

GEOGRAPHY, *je-og'-raf-e* (Gr., from *ge*, the earth, and *graphe*, a description), is that science by means of which we obtain a knowledge of this earth, both as it is in itself and as it is connected with a system of other similar bodies. It comprises a knowledge of its figure and dimensions; of the natural features, divisions, and productions of its surface; of the position of the various places upon it; and of its various inhabitants. It is usually arranged under three principal branches—Mathematical, Physical, and Political. *Mathematical Geography* deals with the earth principally in its planetary relations, as a member of the solar system; a great part of this being common to it with astronomy; and hence it is sometimes termed astronomical geography. (*See* EARTH, DEGREE, ECLIPTIC, LATITUDE, LONGITUDE, MERIDIAN, &c.) *Physical Geography* comprehends a description of the principal features of the earth's surface, as consisting of land and water, the different animal and vegetable products; climate, elevation and direction of mountain-chains, &c. (*See* PHYSICAL GEOGRAPHY.) *Political Geography* describes the countries and nations of the earth as they are politically divided, and deals with mankind in their social aspect and organization. It gives an account of the extent and boundaries, the population, the laws and government of the different countries, their language, religion, civilization, resources. These subjects are comprehensively treated in the First Division of this Encyclopædia, GEOGRAPHY, HISTORY, and BIOGRAPHY.

Progress of Geographical Science and Discovery.—The enterprising Phœnicians were the first to collect materials by the use of which an approximation to a knowledge of the configuration of the earth could be obtained. Phœnician mariners were familiar with the Euxine and the Mediterranean, and they penetrated into the great western ocean, and even visited the southern shores of the British Islands, before the 9th century, B.C., and the accounts of their voyages, however imperfectly recorded, must have stimulated a desire to obtain further information. Homer seems to have believed the world to have been a flat disc, including little more than the Greece with which he was acquainted, and the Troas where his heroes fought; but a hundred years later, Hesiod showed that Italy, Sicily, Gaul, and Spain, and even a considerable portion of Africa, were known with more or less accuracy by the Greeks of his time. Long before then the Assyrians, the Hebrews, and the Egyptians, must have had a general knowledge of the lands lying between the Euphrates and the Nile; but beyond them all was a blank. In the 7th century, B.C., Phœnician navigators are said by Herodotus—and there is strong evidence in favour of the authenticity of the statement—to have sailed round Africa, starting from the Red Sea and returning by way of the Mediterranean. Herodotus, styled "the father of history," contributed also largely to the knowledge of geography, by describing with considerable minuteness the various countries he visited in his travels. The expedition of Alexander into the hitherto almost unknown East, and the explorations undertaken by his order, made important contributions to geographical knowledge; and about the same time, Pytheas, a daring navigator, visited the eastern shores of England and reached northward as far, it is supposed, as Iceland, which he named Thule. The first attempt of Greek geographers in the way of geography as a science was to divide the earth into "climates;" but the results were necessarily unsatisfactory. A more practical method was the use of the *gnomon*, an upright post, by which the length of meridian shadows at various places was noted. Eratosthenes (who lived between 276 and 196 B.C.), who was acquainted with the sphericity of the earth, endeavoured to delineate the surface of the earth, so far as it was known, and even attempted to measure an arc of the meridian, and so ascertain the dimensions of the globe. About 170 years afterwards, Posidonius made another attempt to measure an arc of the meridian between Rhodes and Alexandria. There being no means of calculating longitudes, but only guesses of travellers as to distances, considerable errors were unavoidable. The earliest maps having anything of a practical character which have reached us are those of Ptolemy, the geographer of Alexandria, who lived in the second century of the Christian era. The Ptolemies of Egypt had greatly encouraged the study of geography; and considerable advance in the knowledge of the subject had been made by the Romans, under Julius Cæsar. A survey of the empire was undertaken and completed under Augustus. Pliny (born 23 A.D.), himself a traveller, collected all the information available from the best sources, the writings of Sallust, Cæsar, Tacitus, and others; and how much was really known is proved by his descriptions of the northern lands of Europe and allusions even to the Arctic regions, and his knowledge of the fact that Ceylon was an island and not, as was generally thought, a portion of a continent of which nothing further was known. After Pliny and Ptolemy so much extended geographical knowledge, the great landmarks of the history of geographical exploration were from the 14th to the 16th centuries. The travels of the Venetian Marco Polo, the discovery of the New World by Columbus, the passage round the Cape of Good Hope by Vasco de Gama; and the circumnavigation of the globe by Ferdinand Maghaelan. In the succeeding century, the coast of North America (some portions of which had been reached long before by Scandinavian adventurers), was explored, and the Arctic regions revealed by Frobisher, Willoughby, Davis, Hudson, Baffin, and others; between 1616, and 1624, the Dutch navigators discovered Australia, and Van Diemen's Land. Captain Cook's voyages, between 1768 and 1779, almost revealed the islands of the Pacific to the geographer; and since then a long series of indomitable explorers have penetrated Africa, Australia, Central Asia, and the frozen Arctic regions, and enabled us to map out, with considerable accuracy, the surface of the earth, while the advance in astronomical and mathematical knowledge, more extended acquaintance with the peculiarities of climate and the distribution of animal and vegetable life, has advanced in a corresponding ratio the science of physical geography.

Geographical Societies.—The Geographical Society of Paris was founded in 1821, by Malte-Brun, the eminent French geographer. The Royal Geographical Society of London was established in 1830.

GEOLOGY, *je-ol'-o-je* (Greek, *ge*, the earth; *logos*, discourse).—That department of natural science which refers to the structure of the earth, the nature of the matter of which the crust or outer cover of the globe is composed, and the forces which have operated to produce its present external aspect. It also includes the development and succession of animal and vegetable life as revealed to us by fossil remains found in the various strata of rocks. Geology is, indeed, the history of the earth, extending into pre-historic times, the chapters of which mark distinct epochs, each with peculiarities of its own, and each marked by a development of fauna and flora in a large number of instances different from those which now exist. The ancient history of the world must be studied in the rocks, deposited strata above strata, but disturbed by stupendous forces which have caused afterwards dislocations and marvellous changes in the aspects of the earth's surface. Sometimes the originally level strata have been depressed into curves, forming immense basins or valleys; sometimes they have changed from a horizontal to a perpendicular position, and the broken edges of the strata, the mass of which lies deeply buried beneath the present surface of the soil, present themselves to the view. Elevated districts, even very lofty mountains, have sunk below the level of the sea, and ages afterwards again risen, carrying on their summits the calcareous deposits of the ocean. Geological details must be studied in works especially adapted to the use of the student. The subject is too vast, the details too complicated and numerous, to permit us to indulge in more than a very brief notice of the fundamental principles of the science. What follows must be taken rather as an index than an exposition. Persons beginning the fascinating study—and scarcely any department of physical science has been found to be more attractive—may refer with advantage, among other works specially prepared for the purpose, to Professor Geikie's "Geology" in the "Science Primers," and Mr. David Page's "Text-books."

Rocks.—Rocks (a term which may be taken to include all kinds of natural stone, whatever may be its hardness or softness, and even clay, peat, and coal) may be divided into three great groups or classes having well-marked characters—*Sedimentary, Organic,* and *Igneous*.

1. *Sedimentary rocks* are those formed by deposits from water. The coarser and heavier the sediment, the more quickly will it sink; but when the sediment is composed of minute and comparatively light particles, it may be carried to a considerable distance by the stream before being deposited; and even in the case of gravel, the distance to which it is carried depends considerably on the velocity of the current of water. Gravel and sand differ only in respect of the size of the particles of which they are composed. The combined action of water and the atmosphere disintegrates rocks, and the fragments are carried onward by rivers and mountain torrents. The smaller fragments are ground by attrition into dust, or sand; the larger have their rough edges and angles smoothed away, and take the form of rounded pebbles. The heavier sediment, being first deposited, forms a layer of gravel; farther on a layer of the finer sand is formed, and, last of all, various substances, mostly of vegetable origin, sink to the bottom and form a layer of mud. In the course of ages, other layers are deposited, the stream being different in power in other places. Sand may cover the gravel of an earlier time, and mud may accumulate on the sand. As the deposits increase, the lower deposits are subjected to an immense pressure which hardens them into solid masses. The pebbles of the gravel are, as it were, cemented together, and form a rock known as conglomerate; the sand is also welded into a solid rock, to which the name sandstone is given; and the muddy sediment is converted into a rock known to geologists as shale. Rivers carry the greater part of

the rocks and other materials which they wash away to the sea, and there the various sediments are deposited, forming rocks. By the action of forces which we shall presently notice, these deposits become raised above the sea level, and form the rocks of which the dry land is afterwards made. There are undoubted evidences of the rising of the land in many well-marked sea-margins now high above the level of the ocean, and not unfrequently rising in terraces marking successive periods of elevation. The rocks thus brought to the surface are, like their predecessors, exposed to the action of water and the atmosphere, and the process is repeated and new rocks are formed beneath the sea. In masses of sandstone may be seen not only the ripple-marks made by the advancing and receding waves precisely like those so familiar to us on the sands on our own shores, but little pits or indentations made by the rain-drops at some very remote time. The sand, hardened into stone, was in course of time covered by other deposits, the result being an arrangement known as stratification (from Latin *stratum*, a layer). Shale and slate (both formed from mud deposits) and other rocks of a similar character are laminated (Latin, *lamina*, thin plate or scale), appearing to be formed by a series of plates placed one above the other. This is because there were successive deposits of similar materials, a long period elapsing between each, so that one had time to harden before the next was placed upon it. Continuous pressure united the successive layers into a mass; but they can now be readily split into separate plates. There is another agent by which sedimentary deposits are changed into solid rocks, and that is known as "infiltration." We avail ourselves of Professor Geikie's terse and lucid description of the two processes:—"When sand and mud are piled up over each other in wide sheets or layers to a depth of hundreds or thousands of feet, the layers at the bottom, lying under such an enormous weight, must be squeezed into a much firmer condition than those at the top. But, besides this, water is always filtering through pores and cracks of the rock, sometimes removing, sometimes depositing, mineral matters, and helping to cement the grains of many rocks more firmly to each other."

2. *Organic rocks* are so named because they originate in the accumulation of the remains of organized substances, vegetable and animal. The sediment deposited by water contains—besides gravel, sand, and mud—leaves, branches and stems of plants, shells and other remains of animals. These are found in the various layers of sediment, and when that is hardened into stone, the "fossil" vegetation, or animal, is embedded in the mass. Immense accumulations of shells, corals, and other animal matters are, by upheavels of the sea-bottom, brought to the surface, and form the chalk ranges and lofty cliffs with which we are all so well acquainted. Besides chalk, nearly all the limestones are composed of the remains of animals, as may be seen by the well-preserved coral, shells, "stone-lilies," and other similar relics. Larger fossils, those of huge and now extinct animals, will be more particularly referred to farther on. Among the most remarkable of the organic rocks are those which compose the carboniferous, or coal system. Coal is entirely a vegetable formation, composed of plants, with large forest trees among them, which at some remote period were, by changes of the earth's surface, buried beneath the sea and covered with deposits of sedimentary rocks. The immense pressure formed a compact mass of stratified matter (the thin layers of which a block of coal is composed are very apparent), and in course of ages a new vegetation appeared over the new soil, and passed through the same process of subsidence and transformation into coal. (*See* CARBONIFEROUS SYSTEM.) Geikie tells us that "in many parts of Great Britain the coal-pits are more than a thousand feet deep; and yet down at the bottom of each of these pits lies the coal-seam which we have found to be a buried swamp or jungle. If you could look at all the rocks which have been cut through in making the long shaft of the pit, you would usually find among them other coal-seams than the one at the bottom. In fact, several seams are sometimes worked for coal at different levels in the same pit." Peat-mosses, or bogs, may be taken to represent one of the steps in the formation of coal—vast accumulations of vegetable matter which have gradually filled up the basins formerly occupied by lakes, but which, not having been submitted to superincumbent pressure, have not been formed into hard, solid masses as the coal formations have been.

3. *Igneous rocks.*—Whether or not the interior of the earth is composed of mineral matter in a molten condition, it is certain that volcanoes in a state of activity pour forth igneous (that is, fiery) matter known as lava, which in course of time (sometimes where the mass is of enormous dimensions hundreds of years are required) cools and hardens into solid rock. This lava, when examined under a microscope, will be found to be made up of separate crystals firmly united, and masses of this nature form what are known as "crystalline" rocks. In some instances, the lava as it cooled assumed the form of columns, by contraction, the result being such an arrangement as may be seen at Fingal's Cave, in Staffa, or the Giant's Causeway, in Ireland. Another kind of igneous rock is granite, which has not been thrown to the surface by volcanic action, but which has cooled and crystallized beneath great masses of other rocks. Granite is described as "a stone composed of distinct crystals not laid down in layers, but irregularly interlaced with each other." The crystals are those of felspar, mica, and quartz. (*See* headings.) Although formed deep down in the lower part of the crust of the earth, so powerful are the forces at work that granite is now found in the form of huge mountains, many of the loftiest summits in Scotland, and some of the Alpine heights being masses of granite. Rocks of igneous origin are not only found in elevated positions as just described, but are met with forming strata interposed between other rocks, or in vertical positions, interrupting, as it were, other strata. Geologists describe the different appearances in this manner. The igneous rocks present themselves on the crust of the earth as disrupting, interstratified, or overlaying masses, or in detached blocks or *boulders*. When the molten mass has forced its way through the stratified rocks and filled up rents and fissures, it is *disrupting*; when having passed through the strata, it has spread over the surface in sheet-like masses, it is *overlying*; when the discharges have taken place at the bottom of the sea, and has been in turn covered over by new deposits of sediment, then the igneous rocks are *interstratified* with the sedimentary rocks. Isolated masses of granite, or "boulders," are found at great distances from any other granite formation, and frequently deposited at considerable elevations, their position being due to glacial action, described farther on. There is another group of igneous, or rather volcanic rocks, formed by the dust, sand, and stones, cast up into the air during an eruption, and forming immense deposits, in some cases covering many miles around the base of the volcano. It was a shower of this kind that burned the cities of Pompeii and Herculanæum. In the course of time this deposit hardens into a solid rock, known as "fragmental," being composed of irregularly shaped fragments of various kinds of stone, and of all sizes from the finest dust up to blocks of great size. The name "Volcanic tuff," or "tufa," is given by some geologists to this rock. When the volcanic discharge fell into the sea, it covered up the remains of plants or animals which might be lying there, and when, in course of time, the sea bottom was upheaved the "tuff" rocks were found to contain shells and other marine organisms. Igneous rocks do not present a succession of layers or strata, but appear in "amorphous" masses (Greek, *a*, without, *morphè*, form, or shape), that is, of no regular or determinate form.

These are the three classes, sedimentary, organic, and igneous, into which most rocks may, with tolerable distinctness, be divided; but there are *metamorphic* rocks—that is, rocks which have undergone a change. The oldest of the rock systems, originally sedimentary, are very different from the silt and mud, the sand and the gravel, and the shell and coral rocks of later formations The difference, however, is one of conditions rather than of composition. Deeply buried in the earth under newer sediments, the Laurentian rocks have been "baked," until sandstones, gravels, and clays have become crystalline, as gneiss, mica-schist, horneblende-schist, and in other forms, showing at first sight no resemblance to the original material, except in the regularly stratified and bedded arrangement which seems to distinguish them from igneous rocks.

Disturbing Forces.—From a superficial view of the subject, it might appear that the strata, if deposited as described, would appear in regular succession, but we find that they are disturbed and distorted in the manner described at the commencement of this article. One of the most powerful of these forces is the shrinking of the earth during the process of cooling. Under the enormous strain of contraction, the outer crust—that is, the solid matter which envelopes the fiery interior—is broken up into ridges with wide depressions between. These ridges are the mountain ranges, and the sunk spaces are the seas and oceans. Geikie describes these ridges as "the folds or puckerings of the earth's surface." Another powerful force is volcanic action, which upheaves the surface in some places and causes depression in others. Sea-bottoms become table lands, and lofty mountains are sunk beneath the waves. "By volcanic forces," says Mr. Page, "stratified rocks are broken up, lose their horizontality, and are thrown into positions more or less inclined and irregular—may be thrown on edge, subside into lower formations, or be bent and contracted in a most fantastic manner." The angle or slope at which a stratum inclines to the horizon is called the *dip;* when an inclined stratum comes to the surface, its edge is called the *outcrop.* It is often observed that a stratum of one kind of rock appears to end abruptly; but that at a considerable distance another stratum of the same rock appears at a different level. This is particularly observable in coal-mines, where the seams of coal are, as it were, disjointed. Again, on the opposite sides of gorges and deep valleys, there is a correspondence between the geological formations, although a depression of considerable breadth intervenes. These gaps are known as "valleys of dislocation." The fact is that the continuous strata have been broken by volcanic action. When an earthquake or volcanic shock is unaccompanied by discharges of igneous matter, the fissures will simply be *slips,* or *faults;* when accompanied by igneous discharges, the molten matter will force its way through and fill up the fissures, producing *dykes;* and when the rents are, by the percolation of water, subsequently filled up by the slow infiltrations of mineral and metallic matter, the result will be *lodes* and *veins.*

Climatic Changes.—There can be no doubt that at different periods in the history of the earth, there were marked differences of temperature. Professor Geikie tells us, "Once a great part of this country, as well as of Europe and North America, was buried under ice like Greenland. Earlier still, it had jungles of palms and other tropical plants; yet further back, it lay beneath a wide deep ocean; and beyond that time can be traced many still more remote periods, when it was forest-covered land or wide marshy plains, or again buried under the deep sea." The glacial, or ice-covered period is supposed to have almost immediately preceded the period in which the temperate regions of the earth assumed their present general appearance, and the existing fauna and flora sprang into existence. Most geologists are now of opinion that our continents were, even in what are now the temperate latitudes covered with a sheet of ice; and about the same time occurred a very general subsidence, in which they were submerged under the water of a cold icy sea, tenanted by marine animals now found only in arctic regions. After this they rose and contributed the dry land of man and the contemporary animal world. Traces of the movements of glaciers of enormous extent are easily discernible in the "striations" or scratches which mark the course they took. The glaciers now existing in the Alps, Greenland, and other parts of the surface of the earth, show the action of these prehistoric glaciers. The rounded summits of many mountain ranges show the wearing action of the ice on the rocks; and the enormous masses of granite and other hard rock found in isolated situations were broken off by the moving glaciers, and when the ice melted, left where we now find them, the action being exactly that observable to-day by which "moraines," huge blocks of stone, are deposited in the Alpine valleys.

Fossils.—Every great change in the surface of the earth by which old strata were submerged and new strata deposited, must have buried in the formations the animals existing at that time. Consequently we find in most of the sedimentary and cretaceous rocks fossilized skeletons and fragments of many animals, some similar in general organization, others differing largely in scale, from existing animals; and others bearing scarcely any resemblance. Many of them are of dimensions which no living creature now attains, proving that, under other conditions, living organisms possessed characteristics differing from those of their successors. The earliest traces of organic life are found in the Cambrian and Silurian strata—compound polyps, trilobites, cephalopods, corals, and the earliest forms of fishes. In the Devonian (old red sandstone) are corals, shell-fish, sea-lilies, the first land plants, especially cryptogamia, and the first pine. In the carboniferous formation are molluscs, reef-forming corals and fishes, ferns, reeds, mosses, annularia and coniferæ. The Permian strata reveal the first reptiles and insects, mussels, insects, and fishes; tree ferns, fossilized forests of palms, grasses, and coniferæ. In the Triassic formations are saurian frogs, crustaceæ, cephalopods, snails, mussels, crocodiles; and calamites, and a few endogenous plants. The first remains of mammals appear in the bone beds between the Triassic and Jurassic formations. In the Oolitic strata appear the gigantic saurians (ichthyosaurus and plesiosaurus), marsupials, sponges, first vertebrate fish, tortoises, pterodactyl (flying lizard), the first traces of a bird, and sea-weeds. Between these strata and the chalk formation is the great saurian, the iguanodon; and in the chalk, foraminiferæ, sponges, crustaceæ, worms, ferns, palms, pines, the first dicotyledons, and many large leaved trees. In the Eocene (in Central Europe) a genuine tropical flora; and in the upper strata, the first great mammal fauna, proboscidians, edentata, insect eaters, and apes. Amber, with its many insect enclosures, belongs to this period. The second great mammal fauna, including the mastodon and dinotherium, are found, besides the horse, cat, hyena, and ape. In plants, there is a prevalence in Europe of what are now known as American types. Palms, acacias and mimosas have disappeared, and there is an abundance of willows, poplars, and maple. Then followed the glacial period, succeeded by our present flora and the great mammals, the mammoth, cave-bear, giant elk, auroch, and rein-deer, some of which survive: and at length man appears upon the scene.

Geological History of the Earth.—We obtain an insight into this wonderful record by studying the successive beds of rock which have been deposited on its surface, and the masses which have been forced up in a liquid state from within the crust of the earth, together with the fossil remains of animals and plants which certain of its beds contain. This geological period is usually divided into four great periods, the names of which are taken from the progress of animal life, as this at present affords one of the best criterions for geological classification. The periods are the Eozoic (from Greek, *eos,* the dawn; *zoe,* life), "period of the dawn of life;" the Palæozoic (*palaios,* ancient), "period of ancient life;" Mesozoic (*mesos,* middle), "middle period of life;" and Neozoic (*neos,* new), "recent period of life." Each of these periods is subdivided as shown in the following tabular arrangement. All the principal systems and groups are described under the respective headings (which *see*).

NEOZOIC, OR CAINOZOIC (*kainos,* ancient).
 Post Tertiary or *Quaternary*—
  In progress.
 Tertiary—
  Pleistocene (*pleistos,* most; *kainos,* recent).
  Pleiocene (*pleion,* more).
  Miocene (*meion,* less).
  Eocene (*eos,* dawn), the earliest tertiary deposits.
MESOZOIC.
 Cretaceous—
  Chalk.
  Greensand.
 Oolitic, or Jurassic—
  Wealden.
  Oolite.
  Lias.
 Triassic—
  Saliferous marls.
  Muschelkalk (German, shell limestone)
  Upper new red sandstone.
PALÆOZOIC.
 Permian—
  Magnesian limestone.
  Lower new red sandstone.

Carboniferous—
Coal measures.
Millstone grit.
Mountain limestone.
Lower coal measures.
Old red sandstone (*Devonian*)—
Yellow sandstones.
Fossiliferous limestones and slaty shales.
Red conglomerates, sandstones, and corn-stones.
Grey sandstones, flags, and conglomerates.
Silurian—
Upper, shales and limestones.
Lower, grits and flags.
Cambrian—
Upper slates and flags.
Lower slates and grits.
Laurentian—
Upper, or Labrador series.
Lower, or Laurentian.
Eozoic—
Metamorphic—
Clay slate.
Mica-schist.
Gneiss and granitoid schist.

Geological Time.—Geologists estimate the age of the known strata by periods of immense duration, extending over millions of years, drawing their conclusions chiefly from the time required to deposit the sedimentary rocks and the thickness of the various strata. There is, however, considerable difference of opinion among scientific geologists, and at the best only vague estimates can be arrived at.

History of Geology.—So early as the times of Pythagoras and Strabo, some speculations were indulged in as to the structure of the earth and the effects of volcanic actions and the changes in the level of sea and land were noticed. About the 16th century, the nature of fossils was the subject of inquiry. Some suspected that they were remains of animals, but the majority regarded them as freaks of nature. When, at length, about two hundred years later, organic origin was established, the Deluge was accounted to have been the cause of their deposit. Leibnitz, in 1680, suggested that the earth was originally in a molten condition, that the rocks were formed by the cooling of the surface, which condensed the surrounding vapours and produced the ocean, the subsidence of which from the cooling of the crust of the earth produced the sedimentary strata. Hutton, about 1788, laid the foundation of the science as now accepted.

GEOMETRY, *je-om'-e-tre* (Gr., *geometria*, *geo*, the earth, and *metreo*, I measure), may be strictly defined to be the doctrine of the extension of such things as lines, surfaces and solids. The attributes or properties of bodies may, in order to be more readily explained, be resolved into two classes, one comprising the general characteristics of all, and the other such only as are included in particular or peculiar bodies. Extension, figure, magnitude, mobility, divisibility, impenetrability, weight, and inertia, may be mentioned as some of the properties which belong to the first class; whilst some of those in the second are solidity, liquidity, transparency, and such-like. Of all these properties mentioned, only *extension*, *magnitude*, *figure*, and *divisibility*, come under the special branch of science denominated Geometry; the different properties which remain coming under the head of Natural Philosophy, or Physics. All notions of geometrical magnitudes are obtained by means of contemplating a body or solid, which is extended in three different forms; that is, in length, in breadth, and in thickness. The outside boundary of a solid which separates that particular portion of space which it occupies from space in general, is termed the surface, or superficies—that is, the external area; and a surface cannot be considered as possessing any other qualities except length and breadth. Solids, surfaces, and lines, therefore, are the subjects of geometrical investigation and discussion. There is no limit whatever to the number of these surfaces, solids, and lines which may be considered in this science. The elements of geometry, however, are restricted to a few, which include straight lines, circles, rectilineal plane figures, and their consequents, which constitute one branch of the science; and solids, bounded by planes, and the cylinder, the cone, and the sphere, all of which are formed by the intersection of planes, and which go to make up the other portion of the subject. Geometry is, consequently, divided into two branches, one of which treats of figures on a plane, the other of the formation and ramification of solids. The fundamental axioms on which the science is based may be said to be six in number. 1st. Two quantities, each of which is equal to a third, must be equal to one another. 2nd. The whole of anything is greater than a part of the same. 3rd. The whole of anything is equal to the sum of its parts or sub-divisions. 4th. Only *one* straight line can be drawn between any two points. 5th. Two magnitudes, whether they are lines, surfaces, or solids, are equal, if, when applied to one another, they exactly coincide, or fill the same space that is. 6th. All right angles are equal to one another. The application of these axioms; and the foundations of others, are laid down in the first and second books, whilst the proportions of the circle occupy the third and fourth books, of "Euclid's Elements."

Geometrical Definitions.—A *point* has position, but no magnitude, and a *line* possesses only length: hence points and lines are closely allied; as the termination of every line, and the intersection of one line with another, must always be a point. A *straight line*, or *right line*, as it is termed in Geometry, is always the shortest way from one point to another. Every line, which is neither straight nor composed of straight lines, is a *curve line*. A *superficies* has only length and breadth; and, consequently, the extremities and intersections of superficies are always lines. A *plane superficies* is that in which any two points being taken, the *right line* drawn between them lies wholly in that superficies. Every superficies which is neither a plane, nor composed of plane superficies, is termed a *curve superficies*. A *solid* has length, breadth, and *thickness*; hence the boundaries of all solids are superficies, and the contiguous boundary to two solids which are connected is also a superficies. A *plane rectilineal angle* is the inclination of two straight lines to one another which meet at one point, but are not in the same straight line. The point of meeting between them is called the *vertex* of the angle. Angles, in common with other quantities, admit of addition, subtraction, multiplication, and division. When one straight line erected on another straight line makes the adjacent right angles equal to one another, then each of the angles thus formed is a *right angle*, and has 90 degrees; the line which makes them with the *base* is termed the *perpendicular*. An *obtuse angle* is that which is greater than a right angle; and an *acute angle* is less than a right angle. *Parallel straight lines*, which are in the same line, are such as, when produced, can never meet. A *plane figure* is a plane terminated everywhere by lines; if the lines are straight, the space they enclose is termed a *rectilineal figure*, or *polygon*, and the lines themselves are termed the *perimeter* of the same. When this polygon has three sides (the least number it can possibly have), it is called a *triangle*; when four, a *quadrilateral*; when five, a *pentagon*; and so on. An *equilateral triangle* is that which has three equal sides; an *isosceles* triangle has two sides equal; and a *scalene* triangle has all three sides unequal. A *right-angled* triangle has a right angle, and the side of the triangle opposite this angle is called the *hypothenuse*. An *obtuse-angled* triangle has an obtuse angle, and an *acute-angled* triangle has an acute angle. Among quadrilateral figures, a *square* is that which has its four sides all equal to one another, and all its angles *right angles*. A *rectangle* has all its angles right angles, but its opposite sides only are equal. A *rhombus* has all its sides equal, but its angles are not right angles. A *parallelogram*, or *rhomboid*, has its opposite sides parallel and equal; and a *trapezoid* is a figure which has only two of its opposite sides parallel. The straight line which joins the vertices of two angles which are not adjacent to each other is called a *diagonal*. A polygon which has all its sides equal, is called an *equilateral* polygon; and if the angles are all equal, it is called an *equiangular* polygon; if both the angles and the sides of the polygon be all equal, it is called a *regular* polygon.

Geometrical Terms and Signs.—An *axiom* is a proposition the truth of which is evident at first sight to the observer; a *theorem* is a truth which has been demonstrated or reasoned; and a problem is a question proposed which requires solution; a *lemma* is only a subsidiary truth employed in the solution of a problem or the demonstration of a theorem; a *corollary* is a consequence which follows the theorems of one or several propositions or problems solved; a *scholium* is a remark made upon one or more preceding propositions and it tends to show the application, the restriction, or the extension of the same, an *hypothesis* is a supposition made in order to effect more easily the demonstration or enunciation of a problem or theorem; and, lastly, the term *proposition* is applied generally to problems, theorems, and lemmas. The signs used in geometry are the same as those in algebra.

History of Geometrical Science.—Herodotus dates the origin of geometry as a science from the following circumstance:—Sesostris, the king of Egypt, shared the lands at Thebes and Memphis between his subjects, and each portion was marked out by different landmarks; but, owing to the inundations of the Nile, these boundaries were frequently destroyed, and it became necessary, as often as this was done, to restore them by measurement; hence a system was invented which was termed geometry. This statement is not very authentic; but it is more certain that Thales, a philosopher who lived some 640 years before Christ, brought the science into Greece from Egypt, whither he had, it is related, gone in search of knowledge at rather a late period in life. After Thales came Anaximander, who is said to have invented geometrical charts and the sphere and gnomon; next followed Anaximenes, who invented the sun-dial, and must thus have been acquainted both with astronomy and geometry. Pythagoras instituted the theory of regular solids; and under his school it was improved gradually during the two centuries which elapsed after the introduction of geometry, until the school of Plato took it in hand. The theory of conic sections dates its birth from the Platonic schools, and to the same source may be ascribed the method of geometrical analysis. The school of Aristotle cannot be said to have done much towards the forwarding and improvement of geometry, although one of the writers of the same period has transmitted to us the only written accounts we possess; Eudemus having written a history of geometry in six books. The school of Alexandria is undoubtedly the first grand starting-point of geometry: it is justly celebrated in general history, but in mathematics its importance can hardly be over-rated. The school was founded shortly after the death of Alexander, when the vast empire which had been built up by that conqueror was dismembered, and the greater portion of it fell to Ptolemy Lagus, who established his capital in Egypt. His wealth and encouragement, coupled with the disturbed state of their homes, induced many of the Greek philosophers to place themselves under his protection; and amongst these was Euclid, who is entitled to one of the highest places in the history of geometry. Euclid's Elements are the foundation of the science, and all modern geometry is composed only of variations on his well-known theorems, axioms, and deductions. The writings of Archimedes are likewise most important; and although they are less studied in the present day, on account of their being less elementary than Euclid, yet they should be carefully conned by every mathematician, as they give a keen insight into the workings of ancient geometry—more so, in fact, than Euclid. The study of the mathematical sciences declined considerably in the 1st century of our era, but it regained its supremacy during the 2nd. Menelaus wrote on trigonometry and spherical geometry; and his work on the same reached us by means of a translation from the Arabic, which is in existence at the present day. From the 2nd century up to the 8th, geometry again languished considerably, and it was then taken up by the Arabians, as the Greeks had neglected it. It is from the Arabians, in fact, that some of the books of Euclid have been preserved for the benefit of science in general. The Persians have also possessed their geometricians, the most distinguished of whom was Nassir-Eddin al Tussi, who wrote a commentary on the great Euclid, which was published in Italy in the year 1590. Geometry remained quiescent from the 8th century to the 17th, when it was again taken up with a similar zeal as that by which it was prosecuted in the old Greek empire. Lucas Valerius, an Italian, was the first who gave it his serious consideration; and his researches led him beyond the timeworn pathway in which his predecessors had been contented to work. He selected a subject which Archimedes seemed to have forgotten—namely, the centre of gravity in solids, and he carried out his purpose in a very satisfactory manner. In England, geometry, or the spirit of it, seemed now to have been imbibed; and Robert Record was the author of the first book on the subject printed in this country, entitled the "Pathway of Knowledge;" Edward Wright, another geometrician, was the inventor of the "Mercator's Chart." Kepler was the first of the moderns, however, who thoroughly understood and enlarged his subject. He opened one of the unexplored pathways of science which had long been closed—that of introducing the notion of infinity into science. The views of Kepler were eagerly adopted by Roberval and Cavalieri, and the earnest investigations of the three led to a fruitful harvest of discovery. The theory of tangents of Fermot, the differential calculus of Leibnitz, and the fluxional theory of Newton (*see* article on FLUXIONS), may be traced as consequences to the new views of Kepler. Guildin, a Jesuit, discovered the centre of gravity applicable to the measurement of solids formed by revolution; Galileo first suggested the *cycloid;* James Gregory was the author of the logarithmic curve; and Leibnitz showed the two properties of the catenary. Before the time of Newton, pure geometry and algebra were the only subjects on which mathematical students could exercise their genius; but his great and sublime discoveries opened a vast field for new studies. The fact of the orbits of the planets being in the form of ellipses, naturally connected their motions with the theory of conic sections; and this is ably pourtrayed in Newton's "Principia."

GEOMETRICAL MEAN.—The mean of two numbers is that number the square of which is equal to the product of the two numbers. It is found by multiplying the two numbers together, and extracting the square root of the product. Thus the geometrical mean of the two numbers 5 and 20 is 10, because $5 \times 20 = 100$, the square root of which is 10.

GEOMETRICAL PROGRESSION.—A series of quantities each term of which is equal to that which precedes it, multiplied by some factor which is the same for all the terms. Thus, employing 4 for the multiplying factor, we can have, in geometrical progression—2, 8, 32, 128, and so on to any extent.

GEORGIA BARK. (*See* PINCKNEYA.)

GEOTEUTHIS, *je-o-teu'-this.*—A genus of fossil catamaries, found only in formations of the Oolitic periods, resembling in some respects the cuttle-fish.

GERANIUM, *je-rai'-ne-um* (Gr., *geranos*, a crown), the typical genus of the natural order *Geraniaceæ*, or Crane-bill family. The species are chiefly European plants, in many cases being mere weeds of no interest, and in others being extremely showy border-flowers. The favourite plants called geraniums do not belong to this genus, but to the genus *Pelargonium* (which *see*). The root *G. maculatum* is a powerful astringent, and is much used medicinally in North America, where it is called alum-root. *G. parviflorum* produces edible tubers, which are known in Van Dieman's Land under the name of native carrots.

GERANIUM OIL. (*See* ANDROPOGON.)

GER-FALCON, OR JER-FALCON, *jer'-fawl-kon* (Fr., *gerfaut*) (*Falco Gyrfalco*), a species of falcon, considered as the boldest and most beautiful of the tribe. In size it approaches closely to that of the osprey. Its general colour is brownish-grey, of varied tints above and white beneath, with brown longitudinal spots, but one variety is entirely white. The tail is crossed with a number of deeper and lighter bands, and the bill and legs are usually of a pale blue or yellowish colour.

GERHARDT'S NOTATION, *zher-hardtz'*, a method of expressing chemical formulæ, proposed by an eminent French chemist, M. Charles Gerhardt, and differing from that in general use by the doubling of certain equivalent numbers. This system, which, at first, was somewhat slighted, has gained ground in a remarkable manner, and in this country it has been used for some time, both in teaching and writing, by eminent chemists. M. Gerhardt doubles the equivalent numbers of oxygen, sulphur, carbon, selenium, and tellurium, on the assumption that *equal volumes of elementary gases and vapours contain the same number of atoms when compared under similar conditions of heat and pressure;* which is equivalent to saying that an atom of oxygen weighs sixteen times as much as an atom of hydrogen, because a cubic foot of the former gas weighs sixteen times as heavy as a cubic foot of the latter. According to this new system, therefore, the equivalents of oxygen, carbon, sulphur, selenium, and tellurium are doubled. Besides the change in the equivalents, Gerhardt revived and fully carried out a theory of the constitution of acids and salts, first propounded by Sir Humphrey Davy. From numerous anomalies, occurring chiefly in organic bodies, Gerhardt came to the following conclusions:—1. That every uncombined acid necessarily contained one or more equivalents of hydrogen. 2. That the bodies hitherto regarded as dry acids possessed no acid properties until united with hydrogen and oxygen. 3. That salts were formed by the substitution of one or more atoms of hydrogen, by one or more atoms of a metal, or some substance acting as such. Gerhardt also originated the system of arranging compounds according to types, and fully worked out the theory of the formation of all bodies by the substitution of one element or group of elements by others of a similar character.

GERMINATION, *jer-min-ai'-shun* (Lat., *germino*, I sprout), the beginning of vegetation, or the development of the embryo into an independent plant, capable of supporting itself. (*See* ROOT, SEED, SPORE and STEM.)

GEROPIGIA. (*See* JERAPIGIA.)

GERVAS, *jer'-vas.*—A small shrub (*Stachytarpheta Jamaicensis*) of the natural order *Verbenaceæ*. It is a native of the West Indies. The leaves are used as a substitute for tea, and also for the purpose of adulterating tea.

GESNERACEÆ, *ges-ne-rai'-se-e* (after Gesner, the naturalist), the *Gesnera* family, a natural order of *Dicotyledones*, sub-class *Corolliflorœ*. They are herbs or soft-wooded shrubs, and are chiefly natives of warm or tropical regions. On account of the beauty of their flowers, they are much cultivated in this country. There are about 120 species.

GESTATION, *jes-tai'-shun* (Lat., *gestatio*, from *gero*, I carry).—A term applied to the period which intervenes in the mammalia between the time of conception and that of delivery. This period differs greatly in different animals. In the human species it is nine calendar months, or, more strictly, forty weeks, or 280 days; but by certain circumstances the period may be prolonged or shortened by several weeks; and sometimes the birth takes place as early as the seventh month. In the cow the period of gestation is nine months, in the mare eleven, in the dromedary twelve, and in the elephant twenty-one. In the smaller animals it is much less; being in the dog about sixty-three days, in the cat fifty-six, the rat twenty-eight, in the sow four months, and in the sheep and goat about five.

GEUM, *je'-um* (Lat.), a genus of the natural order *Rosaceæ*. The most interesting species is *G. urbanum*, the wood avens, a common herb in our hedges and thickets. The roots have an aromatic flavour, something like that of cloves. They were formerly much used for flavouring ale, and to some extent in medicine, for their tonic and astringent properties.

GEYSER, *gai'-ser* (Icelandic, *geysa*, to burst forth).—A name given in Iceland to thermal springs, which give forth eruptions of hot water. The jets are of various sizes, some only about an inch in diameter; but the Great Geyser is a pool of hot water about 70 feet in diameter and four feet deep, with a pit in the centre six feet deep and eight feet wide. At intervals of a few hours, jets of water, almost at the boiling point, are violently thrown off, and about once a day the water is thrown to a height of nearly 80 feet, accompanied with clouds of steam. Another geyser, known as the Strokr (churn), is nearly as large, and also gives forth lofty jets, but at irregular intervals. The spring first broke out in 1784, at the time of a great earthquake. The Little Geyser is in a separate group of hot springs, 36 miles from those mentioned, and throws out water to a considerable height about six times every twenty-four hours. Similar geysers, known to the natives as *puia*, are numerous in New Zealand, especially in the valley of the Waikato river.

GHOST MOTH.—A species of moth (*Hepialus humuli*), which generally flies in the twilight, and appears to prefer lonely places. It is white, and has a habit of suddenly folding its wings so that it appears to vanish in the fading light. The caterpillar, commonly known as the Otter, and very destructive in hop plantations, is yellowish white and nearly two inches long.

GIANT, *ji'-ant* (Fr., *géant*, from *gigas*, the Latinized form of a Greek word, probably formed from *ginesthai* and *ge*, signifying "the earth-born"), an individual of extraordinary stature and bulk. In most of the cases where the existence of giants has been based upon the discovery of colossal bones, it has been afterwards discovered that the remains were not those of human beings, but of extinct quadrupeds. Among classical writers, statements respecting giants are numerous, but not worthy of belief. Coming to more reliable evidence, it seems certain that a height of even more than

nine feet has been attained. In the museum of Trinity College, Dublin, there is a skeleton 8 feet 6 inches in height; in the museum of the College of Surgeons of England, is another 8 feet 2 inches; and another in the museum at Bonn, 8 feet. As a general rule, giants are of rarer occurrence than dwarfs; they are usually of a lymphatic temperament, of a delicate complexion, often deformed, and generally badly proportioned. Their muscles also are flabby, and their voices weak. They are seldom long-lived, and in this respect are the reverse of dwarfs. It has also been observed that giants show a want of activity and energy both in body and mind, while dwarfs are usually lively, active, and irascible.

GIBBON, *gib'-bon.*—A genus of apes, or tailless monkeys (*Hylobates*), nearly allied to the orangs and chimpanzees, but much smaller and distinguished by the extraordinary length of arm. They live chiefly in forests, swinging with great activity from branch to branch, but moving awkwardly and slowly on the ground. They are natives of India and the Eastern Archipelago. One species (*H. albimana*) in Sumatra has white hands, the rest of the body being black. All the gibbons are easily domesticated.

GIBBOSITY, *gib-bos'-e-te* (Lat., *gibbositas*, from *gibbus*, a swelling or protuberance).—A hump or other irregularity or swelling on the back, or any other part of the body, arising from disease of the spinal column.

GIBBOUS, *gib'-bus* (Lat., *gibbus*, hunched, humped), an expression applied to the convex or protuberant shape that the moon presents in its second and third quarter, before attaining the perfect circular form that it exhibits when it is full.

GIBEL, *gi'-bel.*—A small fish (*Cyprinus gibelio*), of the same genus as the carp, but easily distinguished by the absence of barbules at the mouth. It is generally known in this country as the Prussian carp.

GIDDINESS, *gid'-de-nes* (Sax., *gidig;* Lat., *vertigo*, from *verto*, I turn), a dizziness or swimming of the head, with more or less of mental confusion, and a loss of power to balance the body. It generally comes on suddenly, and is symptomatic of various diseases, arising, as it does, from some disturbance or debility of the nervous power. It not unfrequently arises from some organic disease of the brain or heart. Most frequently, however, it arises from indigestion, and may be got rid of by means of some aperient medicine.

GILLENIA, *gil-le'-ne-a*, a genus of the natural order *Rosaceæ*. *G. trifoliata* and *stipulacea* are pretty North American plants, with lobed, discoloured leaves and white flowers. They are about two feet high, and the foliage is very graceful. The roots of both species are used medicinally, and are commonly known under the names of Indian physic and American ipecacuanha. In small doses they are tonic; in larger doses, emetic.

GILLIESIACEÆ, *gil-le-se-ai'-se-e* (after Dr. Gillies, of Conception, in Chili), the *Gilliesia* family, a natural order of *Monocotyledones*, subclass *Petaloideæ*, consisting of small herbaceous bulbous plants, with grass-like leaves and spathaceous flowers. There are but two genera—*Gilliesia* and *Miersia*, containing five species, all natives of Chili.

GILLS, *gilz* (Swedish, *gel*), a term applied to the apparatus possessed by all fishes, by means of which their respiration is effected exclusively through the medium of water. The gills, or branchiæ, are situated on each side of the neck, and are composed of several laminæ fixed on arches. These laminæ are covered with a vast number of minute blood-vessels, and are so formed as to present a considerable surface to the water, so that a sufficient portion of oxygen may be received by the blood. As the oxygen is continually being removed, the water becomes deteriorated, and it is consequently necessary that a constant current should flow over them. This is effected in most fishes by their taking the water in at the mouth and expelling it under the gill-covers in regular respirations.

GINGER, *jin'-jer.*—A genus of perennial herbaceous plants (*Zingiber*) of the natural order *Zingiberaceæ*, natives of the East Indies, but cultivated in other tropical countries. The root stocks of most of the species, especially the Common Ginger (*Z. officinalis*), are used as a condiment and in medicine. The valuable qualities depend upon a volatile oil of a pale yellow colour. The young root-stocks, preserved in sugar, and known as candied ginger, are a choice sweetmeat. Syrup of ginger and essence of ginger are used for flavouring.

GINGKO, OR GINKO, *ging'-ko.*—A tree of the natural order *Taxacea*, in some respects similar to the yew, and named *Salisturia adiantifolia*, a native of China and Japan, but is now grown in many parts of Europe. It is a tall tree, with a conical head. The wood, of a yellowish colour, is easily worked. The fruit has a farinaceous kernel, with an almond flavour, cooked and eaten in China and Japan.

GINSENG, *jin'-seng.* (*See* PANAX.)

GIRAFFE, *je-raf'* (Arab., *zarifa*).—This animal, *Camelopardalis Giraffa*, is the tallest of quadrupeds, and the largest of the Ruminant order. It is a native of Central and Southern Africa. In points of resemblance, the giraffe approaches the deer, the antelope, and the camel; and, besides this, has many singularities about it which are especially its own. In the length, slenderness, and flexibility of its neck, it surpasses all other quadrupeds, and peculiarities of conformation adapt it eminently for the life which it leads on the sandy desert. Its head resembles that of the camel, from the absence of a naked muzzle, and in the shape and organization of the nostrils, which are oblique and narrow apertures, defended by the hair which grows at their margins, and surrounded by cutaneous muscular fibres, by which the animal can close them at will. This is a beautiful provision of nature for the defence of the air-passages and the irritable membranes lining the olfactory cavities, from the fine particles of sand which the storms of the desert raise up and whirl about in suffocating clouds. The eyes of the giraffe are so placed as to take in a wider range of vision than those of any other quadruped, and it is thus able to see an enemy in the rear as well as in the front when its head is elevated during the time that it is browsing on its favourite acacia plant. The weapons by which it defends itself are its horns and its hoofs. The former it does not wield by *butting*, as is the case with other *Cervidæ;* but swings round with a lateral movement of the neck, and hits with them sideways: the latter are very powerful; and sometimes a giraffe has been known to prostrate a lion with a single kick. Its motion in progressing is most peculiar; travelling, as it does, in a sort of crab-like movement. It lifts both its hind and fore legs on each side of the body together, and its appearance when cantering is peculiar in the extreme. The tongue is formed to suit its habits of life, and is used to hook down the branches of trees which grow beyond the height at which its muzzle can reach. The two horns with which it is provided are peculiar to both sexes, the bony part of the same being articulated by a broad, rough, epiphysial basis to the cranium, and covered by a hairy tegument. The female brings forth one young one at a birth, and the period of gestation is fifteen months. The new-born giraffe measures six feet from the fore hoofs to the top of the head, and in a few hours after birth it is able to follow the dam. The flesh is eaten by the natives of Africa, and the marrow is considered a delicacy.

GIRASOL, *ge'-ra-sol* (Italian, sun-turning). A precious stone, resembling both quartz and opal. It reflects light, which seems to come from the interior of the stone. One variety found in Mexico, and known as the "fine opal," is very beautiful, the brightest stones of this kind are now brought from Brazil, and very fine specimens are obtained from Siberia.

GIRDLE OF VENUS, *Cestum Veneris*, a gelatinous ribbon-shaped animal found in the Mediterranean; about five feet long and two inches wide. The mouth is situated in the middle of the lower edge. It exhibits beautiful indescent colours by day and is luminous by night.

GLACIER, *glas'-e-er* (Lat., *glacies*, ice), an accumulation of ice, or of snow and ice, formed in a valley or ravine of a snowy mountain. The average annual fall of snow in the region of the Swiss Alps, from 8,000 to 10,000 feet above the level of the sea, has been estimated at sixty feet; that is to say, sufficient snow descends in one year to form a bed of this thickness. The accumulation of snow on the high table-land is called the *névé*, and is found to consist of layers of more or less crystalline snow, which diminish in thickness as their depth increases. The *névé* is the source of the glaciers, or rivers of ice, which fill all the valleys radiating from the central mass of a great mountain. Sometimes valleys twenty miles long and three or four broad are filled up with ice to the depth of some 600 feet. Although apparently solid and stationary, glaciers move slowly down their valleys, and carry with them, either on the surface, frozen into their mass, or grinding and rubbing along the bottom, all the fragments, large and small, from blocks many tons in weight down to the finest sand and mud, that rain, and ice, and the friction of the moving glacier itself, detach from the adjacent rocks. The glaciers of the Alps, and probably those of other regions, descend to a vertical depth of nearly 4,000 feet below the line of perpetual snow, and into a warm climate, before they finally melt away and leap forth as rivers of running water. The heap of materials of all sorts and sizes, which they deposit at their melting extremity, is called the *moraine*, a term which is also applied to the lines of blocks that are being carried along on the surface of the glacier. Combined with the *avalanche* and the *iceberg* (*see* these words), the glacier is now, as it has been in ages past, one of the most important of geological agents. (*See* GEOLOGY.) In continental Europe glaciers are almost limited to the Alps and Norway, but in Iceland, Spitzbergen, and Greenland they are of great size; and there are many among the lofty Himalayas of central Asia.

GLADIOLUS, *glad-e-o'-lus* (Lat., *gladius*, a sword, in allusion to the shape of the leaves), a genus of the natural order *Iridaceæ*, consisting of plants with ensiform leaves and very showy flowers, purple, red, or white. Many species and varieties, especially *G. communis* and *G. cardenales*, are in cultivation as border flowers.

GLANCE (Ger., *glanz*, brightness).—A popular name for many metallic minerals in which the metal is combined with sulphur, selenic, arsenic, or tellerium.
