THIS little tract having been composed at my request, and sent me from the author, as a present to the Royal Society, I was encouraged to think a translation of it would not prove unacceptable to English Naturalists. Most of the experiments are entirely new, and, for that reason, as well as on account of the singular conclusions that may be deduced from them, deserve to be repeated by different hands, and seen by different eyes. This is what our Italian observer wishes may be done, both in his own country and in this, before he publishes his large work. Facts in appearance so little reducible to the known laws of animal œconomy, must be duly authenticated in order to be believed; and that evidence, which is sufficient in things more analogous to the general course of nature, can hardly be thought so in the case of discoveries, which seem to be deviations from it. But universal laws are few, and exceptions to

to them are grown more and more common. In this age, when the talent of observing has been so much improved, and experience has taught us the vanity of opinions and systems, it would be imprudent to reject, without trial, observations, or even hints, which, at the same time that they enlarge our views of nature, tend to increase proportionally our admiration of its GREAT AUTHOR, and may become in time not only instructive, but useful to mankind.

## ANIMAL REPRODUCTIONS.

**T**HE subject of Animal Reproductions, one of the most interesting and extensive in natural history, remains hitherto concealed under thick clouds, for want of a sufficient number of experiments and observations. This truth appears the more evidently, as it is supported by the authority of an eminent philosopher, whose genius and industry have been employed for a long time upon this subject, and who acquired the greatest honor in

B

the

the pursuit of this grand mystery\*. With candor equal to his merit, he owns that the regeneration of the polypes, and some other of the smallest and most simple insects, renewed by sections, is by no means sufficient to elucidate the theory of reproductions, and that animals of larger bulk and more complicated organisation are necessary to answer this purpose. As he had discovered jointly with Reaumur, that the earth-worm, cut in pieces, has the property of reproducing itself, he invites philosophers to try experiments of the same kind, as his own eye-sight, weakened by investigating the most delicate works of nature, deprived him of that satisfaction; and that, by the death of the great French naturalist, the world had lost the account of the experiments made by him upon that reptile. This advice, animated with the true spirit of philosophy, is to be found in his *Considerations upon organised Bodies*, and is of too much consequence not to be quoted.

“ The reproduction, says he, † of the earth-worm is much more surprising than

\* Mr. Bonnet of Geneva, F. R. S. and author of many important works, and particularly of the two following; viz. *Considerations sur les Corps organisés*, à Amsterdam, 1762; and *Contemplation de la Nature*, 1764.

† *Contemplation*, &c. tome i. p. 257.

“ that

“ that of the polype, as being of a size in-  
 “ finitely greater, and much more compli-  
 “ cated in its structure. In him you find a  
 “ large apparatus of viscera, vessels, tracheas,  
 “ muscles, &c. He has blood, and that  
 “ blood circulates. But above all, the first-  
 “ mentioned insect is an *hermaphrodite*; it  
 “ unites the organs proper to both sexes,  
 “ and these organs are of the most exquisite  
 “ structure. The earth-worm, though in  
 “ appearance the lowest of animals, might  
 “ exhaust the industry of the most sagacious  
 “ observer, who with the steadiness of a  
 “ philosopher should confine himself to the  
 “ examination of this one object alone.  
 “ How much might not physiology be im-  
 “ proved by such an inquiry! how many  
 “ truths, even beyond our expectations,  
 “ might be added to our stock of know-  
 “ ledge! To be admired, the earth-worm  
 “ only wants to be investigated with as much  
 “ accuracy as the polype has been.”

Is there any one who would not wish to  
 obey such an invitation, coming from a  
 man universally allowed to be one of the  
 first naturalists of the age? But how much  
 more powerfully must I have been influ-  
 enced by it, who, besides these invitations  
 in common with other philosophers, was  
 frequently and particularly solicited by him

on this account, and who am also connected with him by the strictest friendship, which constitutes one of the chief blessings of my life?

From what I learned by the section of the earth-worm, I was induced to examine other animals, in which I likewise discovered the same regenerating power. These several reproductions, as they are equally new and curious, I intend to enumerate briefly in this essay, and afterwards fully to describe them in a larger work, which I hope will soon see the light. This work will consist of many dissertations, each of which, for the conveniency of the readers, will be subdivided into chapters. To lay down facts with the faithfulness of a true historian of nature; to pass, as much as possible, from the most simple to the most complicated; to bring them together, to analyze and compare them both with themselves and with the discoveries of other authors; to deduce with impartiality the immediate consequences, either favorable or contrary to the explanations given of these extraordinary phenomena; to shew how far the limits of animal physiology are extended by, and what utility and advantage may be derived from, observations of this kind, will be the principal design of this work.

I shall

I shall not, however, deny myself the liberty of introducing some similar circumstances, and at times even some of a different nature, which fell in my way by chance, and may serve either to clear up some dark or controverted points, or to promote and confirm some evident and important truths. Such for instance is the discovery of the tadpoles, existing in the eggs of frogs, before fecundation by the male. This agrees exactly with Haller's observation on the chicken\*, and helps to determine the great question, so long in dispute among philosophers, on the first origin of the germ.

As several of the results of my experiments will appear singular, I shall make it my business to describe them with precision, to mention the precautions and means I have used in making these observations, the temperature of the air, and the situation proper for the animals, together with the food I gave them ; and in short, to disclose all the circumstances which may contribute to the understanding, and establishing of the facts, so, that the lovers of natural history, on repeating my experiments, may, if they please, confirm and extend them still farther.

\* *Memoires sur la formation du cœur dans le poulet.*

I have thought a sufficient number of figures would be of the greatest importance to the subject; if they are generally ornaments in books of natural history, they may be said to be the life and spirit of mine.

I shall endeavour to distribute my subjects in such manner, as that the reproductions of the first class may give light to those of the second, and so on of the rest. This order, indeed, I have not observed in this Essay, not thinking it necessary, as my sole intention was partly to enumerate, for reasons it would be needless to specify, the mere result of many of my experiments, and partly to point out several questions proposed to nature, in order to search into her secrets, and find out her ways of acting in these wonderful operations: her answers shall be reserved for my other work.

## THE REPRODUCTIONS OF THE EARTH-WORM.

**T**HREE parts may be considered in an earth-worm, transversely divided; the *fore part*, or head; the *hinder part*, or tail, and the *intermediate part*.

Having found that the anterior part, or the head, reproduced the tail, I was willing to try whether this took place, when the head was cut at different distances, and whether any difference in the method of dividing would prevent the usual reproduction.

It was, therefore, necessary to observe, whether the regenerative power existed in the whole length of the worm, so that the head, however long or short, would be equally fit to reproduce a tail. I found that nature has limits, which shall be determined in my work, and beyond which this reproduction of the tail can no longer be effected.

But as heads, differing in their length, (within certain limits) still reproduce a tail, the following enquiries could not be omitted.

1. Are these tails equal, that are produced

B 4

from

from unequal heads? 2. Do they become so in the same length of time? 3. Does that equality of the tails take place at every point, within the limits assigned for the reproduction? 4. And does it continue during the whole course of this operation?

These experiments, having first been made upon full-grown earth-worms, of one particular species, were repeated on others of the same species, young and still growing; and proper comparisons were made between the reproductions of the first and those of the last.

It was then proper to examine whether the heads in earth-worms of different species, likewise produce new tails. Having found it to be so, I inquired, 1. Whether there is any difference of time between the reproductions of the tails in different species. 2. And being convinced that there was a difference, what might be the reason of it. In the course of these researches, I met with one species of the earth-worm, distinguished from all others, not only by the very long time it requires to begin this reproduction, but likewise by the reproduction itself, which is intirely different from any thing that has been observed, not only on the reproduction of earth-worms, but also on that of other animals.

animals. And thus far I proceeded on the reproduction of the tail from the anterior part, or the head.

The next inquiry was, whether the posterior part, or the tail, likewise could produce a new head. I found that, upon cutting off a certain number of rings from the anterior part, the reproduction of the head took place in every species of earth-worms known to me; and I did not fail to attend in great measure to the same things I had noted in the reproduction of the tail.

If the number of rings taken off is such, that the quantity of the anterior part separated be considerable, the reproduction of the head will not take place till after a long time, and then with difficulty; and not in every species of these insects. But as reproduction is only delayed, not prevented, by this kind of section, it may be concluded, that earth-worms, or at least some species of them, not only reproduce the tail, but the head.

To settle this point, I shall examine the little that has been written upon the cutting of the earth-worm by Count Ginnani\*, Dr.

\* Racolta Calogeriana, tome xxxvii.

Vandelli\*, and Valisneri, now professor of natural history at Padua†.

When the rings cut off near the head are but few, the part reproduced is always equal to that which was taken off; but when there are many, the new head is commonly shorter, and has fewer rings, than the first.

The preceding facts deserved to be still more illustrated by the following queries.

1. Whether the reproduction of a small portion of head appears sooner than that of the tail? and as this is found to be true;
2. What proportion and what laws nature follows in the lengthening of these two productions? This having been found out, I examined,
3. Whence it comes to pass, that head springs forth sooner than the tail?
4. Why it happens, that, when much of the head is cut off, the reproduction is so much retarded, and so very quick when but little is taken off?
5. What is the reason, that in the first case the new head does not, for the most part, equal the first, either in its length, or the number of its rings?
6. Why in many other species of earth-worms the reproduction of the head does not take

\* Dominici Vandelli, de Vermium terræ reproductione.

† Sopra alcune Riproduzioni de' Lombrici terrestri, Padua, &c.

place, when the separated part is considerable?

Being, lastly, come to the middle parts, I was desirous to know whether both a new head and a new tail could be reproduced. I found that they really are both renewed, provided a large portion of the head be not taken off; for then the same thing will happen that we mentioned before. If a small portion of the anterior part be cut off, both head and tail will spring forth; but as we have already observed, the head appears first, and then the tail, according to the law which nature was found to adhere to.

The difficulty, therefore, with regard to the intermediate parts, lies in the reproduction of the head; and although this often fails, the tail will still begin to be regenerated; but this dies sooner or later, together with the middle part.

But how comes it to pass, when equal portions are cut off from the two extremities, viz. the head and tail, of an earth-worm, that, although both extremities perish, yet if they are kept in a proper situation, the point of the tail survives that of the head?

These reproductions take place in the earth-worm, when it is cut across with a pair  
of

of scissars; but what happens, 1. If instead of being cut, the insect be torn asunder; 2. or if fire be applied to the divided part?

Hitherto the animal is supposed to have been cut in three parts, viz. the head, the tail, and the middle piece.

I was then induced to enquire what happened to the earth-worm, when cut in four, five, six, or more parts, which I ascertained by a great variety of experiments.

I should not have done justice to the system of animal reproductions, had I omitted to consider three different states in the earth-worm; one preceding the section; another attending the operation; and a third which succeeds it.

As to the first, we know that an earth-worm being placed upon loose and moist ground, hides itself by boring it with its head. It avoids every obstacle in its way; it generally advances forwards, or with its head foremost; it glides without any difficulty along the sides of vases, &c.

Now do the same phenomena appear in a head just deprived of its tail? in the intermediate part? or in the tail alone?

The

The great artery runs, as was found by Bonnet, from the tail to the head, all along the back. Through this the blood circulates ; and its pulsations may easily be counted.

Is the direction of this circulation the same from the tail to the head in the divided part ? It was observed to be so, whether this part was the head, the middle piece, or the tail.

If the piece first cut off be farther subdivided, has this section any influence on the former direction of the circulation ? By no means ; and I was much astonished to see that the blood proceeded regularly in its former course, when the portion of the head, the tail, or the intermediate part did not exceed the tenth part of an inch.

But does this division retard at least the velocity of the blood ? does it diminish its quantity ? does the blood flow copiously, or not, from the divided vessels ? What alteration do these vessels undergo in their structure ? what change is produced in the other component parts of the earth-worm ?

With regard to the consequences of the section, I examined, 1. What new order  
and

and disposition the divided fibres and vessels acquire? 2. What time it takes up after the section, before a new production begins to make its appearance? 3. What is the form and structure of the reproductions; and, in consequence, how far they agree or disagree with the first parts? 4. Whether the circulation in the great artery, formed by the reproduction, is analogous to that of the whole worm; viz. from tail to head? 5. In what manner are the great artery, the intestinal tube, and the other parts existing in the old animal, united to the new parts? 6. Whether, *cæteris paribus*, the reproduction grows in proportion to the length of time, and the warmth of the weather? 7. Whether all the parts, similar or dissimilar, which existed in the old, are also found in the new, worm? 8. Whether the reproduction, after sections parallel to the plane of the rings, keeps the longitudinal direction of the worm. 9. Whether this direction varies with that of the plane of the section? 10. What interval of time is required before the new-produced parts are able perfectly to perform the functions of those that were cut off? 11. Whether, on the lengthening of the reproduction, the trunk increases likewise? 12. Whether after a certain time the reproduction becomes equal to the old part, both in bulk and length?

But

But is this regenerating power exhausted in the first operation? I found the reverse. A second reproduction being cut off, is succeeded by a third; this by a fourth; that by a fifth; and so on.

I procured these successive reproductions, not only by cutting off, from time to time, the new-recovered parts, but by making the second division within the first reproduction, the third within the second, the fourth within the third, &c. In this manner I obtained a scale of reproductions united to the whole trunk, and becoming gradually younger, slenderer, and of a lighter colour.

It may be inferred from hence, that the reproductive power takes place not only all along the old animal, but likewise throughout the new one.

Is the bulk of the animal sensibly diminished by a series of so many successive reproductions? what proportion of the power is consumed in the last? may we believe, that it would always continue, or at last cease to act?

Instead of dividing entirely a part of the earth-worm from the other by a transverse section, what would happen to him,  
 1. by

1. by cutting transversely through one half of the body, and leaving the other untouched? 2. By cutting the worm almost entirely through, and leaving him hanging only by a thread?

From a transverse, I proceeded to a longitudinal, division, in order to find, 1. What would happen to the earth-worm from a longitudinal division carried through his whole length? 2. By extending the longitudinal section to the length of an inch in the fore part? 3. By doing the same in the back part? 4. By taking away a longitudinal piece of the intestine? 5. By cutting off a piece of the great artery, and thus interrupting the circulation through it? 6. By opening part of the body longitudinally, either on the back or belly?

As many of these experiments succeeded on earth-worms, when whole, they were afterwards repeated on heads, middle-pieces, and tails.

It was necessary to prefix to the present inquiry an accurate anatomical description of the earth-worm. It is not sufficient to say that a new tail or a new head is reproduced, unless at the same time we describe the number, diversity, and nature, of the parts

parts concurring to form this new tail or this new head. The various relations these parts bear to each other, and to all the rest, are likewise to be traced; and lastly, the organical texture of the reproductions is to be compared with that of the parts that were cut off, with the nicest exactness and greatest circumspection. This indeed is the best method of improving and illustrating this doctrine, but it could not be pursued without the assistance of the anatomical knife.

Rhedi \* and Willis † have given anatomical descriptions of this animal. But to say the truth, as it was only occasionally that they considered him, they did not trouble themselves much about the mechanism of his organs. I have taken upon me to go a little farther, and have found some organs in these insects unknown or undescribed by them.

To proceed regularly and with clearness in my anatomical descriptions of the earth-worm, I intend to treat particularly of the following organs; viz. Of the two sexes found in the earth-worm; of the arteries and veins, and of their communication; of the muscles;

\* Degli animali viventi negli animali viventi,

† De anima Brutorum.

and of the tube, from whence the œsophagus, the stomach, and the intestines are continued. I shall examine afterwards, whether the earth-worm has a real heart, a brain, and spinal marrow; and whether it has nerves, and vessels inservient to respiration.

Under this last head I shall have occasion to insert a very great number of experiments concerning the respiration of caterpillars, made many years ago by Mr. Bonnet, and by him most obligingly communicated to me. I thought proper to give previous notice of this circumstance, that, from the merit of the author, the public may form some idea of the value of the work.

The experiments of the naturalist of Geneva, will be joined to my own on the same subject; in order to judge (if I may be allowed so to do) of what the two celebrated naturalists, Malpighi \* and Reaumur † have advanced about the very dark work of respiration in caterpillars.

\* De Bombyce.

† Memoires pour servir à l'Histoire des Insectes, tome i.

## REPRODUCTIONS OF THE AQUATIC BOAT-WORM.

**I** Think it not inexpedient to give a slight idea of this insect, which, if I am not mistaken, is hitherto unknown to naturalists. It is composed of rings like the earth-worm, and by the help of these is able to shorten or lengthen itself as it pleases, and to move from one place to another. Its size towards the head is equal to one of the largest goose quills, and its length about a span. The largest indeed may reach to the middle of the arm, especially when stretched. The colour of their back is dark, but grows lighter towards the tail; the belly is of a pale flesh hue.

They live in sweet, shallow, and clear waters, either stagnating, or flowing gently. The fore part of the body is stuck in the mud, whence they draw their nourishment. The back part reaches the top of the water, and being stretched and hollowed out, forms a kind of boat, horizontally extended over the surface of the water. This boat, the cavity of which is towards the sky, and whose sides, rising above the water, prevent its getting in, is extremely serviceable to the

insect, as it enables him to hold out a great part of his tail, which he could not do without this contrivance, as the specific gravity of his body exceeds that of the water.

The usual position of the fore part of this animal, the element he inhabits, and his organisation, which, as we shall see hereafter, is like that of the earth-worm, have induced me to call him the aquatic boat-worm.

The fibres in this worm are very irritable. Upon the least swell or agitation of the water, the insect immediately undoes his boat, then shortening, and at the same time collecting his body together, he withdraws in the twinkling of an eye from the sight of the observer, and hides himself in the mud, his natural place of refuge. When the motion of the fluid ceases, and his fears are over, he rises again with his tail out of the water, and makes his boat afresh, which he keeps entire, till some new accident happens to disturb him. He delights so much in this boat, which enables him to feel the impression of the air, that he does not fail to make it, though the mud is removed, and he left with little water. Even when the worm is broken in several pieces, that which has the tail, or is the nearest to it, continues the same sport.

But

But for what reason does our insect constantly form his tail into a boat, which lies secure on the surface of the water? Are we to suppose that this is done because the organs of respiration are placed there, as we certainly know that other aquatic animals have them in the same part, which they lengthen out, till it reaches to the top of the water, and thus enjoy the benefit of the air? This was my first idea, and it was afterwards confirmed by anatomical dissections.

Another curiosity, which I discovered in the said boat-worm, is particularly interesting, as it immediately relates to the animal œconomy. The canal, which runs all along the back of many insects, would have been universally believed, from the nice experiments of two eminent academicians\*, to be the great artery, supplying the place of the heart in them, if the wonderful caterpillar of Lyonet † had not appeared to call in question this received opinion. An attentive inspection of this canal in the boat-worm, may probably put this affair beyond doubt. The state of perfect rest in which the insect is, the blood passing through the canal, and striking the

\* Reaumur and Bonnet.

† La chenille qui ronge le bois de saule : à la Haye, 1762.

eye by its lively purple color, and the number of blood-vessels branching out from the sides, give the observer an opportunity of making, at leisure, the most important enquiries: an advantage not easily obtained in other insects; as they are naturally of a very restless disposition, and their blood is commonly so transparent, that it hardly makes any impression upon the eyes.

These remarks being premised, I now come to my principal object, concerning which, I have discovered, that my boat-worm is very easily reproduced; having tried upon him most of the experiments made upon the earth-worm. I shall not, therefore, enumerate either these experiments or the results, as most of these agree perfectly with those of the preceding insects, except in some particulars; three of which shall be mentioned at present.

The first is, that the aquatic -worms are quicker and readier in their reproduction than the earth-worms. It is therefore no wonder, 1. That they more easily recover their heads, even when consisting of many rings. 2. That this power exerts itself even in winter. 3. That upon repeated sections of the same part, a greater number of reproductions is obtained in the same time.

The

The second particular is, the facility with which two thirds of the lower part of the body towards the tail may be broke; which is not to be observed in the remaining third part of the body towards the head. Hence, 1. reproductions of the tail, and these even very long, are frequently found in these insects, when just taken out of the water. And, 2. reproductions of the head are very rarely met with in this state.

The last particular concerns the origin and unfolding of the arterial vessel, which manifests itself upon the trunk of a boat-worm, after his tail is cut off. At first, nothing is seen but the podex, of an elliptic form, except towards the upper part, where the angle is very acute. Hence a small one becomes visible, having the anus at its apex. The two sides of the very acute angle form a very fine straight line, of a red colour; this joins the trunk, in the direction of the longitudinal arterial vessel of the insect. The blood soon begins to shew itself at this line: we see it gently flow on through the whole length of it; hence it passes into the old artery, and this anastomoses in a right line with the new vessel, the developement of which clearly appears. In the mean while, the cone grows bigger, and the sides of the

podex appear tinged of a light brown, which gradually becomes deeper. The brown sides change into two very fine arterial branches, which discharge their blood into the regenerated artery, from whence it flows into the old vessel. Now as the artery of the tail, in its natural state, appears to be produced in a similar manner, although this is not so manifest on account of the opacity of the parts; it follows that, in my worm, the arterial vessel is immediately produced from two arterial branches, united on the sides of the oval which forms the anus.

But from whence do these two branches derive their blood? Perhaps from some smaller arterial ramifications? perhaps from a vein?

REPRO-

## REPRODUCTION OF THE TAIL IN THE TADPOLE.

THE tadpoles are those aquatic animals, which grow into frogs or toads. The reproduction of their tail could not but take up a great part of my time, as much was to be learned from thence. The extreme transparency of the membranes is equivalent to the finest and most accurate dissection; since, besides shewing the texture of the solids, it gives the clearest view of the circulation of the fluids. On viewing therefore through a lens the tail newly produced, we have the advantage of examining how the fibres of the old part unite themselves with those of the new; at what time, by what means, and how the circulation passes on from the trunk to the reproduction; and lastly, what order is observed by nature in the growth of these fibres, and the addition of the fluids. Every body must be sensible of the great importance of all these things in the present subject.

The circulation of the blood in the newborn tadpole shews itself sooner in the bronchial vessels, or organs of respiration, than in the tail. This blood is then composed

of small globules, of a pale yellow hue; this is likewise the color of the liquor which soon begins to run through the arteries of the tail; but the course of circulation is different. One half of the length of the tail is an aggregate of oblique muscles, parallel to each other, but converging towards the axis. The sides are composed of a membranous skin, spotted here and there in a very elegant manner.

Small rivulets, at first but few, afterwards in greater number, issue from the muscles, make many serpentine turns in the membrane, and, by fresh windings, conceal themselves behind the muscles. A dark veil does not permit the eye to observe the origin of these rivulets. The tadpole being somewhat older, the veil disappears, and the source of these ramifications shews itself in two real vessels; the one arterial, the other venous. The first takes its origin from the root of the tail, and runs to the top; where, after some turns upwards, it forms the second. Both run in a longitudinal direction all along, and very near the middle of, the tail. The vein issues forth before the artery.

The ramifications grow more and more numerous, and in a short time fill the whole tail. The sight of these numberless rivulets  
of

of blood affords real delight to the philosopher. This blood comes from the two great vessels; and after a greater or lesser number of turns, is brought back to them.

These ramifications at first appear few, afterwards copious, and lastly crowded; but were they successively formed, or did they exist from the first, and require nothing but to be gradually unfolded?

A portion of the tail being taken off by a section perpendicular to the axis, we discover wonderful phenomena about the circulation, both in the part cut off, and in what remains of it. These will be described in my book: I shall confine myself at present to some of the effects of the reproduction.

If the whole tail, or very near the whole, be cut off, the tadpoles go to the bottom of the water, and there lie down and perish. But if a lesser part be taken off, not one of them dies; and all without exception recover what they lost.

Nature observes the following laws in the growth of these reproductions. They are more considerable, when a great part of the tail is taken off; not so large after a lesser section;

section ; and least of all, when a very small bit has been cut off. The greatest length seems however rather to take place, when the tail is divided in the middle, than when the section is higher.

If the tadpoles were very young when cut, the reproduction appears very soon. In one summer day it makes the most rapid progress ; and in a short time the new part not only equals that which was cut off, but the new part of the tail and the old one joined equal in every dimension the tail of unmutilated tadpoles born at the same time. The reproduction, being arrived at this height, continues to increase in the same proportion as the tail of similar animals, to which nothing has been done.

When, therefore, this operation is performed at different periods upon tadpoles of the same species, the reproduction of the second period is equally quick with that of the first.

But if the tadpoles be greatly advanced, the beginning of the reproduction is retarded ; and all other circumstances being the same, its progress will be slower. Hence follows this law, which I always found unvaried ; that the quickness of the reproduction,

tion, both in its beginning and growth, is in an inverse ratio to the age of the tadpole.

This rule equally takes place in the second, third, fourth, &c. reproductions, which constantly follow upon a second, third, &c. section; in a word, these successive regenerations are never found to fail as long as the tadpole keeps its tail.

The differences observed in the manifestation and increase of the new-produced part, are analogous to what is found in the trunk. In the most advanced state, the old part does not grow in the least; in the middle state or in youth it increases but little; but in infancy the growth is very rapid.

The tadpoles, to which no kind of nourishment is given, do not grow in size, at least sensibly; the legs do not come forth, nor are the membranes of the infant state cast off. I have kept some in that state of abstinence during the greatest part of the summer; and when these were still no bigger than a small pea, the tadpoles born at the same time, and continually fed, were, at least, ten times fuller and bigger than their fasting friends; nay the greatest part of the first had already got clear of their first envelopes,

velopes, and were converted into frogs. Hence the want of food retards in a frog the progress towards the state of full growth; that is, in other words, it lengthens the periods of life in these animals, in the same manner that cold operated upon the caterpillars of Reaumur\*, who were slower in becoming cryfallids; and, when cryfallids, longer in becoming butterflies. But yet I was not a little surprised to observe, that, in these abstemious tadpoles, the tail was still reproduced, and considerably increased.

Hitherto we have seen the phenomena of reproduction, as they appear with the naked eye in the tadpole; let us now take a microscopical view of these appearances.

When any piece of the tail is separated by a section perpendicular to the axis, the sides, which, as we have seen, are formed of a membranous skin, are often the first that appear. The reproduction presents itself to the eye as a prolongation of the old membrane; it is only somewhat finer and more transparent.

\* *Memoires pour servir, &c. tome ii.*

Not long after this, a blackish thread issues forth from the axis or center of the trunk. Upon viewing it with a glass of a very great power, it appears to be nothing else but a contexture of longitudinal fibres, parallel to one another.

The blood of the great artery does not as yet reach the reproduction; but it comes close to the section by means of several ramifications, opening into the great vein, into which it discharges itself.

The issue of longitudinal threads increases in the mean while, by the addition of many more fibres arising from the sides; and growing larger in every dimension, it soon unites to the membranous skin. It then assumes the form of a small slip or pyramid; the extremity of which is that of the tender new-born reproduction, and the basis remains engrafted on the trunk.

The arterial blood then begins to pass the limits of the section, and to advance a little way among the new fibres; but it soon takes a turn to the part whence it came, re-enters the trunk, and by other branches gets into the large venous vessel. In proportion as the reproduction increases in bulk, the large artery throws more and more blood  
into

into it, by means of the increased number of its ramifications, which after some days become very considerable. The greatest part of these branches having been carried on to the extremity of the tail, they all turn up again towards the trunk: from arterial, they become venous branches; and having been distributed by many circumvolutions throughout the whole extent of the reproduction, they discharge all their blood, as usual, into the great vein. The same process is afterwards continued by the aforesaid ramifications; except only, that as their diameters increase, they carry, in consequence, a greater quantity of blood.

Hence arises a very considerable difference between the circulation of the blood in the reproduction, and that in the original part. For although the two real vessels in the original part, viz. the artery and vein, do send off from their sides similar and very fine ramifications, yet they both keep themselves quite distinct from the root to the extremity of the tail; and, besides their direction, have a much larger size. This happens whatever be the age of the tadpole. On the contrary, these two canals, in passing from the old to the new parts, become less, and dividing, as was before said, into a vast number of serpentine

pentine ramifications, occupy the greatest space of the new produced tail.

It is also necessary to observe that this irregularity in the circulation does not only take place in the first reproduction, but is likewise observed in all the succeeding new tails of the same tadpole, when mutilated over and over again.

On considering the new organisation with regard to the solids, the following phenomena present themselves. As to the membranous skin, we have already said that the new one only seems a continuation of the old, and this, at least in appearance, is likewise the case with the longitudinal and parallel fibres. On the untouched part of the tail, the oblique muscles, which unite in an angle at the axis, form at the same time a large bundle of fibres running towards the lower part of the tail, in a direction parallel to the axis, and this bundle remains cut by the mutilation of the tadpole. Now, if we examine the reproduction, when still growing, besides the evident regeneration of the oblique muscles, we shall find that the new longitudinal *fibrillæ* coincide and join so well with the old divided fibres, that the first have all the appearance of being continued from the last.

Nevertheless it sometimes happens that a small fold or deviation from the right line shews itself at the point of union between the old and new fibres; but this blemish in time is either removed, or is at least not so apparent; and it is indeed very astonishing to see the effect of time, in making the new and the original unmutilated tails similar to each other.

When the tadpole is sufficiently advanced, the increased opacity of the natural tail prevents a microscopical view of the viscera inclosed in it; and the same obstacle presents itself in the part where the reproduction has been. This part being formed upon a trunk of some thickness, is likewise pretty large in its origin, and therefore not an object of microscopical observation. Dissection however, here steps in to our assistance, and shews that nature proceeds in the reproductions formed on the trunks of tails in the more advanced tadpole, in the same unalterable way as in those that are young, and whose tails are still tender.

If, instead of cutting off the tail in this manner, the membranous skin be taken from the tadpole at any age, without touching the muscles, another membrane, exactly like the former, succeeds, and upon removing this a  
third.

third. The order only and position of the venous and arterial ramifications, differ from the situation of those, which are found winding in the skins of unmutilated tails.

The tadpoles I examined, are such as are changed into frogs and toads. Notwithstanding the diversity of species of these two animals, the organization of the tail is essentially alike, and the issue of my experiments was also the same.

## OF THE EXISTENCE OF THE TADPOLES IN EGGS BEFORE FECUNDATION.

**I**T is now sufficiently known to naturalists, that the eggs of frogs and toads are not fecundated in the maternal womb, but at the time they issue from the mother. The male gets upon her back, embraces and holds her fast, with his fore legs extended round about her breast; and, performing the office of a midwife, seizes the eggs of the parturient female with the toes of his hind legs, facilitates their coming out, and as they are ejected, sprinkles and fecundates them with his seminal liquor. To the happy investigations of the great Swammerdam \* we are indebted for this curious discovery, which has since been fully confirmed by Roesel † in his natural history of frogs, an elegant and famous work. From this discovery it is evident beyond a doubt that the eggs of frogs, so long as they remain within the body, are not in a state of fecundation.

\* *Biblia Naturæ.*

† *Historia Naturalis Ranarum.*

I set out with this fact, when I undertook to make a particular and strict comparison between those unfecundated eggs and others, that have been fecundated by the male; whatever the event might be, either contrary or favourable to the various systems on generation.

I first examined the fecundated eggs newly discharged from the female, and found them inclosed by their mucilaginous part, divided into a number of small spheres, connected and glued together. An egg is placed in the center of each sphere; it is surrounded by two circular delicate and concentric membranes, a little distant from each other, and easily discernible with the eye, on account of the infinite transparency of the small mucilaginous spheres. On piercing the membrane nearest to the egg, there follows a small drop of a watery fluid, in which the egg always floats.

The egg being freed from its concentric membranes, and its mucilage, appears perfectly round, has a beautiful lustre, and a smooth slippery surface, one half of which is blackish, and the other whitish. On pricking it with a needle, a half fluid and viscid substance of a pale yellow color oozes from it. If a larger opening is made, a greater

quantity of this substance comes out; soon after this the egg shrinks and shrivels up, and being at last entirely emptied of its contents, nothing remains besides the dry, double colored skin, which being left to itself, liquifies and dissolves.

The yellowish matter being viewed through a lens, appears composed of an infinite number of roundish particles of the same colour. It unites and incorporates with a drop of water, and gives it its tinct. When the eggs are hardened with spirit of wine, or boiling water, the internal parts, being examined with the greatest attention, give no marks of organization. When softened again and dissolved in water, the round yellowish particles are again apparent. This, in short, is the analysis I made of eggs newly laid by frogs, and impregnated by the male.

I then proceeded directly to examine those eggs, which still remained in the body of the frog, and consequently were not fecundated. The first frog I opened was in the act of copulation; all her eggs were already descended into the womb, excepting four or five, which still remained in the oviducts, and two or three in the ovaries. These contained moreover a very large quantity of immature eggs, no bigger than poppey seeds, and of a dark hue.

hue. The usual gelatinous matter was not yet found surrounding the eggs of the ovaries, but it did encompass those of the oviducts, and much more those that had already got into the womb.

These last were in great abundance, and upon a close examination, appeared not to differ in the least from the fecundated eggs examined before. Besides that the nature and size of the viscid spheres was perfectly similar, that the position, figure, and colour of the two membranes were exactly alike, and that the liquor contained in the membrane nearest the egg was the same, there was no circumstance, by which the unfecundated eggs might be distinguished from those that were fecundated. No difference could be observed in their size, roundness and surface, or in their colour and skin. The inclosed fluid issued with the same facility from this egg, when pierced with a needle, and the nature, property and characteristics of this fluid were the same. In short, if I had not been convinced that the first eggs were fecundated, and that the last were not, it would have been impossible to find it out from the most attentive analysis and the most accurate comparison. I therefore was obliged to admit of the most perfect similarity between eggs in these two different states.

The same conclusion was deduced from my examination of many more frogs which I opened. There was only this trifling difference to be observed, that the eggs of those females, who had not yet suffered the embraces of the male, besides being confined within the ovaries, and something smaller on account of their being less advanced, were also deprived of the mucilage, which they take up, as it is well known, on passing through the long and intricate convolutions of the oviduct.

In order to compleat the comparison I had begun between these two species of eggs, the changes, which were afterwards to take place in them, were now to be examined. As to the unfecundated eggs, they only spoil, dissolve, and come to nothing. Little by little the mucilage separates, the membranes shrivel, break, and disappear, and the eggs, after wasting away, soon break into several pieces, which are scattered about the surface of the water. But the case is very different with the fecundated eggs. Round as they were before, they lengthen first without growing bigger, but afterwards with an evident increase of bulk. The superficies of the whitish half grows somewhat darker, and on the blackish part there soon appears a slight longitudinal furrow, bounded by two risings, which

which extend in a right line over the greater diameter of the lengthened egg. In proportion to its increase, the internal membrane dilates itself, and contains a larger quantity of fluid.

The small furrow with its risings grows longer, and soon after disappears on one side of the egg. This still keeps up the form of a lengthened sphere, but has on one side of the elongated part a kind of stalk, or small appendix. The opposite or deep coloured white part of the egg retains its color, but swells a little. The other blackish part is thrown into a curvature, the little appendix lengthens, and shews itself then, although more conspicuously some time after, to be nothing else but the tail of the tadpole; the black curvature turns out to be its back, and the swelling on the opposite part its belly.

In fact, the part opposite to the tail then puts on an appearance so much resembling the head of the tadpole, that it cannot be mistaken. On the fore part of his head the form of the eyes is to be seen, although still close; the two small buttons like prominences also shew themselves, by which the animal, when tired with swimming, fastens itself to bodies, even such as are smooth. The beginning

ginning of an opening for the mouth likewise manifests itself; and lastly, the two gills become apparent, and the blood is seen flowing within their substance.

In these early times the animal gives yet no sign of life, either in moving or twisting itself, if pricked with a needle, or suddenly exposed to the rays of the sun, even when concentrated by a lens. These impressions indeed excite great feelings, in a more advanced state of the organs; which, acquiring a greater firmness and strength, enable the tadpole to break through its confining envelopes, and to swim freely in the water.

Such are the phenomena, which gradually make their appearance in the fecundated eggs. Hence it must be obvious, that these are not properly, as was imagined before, the eggs from which the tadpole grows, but rather the tadpoles concentrated and coiled up in themselves.

This important fact is still more fully established by the perfect similarity between the parts composing the internal substance of the fecundated egg, from the time it begins to lengthen, to the manifest developement of the tadpole, and the parts found in the same  
egg

egg before it begins to unfold itself. We shall give the most authentic and indisputable proofs of this similitude in due time.

It appears therefore plainly, that the tadpoles exist before fecundation, which most interesting truth may for the sake of precision be thus demonstrated. The unfecundated eggs do not differ in the least from those that are fecundated; these last are nothing else but the tadpoles themselves coiled up and concentrated; the same is therefore equally true of the unfecundated eggs; and consequently the tadpoles exist before fecundation, and require only the fecundating liquid of the male to unfold themselves.

Hence it follows, that frogs ought not to be reckoned among the oviparous class of animals, as naturalists have ranged them, but that they more properly belong to the viviparous class. Indeed they would rather seem to constitute a separate class, from the circumstance of their fetuses not shewing the form and features of their species before they are come to light. Thus nature seems to delight in diversifying the modes of animal generation.

I would

I would not, however, have the word egg entirely laid aside, as it seems convenient enough to distinguish the immature tadpoles, under the form of small eggs, from those that are already disclosed, and shew their real make.

The present discovery leads on to other truths, which throw some light upon the obscurities, in which the system of generation is involved. I shall for the present only mention briefly one of these truths. The most esteemed naturalists observe, that the first constituent parts of birds known to us, do not disclose before the operation of the male. Hence they infer that the seminal fluid serves both as a stimulating and a nutritious juice to the germ. Before fecundation, the small heart of the germ wants force sufficient to overcome by its impulse the resistance of the solids. This force it receives from the fecundating liquor, which stimulates, gently irritates, and obliges the heart to propel with greater power the fluids through the smallest canals. The same liquid afterwards becomes nutritious, bringing about the developement of the germ, which implies nourishment.

It is evident from my observations, that this noble and ingenious theory cannot universally

versally be received in regard to the great work of generation. The tadpoles, or if you please, the eggs of tadpoles, unfold themselves considerably before fecundation. One of these, when in the uterus, is at least three times bigger than the same, while still attached to the ovaries. There are animals therefore, the germs of which are not disclosed at first by the spermatic fluid, but by the juices of the mother, and since this unfolding or increase of bulk is performed by nutrition, which must imply a circulation of fluids, and that such a circulation cannot be carried on without the action of the heart, we are obliged to infer that these maternal juices are themselves that kind of stimulus which the seminal liquor is supposed to be in birds. Consequently the heart in the germ of the tadpole, must beat sufficiently to produce a circulation of fluids, without an insuperable impediment from the solids.

But if tadpoles are already animated by the action of the heart, if they have acquired a considerable increase of size before they come to light, how happens it that, without the intervention of the male seed, they cease to grow, and perish, notwithstanding the liquor in which they swim, and which is certainly their nourishment in the first periods of life? If the assistance of the  
 seminal

feminal liquor is necessary, in what does its efficacy consist? What are the proper and distinguishing characteristicks of this liquor? As it fecundates the young tadpole fetuses in a particular manner, that is, after their coming out of the womb, does it perchance differ in its method of acting from the semen of other animals? How is the fecundation of frogs eggs brought about? Are there any openings, or holes for suction on their external surface, to be discovered by means of a very powerful magnifier, by which the feminal fluid may be internally absorbed? Again, since this liquor acts externally, could not the eggs of frogs be fecundated artificially, by sprinkling them before fecundation, with the liquor extracted from the spermatic vessels of the male? What would happen if this liquor was used to sprinkle the eggs of fish, which are commonly supposed to be fecundated in the same manner as those of frogs? What would follow from sprinkling the eggs of frogs with the feminal substance or the soft rows of fish?

The elucidation of these questions encouraged me to attempt others. These experiments were too curious and interesting not to be varied in several ways. The fecundation of our frogs eggs requires the assistance of the the males only at the time  
 3 when

when they are emitted from the body of the females. Why therefore the continuation of these tenacious and amorous embraces, which sometimes last forty days, according to the observations of the indefatigable Swammerdam? \* Do they serve to express the eggs from the ovaries, and to facilitate their descent through the oviducts to the womb? When the frogs are by chance disturbed in this amorous conflict, during the efforts of the males, and are obliged to keep to themselves, do they still lay their eggs? Do those who were never compressed by the males also deposit their eggs?

The eggs of toads, which form a string of about two feet in length, are, according to Roefel, † fecundated in the same manner as those of frogs. But what shall we say of these horrid and enormous monsters, when compared to other toads, whose females discharge at once many thousands of eggs? I shall not fail describing what I observed in regard to their copulation, and to compare my discoveries about the origin of the young ones of that species, with the small account

\* Biblia Naturæ.

† Historia Naturalis Ranarum.

given of this matter by Valisneri\*. In this discourse I shall likewise speak of the judicious care the females take of their eggs, of the choice of the water in which they deposit them, and of the surprizing power the mucilage has of preserving these eggs.

\* Tom. i. Istoria del Cameleonte Africano.

REPRO-

REPRODUCTIONS OF THE HEAD  
AND OTHER PARTS IN THE  
LAND SNAIL, AND OF THE  
HORNS IN THE SLUG.

THE head of the snail is more complicated than I imagined. It has a brain of considerable bulk, consisting of two lobes, united in the middle. From the lower part of the brain, or that towards the body, two very remarkable nerves, which are only a bifid medulla spinalis, issue forth; ten other nerves take their course towards the upper part, diffuse themselves through the head, and some of them throw out many ramifications. Four of these ten nerves are placed within the four horns of the snail; and the two belonging to the large horns are very beautiful. At the top of their extremity, which spreads out into a bulbous form, the two eyes of this reptile are placed. In each of these eyes we may discern five parts; viz. two coats, and three humors; the aqueous, the cristalline, and the vitreous.

The various and strange motions of the head require the assistance of a great number of muscles. Each horn is furnished with

E

a par-

a particular muscle, by which the animal draws it in, and hides it within its head at pleasure.

The snail, besides its mouth, has lips belonging to it, a tongue, a palate, a stomach, teeth, &c. These teeth are of a horny substance; and being closely united to one another, seem to form but one tooth.

This multiplicity of parts, which compose the head of the snail, were clearly discovered by Swammerdam's dissections. I found that his observations were true, and thought proper to mention these few particulars, in order to shew that the reproduction of the head in snails has in it something very singular and great: but this will appear still more evidently from an account of the facts.

In the first place, snails can reproduce their horns; and as this operation differs from any other in the manner in which it is performed, it throws new lights upon the theory of animal reproduction. Upon the trunk of other animals appears a small cone or slip, the basis of which is at first without any comparison less than that of the trunk; and the difference is only removed in process of time.

The

The case is not the same when the snail's horns have been cut off. The trunk itself becomes roundish, like a small knob, of a lighter color than the rest of the horn. This knob grows bigger; its color becomes deeper; and from the top of it, if it is a large horn, springs forth a black point, which is the eye of the snail. In the meanwhile, the mutilated horn increases in size, and after some time equals that which has not been touched. This reproduction seems at first sight to be nothing else but a prolongation of the trunk. The color of the new part is at first lighter than that of the old one. The reproduction of the two small horns is carried on in the same manner.

Nature, however, does not always proceed in the same way in the production of these horns. It frequently happens, that the trunk, instead of becoming round, grows tapering into a point, and, in appearance, longer. From the top of this, the black point or eye is seen to squeeze out. The point afterwards spreads, and changes into a small globe. The eye appears at top, and the rest of the process is the same as before. If it be asked, whether the number of the constituent parts is exactly the same in the old and new horn? the answer is, that

by the nicest dissection no difference can be found.

But does this reproduction constantly succeed, whatever be the number of the horns taken off, and in whatever situation they are cut? As nature deviates here from her usual method of proceeding in other reproductions, so it will be seen, that she does not always answer the observer's expectations.

If, instead of the horns alone, the head of the snail is quite cut off, a new one will succeed. But here again the reproduction is performed in a singular manner. When, for instance, an earth-worm loses its head or tail, the succeeding reproduction is an entire organic body; that is to say, a part in miniature exactly similar to that which was cut off, and wanting only a farther unfolding of its rings.

On the contrary, what appears on the trunk of a snail, is not an entire organic body, containing at once all the parts which constituted the head that was cut off. But these parts are often made separately at first, or grow piece by piece at different intervals; and a pretty long time is required to unite and consolidate them into one mass,  
very

very little, if at all, dissimilar from the original pattern. Some instances I am going to mention will make this more clear.

Sometimes the reproduction appears like a small round body, containing the primary parts of the two lips, and of the small horns, which are united to the mouth and to the new-formed tooth. The little round body is placed on the centre of the trunk like a small ball, resting by some few points upon a subjacent plane. The other parts, as the large horns, and the fore part of the sole or foot of the snail, which in the unmutated animal are contiguous to the head, will be entirely wanting. Another trunk shews the larger horn on the right side more than one tenth of an inch long, already provided with its eye; and under this, at some distance, the first lineaments of the lips appear separately. The reproduction in a third snail is a group of three horns; two of which are already arrived to their natural length, while the third is still but just above the skin. Some snails only reproduce at first a small knob, which is nothing but the first mark of the lip. Others are already provided with the whole head, wanting only one horn, or more. In others, the reproduction begins by the two large horns springing from the trunk, or by

the small horns, or by one large and one small horn.

Again, some shew nothing but the trunk, without any true sign of reproduction, although the head was taken off at the same time with others, from which such a number and variety of organs came forth, as were just now described. On the contrary, in some snails there is no difference between the head which was cut off, and that which is newly produced, except an ash-coloured line perpendicular to the axis of the head, pointing out exactly the mark left by the scissars in taking off the head of the snail.

This mark is not always a simple line. Sometimes there appears a deep cavity, constantly of a white color, perpendicular to the axis of the neck, or oblique, according to the direction in which the section has been made. In this last case it sometimes happens, that on the side where the greatest portion of the head has been cut off, the cavity will be much larger; and in some snails an enormous gap will be seen on one side, while nothing appears on the other, except perhaps the mark of the ash-coloured line.

Though

Though these cavities fill up in process of time, yet the mark of the section, or the line just mentioned, is seen upon the neck of some snails, two years after. Even after so long an interval, the reproduction of the head is not quite completed in some: one or several horns may be wanting; they may not all, be come to their natural size, or they will appear full of tubercles, and monstrous. Such appearances, consisting of an unnatural position of the newly-generated parts, have frequently occurred.

I have here given a specimen of the singular varieties, which are observed in the reproduction of snail's heads, although cut off all at the same time. But are these singularities to be reckoned defects or *lusus* of nature, or should they rather only be considered as singularities in appearance, and really founded upon constant and invariable laws? Should we be induced to think, that the circumstances of the section, with regard to greater or less depth, or a difference in the obliquity of the division, will determine the laws by which the future reproduction is to proceed; and consequently, that an attentive and minute examination will at last discover to us the whole system of these

E 4

laws,

laws, so as to enable us to account for these seeming oddities?

The use which the snails made of their reproduced heads in eating, seemed to be a certain proof that all the constituent parts of the head were regenerated. But yet I thought proper to ascertain this point by dissection. By this I obtained infallible proofs that the new head is perfectly well provided not only with the similar and dissimilar parts first mentioned, but also with many others which I shall describe somewhere else; and which, joined to the former, make up the complete head. Hence it was also evident, that each of the new parts is so well united and inosculated with the old ones, that nobody would suspect the snail to have ever been mutilated, except by the ash-coloured line which runs across its neck.

The same effects followed from sections above or below the brains, or through the medulla spinalis. In this last case, a part of the medulla is supplied, together with a new brain; from which the ten nerves before mentioned proceed.

The reproduction of the head having thus been obtained, it was natural to think, that the snail would recover other parts less complicated

plicated than this. Such are that projecting collar, which furrounds and adorns the neck, when the animal is out of its shell, and the flat and large foot, on which the body supports itself in its motions. These two parts grow again perfectly after having been cut off.

But is the power of recovering parts, separated in this manner, common to all the species of land snails? In all those I have examined, the reproduction has always taken place: but there is one species I shall more particularly describe, as being privileged by nature in a particular manner.

The naked slugs, whose manner of generating has been so elegantly described by Redi\*, deserved likewise to be examined. But my investigations of the snail left me but little time to bestow on them. The few experiments I made amount to this, that they are upon a par with the snails in the reproduction of their horns; but in that of the head seem to be much inferior.

\* Degli Animali viventi negli Animali viventi.

## REPRODUCTIONS OF THE TAIL IN THE AQUATIC SALAMAN- DER.

THE wonderful things asserted of the Salamander, its terrible poison, and the pretended privilege which has been given to it of living unhurt in fire, have been entirely disproved by the observations of curious and unprejudiced philosophers \*. This animal will now appear in a much higher light, and become more properly the object of our admiration. If a small lizard excites our wonder, by the power of reproducing its tail, and lobsters or craw-fish by the recovery of their claws, how much more should the salamander be admired, who, besides other parts, may, as I have discovered, repair the loss of both its tail and its legs? This regeneration is so much more surprising than that which takes place in the craw-fish and small lizard, as the structure of these parts in the salamander is infinitely more complicated and refined.

Our astonishment does not end here. The tail of the salamander, besides a compleat

\* Maupertuis Mem. de l'Acad. des Scien. de 1726.  
Valisneri del Camaleonte Africano.

apparatus of nerves, muscles, glands, blood-vessels, &c. is furnished with vertebræ of real bony matter, and their legs do not differ from those of the most perfect animals, in the number of the bones of which they are composed. Now when the legs and tail of this animal are taken away, new vertebræ, new bones are produced; a phenomenon as wonderful, as it is hitherto unknown. But before I describe these regenerations, it will be necessary to premise some observations about the nature and properties of this reptile.

Mr. Du Fay reduced to three species all the salamanders which are found about Paris \*. Whatever pains I have taken, I have not been able to meet with these three; but, on the other hand, have discovered some of a different kind. It appears therefore, that the species of Salamanders vary according to the nature of the climates. Those I have examined I chuse to call aquatic, as I always found them in the water. They can however live out of it, and even live well. I have also been told by persons of veracity, that in the winter they have sometimes been found in holes under ground, and under the turf; so that if any body

\* Du Fay Mem. de l'Acad. des Sc. de 1729.

chuses rather that they should be called amphibious animals, I should hardly think it necessary to dispute about it.

My salamanders keep alive for a considerable time under water; but they die at last, although sooner in one season than in another: air is therefore necessary for them. To ascertain this, I made some experiments with the air-pump; sometimes having the salamanders dry in the vacuum, and sometimes keeping them under water in the said vacuum. The same experiments have been made with frogs, in order to compare the nature of these different animals.

The notion that salamanders can live in the fire is, as we have said, a mere fable. But do they bear it better than other animals? What degree of heat destroys them? This was not yet known; and I endeavoured to come at the truth, by exposing the salamanders to the sun-beams in summer, either on the ground, or in water. I encreased, by degrees, the heat of the water in which they were confined, by putting fire under it. At last I tried them with hot embers; and found, by the help of the thermometer, that these creatures can hardly bear the same degree of heat, which is borne by other animals  
of

of the terrestrial, amphibious, and aquatic kind.

Mr. Du Fay observed, that they resist cold much better than heat \*. Having put them in water, and made that water freeze, so that they were surrounded with ice, he found that they still kept alive. This experiment deserved to be repeated and improved. I shall therefore shew what degree of cold they can bear without dying; and it will appear, that as there is nothing marvellous in the power of the salamander (at least of these of our country) in resisting heat; so the power of resisting cold is so far from being more considerable in them, that on the contrary, they can bear it less than many other animals.

These experiments brought on others of the same kind. It is well known, that not only insects, but many animals, commonly called perfect, pass the winter in a kind of torpor or sleep, which ties and benumbs their limbs in such a manner, as to make them incapable of performing any of the functions of the body. Such are dormice, bats, marmots, frogs, &c.

\* Ibid.

Salamanders are in the same class. The immediate cause of this lethargy is by philosophers attributed to the exceeding slow motion of the fluids, which being congealed to a certain degree, probably can no longer circulate, except in the large vessels. This opinion was very plausible, but still wanted to be confirmed by experience. I therefore made several trials, not only on salamanders, but likewise upon several other animals of cold blood, as they are called. In order to procure the best lights, I thought proper to examine this in different ways. I observed that an equal degree of cold did not benumb every species of these creatures equally; some require a greater, some a less, degree of it. The same thing takes place with regard to the death of those animals, occasioned by an increase of cold. The limbs are the first parts that congeal and grow hard. The centre is the last part. When that is froze, the animal never comes to life again; whereas the limbs, after being thawed, become as useful as before. These experiments, together with many others I made, by means both of natural and artificial cold, were intended to observe the change or want of equilibrium in the circulation of humours, which begins, increases, and comes to its height, and afterwards takes the opposite turn, increases, and dis-

disappears in proportion as the animal, from a moderate degree of cold, passes to the extreme, and from hence, by degrees, returns to the temperate.

Our salamanders are oviparous, contrary to the terrestrial, which are viviparous \*. Their eggs are of a dun color, and surrounded with a glutinous matter, not unlike that of frogs. Naturalists are still ignorant, whether salamanders copulate as the more perfect animals, or as frogs and fish. The doctrine of generation being concerned in enquiries of this kind, I have given myself a good deal of trouble about them, and will take notice in my book of every thing that fell under my observation relative to this subject. My observations about the eggs of the salamanders passing from their ovaries into the oviducts, a point which has been hitherto in the dark and not well understood, shall be exposed at the same time; and I shall mention the changes these eggs undergo in this passage.

Mr. Du Fay † says, he could never succeed in bringing the salamanders out of the eggs, nor see them in their earliest state of infancy. I have been more successful in

\* Maupertuis, *ibidem*.

† *Ibidem*.

both these instances. In the first moments after the birth of these animals, the circulation of the blood through their gills is very beautiful. Besides the bronchia described by Du Fay, and supposed to have been discovered by him, I have found some others, which afterwards perish. Those, which were described by the French observer, disappear entirely in three weeks time; but in my salamanders they lasted an equal number of months.

The transparency of these very small salamanders enabled me to find out distinctly how the arteries of the tail become veins; in what manner, from the two principal vessels, viz. the vein and the artery, smaller and smaller branches gradually come forth, and how the blood, which was yellow at first, afterwards acquires a red color. I have discovered some other particulars, which have been of no small use to me in comprehending the regeneration of the tail.

My chief experiments about the cutting off the tail, may be comprised under the following queries.

I. Does the reproduction take place, 1. in every known species of the salamander? 2. And at any period of their life? 3. Does it happen

happen in whatever situation they are kept, upon the earth, or in water? 4. Is it brought about, let the length of the divided part be greater or less? The result of my experiments on these several points has constantly been in the affirmative.

II. Is the regenerated part equally long, when much or little of the tail has been cut off? and is it so in all salamanders of the same species and age? Is it equal when the salamanders are of the same species, but of a different age? Is there no inequality when both species and age are different? A difference in each of these particulars occasions a diversity in the reproduction.

III. Do the constituent parts of the new tail differ from those of the part that was cut, in number, structure, or connexion? By no means; notwithstanding the union of similar and dissimilar parts. The chief of these constituent parts are the *cuticle*, the *skin*, the *glands*, the *muscles*, the *vertebral bones*, the *oblongated medulla spinalis*, and the *blood vessels*.

IV. Is the number of the reproduced vertebræ equal to those that were cut off? Are they formed, one after another, at the end of the tail? What time is required to bring

the new vertebræ to the size and firmness of the former? In the course of the last enquiry, I found that a whole year was not sufficient to render the new part equal to that which was cut off, especially when much was taken away. It is however proper to observe, that, during one half of the year, or the winter, the regenerating power ceases in the salamander.

Hitherto the section was made perpendicular to the axis of the tail. It was therefore necessary to give it a different direction, which led me to enquire,

V. What happens to the tail by cutting it, 1. all along the middle part of the spine, beginning from the extremity of the tail, and extending the incision upwards to the roots, in order that the tail may be divided in its whole length into equal portions, without being separated from the body? 2. What is the consequence of such a section, when not extended so far? 3. What happens when the section is in an oblique direction to the axis of the tail? 4. What happens when either two, or only one slip is cut off lengthways from the tail, without damaging the spine?

VI. How

VI. How far is the tail affected, 1. if the spine only is cut in two or three places? 2. When it is cut across, either close to the spine exclusively, or beyond it, so that the part cut remains attached by a small slip? 3. When several incisions have been made here and there upon the muscles? 4. When a whole ring, or slice of the flesh, is cut off transversely? The results of these last reproductions were exactly similar to those of the foregoing.

VII. When the new reproduction is cut off, is it succeeded by another? Does this last proceed in the same manner as the former? The same process takes place not only in a second reproduction, but also in a third, in a fourth, &c. and the salamanders deprived of many successive reproductions, still follow in the formation of new parts, the same unalterable laws.

## REPRODUCTIONS OF THE LEGS IN THE AQUATIC SALAMANDER.

**D**ISCOURSING on this reproduction, I cannot avoid being more particular than I have been hitherto. Naturalists might even accuse me of being much too concise, if the summary of my experiments was not much less than the detail in my journals. An animal of the most perfect class, which, in the reproduction of its limbs, always presents something to satisfy the curiosity of a nice observer, justly deserves to be studied very assiduously, and to be attended to with much accuracy and reflection. Whoever is in the least acquainted with these matters, evidently sees how much light the consideration of this animal alone may throw on many obscure parts of physiology and natural history.

In whatever place the salamander's legs are cut off, the regeneration is equally well performed. It succeeds alike, whether one or all the four legs be cut off at once, or at different times. This reproduction is obtained in the same manner, when either

one or all the legs are intirely disjointed close to the body of the animal. And as I have found it to be an universal law of nature, that it only repairs the lost part; so I have observed, that when the legs are taken away, the reproduction consists in the pushing forth of entire legs; but that when one or more of the legs are cut, through the middle, for instance, nothing is reproduced but the part taken away.

When the legs have been disjointed close to the body, the new-produced legs keep in their whole length the just and exact proportions observed in the natural legs. But when they have only been partially cut off, the reproduction seems, at their union with the trunk, to be straightened and deformed. This however does not take place in the salamanders of the small species, though already grown up; and I have never observed it in the young animals.

The legs are reproduced, without any exception, in all the different species of salamanders I know, and of whatever age they are. I have never found it otherwise, in any one instance out of many hundred animals I have cut in this manner. Yet, 1. the reproduction happens sooner in young salamanders; and in such the growth of the

leg is so quick, that in a very short time it appears in all respects the same as the old one. 2. When the four legs are cut off close to the body, the anterior ones commonly appear first. What may be the cause of this phenomenon? 3. In full-grown salamanders, the reproduction is quicker when they are of the small species, than when they are of the larger. 4. When the toes of one leg (the right, for instance) are cut off, the reproduction is so slow, that if the whole of the left leg has been taken away at the same time, the toes, which unfold themselves in the new leg, become equal, in the same space of time, to those that grow from the right leg.

The beginning of this reproduction is a cone, which is nothing but the leg in miniature, and only wants to be unfolded. At first the cone is of a gelatinous substance, endued with the most exquisite feeling; and though the new leg be still very small, the articulations are visible, and the salamander uses them very soon. This is likewise observed in new-born unmutated salamanders, just beginning to shew their legs.

Some other resemblances are observed in the growth of the natural and of the artificial legs. All salamanders have four toes  
on

on their fore-legs, and five on their hind-legs. I have found that these toes, both in the fore and hind-legs, do not come out all at once. At first, the small legs are only four cones, ending in a point. On either side of this are soon seen two smaller cones; which, together with the middle point, are nothing else but the three middle toes, as it appears afterwards. Then the remaining toes, viz. one in each of the fore-legs, and two in the hind-legs, unfold themselves nearly in the same manner. The same appearances are observed in the reproduction of the legs that have been cut off.

Moreover, as the natural legs take their greatest increase when they are still soft, and lengthen less when they begin to harden, the same thing happens in the reproductions.

It is necessary to note the following periods, at least when we speak of salamanders already come to their growth, viz. the *considerable time*, which passes after the cutting off of the leg, *before the reproduction begins*; *its slowness in the first period*; *its quick progress afterwards*; and, *lastly, its tardiness when the leg begins to harden.*

There is still this difference between the natural and the reproduced leg, that not only the cone, but the leg itself during its reproduction and unfolding, appear much larger than the first cone and leg produced by nature. The reason of this difference is obvious. Both the cone and natural leg come out from the salamander when yet very small, or new-born; whereas the new cone and leg come out from a full-grown and much larger salamander. In this case the juices, which contribute to the unfolding and increase of the leg, must be more powerful and more abundant than in the former.

Hence the reason may be deduced why the reproduced cone and leg are bulkier when both the animal and trunk from which the cone issues are larger; this I found constantly in every animal reproduction.

The circulation of the blood, viewed through a microscope, appears the same in the natural and the reproduced leg. This indeed can only be thus viewed in small salamanders; as the opacity of the larger kind prevents such an examination. Recourse was therefore had to dissection; and this being carefully performed without hurting  
ing

ing the principal vessels, gave an opportunity of tracing, without the help of a lens, the arteries which bring the blood to the legs, and the veins which carry it back to the heart.

Besides the similarity of the circulation in the natural and reproduced legs, an enquiry was made, whether the same was observable among the constituent parts of the leg, viz. the *cuticle, skin, glands, muscles, bones, and nerves.*

I first began by analysing the parts entering the composition of the cone, which comes out of the trunk, and is the small leg, concentrated in itself. The reproduction of the bones had the greatest share in this analysis. I shall describe the manner in which these bones are formed and unfolded in my large work; beginning from the day of their first appearance, to the time of their perfect growth. This description will comprehend both the bones which are to be reproduced entirely, and those which are only to be reproduced in part. This will give me an opportunity to speak of the effects of the madder root given to salamanders; a root to which we are indebted for so many curious discoveries, on account of its surprising property in dying the bones of animals

animals red, without affecting any of the other parts. I shall take the liberty of describing, on this occasion, what I have observed on the famous question debated between those two eminent philosophers, Haller\* and Du Hamel†, on the formation of the bones. From the bones, I shall pass to the formation and unfolding of the other parts, viz. the muscles, the nerves, the glands, &c. These were next the objects of my analysis. I have not neglected, in this minute and laborious disquisition, to enquire principally into the law, which nature follows in uniting and adapting the tender stamina of the growing reproduction to the divided and consolidated fibres of the trunk.

At present I shall only speak of the reproduced bones, as being supposed to have already acquired a sufficient degree of maturity and firmness. There are in all ninety-nine bones, which enter into the composition of the four legs of an unmutated salamander; and the same number has likewise most commonly been found in the four regenerated legs, after the old legs have been taken off at the *articulation*, close to the trunk. The form, portion, and internal

\* Memoires sur le formation des os.

† Mem. de 1739, 1741, 1743, &c.

structure of the reproduced and natural bones is the same; but the color of the new bones is somewhat different, and their substance more tender.

The regenerated bones do not acquire their due powers and necessary length in the space of a whole year; as they are found, even after such a length of time, somewhat shorter than the natural bones. This however must be understood of salamanders which are come to their full growth. In such as are still young and growing, the new bones are not to be distinguished from the original bones, in a few days after the operation.

The reproduction of so many bones (and this may likewise be said of the other constituent parts of the legs) is not only obtained in the same way when food is given to salamanders, but even when they are kept fasting during the whole time of this great process. By comparing minutely, after two of the hottest summer months, bones reproduced in salamanders which had been constantly fed, with those that grew in salamanders which had not partaken of any food, no difference whatsoever could be found. The same thing was observed in the reproduction of the tails.

More-

Moreover, after such a length of time, there was no visible difference between the size of the first and the last salamanders. This is an evident proof of the great regenerating powers of this animal, and of their perspiring little. Yet when salamanders are kept fasting a longer time, they begin to grow more lean and tapering than those that are fed. But the reproduction continues still in the same way.

If we compare bones reproduced in the said two summer months with the corresponding natural bones; for instance, those that were reproduced in the right hind leg, with the natural bones of the left leg in the same salamander, we shall find, that although the larger bones of the reproduction, viz. the thigh-bone and the tibia, are shorter than the natural corresponding bones; yet the disproportion between them is less than between the smaller bones; as those of the metatarsus reproduced in the same leg, and the natural small bones of the fellow-leg.

But is this odd phenomenon likewise observable in the legs of young unmutated salamanders? Does it take place in other animals? What is the cause of it? Is it perhaps,

perhaps, that the larger bones of the reproduction are quicker in their growth than the less; as the first have already acquired a considerable degree of firmness when the latter are still very soft?

But although the new bones were found after two summer months considerably shorter than the natural corresponding bones, yet they always were equal in thickness, and oftentimes even thicker; a circumstance which deserves to be particularly attended to.

Having spoken of the reproduction of whole bones, let us now say something of those which are reproduced in part. If, instead of taking off the whole leg from the body, part of it only is separated; no bones are reproduced but such as were taken off. If, for instance, a leg be cut off at the articulation of the radius, the new joint will be reproduced with the precise number of bones contained under that joint. If the radius, the os humeri, or the tibia, be cut in the middle, the lower half will be reproduced, together with all the lesser bones separated with it.

Upon considering attentively in this last, and in similar instances, the portions of the  
old

old and new bones united together, it will be found, 1. that the old bone (at least in full-grown salamanders) did not lengthen in the least, and that it preserved, when united with the new part, the same figure it had acquired by the section. 2. That the nature both of the old and new bones, except in color and firmness, is the same. 3. That after a certain time the old bone unites with the new one in such a manner, that the basis of the first is equal to the basis of the last. 4. That it often happens however, that the diameter not only of the basis, but of the whole of the new bone, is larger than that of the old bone. 5. That sometimes the old bone is in a manner sheathed within the new one. 6. That when longitudinal slips are cut with a knife from the old bone, and that this division is continued to the upper part of the new bone, the longitudinal fibres are found to run in the same direction from the one to the other. 7. That the marrow of the old bone is produced along the new one. 8. That sometimes the new bone deviates, at the point of union with the old one, from the straight line, and forms an obtuse angle. 9. That when this irregularity or deviation at the point of contact does appear, the bones reproduced below this, are, in general, perfectly regular as well as the old bones.

We have asserted, that when the legs of salamanders are cut off, the precise number of parts which were separated is commonly reproduced. It cannot however be denied, that such divisions have some influence in producing monstrous appearances in the new legs. 1. The same number of toes is not always produced. 2. Some parts are wanting in some instances; in others there are too many. 3. Irregularities of the last kind are more common than the former. 4. Even when the same number of toes is produced, there may not be the same number of joints, nor consequently of small bones entering into the composition of the toes. The unfrequency of these monstrous appearances in the toes of the unamputated salamanders is a sufficient proof of their being occasioned by the section.

If the four reproduced legs be cut off again, four new legs will make their appearance the second time as they did the first; and this is repeated several times. In fact, when salamanders were quite young, at which time the reproduction is soonest performed, I have obtained in the course of the months of June, July and August, six successive reproductions of the four legs, and an equal number of successive reproductions of

of the tail at the same time. In one of these salamanders, the reproduced bones of the legs and tail amounted in these three months to six hundred and eighty-seven. This number of reproductions seemed not to have lessened in any considerable degree the regenerating power, as the last was obtained in the same number of days as the former. As this power manifests itself from April to September, it is very probable, that, by beginning these sections in April, and continuing them during all that time, one might obtain in these six months twelve reproductions both of the legs and tail.

If, instead of being cut, the salamander's legs are broken, a callus will be formed in the usual manner; this afterwards hardens, unites, and knits together the extremities of the fractured bone. But the loss of the legs is commonly less injurious to the animal than a mere fracture. In the first instance they are completely reproduced, and the salamanders make the same use of them as before: but in the second case it often happens, that they cannot recover the use of them, but are forced to drag their legs after them, and to limp.

The same observations, which I made on the formation and increase of the reproduced bones, I thought proper to repeat on the callus, and at the same time strictly to compare the nature of this callus with that of the reproduced bones.

But in order to follow more closely the progress of nature, and the means she employs in bringing about the surprising reproduction of the salamander's legs, I endeavoured to find out how to check her operations, or, if possible, to put a stop to them entirely. I shall therefore, point out in the course of my work, the effects produced; 1. When, after having cut off the leg at the joint either of the *radius* or *tibia*, a portion of the *os humeri* or of the thigh bone was left naked, and without any flesh upon it. 2. When a ring or circular slip of flesh was cut off somewhat above the trunk, and close to the bone. 3. When small pieces were cut off here and there over the trunk. 4. When a circular incision was made on the same place quite to the bone. 5. When a tight ligature was made on the trunk, so as to prevent or retard the descent of the humors to it. 6. When the bone of the leg above the trunk was broken in one or more places. 7. When only a small piece of the *tibia* and *os femoris*, or of the *radius*

and *os humeri*, was taken off. 8. When, after having broken a leg at the *tibia* or the *radius*, the lower part was raised, and fastened gently with a thread to the upper part of the same leg.

REPRO-
