Numa Pompilius calling the Roman Husbandmen before him, to encourage those whose Lands were well cultivated, & reproach others with the want of Industry.

THE

COMPLETE FARMER:

OR, A

GENERAL DICTIONARY

OF

HUSBANDRY,

IN ALL ITS BRANCHES;

Containing the Various

Methods of Cultivating and Improving every Species of Land,

According to the PRECEPTS of both the

OLD AND NEW HUSBANDRY.

In which every Thing valuable from the beſt Writers on this Subject will be extracted, viz. LINNÆUS, CHATEAUVIEUX, the Marquis of TURBILLY, PLATT, EVELYN, WORLIDGE, MORTIMER, TULL, ELLIS, MILLER, HALE, LISLE, ROQUE, MILLS, &c.

TOGETHER WITH

A Great VARIETY of NEW DISCOVERIES and IMPROVEMENTS.

ALSO

The Whole Buſineſs of Breeding, Managing, and Fattening CATTLE of all Kinds; and the moſt approved Methods of curing the various Diſeaſes to which they are ſubject. Together with the Method of raiſing BEES, and of acquiring large Quantities of WAX and HONEY, without deſtroying thoſe laborious Inſects. Likewiſe the uſeful Parts of GARDENING; or thoſe neceſſary for the FARMER, and COUNTRY GENTLEMAN.

Illuſtrated with a great VARIETY of Folio COPPER-PLATES, finely engraved; exhibiting all the Inſtruments uſed in this neceſſary ART; particularly thoſe lately invented, and preſented to the SOCIETY for the Encouragement of ARTS, &c. in LONDON; many of which have never yet appeared in any Work of this NATURE.

By A SOCIETY of GENTLEMEN,

Members of the SOCIETY for the Encouragement of ARTS, MANUFACTURES, and COMMERCE.

LONDON: Printed for the AUTHORS;

And ſold by S. CROWDER, at the Looking-Glaſs; J. COOTE, at the King's Arms, in Paternoſter-Row; and F. BLYTHE, near the Royal Exchange.

MDCCLXVI.

TO THE

P U B L I C.

HUSBANDRY is, with great juſtice, placed at the head of human arts, as having a very great advantage over all others, both with regard to antiquity and uſefulneſs. It had its birth with the world, and has always been the genuine ſource of ſolid wealth, and real treaſures; for it will furniſh a people with every thing neceſſary to render life happy and deſirable, form the principal revenues of the ſtate, and even ſupply the defect of all others, when they happen to fail.

It is therefore no wonder that the wiſeſt princes, and the moſt able miniſters, among the ancients, made it their principal ſtudy to encourage and improve the Art of Huſbandry: they well knew that the ſtrength of a ſtate ſhould not be eſtimated by the extent of its territories, but by the number of its inhabitants, and the utility of their labours. And it ſhould be remembered, that ſome of the moſt noble conſuls and dictators among the ancient Romans were taken from the Plow, and that the ſenators of that flouriſhing people ſpent the greater part of their time in the country, where they tilled their fields with their own hands. "In thoſe happy times, ſays Pliny, the earth, pleaſed at ſeeing herſelf cultivated by the hands of triumphant victors, ſeemed to make ſtronger efforts, and to produce her fruits in greater abundance." Doubtleſs becauſe they applied themſelves to the taſk with greater attention, and took the wiſeſt precautions to render their labours ſucceſsful: for when men of genius and abilities apply themſelves to any art, they ſoon make very great improvements, and advance it to a much higher degree of perfection: while the common people, by ſervilely confining themſelves to the common mode of practice, never make any farther progreſs in their profeſſion.

But when deſtructive luxury was introduced among the old Romans, Huſbandry declined, and has never ſince reached the honourable ſtation it before poſſeſſed: owing, in a great meaſure, to an opinion founded on falſehood, namely, that the Practice of Huſbandry requires neither ſtudy, reflection, nor precepts; and is therefore beneath the notice of men of fortune and genius. The ancients, however, thought very differently: they were perſuaded, that, in order to cultivate Lands to advantage, it was neceſſary to ſtudy the works of thoſe who had written on this ſubject, and to add the experience of others to their own. This opinion is now once more happily eſtabliſhed; and the Study of Huſbandry purſued with ſuch aſſiduity in different of Europe, that an amazing number of the moſt important diſcoveries have been lately made in that uſeful and neceſſary branch of knowledge.

But theſe uſeful Diſcoveries and Improvements are ſcattered through a multitude of volumes, written in different languages, and publiſhed in different countries; ſo that they can only be known to thoſe who have abilities to purchaſe, and leiſure ſufficient to peruſe ſo great a variety of books.

The

The Authors of this Undertaking were therefore perſuaded, that the Public would very willingly encourage a work in which the Theory and Practice of every branch of Huſbandry were delivered in the plaineſt and moſt intelligent manner, and enriched with all the Diſcoveries hitherto made in any part of Europe. This laborious taſk they have accordingly undertaken, and will venture to promiſe the Reader, that he will find in this Dictionary all the valuable Precepts, Obſervations, Diſcoveries, and Improvements, contained in the writings of *Linnæus*, *Barck*, *Tarello*, *Duhamel*, *Chateauvieux*, *De Lille*, the Marquis of *Turbilly*, *Platt*, *Sharrock*, *Evelyn*, *Houghton*, *Worlidge*, *Stillingfleet*, *Mortimer*, *Tull*, *Ellis*, *Miller*, *Hale*, *Liſle*, *Mills*, and ſeveral other Authors; together with thoſe publiſhed by the Societies of *Berne*, *Lions*, *Tours*, *Paris*, *Rouen*, *Edinburgh*, *Dublin*, and *London*.

And they hope it will be remembered, that this is the Firſt Attempt to give a COMPLETE SYSTEM of every branch of Huſbandry, and to blend in One Work the various Diſcoveries made in different nations. They alſo hope that the pains they have taken to inſert every thing belonging to the ſame ſubject in one article, and to range the whole in alphabetical order, will be approved of by their Subſcribers, as it evidently tends to facilitate the Study of Huſbandry, by enabling the Reader to find, with the greateſt eaſe and expedition, whatever ſubject he may be deſirous of conſidering; which cannot fail of being very ſerviceable to the public, it being the general complaint, that in all the books of Huſbandry, though they contain very valuable materials ſcattered throughout, it requires much time and trouble to diſcover them.

The great number of large COPPER-PLATES, with which this Dictionary will be illuſtrated, muſt prove a very valuable addition, and render it far ſuperior to any treatiſe of this kind ever yet offered to the world; as it is impoſſible to convey an adequate idea of the various inſtruments, lately invented or improved for facilitating the practice of Huſbandry, without the aſſiſtance of large and accurate drawings. This has, however, rendered the work far more expenſive to the Proprietors; but being determined to make it as complete as poſſible, they have ſpared nothing in their power to ſucceed; and flatter themſelves with receiving proportionable encouragement from the Public.

THE

THE COMPLETE FARMER: OR, A GENERAL DICTIONARY OF HUSBANDRY.

ABELE-TREE, a ſpecies of poplar, growing naturally in all the temperate parts of Europe, and called by botaniſts *populus foliis lobatis dentatis ſubus tomentoſis*.

The leaves of the abele-tree are large, and divided into three, four, or five lobes, which are indented on their edges, of a very dark colour on their upper ſide, but very white and downy on their under, ſtanding upon foot-ſtalks about an inch long. The young branches have a purple bark, and are covered with a white down; but the bark of the ſtem and older branch is grey. In the beginning of April, the male flowers or catkins appear, which are cylindrical, ſcaly, and about three inches long: about a week after come out the female flowers, or catkins, which have no ſtamina like thoſe of the male. Soon after theſe come out, the male catkins fall off, and in five or ſix weeks after, the female flowers will have ripe ſeeds incloſed in a hairy covering; then the catkins will drop, and the ſeeds will be wafted by the winds a great diſtance. This tree is often confounded with the white poplar; but they are in reality diſtinct ſpecies.

The abele-tree may be propagated either by layers or cuttings, which will readily take root, or by ſuckers, which they ſend up from their roots in great plenty. The beſt time for tranſplanting theſe ſuckers is in October, when their leaves begin to decay. Theſe may be placed in a nurſery for two or three years to get ſtrength, before they are planted out where they are deſigned to remain; but if they are propagated from cuttings, it is better to defer the work till February, at which time truncheons of two or three feet long ſhould be thruſt about a foot and a half into the ground. Theſe will readily take root, and if the ſoil, in which they are planted, be moiſt, will arrive to a conſiderable bulk in a few years.

A conſiderable advantage may be made by planting theſe trees upon boggy ſoils, where few other trees will thrive. Many ſuch places there are in England, which do not at preſent bring in much money to their owners; whereas, if they were planted with theſe trees, they would, in a very few years, be of more value than the ground, clear of all expences; but there are many perſons, who think nothing, except corn, worth cultivating in England; or, if they plant timber, it muſt be oak, aſh, or elm; and if their land be not proper for either of theſe, it is conſidered as of little value: whereas, if the nature of the ſoil was examined, and proper ſorts of plants adapted to it, there might be very great advantages made of ſeveral large tracts of land, which at this time lie neglected.

The wood of the abele-tree is very good for floors, where it will laſt many years, and for its exceeding whiteneſs is, by many perſons, preferred to oak; but, being of a ſoft nature, is very ſubject to take the impreſſions of nails, &c. which renders it leſs proper for this purpoſe. It is alſo very good for wainſcoting rooms, being leſs ſubject to ſwell or ſhrink than moſt other woods; but for turnery-ware there is no wood equal to this for its exceeding whiteneſs, ſo that trays, bowls, and many other utenſils are made of it; the bellows-makers alſo prefer it for their uſe, as do alſo the ſhoemakers for heels of ſhoes; it is likewiſe very good to make light carts, and the poles are very proper to ſupport hops, vines, &c. and the lopping will afford good fuel, which in many countries is much wanted. *Miller's Dict.*

The abele-tree is very proper for planting where you deſire a ſpeedy ſhelter and walks, it often making ſhoots of eighteen or twenty feet long in a year. *Mortimer's Huſbandry.*

ABLACTATION, a term formerly uſed for a particular method of grafting, called by modern gardeners, inarching, or grafting by approach. *See* GRAFTING *by approach.*

ABLAQUEATION, the removing the earth, and laying bare the roots of fruit trees in winter, that they may be the more readily expoſed to the influence of rains, ſnow, air, &c. an operation formerly thought neceſſary for their future welfare; but experience has ſhewn it to be a dangerous practice, eſpecially where the trees are much expoſed to the winds, particularly the ſouth-weſt, which are generally the moſt violent. The practice of ablaqueation is therefore with very good reaſon laid aſide in the preſent practice.

ABORTIVE CORN, a diftemper of corn mentioned by Mr. Tillet, in a differtation which gained the prize at the academy of Bourdeaux.

This diftemper, fays that ingenious naturalift, fhews itfelf long before harveft, when the ftalk is not above eighteen inches high; and may be known by a deformity of the ftalk, the leaves, the ear, and even the grain.

The ftem of abortive corn is generally fhorter than that of other plants of the fame age; it is crooked, knotted, and rickety; the leaves are commonly of a bluifh green colour, curled up in various forms; fometimes turned like wafer cakes, and often rolled in a fpiral form. The ears have very little of their natural form; they are lean, withered, and fhew very imperfect rudiments, either of the chaff or grain.

All thefe fymptoms are however only to be found in plants that are in the height of the diftemper. The ftalks are often pretty ftrait, the leaves but little curled, and the chaff tolerably well formed; but inftead of enclofing a fmall embryo, white and foft at the fummit, it contains only a green kernel, terminating in a point, not unlike a young pea when forming in its pod.

Thefe abortive kernels have two or three points very vifible; they are then fafhioned as if two or three kernels were joined together at the bafe. When thefe kernels are ripe, or rather when they are dried up, they grow black, and fo greatly refemble the feeds of cockle, that hufbandmen, who are not acquainted with this diftemper, often confound abortive wheat with the feeds of that weed.

This diftemper M. Tillet fufpects to be occafioned by infects; for he perceived on the fickly plants fmall drops of a very limpid liquor, which he judged to be extravafated fap.

ACORNS, the fruit of the oak, and too well known to need any defcription. *See* OAK.

Acorns are faid to have been the primitive food of mankind; but at prefent they are principally ufed in fattening hogs, for which they are very proper.

Some care is, however, neceffary to be taken when hogs feed upon acorns, for otherwife they will be fubject to a diftemper, called the garget. To prevent which, the beft way is to moiften fome peafe or beans with water, and fprinkle over it fome antimony pounded and fifted; if this be repeated every other day for a fortnight or three weeks, it will effectually preferve them from the diforder. Or if the acorns be collected and prepared in the following manner, they may be given to hogs without any danger.

Dig a hole in the ground in a warm place, large enough to contain feveral bufhels of acorns; in this let the acorns be put, and well moiftened with water, in which a handful or two of common falt has been diffolved: in a few days they will begin to heat and fpire; obferve them therefore attentively, and when they have made a fhoot about three inches long, take them out of the hole, and fpread them to dry on a barn floor, and in a day or two they will be fit to be given to the hogs. This matter muft, however, be managed with care and caution; they muft not have too many given at a time; at firft twice a day is often enough to feed them for a day or two; afterwards three times a day. Nor fhould they, while they eat this food, be confined to a ftye, but fuffered to run at large; for if their liberty be too much abridged, they will never thrive well, or grow fat on acorns.

It is no uncommon thing in Hertfordfhire, with the management above directed, and the affiftance of a little wafh, and a few grains now and then, for a farmer to kill feveral hogs in a feafon, which fhall weigh from eight to ten fcore, and fometimes even more.

Thefe hogs make very good meat, but it is not fo fine as when the hogs are taken up, and four or five bufhels of peafe or barley meal given to each, to complete their fattening before they are killed. *Mufeum Rufticum, vol.* I. *p.* 475.

ACRE, a fuperficial meafure of land, containing, according to the ftatute, one hundred and fixty fquare poles or perches, of fixteen feet and a half each.

But this meafure does not prevail in all parts of England; for though one hundred and fixty fquare poles or perches are allowed to be an acre, yet the length of the pole varies in different counties, and is generally called cuftomary meafure.

Thus the cuftomary perch in Staffordfhire is twenty-four feet. In the foreft of Sherwood twenty-one. In Herefordfhire the perch of walling is fixteen feet and a half; but a perch for digging twenty-one feet.

Old farmers alfo eftimate the acre of land by the proportion of feed ufed in fowing it; by which means it muft vary in proportion to the fertility or barrennefs of the foil; and hence in many counties of England they have two forts of acres, diftinguifhed by feed-acres and ftatute-acres.

The French acre, or arpent, according to Mr. Greaves's calculation, confifts of 100 perches of twenty-two feet each, amounting to 48,400 fquare French feet, which are equal to 51,691 fquare Englifh feet, or very near one acre, and three quarters of a rood, Englifh meafure.

The Irifh acre is to the Englifh, as 196 to 121. For the number of poles in each are the fame; but the Irifh pole is twenty-one feet, whereas the Englifh contains only fixteen feet and a half; and the Welch acre is equal to two Englifh ftatute acres.

ACREME, a quantity of land, confifting of ten acres.

ADDERS-TONGUE, a weed growing in low moift meadows, where it is commonly hid among the grafs.

From a very low ftalk arifes a fingle, thick, fmooth, oblong leaf, from the bottom of which iffues a kind of tongue, ending in a point, and indented on each fide like a file.

ADZE, a kind of crooked axe ufed by carpenters, fhipwrights, coopers, &c.

AFTERMATH, the fecond crop, or grafs which fprings up after mowing, or the grafs cut after the corn.

In the neighbourhood of London, the aftermath when made into hay, is of confiderable value: but in haying this crop, fo as to make it fell well, great nicety is requifite; the nature of the aftermath-grafs being more foft, fpongy, and porous, than the firft growth, and therefore more liable to be hurt by rains. *See* HAY.

AGE *of a horfe.* This is eafily known by his mouth till he comes eight, after which the ufual marks wear out. A horfe, like many other brute animals, has his teeth divided into three ranks, viz. his fore-teeth, which are flat and fmooth, his tufhes, and his back-teeth. His back teeth, or jaw-teeth, are called his grinders, being thofe by which a horfe chews and grinds his provender, and are twenty-four in number, twelve above, and twelve below: they are ftrong double teeth with fharp edges; but when a horfe grows old, they wear much fmoother.

The firft that grows are his foal teeth, which begin to appear a few months after he is foaled: they are twelve in number, fix above, and fix below; and are eafily diftinguifhed from the teeth that come afterwards, by their fmallnefs and whitenefs, not unlike the fore-teeth of a man.

When the colt is about two years and a half old, he cafts the four middlemoft of his foal teeth, viz. two above, and two below; but fome do not caft any of their foal teeth till they are near three years old. The new teeth are eafily diftinguifhed from the foal teeth, being much ftronger, and always twice their fize, and are called the nippers or gatherers, being thofe by which a horfe nips off the grafs, when he is feeding abroad in the fields, or, in the houfe, gathers his hay from the rack. When a horfe has got thefe four teeth complete, he is reckoned three years old.

When he is about three and a half, or in the fpring before he is four years old, he cafts out four more of his foal teeth, viz. two above, and two below, one on each fide the nippers, or middle teeth: fo that when you look into a horfe's mouth, and fee the two middle teeth full grown, and none of the foal teeth, except the common teeth remaining, you may conclude he is four that year, about April or May. Some indeed are later colts, but that makes little alteration in the mouth.

The tufhes appear near the fame time with the four laft mentioned teeth, fometimes fooner than thefe, and fome-ſometimes not till after a horſe is full four years old: they are curved like the tuſhes of other beaſts, only in a young horſe they have a ſharp edge all round the top, and on both ſides, the inſide being ſomewhat grooved and flattiſh, inclined to a hollowneſs.

When a horſe's tuſhes do not appear for ſome time after the foal teeth are caſt out, and the new ones come in their room, it is generally owing to their foal teeth having been pulled out before their time, by the breeders or other dealers in horſes, to make a colt of three years old appear like one of four, that he may be the more ſaleable; for when any of the foal teeth have been pulled out, the others ſoon come in their place; but the tuſhes having none that go before them, can never make their appearance till their proper time, viz. when a horſe is about four, or coming four; and therefore one of the fureſt marks to know a four year old horſe, is by his tuſhes, which are then very ſmall, and ſharp on the top and edges.

When a horſe comes five, or rather in the ſpring before he is five, the corner teeth begin to appear, and at firſt but juſt equal with the gums, being filled with fleſh in the middle. The tuſhes are alſo by this time grown to a more diſtinct ſize, though not very large: they likewiſe continue rough and ſharp on the top and edges. But the corner teeth are now moſt to be remarked; they differ from the middle teeth in being more fleſhy on the inſide, and the gums generally look rawiſh upon their firſt ſhooting out, whereas the others do not appear diſcoloured. The middle teeth arrive at their full growth in leſs than three weeks, but the corner teeth grow leiſurely, and are ſeldom much above the gums till a horſe is full five: they differ alſo from the other fore-teeth in this, that they ſomewhat reſemble a ſhell; and thence are called the ſhell teeth, becauſe they environ the fleſh in the middle half way round; and as they grow, the fleſh within diſappears, leaving a diſtinct hollowneſs and openneſs on the inſide. When a horſe is full five, theſe teeth are generally about the thickneſs of a crown piece above the gums. From five to five and a half they will grow about a quarter of an inch high, or more; and when a horſe is full ſix, they will be near half an inch, and in ſome large horſes a full half inch above the gums.

The corner teeth in the upper jaw fall out before thoſe in the under, ſo that the upper corner teeth are ſeen before thoſe below; on the contrary, the tuſhes in the under gums come out before thoſe in the upper.

When a horſe is full ſix years old, the hollowneſs on the inſide begins viſibly to fill up, and that which was at firſt fleſhy grows into a browniſh ſpot, not unlike the eye of a dried garden bean, and continues ſo till he is ſeven; with this difference only, that the tooth is more filled up, and the mark, or ſpot, becomes faint, and of a lighter colour. At eight the mark in moſt horſes is quite worn out, though ſome retain the veſtiges of it a long time; and thoſe who have not had a good deal of experience, may ſometimes be deceived by taking a horſe of nine or ten years old for one of eight. It is at this time only, when a horſe is paſt mark, that one can eaſily err in knowing the age of a horſe; for what practices are uſed to make a very young horſe or colt appear older than he is, by pulling out the foal teeth before their time, may be diſcovered by feeling along the edges where the tuſhes grow, for they may be felt in the gums before the corner teeth are put forth; whereas, if the corner teeth come in ſome months before the tuſhes riſe in the gums, we may reaſonably ſuſpect that the foal teeth have been pulled out at three years old.

It will, perhaps, be needleſs to mention the tricks that are uſed to make a falſe mark in a horſe's mouth, by hollowing the tooth with a graver, and burning a mark with a ſmall hot iron; becauſe thoſe who are acquainted with the true marks, will eaſily diſcover the cheat by the ſize and colour of the teeth, by the roundneſs and bluntneſs of the tuſhes, by the colour of the falſe mark, which is generally blacker, and more impreſſed than the true mark, and by many other viſible tokens, which denote the advanced age of a horſe.

After the horſe has paſſed his eighth year, and ſometimes at ſeven, nothing certain can be known by the mouth. It muſt, however, be remembered, that ſome horſes have but indifferent mouths when they are young, and ſoon loſe their mark; others have their mouths good for a long time, their teeth being white, even, and regular, till they are ſixteen years old and upwards, together with many other marks of freſhneſs and vigour; but when a horſe comes to be very old, it may be diſcovered by ſeveral indications, the conſtant attendants of age, viz. his gums wear away inſenſibly, leaving his teeth long and naked at their roots: the teeth alſo grow yellow, and ſometimes browniſh. The bars of the mouth, which in a young horſe are always fleſhy, and form ſo many diſtinct ridges, are, in an old horſe, lean, dry, and ſmooth, with little or no riſing. The eye-pits in a young horſe (except thoſe come of old ſtallions) are generally filled up with fleſh, look plump and ſmooth; whereas, in an old horſe, they are ſunk and hollow, and make him look ghaſtly, and with a melancholy aſpect. There are alſo other marks which diſcover a horſe to be very old, viz. grey horſes turn white, and many of them all over flea-bitten, except about their joints. This, however, happens ſometimes later, and ſometimes ſooner, according to the variety of colour and conſtitution. Black horſes are apt to grow grey over their eye-brows, and very often over a good part of their face, eſpecially thoſe who have a ſtar or blaze fringed round with grey when they are young. All horſes, when very old, ſink more or leſs in their backs, and ſome horſes, that are naturally long backed, grow ſo hollow with age, that it is ſcarce poſſible to fit them with a ſaddle. Of this kind are ſeveral Spaniſh and Barbary horſes, and many of the Daniſh and Flanders breed. Their joints alſo grow ſo ſtiff with old age, and their knees and hocks bend ſo, that they are apt to trip and ſtumble upon the leaſt deſcent, though the way be ſmooth, and no ways rugged. After which they can be of little uſe to the owner. *Gibſon on Horſes.*

Age *of neat cattle*, viz. *the ox, cow, and bull.* The age of theſe animals is known by the teeth and horns. At the end of ten months they ſhed their firſt fore-teeth, which are replaced by others, larger, but not ſo white; and in three years all the inciſive teeth are renewed. Theſe teeth are at firſt equal, long, and pretty white; but as the creatures advance in years, they wear, become unequal, and black. They alſo ſhed their horns at the end of three years; and theſe alſo are replaced by other horns, which like the ſecond teeth continue. The manner of the growth of theſe horns is not uniform, nor the ſhooting of them equal. The firſt year, that is the fourth year of the creatures age, two ſmall pointed horns make their appearance, neatly formed, ſmooth, and towards the head terminated by a kind of button. The following year this button moves from the head, being impelled by a horny cylinder, which lengthening in the ſame manner, is alſo terminated by another button, and ſo on; for the horns continue growing as long as the creature lives. Theſe buttons become annular joints, which are eaſily diſtinguiſhed in the horn, and by which the age of the creature may be eaſily known; counting three years for the point of the horn, and one for each of the joints. *Buffon's Hiſtoire Naturelle, tom.* IV.

Age *of ſheep.* Theſe animals in their ſecond year have two broad teeth; in their third year they have four broad teeth before; in their fourth year ſix broad teeth, and in their fifth year eight broad teeth. After which none can tell how old a ſheep is while their teeth remain, except by being worn down. *Ellis on Sheep.*

At the end of one year, rams, ſheep, and weathers, loſe the two fore-teeth of the lower jaw; and they are known to want the inciſive teeth in the upper jaw. At eighteen months the two teeth joining to the former, alſo fall out; and at three years, being all replaced, they are even and pretty white. But as the creature advances in age, they become looſe, blunt, and afterwards black. The age of the ram, and all horned ſheep, may alſo be known by their horns, which ſhew themſelves in their very firſt year, and often at the birth, and continue to grow a ring annually to the laſt period of the creature's life. *Buffon's Hiſtoire Naturelle, tom.* V.

AGE *of goats*. The age of goats is known by the fame tokens as thofe of the fheep, viz. by their teeth, and the annular rings on their horns.

AGRICULTURE, the art of tilling, manuring, and cultivating the earth, in order to render it fertile.

This art claims the precedency of all others in point of antiquity, it having been the fole employment of our firft parents in the delightful garden of Eden.

Adam inftructed his children in this neceffary art, both by precepts and example; and we are told by the facred hiftorian, that Cain applied himfelf to hufbandry, while Abel led the life of a fhepherd, and contented himfelf with feeding his flocks.

After the deluge the defcendants of Noah carried with them the art of hufbandry, and eftablifhed it in the various countries where they fettled. It was, however, very fimple in thefe early ages, and its advances towards perfection flow and almoft imperceptible.

Abraham, and the reft of the patriarchs, who had no fixed refidence, applied themfelves to a paftoral life, ennobling, by their example, a profeffion, which has now for many ages loft its original dignity, from its being practifed only by the meaner fort of people. But as foon as their defcendants were fixed in Paleftine, they all became hufbandmen, from the chief of the tribe of Judah, to the loweft branch of the family of Benjamin: birth at that time made no diftinction, and agriculture was confidered as a very honourable employment.

The Chaldeans, who inhabited the countries where agriculture had its birth, carried that valuable art to a confiderable degree of perfection: they cultivated their lands with great affiduity, and enjoyed the pleafing fatisfaction of receiving from their fields a very plentiful harveft. The Egyptians, who from the fertility of their country, caufed by the annual overflowings of the Nile, raifed prodigious quantities of corn, were fo fenfible of the bleffings refulting from agriculture, that they afcribed the invention of it to Ofiris; and even carried their fuperftitious gratitude fo far, as to worfhip thofe animals that laboured in tilling the ground.

The Phœnicians, fo well known in the facred writings by the name of Philiftines, were alfo famous for their fkill in agriculture; but finding themfelves too much confined in their native country by the conquefts of the Ifraelites, they fpread themfelves through the greater part of the iflands of the Mediterranean, and carried with them their knowledge in hufbandry.

The Carthaginians followed the tafte of their anceftors, and applied themfelves affiduoufly to the ftudy of agriculture. Mago, their famous general, wrote no lefs than twenty-eight books on that fubject, and which Columella tells us, were tranflated into Latin by an exprefs decree of the Roman fenate. Servius adds, that Virgil ufed thefe books as a model when he wrote his Georgics.

The ancients tell us, that the goddefs Ceres was born in Sicily, where fhe invented the art of fowing corn, and the tillage of land. The meaning of this fable is very evident; that ifland was very fruitful in corn, and agriculture was there efteemed fo honourable an employment, that even their kings did not difdain to practife it with their own hands.

But time, which at firft gave birth to arts, often caufed them alfo to be forgotten, when they were removed from the place of their origin. The children of Noah, who fettled in Europe, doubtlefs carried with them the knowledge of agriculture; but their defcendants, who took poffeffion of Greece, were fuch a favage race, that they fed on herbs, after the manner of beafts. Pelafgus taught them the culture of the oak, and the ufe of acorns as food, for which divine honours were paid him.

The Athenians, who were the firft that received any tincture of politenefs, taught the ufe of corn to the reft of the Greeks; they alfo taught them the manner of cultivating the ground, and preparing it for the feed. The Greeks foon perceived that bread was more wholefome, and its tafte more delicate than acorns; and accordingly thanked the gods for fuch an unexpected and beneficial prefent. After this the Athenian kings thinking it more glorious to govern a fmall ftate wifely, than to aggrandize themfelves by foreign conquefts, withdrew their fubjects from war, and employed them folely in cultivating the earth. This conftant application carried agriculture to a confiderable degree of perfection, and foon reduced it into an art.

Hefiod, who is generally thought to have been cotemporary with Homer, was the firft among the Greeks who wrote on this fubject. He calls his poem, "Works and Days;" becaufe agriculture requires exact obfervations of times and feafons.

The other eminent Greek writers upon agriculture, are Democritus of Abdera, Socraticus, Xenophon, Tarentinus, Architas, Ariftotle, and Theophraftus, from whom the art received confiderable improvements; as alfo from Hieron, Epicharmus, Philometor, and Attalus.

The old Romans efteemed agriculture fo honourable an employment, that in the earlieft times of the republic, the higheft praife that could be given a man, was to fay of him, that he cultivated well his own fpot of ground. The moft illuftrious fenators applied themfelves to this profeffion; nor had they either fplendor or majefty, but when they appeared in public. And their greateft generals at their return from the toils of war, from taking of cities, and fubduing of nations, were impatient till they were again employed in cultivating their lands, and thought it no difgrace to follow the plough, though they were at the fame time prepared to ferve the wants of the republic, attend her councils, or put themfelves at the head of her armies.

It muft indeed be allowed, that when the Romans became tainted with the luxury of Afia, they gradually loft the noble fimplicity of their anceftors, and employed their flaves in the feverer labours of a country life. But though they did not themfelves hold the plough, yet even men of confular dignity looked upon it as a reward for their public fervices, when they obtained leave to retire into the country, and were equally refpected when overlooking their farms, as when feated in the chair of magiftracy. M. Cato, the cenfor, that illuftrious Roman general, orator, politician, and lawyer, after having governed provinces, and fubdued nations, did not think it below his ftation to write a large treatife on agriculture.

This work, according to Servius, was dedicated to his own fon, and was the firft Latin treatife on that fubject. This work has been handed down to us in all its purity, in the fame manner as Cato wrote it. Varro compofed a treatife on the fame fubject, and on a more regular plan. This work is embellifhed with all the Greek and Latin erudition of that learned author. Agriculture alfo received great improvements from the two Safernaes, and likewife from Scorfa, Tremellius, and M. Terentius. Virgil has adorned it with the language of the mufes, and given it majefty by his verfe. He has finely embellifhed the precepts of hufbandry left by Hefiod and Mago.

Columella, who flourifhed in the reign of the emperor Claudius, wrote twelve books on hufbandry. He was a native of Bœtica in Spain, and had devoted his time to the ftudy of hufbandry.

From this time till the reign of Conftantine IV. hufbandry continued in a declining ftate, when that wife emperor caufed a large collection of the moft ufeful precepts relating to agriculture to be extracted from the beft writers, and publifhed under the title of Geoponics. Some fay he made this collection with his own hand. Nor is this at all improbable, as it is well known, that after he had conquered the Saracens and Arabians, he not only practifed, but ftudied the arts of peace, fixing his chief attention on the advancement of hufbandry.

But from the time of Conftantine IV. till about the year 1478, agriculture lay in a kind of dormant ftate, when Crefcenzio publifhed an excellent performance on agriculture at Florence. He was foon followed by feveral of his countrymen, among whom Tatti, Stefano, Auguftino Gallo, Sanfovino, Lauro, and Tarello, deferve particular honour.

In the mean time Fitz-Herbert, judge of the Common Pleas, fhone with unrivalled luftre in in the practical parts of hufbandry. He publifhed two treatifes on this fubject; the firft, which was entitled, The Book of Hufbandry, appeared 1534, and the fecond, called, The Book of Surveying and Improvements, in 1539.

Fitz-Herbert's books of agriculture foon raifed a fpirit of emulation in his countrymen, and many treatifes of the fame kind fucceffively appeared; but time has deprived us of many of thofe writings, or at leaft they are become fo very fcarce, as only to be found in the libraries of the curious.

About the year 1600, France made fome confiderable efforts to revive hufbandry, as appears from feveral large works, particularly *Les Moyens de devenir Riche*, and the *Cofmopolite*, by Barnard de Paliffy, a poor potter; *Le Theatre d'Agriculture*, by de Serres; *L'Agriculture, & Maifon Ruftique*, by Meffrs. Etienne and Liebault, &c.

The Flemings, about the fame period, dealt more in the practice of hufbandry, than in publifhing books on the fubject; fo that their intention doubtlefs was to carry on a private lucrative trade, without inftructing their neighbours: and hence it happened, that whoever was defirous of copying their method of agriculture, was obliged to travel into their country, and make his own remarks. Their principal, and indeed juft, idea of hufbandry confifted in this, namely, to make a farm refemble a garden as near as poffible. Such an excellent principle at firft fetting out led them of courfe to undertake the culture of fmall eftates only, which they kept free from weeds, continually turning the ground, and manuring it plentifully and judicioufly.

When they had by this method brought the foil to a proper degree of cleanlinefs, health, and fweetnefs, they ventured chiefly upon the culture of the more delicate graffes, as the fureft means of acquiring wealth in hufbandry upon a fmall eftate, without the expence of keeping many draught horfes or fervants.

A few years experience was abundantly fufficient to convince them, that ten acres of the beft vegetables for feeding cattle, properly cultivated, would maintain a larger ftock of grazing animals, than forty acres of common farm grafs. They alfo found that the beft vegetables for this purpofe, were lucerne, faintfoin, trefoil of moft denominations, fweet fenugreek, buck and cow-wheat, field turnips, and fpurrey.

The political fecret of their hufbandry therefore confifted in letting farms on improvement. They alfo difcovered eight or ten new forts of manure. They were the firft among the moderns who ploughed in living crops for the fake of fertilifing the earth, and confined their fheep, at night, in large fheds built on purpofe, whofe floors were covered with fand or virgin earth, &c. which the fhepherd carted away every morning to the compoft dunghill.

Our fatal domeftic wars, during the reign of Charles I. changed the inftruments of hufbandry into martial weapons; but after the death of that unfortunate monarch, artful and avaricious men crept into the confifcated eftates of the nobility, gentry, and clergy; and as many of thefe new encroachers had rifen from the plough, fo they returned with pleafure to their old profeffion, being chiefly animated by the love of gain. Plattes, Hartlib, Blythe, and others, feized this favourable difpofition of the common people, and encouraged it by writings which have fince had few equals; nor was Cromwell wanting to lend his affiftance.

Sir Hugh Platt was one of the moft ingenious hufbandmen of the age in which he lived; yet fo great was his modefty, that all his works, except his Paradife of Flora, feem to be pofthumous. He held a correfpondence with all the lovers of agriculture and gardening in England; and fuch was the juftice and modefty of his temper, that he always named the author of every difcovery communicated to him. Perhaps no man, in any age, difcovered, or, at leaft, brought into ufe fo many new forts of manure. Witnefs his account of the compoft and covered dunghill, and his obfervations on the fertilifing qualities lodged in falt, ftreet-dirt, and the fullage of ftreets in great cities, clay, fuller's earth, moorifh earth, dunghills made in layers, fern, hair, calcination of all vegetables, malt-duft, willow-tree earth, foap-boilers afhes, marle, and broken pilchards.

Gabriel Plattes may be efteemed an original genius in hufbandry. He began his obfervations in the time of queen Elizabeth, and continued them through the reigns of James I. Charles I. and during the firft three or four years of the common-wealth. But notwithftanding the great merit of this writer, the public fuffered him to ftarve and perifh in the ftreets of London; nor had he a fhirt upon his back when he died.

Samuel Hartlib, a celebrated writer on hufbandry in the laft century, was highly beloved and efteemed by Milton and other great men of that time. In his preface to a work commonly called his Legacy, he laments that no public director of hufbandry was eftablifhed in England by authority; and that we had not adopted the Flemifh method of letting farms upon improvement. This remark of Hartlib procured him a penfion of one hundred pounds a year from Cromwell; and the writer afterwards, the better to fulfil the intention of his benefactor, procured Dr. Beati's excellent annotations on the Legacy, with other valuable pieces from his numerous correfpondents.

About the time when this author flourifhed feems to have been an æra when the Englifh hufbandry rofe to great perfection; for the preceding wars had made the country gentry poor, and, in confequence thereof, induftrious. They found the cultivation of their own lands to be the moft profitable poft they could occupy. But a few years after, when the reftoration took place, all this induftry and knowledge were exchanged for diffipation and heedleffnefs; and then hufbandry paffed almoft entirely into the hands of farmers.

The famous work attributed to Hartlib, and called the Legacy, was only drawn up at Hartlib's requeft; and, after paffing through his correction and revifal, was publifhed by him. The real author of this treatife was R. Child. It confifts of one general anfwer to the following queftion, namely, "What are the actual defects and omiffions, as alfo the poffible improvements in Englifh hufbandry?"

Several other pieces on hufbandry followed the publication of the Legacy, and greatly improved that neceffary and ufeful art.

The firft writer that infpired his countrymen with a defire of reviving the ftudy of agriculture after the reftoration was Evelyn; who, being followed by the famous Tull, opened a new fphere for the minds of mankind to range in; and fince this period feveral valuable improvements have been made in the Englifh hufbandry, by a great variety of authors.

Ireland, about the middle of the laft century, began to make no inconfiderable figure in the art of hufbandry. It muft, indeed, be confeffed that Ireland had very ftrong prejudices in behalf of a very wretched method of agriculture, till about the middle of the laft century, when Blythe opened the eyes of that people by his incomparable writings. Since which a certain fpirit of improvement has, more or lefs, been promoted and carried on with great zeal and conftancy by the nobility, clergy, and gentry of that kingdom. In proof of which it will be fufficient to obferve, that the tranfactions of the Dublin fociety for encouraging hufbandry, are now cited by all foreigners in their memoirs relating to that fubject.

After the peace of Aix-la-Chapelle, almoft all the nations of Europe, by a fort of tacit confent, applied themfelves to the ftudy of agriculture; and continued to do fo, more or lefs, amidft the univerfal confufion that foon fucceeded. The French found by repeated experience, that they could never maintain a long war, or procure a tolerable peace, without they raifed corn enough to fupport themfelves in fuch a manner as they fhould not be obliged to fubmit to harfh terms on the one hand, or perifh by famine on the other. Their king therefore thought proper to give public encouragement to agriculture, and has ever been prefent at the making of feveral experiments. The great and rich of various ranks and ftations followed this example, and the very ladies put in for their fhare of fame in this commendable undertaking. Even during the hurry and diftreffes of the laft war, fome attention was paid to agriculture. Prize queftions were then propofed annually in rural academies; particularly at the two academies of Lyons and Bourdeaux. And many alterations were made by the fociety for improving agriculture in Britany.

Since the conclufion of the peace matters have been carried on with great vigour. The univerfity of Amiens has made various propofals to the public for the advancement of hufbandry; while the marquis de Tourbilly, a writer who proceeds chiefly on experience, has the principal direction of a georgical fociety lately eftablifhed at Tours.

The fociety of Rouen alfo deferves our notice: nor have the king and his minifters thought it unworthy their notice. The archbifhop of the diocefe is one of the members.

We fhall only add on this fubject, that there are at prefent thirteen focieties exifting in France, eftablifhed by royal approbation, for the promoting of agriculture; and thefe thirteen focieties have nineteen co-operating focieties belonging to them, whenever it happened that a diftrict was too large to be effectually taken care of by one fociety.

The art of agriculture is, at prefent, publickly taught both in the Swedifh, Danifh, and German univerfities, where the profeffors may render effectual fervice to their refpective countries, if they underftand the practical as well as the fpeculative parts, and can converfe to as much advantage with the farmer and peafant, as with Virgil and Columella.

Nor has Italy been inactive. The Neapolitans of the prefent age have condefcended to return back to the firft rudiments of revived hufbandry, and begun to ftudy afrefh the agriculture of Crefcenzio, firft publifhed in the year 1478. The people of Bergamo have purfued the fame track, and given the world a new edition of the *Ricordo d'Agricultura di Tarello*, which was originally publifhed at Mantua in 1577.

The duchy of Tufcany has embibed the fame fpirit. A private gentlemen has lately left his whole fortune to endow an academy of agriculture. The firft ecclefiaftic in that duchy is prefident of the fociety, and many of the chief noblity are members. Even Ferrara, a fmall territory in the papal dominions, has contributed its juft contingent, and made fome laudable attempts in hufbandry.

Animated with a defire that the people under his government fhould excel in hufbandry, his Sardinian majefty has fent fubjects to learn the practice of foreign countries, and made feveral attempts to eftablifh a better method of agriculture among his fubjects.

In Poland, where a natural fertility of foil feems to difpenfe with the neceffity of calling in improvements, Mr de Bieleufki, grand-marfhal of the crown, has made abundance of fuccefsful attempts to introduce the new hufbandry among his countrymen, and procured the beft inftruments for that purpofe from France and other parts of Europe.

The Hollanders give little attention to agriculture, if we except one fingle collateral inftance, namely, the draining of fens and moraffes; and even that has proceeded more from the motive of felf-prefervation, than any particular turn towards hufbandry.

In the year 1759, a fociety eftablifhed itfelf at Berne in Switzerland, for the advancement of agriculture, and rural œconomics. That fociety confifts of many ingenious private perfons, and alfo of fome of great weight and influence in the republic; moft of them men of a true caft for the improvement of hufbandry, being enabled to join the practice with the theory. They have already publifhed feveral ufeful pieces, which we fhall be careful to infert under their proper heads.

We muft not omit to mention here, that Linnæus and his difciples have performed great things in the north of Europe, particularly in difcovering new, profitable, and well tafted food for cattle. At the fame time Sweden has augmented a commerce that had been long cramped within narrow bounds, and beftowed fuccefsful labours on a foil, which was before looked upon as cold, barren, and incapable of melioration; of this the late memoirs publifhed at Stockholm will be a lafting monument.

Denmark, as well as many courts in Germany, follow the like example. His Danifh majefty encourages, in particular, the woollen manufacture; and the late king fent three perfons into Arabia Felix, to make remarks, and bring over fuch plants and trees as may be ufeful in hufbandry, building, &c.

At the fame time the duchy of Wirtemberg, a country no ways unfavourable to corn and pafturage, has not failed to contribute its affiftances towards the improvement of agriculture, having fome time ago communicated to the public its œconomical relations from the prefs at Stutgard.

Nor have the learned of Leipfic and Hanover been inattentive to this great art of fupporting human kind, and that amidft all the rage and devaftations of war; witnefs the *Journal d'Agriculture*, printed at Leipfic, and the *Recueils d'Hanovre*, printed at that city.

Even Spain, naturally inactive on thefe occafions, in fpite of all the prejudices of a bigotted religion, has invited Linnæus, with the offers of a large penfion, to fuperintend a college founded for the fake of making new inquiries into the hiftory of nature, and the art of agriculture.

But England alone exceeds all modern nations in hufbandry; and there is reafon to hope, from the fpirit that now animates a great number of the nobility and gentry, that this ufeful art will, in a few years, be carried to a much greater degree of perfection than it ever yet reached in any age or country. The refpectable patriots that form the fociety eftablifhed at London, for the encouragement of arts, feem determined to contribute all that lies in their power towards the advancement of agriculture. They have already done much, and there is reafon to hope they will do more. A vaft variety of different machines for facilitating the practice of agriculture have been fent them in confequence of their large premiums and bounties. Such munificence and attention to public profperity may be truly called royal, as it would caft a luftre on the greateft monarch that ever fwayed a fceptre. We fhall conclude this hiftory, with obferving, that the reader will find under the proper articles a more minute account of the various improvements that have been lately made in the different parts of Europe.

AGRIMONY, a troublefome pyrennial plant in pafture grounds. It has generally a fingle, round, rough ftalk, with leaves placed alternately upon it, which are winged with fmaller leaves placed between the larger pairs. The yellow flowers grow alternately along the ftalk, in a long row, after the manner of a fpike, and are fucceeded by rough feeds.

AIR, that thin dilatable, and compreffible body in which we breathe, and which furrounds the earth to a great height.

The air, befides its various other ufes, is a principal caufe of the vegetation of plants, an inftance of which we have from Mr. Ray, in the Philofophical Tranfactions, of lettuce-feed, that was fown in the glafs receiver of the air-pump, which was exhaufted and cleared from all air, which grew not at all in eight days time; whereas fome of the fame feed that was fown at the fame time in the open air, was rifen to the height of an inch and an half in that time; but the air being let into the exhaufted receiver, the feed grew up to the height of two or three inches in the fpace of one week.

Another inftance of the ufefulnefs of the air in vegetation, is the fedum, which will pufh out roots without earth and water, and live for feveral months: and fome forts of aloes, if hung up in a room entirely fecured from frofts, will remain frefh for fome years, though they will fenfibly lofe in their weight. Air is capable of penetrating the porous and fpongy parts of plants, and being there contracted, of dilating itfelf again.

The air operates alfo within the bowels of the earth, and, by its fubtilty perfpiring through the pores, affifts in the rarefaction of the crudities of the earth, and in the difpelling all fuperfluous moifture, entering into the very pores and veins of the trees, plants, herbs, &c. carrying along with it thofe falts contained either in itfelf, or lodged in the earth: which falts or juices are altered according to the feveral figures or dimenfions of the different ftrainers or veffels of thofe feveral plants which grow upon the fame fpot of earth, which is fo impregnated with thefe falts: and thence thofe varieties in in taste and smell proceed, notwithstanding they all receive their nourishment from the same stock that is lodged in the earth.

The air also affects the branches, leaves, and flowers of trees, plants, and herbs, entering and perspiring through them, and even through the bark and body of trees: and by the same kind of subtilty it does, by its refreshing breezes, moderate the intenseness of the sunbeams, cooling, chearing, blowing, opening, and extending all the offspring of nature. The air fixes and insinuates its æreal substance into the liquid sap of vegetables: and, as all the agitations in nature proceed from the contrariety of parts inhabiting together, in this æreal and liquid substances, being mixed, caused the agitation and motion in vegetables, or, more properly, set it all into a ferment, whether it be in the roots, or in the stem; and it rises by co-operation of the sun, which is the third agent in vegetation, up to the top of a tree, &c. as liquids rise by fire to the top of the containing vessel.

The air, we find, produces a vibratory motion in several bodies; and, particularly in plants, the air-vessels thereof perform the office of lungs: for the air contained in them, sometimes contracting, and sometimes expanding, according as the heat is increased or diminished, presses the vessels, and eases them again by turns; and thus promotes a circulation of their juices, which could scarce be otherwise effected.

Air, says the learned Dr. Hales, is a fine elastic fluid, with particles of very different natures floating in it, whereby it is admirably fitted by the great author of nature, to be the breath or life of vegetables, as well as animals, without which they can no more live nor thrive than animals can. As a proof of the great quantities of air in vegetables, he refers to the third chapter of his excellent Treatise of Vegetable Statics, where, he says, in the experiments on vines, the great quantities of air was visible, which was continually ascending through the sap in the tubes; which manifestly shews what plenty of it is taken in by vegetables, and is perspired off with the sap through the leaves.

He adds several experiments, as to an apple-branch, apricot-branch, birch, and other plants, to prove the same thing.

And Dr. Grew has observed, that the pores are so large in the trunks of some plants, as in the better sort of thick walking-canes, that they are visible to a good eye without a glass; but, with a glass, the cane seems as if stuck at top full of holes with great pins, so large as very well to resemble the pores of the skin in the ends of the fingers, and ball of the hand.

In the leaves of pines, they likewise, through a glass, make a very elegant shew, standing almost exactly in rank and file through the length of the leaves. Whence it may be thought probable, that the air freely enters plants, not only with the principal fund of nourishment by the roots, but also through the surface of their trunks and leaves, especially at night, when they are changed from a perspiring to a strongly imbibing state.

Dr. Hales likewise tells us, that, in all those experiments that he tried to this purpose, he found that the air entered very slowly at the bark of young shoots and branches, but much more freely through old bark; and that in different kinds of trees it had different degrees of more or less free entrance.

And likewise, that there is some air both in an elastic and unelastic state, mixed with the earth (which may well enter the roots with the nourishment) he found by several experiments, which he gives in the above-mentioned treatise.

The excellent Mr. Boyle, in making many experiments on the air, among other discoveries, found, that a good quantity of air was produceable from vegetables, by putting grapes, plums, gooseberries, peas, and several other sorts of fruits and grain, into exhausted and unexhausted receivers, where they continued for several days emitting great quantities of air.

This put the curious Dr. Hales upon further researches to find out what proportion of air he could obtain out of the vegetables in which it was lodged and incorporated; and, from a vast variety of curious and accurate experiments, concludes, that air abounds in vegetable substances, and bears a considerable part in them: and, that if all parts of matter were only endowed with a strongly attracting power, all nature would then become one unactive cohering lump.

Wherefore it was absolutely necessary, in order to the actuating this vast mass of attracting matter, that there should be every where mixed with it a due proportion of strongly repelling elastic particles, which might enliven the whole mass, by the incessant action between them and the attracting particles.

And since these elastic particles are continually in great abundance reduced by the power of the strong attracters, from an elastic to a fixed state, it was therefore necessary, that these particles should be endued with a property of resuming their elastic state, whenever they were disengaged from that mass in which they were fixed, that thereby this beautiful frame of things might be maintained in a continual round of the production and dissolution of vegetable, as well as animal bodies.

The air is very instrumental in the production and growth of vegetables, both by invigorating their several juices, while in an elastic active state, and also by greatly contributing, in a fixed state, to the union and firm connection of the several constituent parts of those bodies, viz. their water, fire, salt, and earth.

To conclude, by reason of those properties of the air before-mentioned, it is very serviceable to vegetables, in that it collects up and breaks open the clouds, those treasures of rain, which nourishes the vegetable tribe.

The air also helps to waft or disperse those foggy humid vapours which arise from the soil, and would otherwise stagnate, and poison the whole face of the earth.

The air, by the assistance of the sun, assumes and sublimates those vapours into the upper regions; and these foggy humid vapours are, by this sublimation, and the coercive power of the air and sun, rarefied, and made again useful in vegetation.

On the contrary, the air, which in so many ways is subservient to vegetables, is also, upon some accounts, injurious and pernicious to them; not only to the ligneous, herbaceous, and flowery parts above, but also to the roots and fibres below the earth: for as the air penetrates deep into the soil, it is natural to conclude, that a dry, husky, scorching air, may be very prejudicial to the tender fibres of new planted vegetables.

ALDER-TREE, the name of a tree very common in most parts of England. It hath male and female flowers, which are produced at remote distances on the same plant; the male flowers are digested into a long juli or catkin, which is loose, imbricated, and cylindrical. The female flowers are collected into a conical scaly head, and are succeeded by scaly cones.

These trees delight in a moist soil, where few other trees will thrive, and are a great improvement to such lands; they are propagated either by layers, or planting of truncheons about three feet in length. The best time for this is in February, or the beginning of March; these should be sharpened at one end, and the ground loosened with an instrument before they are thrust into it; lest, by the stiffness of the soil, the bark should be torn off, which may occasion their miscarriage. These truncheons should be thrust into the earth two feet at least, to prevent their being blown out of the ground by strong winds, after they have made stout shoots. The plantations should be cleared from all such weeds as grow tall, otherwise they will overbear the young shoots; but when they have made good heads, they will keep down the weeds, and will require no farther care.

If you raise them by lying down the branches, it must be performed in October; and by the October following, they will have taken root sufficient to be transplanted out; which must be done by digging a hole, and loosening the earth in the place where each plant is to stand, planting the young trees at least a foot and a half deep, cutting off the top to about nine inches above the surface, which will occasion them to shoot out many branches.

The

The diſtance theſe trees ſhould be placed, if deſigned for a coppice, is ſix feet ſquare; and if the ſmall lateral ſhoots are taken off in the ſpring, it will very much ſtrengthen your upright poles, provided you leave a few ſmall ſhoots at diſtances upon the body thereof, to detain the top for the increaſe of its bulk.

Theſe trees may be alſo planted by the ſide of brooks, as is uſual for willows, where they will thrive exceedingly, and may be cut for poles every fifth or ſixth year. This wood is in great requeſt with the turners, and will endure a long time under ground, or to be laid in water. *Miller's Gard. Dict.*

Alder makes an extraordinary fence againſt rivers and ſtreams, and preſerves the banks from being undermined by the water; becauſe it is always ſending ſuckers from the loweſt roots, which makes it very uſeful, where ſtreams wear away the banks, and are widening of their courſe. *Mortimer's Huſbandry.*

Alder has one peculiar and beneficial property, namely, that no beaſt will crop it, be it young or old, which ſaves the great charge of fencing it after planting. *Ellis's Timber Tree improved.*

ALE, a fermented liquor obtained from the infuſion of malt, and differing only from beer in having a leſs proportion of malt and hops. *See the articles* BEER *and* BREWING.

GILL-ALE, is ale in which the dried leaves of gill, or ground-ivy, have been infuſed. It is eſteemed good in diſorders of the breaſt, and obſtructions of the viſceræ.

ALLEY, in the new huſbandry, implies the vacant ſpace between the outermoſt row of corn on one bed, and the neareſt row to it on the next parallel bed. *See* BED.

The practice of the new huſbandry has already ſufficiently ſhewn, that too narrow alleys would hardly anſwer any of the ends for which they are intended; and, on the other hand, the making them too wide is a loſs of ground. About four feet, excluſive of the ſpaces or partitions between the rows of corn in the beds, is a good middling breadth.

It is not indeed neceſſary to make the alleys quite ſo wide in good ſoils; an intelligent huſbandman will eaſily judge what breadth is moſt proper. But what greatly merits the attention of every one, and ought never to be loſt ſight of, is, that wide alleys are more eaſily and much better ſtirred than thoſe which are narrower: for when an alley is wide, the large furrow in the middle of it may be cut deep, there being then ſufficient room to turn the earth over towards the rows; while, on the other hand, the earth, in too narrow alleys, cannot be ſtirred deep enough, nor can room be found for what is turned over out of the furrows, without danger of burying great part of the rows.

We will, therefore, ſuppoſe the general breadth of the alleys to be about four feet; but the whole of that breadth is not to be ploughed or ſtirred, either with the plough or cultivator, as ſoon as the field is ſown. Neither of theſe inſtruments ought to go too near the rows of corn, for fear of rooting up the plants; but a ſlip of earth, about ſix inches wide, ſhould be left untouched on the outſide of each bed; by which means the part of the alley that is to be ſtirred, will be reduced to the breadth of three feet; and even that is leſſened in the firſt ploughing before winter by a deep furrow, which is then cut cloſe to, and all along thoſe ſix inch ſlips, and the earth taken out of each furrow, is thrown into the great furrow in the middle of the alley, which it ſerves to fill and arch up. Theſe two ſide furrows make together a breadth of about eighteen inches, and, conſequently leave, in the middle of the alley, a breadth of about eighteen inches more, on which is heaped up the earth thrown out of the two furrows: and thus the alremain all the winter.

The firſt hoeing in the ſpring ſhould turn the earth, heaped up in the middle of the alleys, back towards the rows of corn. The two furrows that were opened before winter are then filled up, and a new one is cut in the middle of the alley.

To perform the firſt hoeing with the common plough, which may be very eaſily done, two turns of that inſtrument will be requiſite, namely, one on each ſide of the alley, as near as poſſible to the beds. But as theſe two turns will not be always ſufficient to form the furrow perfectly, a great deal of earth frequently remaining between it and the bed, a third turn of the plough becomes often neceſſary; and ſometimes a fourth, to hollow the middle furrow as it ought to be.

If this work be performed with the cultivator with two mould-boards, the inſtrument muſt be placed in the middle of the alley, and the horſes in one of the two furrows. The ſhare will eaſily enter a great depth into the earth, which was laid there by the laſt hoeing before winter: and as the horſes advance, that great ridge of earth will be divided into two parts, which will be turned over into, and fill up the furrows that were made before winter, on each ſide of the alley, cloſe to the beds. *See the article* CULTIVATOR.

Thus the great furrow in the middle of the alley will be opened, and the whole operation performed by one turn of the cultivator. The earth thus turned over will be thoroughly ſtirred, and ſo much time and labour will be ſaved by this method, thar the farmer may eaſily afford one or two ſtirrings more in the ſummer, which will always be of great ſervice. *M. de Chateauvieux.*

ALLEY, in gardening, implies a ſtrait walk, bounded on both ſides with trees or ſhrubs, and commonly covered with gravel or graſs.

An alley is diſtinguiſhed from a path, by being broad enough for two perſons to walk a-breaſt, whereas a path is ſuppoſed to admit of only one at a time; but if an alley be wider than ten or twelve feet, it may, with more propriety, be called a walk.

Covered ALLEY, is that where the trees on each ſide meet at the top, ſo as to form a ſhade.

ALMOND-TREE, is generally cultivated in gardens for the beauty of its flowers. Theſe often appear in February, when the ſpring is forward; but if froſt comes on after the flowers appear, their beauty will be of ſhort duration, and in thoſe ſeaſons few almonds are produced; whereas when the trees do not flower till late in March, they ſeldom fail to bear plenty of fruit; many of which will be very ſweet, and fit for the table when green, but they will not keep long.

Almond-trees are propagated by inoculating a bud of theſe trees into a plum, almond, or peach-ſtock, in the month of July. The next ſpring, when the buds ſhoot, you may train them up, either for ſtandards, or ſuffer them to grow for half ſtandards, according to your own fancy.

The beſt ſeaſon for tranſplanting theſe trees, if for dry ground, is in October, as ſoon as the leaves begin to decay; but for a wet ſoil, February is much preferable: obſerve always to bud upon plum-ſtocks for wet grounds, and on almond or peach-ſtocks for dry. *Miller's Gard. Dict.*

ALP, a name in many counties of England for the bulfinch.

AMEL-CORN, the ſame with Spelt. *See* SPELT.

AMERANTHUS, amaranth, or flower-gentle, a genus of very beautiful plants, cultivated in gardens.

There are many ſpecies of this plant, but the three following are the principal generally cultivated, 1. Amaranthus tricolor, 2. Amaranthus bicolor, 3. Flower-gentle, with five ſtamina, and very long cylindrical ſpikes, commonly called princes feathers.

The firſt ſort has been long cultivated in gardens for the beauty of its variegated leaves, which are of three colours, viz. green, yellow, and red; theſe are very elegantly mixed, and when the plants are in full vigour, the leaves are large, and cloſely ſet from the bottom to the top of the ſtalks, and the branches form a ſort of pyramid; ſo that there is not a more beautiful plant than this, when it is in its full luſtre.

The ſecond ſort has been introduced into the Engliſh gardens much later than the firſt ſpecies. It grows to the ſame height with the former, and greatly reſembles it in the manner of its growth; but the leaves have only two colours, which are obſcure purple, and a bright crimſon; theſe are ſo blended as to ſet off each other, and, when the plants are vigorous, they make a fine appearance.

The third ſort, which is a native of America, grows with an upright ſtem above three feet high; the leaves and ftalk are of pale green colour; the fpikes of the flowers are produced from the wings of the ftalks, and alfo in clufters at the extremity of the branches: they are of a bright colour, hang downwards, and fome of them two feet and a half long.

Thefe plants muft be fown on a hot bed in February, or the beginning of March at fartheft; and in about a fortnight's time, if the beds be in good temper, the plants will rife; when you muft prepare another bed covered with good, rich, light earth, about four fingers thick. As foon as this bed is in proper temper to receive the young plants, you fhould raife them up with your finger, fo as not to break off the tender roots, and prick them into your new hot-bed, about four inches diftant every way, giving them a gentle watering to fettle the earth to their roots; but in doing this be very cautious not to bear your young plants down to the ground by hafty watering, for they rarely rife again, at leaft fo as to recover their former ftrength. When your plants are firmly rooted, and begin to grow, you muft obferve to give them air every day, more or lefs, to prevent their drawing up too faft, which weakens their ftems.

In about three weeks or a month's time thefe plants will have grown fo as to ftand in need of another hot-bed, which fhould be of a moderate temper, and covered with the fame rich earth about fix inches thick, into which they fhould be removed; obferving to take them up with as much earth about their roots as poffible, and plant them feven or eight inches diftant every way, giving them fome water to fettle the earth about their roots: and keep them fhaded in the heat of the day, until they have taken frefh root, and be fure to refrefh them often gently with water, and give them air in proportion to the heat of the weather, covering the glaffes every night with mats, left the cold chill your bed, and ftop the growth of the plants.

In the beginning of May you muft provide another hot-bed, which fhould be covered with a deep frame, that your plants may have room to grow. Upon this hot-bed you muft fet as many three-penny pots, as can ftand within the compafs of the frame; thefe pots muft be filled with good rich earth, and the cavities between each pot filled up with any common earth, to prevent the heat of the bed from evaporating, and filling the bed with noxious fteams; then take up your plants from the former hot-bed, with as much earth as poffible about their roots, and place each fingle plant in the middle of one of the pots, filling the pot up with the rich earth, and fettle it clofe to the roots of the plant with your hands; water them gently as before, and fhade them in the heat of the day from the violence of the fun, by covering the glaffes with mats: refrefh them often with water, and give them plenty of air in the day time.

In about three weeks more thefe plants will have attained a confiderable fize and ftrength, fo that you muft now raife the glaffes very much in the day time; and when the air is foft, and the fun is clouded, draw off the glaffes, and expofe them to the open air, repeating it as often as the weather will permit; which will harden them by degrees to be removed abroad into the places where they are to remain the whole feafon, which fhould not be done till the firft week in July, when the air is foft, and in a gentle fhower of rain.

Let them be fet firft near the fhelter of a hedge for two or three days, where they may be fcreened from the violence of the fun, and ftrong winds, to which they muft be enured by degrees. Thefe plants, when grown to a good ftature, perfpire very freely, and muft be every day refrefhed with water, if the weather proves hot and dry; otherwife they will ftint, and never produce fo large leaves, as thofe which are fkilfully treated. *Miller's Gard. Dict.*

AMBERVALIA, a ceremony practifed by the ancient Romans, in order to procure from the gods a happy harveft.

This ceremony confifted of a proceffion in which the victims were conducted thrice round the corn fields before they were facrificed. Twelve priefts walked at the head of the proceffion, which confifted of all the neighbouring inhabitants, every one being crowned with leaves of oak, and finging hymns in honour of Ceres, the goddefs of corn.

AMBLE, a peculiar kind of pace, wherein a horfe's two legs of the fame fide move at the fame time.

In this pace the horfe's legs move nearer the ground than in the walk, and, at the fame time, are more extended: but what is moft fingular in it is, that the two legs of the fame fide, for inftance, the off hind and fore-leg, move at the fame time; and then the two near legs, in making another ftep, move at once; the motion being performed in this alternate manner. So that the two fides are alternately without fupport, or any equilibrium between the one and the other, which muft neceffarily prove very fatiguing to the horfe, being obliged to fupport himfelf in a forced ofcillation, by the rapidity of a motion, in which his feet are fcarcely off the ground. For if in the amble he lifted his feet as in the trot, or even in a walk, the ofcillation would be fuch, that he could not avoid falling on his fide, and it is only by keeping his feet very near the ground, and by the quick alternate motion that he fupports himfelf in this pace, in which the hind leg is not only to move at the fame time with the fore-leg of the fame fide, but alfo to gain on it, or touch the ground a foot, or a foot and a half, beyond the fpot where the latter grounded. The further the hind-leg extends beyond the place where the fore-leg grounded, the better the horfe ambles, and the whole motion is proportionally fafter. Thus the whole difference between the amble and the trot confifts in this, that the two legs moving together in the latter are in a diagonal pofition, whereas, in the former, the two legs of the fame fide move together.

This pace, which is very fatiguing to the horfe, is very eafy to the rider. It has not the roughnefs of the trot, which is caufed by the refiftance of the fore-leg, at the lifting up of the hind; becaufe, in the amble, this fore-leg is lifted up at the fame time with the hind-leg of the fame fide; whereas in the trot the fore-leg of the fame fide is at reft, and refifts the impulfe during the whole time that the hind-leg is in motion.

They who are fkilled in horfemanfhip tell us, that horfes which naturally amble, never trot, and that they are a great deal weaker than others. Colts, indeed, very often move in this manner, efpecially when they exert themfelves, and are not ftrong enough to trot or gallop. Moft good horfes, which have been overworked, and on the decline, are alfo obferved voluntarily to amble, when forced to a motion fwifter than a walk.

The amble may, therefore, be confidered as a defective pace, not being common, and natural only to a very few horfes, which, in general, are weaker than others. Add to this, that fuch amblers as feem the ftrongeft, are fpoiled fooner than thofe which trot or gallop. *Buffon's Hiftoire Naturel, tom.* IV.

There are various methods of difcipline for bringing a young horfe to amble: fome chufe to toil him in his foot pace through new ploughed fields, which naturally inures him to the ftroke required in the amble; but this diforderly toil is very apt to weaken, and fometimes to lame a young horfe. Others attempt it by ftopping him in a gallop, or trot; fo that by lofing both, he neceffarily ftumbles on an amble; but this is apt to fpoil a good mouth and rein, and expofes the horfe to the danger of an hoof-reach, or finew-ftrain, by over-reaching, &c. Some prefer ambling by weights as the beft way; and in order to this, either overload the horfe with exceffive heavy fhoes, or fold thick pieces of lead about the fetlock pafterns, without confidering that the former are apt to make him interfere, or ftrike fhort with his hind-feet; and that the latter, befides that mifchief, expofe the horfe to incurable ftrains, crufhing of the coronet, breeding of ring-bones, &c. Others load the horfe with earth, lead, &c. which often occafion a fwaying of the back, over-ftraining of the fillets, &c. Some endeavour to make him amble in hand, before they mount his back, by means of fome wall, fmooth pale, or rail, and by checking him in the mouth with the bridle-hand, and correcting him with a rod on the hinder hoofs, and under the belly, when he treads falfe; but this is very apt to fpoil a fpirited horfe, even before he can underftand what you would have him do.

The beſt method ſeems to conſiſt in trying with your hands, by a gentle and deliberate racking and thruſting of the horſe forwards, by helping him in the weak part of his mouth with your ſnaffle, which muſt be ſmooth, big, and full; and correcting him firſt on one ſide, then on the other, with the calves of your legs, and ſometimes with a ſpur. If you can by this means make him fall readily into an amble, though in a ſhuffling and diſorderly manner, much labour will be ſaved; for that aptneſs to amble will render the tramel more eaſy to him, and he will find the motion without ſtumbling, or being frighted. *See the article* TRAMEL. *Bradley's Dict. Ruſt.*

AMPHITHEATRE, in gardening, implies a temple of view, erected on a riſing ground, of a ſemicircular figure.

Theſe amphitheatres are formed of ſeveral ſorts of ever-greens, obſerving to plant thoſe of the ſhorteſt growth in front, and the talleſt trees, ſuch as pines, firs, cedars, &c. behind. But as the modern taſte in gardening excludes regularity and ſtiffneſs, amphitheatres are at preſent but little eſteemed.

AMBRY, ACEMBRY, or AUMERY, a pantry, or cupboard to ſet victuals in.

ANBURY, a kind of wen, or ſpongy wart growing on any part of a horſe's body. *See the article* WEN.

ANANAS, the pine-apple. *See* PINE-APPLE.

ANEMONE, or the wind-flower, a genus of fine flowers very common in the Engliſh gardens.

There are various ſpecies of the anemone, but the beſt ſorts are natives of the eaſt, from whence the roots were brought originally; but have been ſo greatly improved by culture, as to render them ſome of the chief ornaments of our gardens in the ſpring. The principal colours of theſe flowers are red, white, purple, and blue, and ſome are finely variegated with red, white, and purple. There are many intermediate ſhades of theſe colours; the flowers are large, and very double, and, when properly managed, are extremely beautiful.

The ſoil in which theſe flowers will thrive extremely, may be compoſed in the following manner. Take from a common or paſture land a quantity of untried or virgin earths of a light ſandy loom, or hazel mould, obſerving not to take it above ten inches deep below the ſurface; and if the turf be taken with it the better, provided it have time to rot thoroughly before it is uſed: mix this with a third part of rotten cow-dung, and lay it in a heap, keeping it turned over at leaſt one a month for eight or ten months, the better to mix it, and rot the dung and turf, and let it have the advantage of the free air.

This earth ſhould be mixed twelve months before it is uſed, if poſſible; but if you are conſtrained to uſe it ſooner, you muſt turn it over the oftener, to mellow and break the clods; and obſerve to rake out all the parts of the green ſward that are not quite rotten before you uſe it; for, if ſuffered to remain, would prove prejudicial to the roots.

The beginning of September is a proper time to prepare the beds for planting, when this compoſt ſhould be laid, at leaſt, two feet and a half thick; and in the bottom there ſhould be about four or five inches of rotten cow-dung, or the rotten dung of an old melon or cucumber-bed, ſo that you muſt take out the former ſoil of the beds to make room for it. Your earth ſhould be laid in the beds at leaſt a fortnight or three weeks before you plant the roots, that it may ſettle properly.

The beſt ſeaſon for planting theſe roots, if for forward flowers, is about the latter end of September, and for thoſe of a middle ſeaſon, any time in October; but obſerve to perform this work, if poſſible, at, or near the time of ſome gentle ſhowers; for if you ſhould plant them when the ground is perfectly dry, and no rain ſhould fall for three weeks or a month after, the roots will be apt to grow mouldy upon the crown; and if once they get this diſtemper, they ſeldom come to good after. The roots ſhould be planted about three inches deep, with the eye uppermoſt, and about ſix inches aſunder.

Towards the latter end of June the leaves of your firſt blown roots will begin to decay; ſoon after which you muſt take them out of the ground, clearing them from decayed ſtalks, and waſhing them to clean the earth from the roots; then ſpread them upon a mat, in a dry ſhady place, till they are perfectly dried, when you may put them up in bags, and hang them out of the reach of mice, or other vermin, which will deſtroy many of the roots if they come at them. *Miller's Gard. Dict.*

ANGORA *goat.* *See the article* GOAT.

ANJOU *cabbage-ſhrub*, an excellent vegetable both for the kitchen, and the food of cattle, cultivated with great ſucceſs in ſeveral provinces of France; and that ingenious huſbandman, the marquis of Turbilly, lately ſent a parcel of the ſeeds to our ſociety for the encouragement of arts, who very readily diſtributed them to ſuch gentlemen as applied to them for that purpoſe, in order to their being cultivated here; ſo that there is reaſon to hope, that this uſeful plant will ſoon become common in England. The following inſtructions are given by the marquis de Turbilly, for cultivating the Anjou cabbage.

" The great Anjou cabbage is one of the moſt uſeful leguminous plants for country people. It will grow in almoſt any ſoil, not excepting even the moſt indifferent, provided it be ſufficiently dunged. It is but little known about Paris, and in many other places, where it might be cultivated to great advantage.

" The ſeeds of this cabbage are commonly ſown in June, in a quarter of good mould, in the kitchen garden, and watered from time to time in caſe of drought. The plants will riſe pretty ſpeedily, and ſhould be thinned ſoon after, wherever they ſtand too thick. The next care is to keep them free from weeds whilſt they continue, by hoeing the ground between them. About the firſt of November, they ſhould be tranſplanted into the field where they are to remain. They ſhould be planted there in trenches dug with a ſpade, pretty deep, that is, they ſhould be buried almoſt up to the leaves. The diſtance between them ſhould be two feet, or two feet and a half every way, according to the goodneſs of the ſoil. Particular care ſhould be taken never to plant them with a dibble, as gardeners plant other ſorts of cabbages. A layer of dung ſhould be ſpread along the bottom of the trench, and the roots of the tranſplanted cabbages covered therewith. The mould taken out ſhould then be returned back upon the dung; and as the trench will then no longer hold it all, there will remain a ridge between each row of cabbages.

" Towards the middle of May enſuing, the ground ſhould be well ſtirred between the plants, with a ſpade, or ſome other proper inſtrument, and its whole ſurface laid quite level. After this nothing more remains to be done, except pulling up the weeds, from time to time, as they appear.

" Many huſbandmen ſow the ſeeds of theſe cabbages with thoſe of hemp; and though this may not be ſo ſure as the former, it often ſucceeds very well, eſpecially in wet years. When the hemp is pulled up, a multitude of little cabbages are ſeen, and which having then a free air, grow apace. They are tranſplanted about the firſt of November in the manner before directed, and are preferred to thoſe of the kitchen garden, becauſe they are not ſo apt to run up to ſeed the next ſpring; an accident which ſometimes happens to a few of theſe cabbages, in certain years; and it then becomes neceſſary to replace them by others which have not run up, and which are reſerved for this purpoſe in a ſeparate ſpot of ground.

" Several farmers uſe a plough to cut the trench for tranſplanting theſe cabbages: but then they do not remove them till the ſpring, leaving them, in the mean time, in the place where they were ſown. They afterwards give the earth a ſtirring with a ſpade, and lay it ſmooth towards the end of May, in the manner before directed. Whole fields of theſe cabbages may be ſeen on many farms in Anjou and Poitou, and which prove a very uſeful reſource.

" In the month of June, ſuch of theſe cabbages as are already large, and do not turn in their leaves for cabbaging, but ſtill continue green, begin to be fit for uſe, and ſoon ariſe at their full perfection, which they retain till the next ſpring, when they begin to run up, and afterwards bloſſom. Their ſeeds ripen towards the end of July, and what is intended for ſowing ſhould then be gathered.

" In

"In Anjou, when these cabbages are entirely run up, they generally grow to the height of seven or eight feet: sometimes they reach to eight feet and a half, or nine feet; nay, some have even been seen of a greater height.

"From the month of June, when these cabbages begin to be fit for use, their leaves are gathered from time to time, and they shoot out again. They are large, excellent food, and so tender that they are dressed with a moment's boiling. They never occasion any flatulencies or uneasiness in the stomach; and are also very good food for cattle, which eat them greedily. They likewise greatly increase the milk of cows.

"Such are the properties of this kind of cabbage, greatly esteemed in Anjou, Poitou, Britany, Le Maine, and some other neighbouring provinces. In Anjou farmers are bound by their leases to plant yearly a certain number of these cabbages, and to leave a certain number of them standing when they quit their farms.

"This cabbage forms a kind of shrub, the great utility of which may be gathered from this, that its leaves afford nourishment to men and cattle; and its stalk, which is about the thickness of one's wrist, is used, when dry, for fuel.

"It sometimes happens in extremely severe winters, that some of these cabbages are frozen; and this, in the above provinces, is considered as a very great loss; but that accident is rare, because this kind of cabbage resists frosts better than most others.

"The ground where these cabbages are planted should be fenced in very carefully by hedges or ditches, to preserve it from the depredations of cattle, which are extremely fond of them. With this precaution I have made several plantations of them, near the houses erected in the midst of the heaths and commons I have broken up and improved; and they have succeeded very well, though the soil is but indifferent in many places.

"I have, near my house in Anjou, two well inclosed fields, destined for this sort of plantation. They are planted alternately every year with young cabbages. When these are pulled up, after they have seeded in the second year, at the time already mentioned, the ground where they stood is dug up, and sowed with pease or beans, the crop of which being taken off before the first of November, makes room for planting new cabbages at the proper season. The soil is loosened and enriched by the pease and beans, and by this means the land is never rested; nor is it ever exhausted, because it is dunged whenever the cabbages are planted.

"These cabbages are of such excellent service to me, that I have often wondered at their not being cultivated in all the different countries of Europe. I believe they would succeed every where, and I advise all husbandmen to make plantations of them.

"I wish that this short memoir, founded on my own experience, may contribute to extend the culture of this useful plant."

ANNUAL *plants*, such as continue one year only; or such as spring up, ripen their seed, and perish in that space of time. Thus wheat, barley, oats, beans, pease, &c. are annual plants.

ANNUAL *meadow-grass*, called in some parts of England, Suffolk-grass, a species of very beautiful grass, making the finest turfs, and seems particularly well adapted to dairy farms. *See* Plate I. Fig. 1. *which represents this grass in its perfection.*

"I have, says Mr. Stillingfleet, seen whole fields of it in High Suffolk, without any mixture of other grasses; and as some of the best salt butter we have in London comes from that country, it is most likely to be the best grass for the dairy." He adds, that he observed, upon Malvern-hill, a walk made there for the convenience of the water drinkers, which was, in many places, covered over with this grass, in less than a year, though he could not find a single plant of it besides in any other part of the hill. This was doubtless owing to the frequent treading, which has the greatest tendency to make this grass flourish; and therefore it is very evident, that rolling must be very serviceable to it. As the flowers and stems of this plant do not grow brown so soon as those of other grasses, nor cover the radical leaves so much, because they are considerably shorter, this affords a more pleasing turf than any other grass." *Stillingfleet's Miscel. Tracts.*

Mr. Ray observes of the common meadow grass, that it is a slender and succulent plant, very agreeable to cattle, and a fattener of them; that it delights in a rich soil; and that it is not injured by being trodden under foot, and therefore is commonly found along the sides of paths and roads. It spindles and ears in the spring, and continues to shoot during the whole summer. *Ray's History of Plants.*

As plenty of the seeds of this grass might be very easily procured from Suffolk, it might be propagated and cultivated in all parts of England, where the soil and situation are adapted to its growth.

It is indeed amazing, that amidst the great variety of grasses which grow naturally in England, that so few farmers have had any thoughts about improving their meadows and pastures; they seem to take every thing upon trust, imagining, perhaps, that the grass they find growing naturally in their grounds, is much better, and more adapted to the nature of the soil, than any other they could sow, or adopt in its stead.

But this is surely a very narrow way of thinking, and, should it be encouraged, would soon put a stop to all improvements in husbandry. We have been too long influenced by custom: it is time for us to shake off our fetters, and rouze ourselves from the deep lethargy which has prevented us from receiving, or at least from removing, the disadvantages of the old husbandry, which, in many respects, is highly disadvantageous both to the farmer and his country.

ANNUAL *poa-grass*. *See* POA.

ANTICOR, a disease among horses, consisting of a malignant swelling in the breast, which extends sometimes to the very sheath under the belly; and is attended with a fever, great depression and weakness, and a total want of appetite.

The cure should be first attempted by large and repeated bleedings, to abate the inflammation; emollient clysters should be injected twice or thrice a day, with an ounce of sal prunella in each. The swelling should be bathed with marshmallow ointment, and an opening poultice, with onions boiled in it, should be daily applied over it. If by this method continued four or five day, the inflammation in the throat and gullet be removed, the attention should more particularly turn to encourage the swelling on the breast, and bring it, if possible, to matter: let the poultice therefore be continued, and give the horse two ounces of Venice treacle, dissolved in a pint of beer, every night. When the swelling is grown soft, it must be opened with a knife, and dressed with turpentine digestive, the danger being then over.

But should it be found impracticable to bring the swelling to matter, and the swelling upwards should increase so as to endanger suffocation, authors have advised to pierce the humour with a hot pointed cautery, and dress part with the turpentine digestive, sharpened with a small quantity of Spanish flies and euphorbium in powder, in order to stimulate and promote a greater discharge; at the same time fomenting and bathing the adjacent parts with ointment of marshmallows.

M. Gueriniere, as well as Soleysel, have advised opening the skin, when the tumour cannot be brought to matter, in order to introduce a piece of black hellebore-root steeped in vinegar, and to confine it there for twenty-four hours; this also is intended as a stimulant, and is said to answer the intention, by occasioning sometimes a swelling as big as a man's head. *Bartlet's Farriery.*

ANTS, or *pismires*, are injurious both to pasture lands and gardens; in the former by throwing up hills, and in the latter, by feeding on the fruit, &c.

The method of keeping them from trees is by encompassing the stem with a circle or roll of wool, newly plucked from the sheep's belly, four fingers in breadth, or by laying saw-dust round the tree. The same will be effected when you anoint the tree with tar; but as tar is prejudicial to trees, human ordure will, perhaps, do better; because if any of it be put into their hills, it will kill them. *Mortimer's Husbandry.*

Ant-*hills*, the habitations of the ants, consisting of little eminences, composed of small particles of sand, lightly and artfully laid together.

These hills, or habitations of the ants, though very convenient for themselves and their own societies, are very destructive to the farmer, depriving him of as much land as these hills cover; which may be often computed at a tenth part, or more, of his valuable grass lands. Nay, in some places, where negligence has suffered them to multiply, almost half of it has been rendered useless: the hills standing as thick together as grass-cocks in hay time: and what is most surprizing, this indolence is defended by affirming, that the area or superficies of their land is thereby encreased: whereas it is well known, by the industrious, that very little or no grass ever grows thereon; and, therefore, if the surface be increased, the produce is proportionably decreased. *See the article* Mole-Hill.

It has been a custom in many places at the beginning of winter, and often when the weather was not very cold, to dig up the ant-hills, three or four inches below the surface of the ground; and then to cut them in pieces, and scatter the fragments about: but this only disseminates the insects instead of destroying them; they can hide themselves among the roots of the grass for the present; and then collect themselves together again upon any little eminence, of which there are great numbers ready for their purpose, viz. the circular ridges round the hollows, where the hills stood, as is very soon visible to a curious observer. A much better method seems therefore to be pointed out by a writer in the *Museum Rusticum*, vol. vi. namely, to cut off the hills entire, and even with the surface; and to let them lie whole at a little distance, with their bottom upwards: by this means the ants, which are known to be very tenacious of their nests, will continue in their habitations, while the rains, by running into their holes of communication, assisted afterwards by the frosts, which will now sooner penetrate to their dwellings, will destroy them. Perhaps a little soot sown on the places, and washed in with the rains, would have a better effect. The hills when rendered mellow by the frosts, may be broken and dispersed about the land. This method of cutting the hills even with the surface, has one advantage; it leaves the pasture-land even and fit for mowing; and at the same time the little eminences being taken away, the insects are exposed to the wet, which is disagreeable to them.

In wet weather these insects accumulate cavernous heaps of sandy particles among the grass, called by the labourers sprout-hills; which quickly take off the edge of a scythe. These hills, which are very light and compressible, the above writer assures us from experience, may be readily stamped down, by the feet of the hay-makers, and the insects, together with their eggs and earth, easily pounded to a mortar. This should be repeated a second, and perhaps a third time, after the itinerant foragers have returned from their quest of food, and have begun to raise new structures near the old demolished habitations.

APHERNOUSLI, or *arkenousli*, a species of pine, or pinaster, growing wild on the Alps, where one would think it impossible that any tree could vegetate and prosper; and therefore would probably thrive to great advantage on our bleak, barren, rocky, mountainous tracts of land. See Plate I. Fig. 2.

The timber is large, and has many uses, especially within-doors, or under cover. The branches resemble these of the pitch-trees, commonly called the spruce fir: but the cones are more round in the middle, being of a purplish colour, shaded with black. The bark of the trunk, or bole of the tree, is not reddish like the bark of the pine, but of a whitish cast, like that of the fir. The husk, or sort of shell, which incloses the kernels, is easily cracked, and the kernels are covered with a brown skin, which peels off: they are about as large as a common pea, triangular like buck-wheat, and white and soft as a blanched almond, of an oily agreeable taste, but leaving in the mouth that small degree of asperity, which is peculiar to wild fruits, and is not unpleasing. These kernels make a part sometimes in a Swiss desert; they supply the place of mushroom-buttons in ragouts; and are also recommended in consumptive cases, on account of their balsamic oil.

Wainscoting, flooring, and other joiner's work, made with the planks of aphernousli, are of a finer grain, and more beautifully variegated than deal, and the smell of the wood is more agreeable. From this tree is extracted a white odoriferous resin.

The aphernousli is of a healthy, vigorous nature, and will bear removing when it is young, even in dry warm weather. The wood makes excellent firing in stoves, ovens, and kilns; but is dangerous to be used on the hearth or in grates, being apt to splinter and fly to a considerable distance.

This tree is the *pinus cembra* of Matthioli and Linnæus, the *pinus foliis quinis* in Haller, the *larix semper-virens* in the German Ephemeris, the *libanus carpathius* of some writers, and the *pin a cinque feüeilles*, N° 20. in Du Hamel. It grows in great abundance on the most mountainous and coldest parts of the Briançonnois, where it is called by the natives *alviez*. It bears some resemblance to the white Canada-pine, which is better known in England by the name of Weymouth-pine. *Essays on Husbandry.*

APIARY, a bee-garden, or place where bees are kept. See the article Bees.

APOPLEXY, or, as the farriers generally call it, the *staggers*, a disease to which the horse is subject, and by which the creature drops down suddenly without sense or motion, except a working of his flanks, proceeding from the motion of the heart and lungs, which never ceases while any spark of life remains.

The previous symptoms are drowsiness, watry moist eyes, somewhat full and inflamed, a disposition to reel, feebleness, a bad appetite, and almost continual hanging of the head, or resting it in his manger, sometimes with little or no fever, and scarce any alteration in the dung or urine. When the apoplexy proceeds from water collected in the sinuses and ventricles of the brain, the horse has generally, besides all the foregoing symptoms, a disposition to rear up, and is apt to fall back, when any one goes to handle him about his head. The reason of his falling backwards seems to be obvious, because when the head is raised with his mouth upwards, the water in the ventricles causes a weight upon the cerebellum, or part lying under the brain, and origin of the nerves, so as to deprive the creature of sense and motion at once: this does not, however, prove suddenly mortal. Young horses are most subject to it, and, with proper helps, and good usage, sometimes get over it: but when the apoplexy proceeds from wounds or blows on the head, or from any other cause producing ruptures in the blood-vessels, or from matter collected in the brain, or its membranes; or if any part of the brain or its membranes be indurated, or grown callous, by long continuance, the horse will not only have most of the symptoms already described, but will be frantic by fits, especially after his feeds, so as to start and fly into motion at every thing that comes near him. These cases are extremely dangerous, and seldom admit of a perfect recovery. But when horses fall down suddenly and work violently at their flanks, without any ability to rise, even after plentiful bleeding, such horses seldom recover.

All that can be done in such cases is to strike the veins in several parts at once, to raise up the horse's head and shoulders, propping them with plenty of straw; and if he survive the fit, to cut several rowels; though in case of ruptured vessels, or if any kind of extraneous matter be lodged on the brain, or its membranes, all these helps will be of little service.

But if the apoplectic fit happens to be only the effect of a plethora, or fulness of blood, from high-feeding, and want of sufficient exercise; or if it be the effect of a sizy blood, which is often the case of many young horses, that have been fed for sale, or from catching cold while the blood is in this state, the cure will not be attended with any great difficulty, notwithstanding a horse, in these circumstances, may reel and stagger, and sometimes fall down suddenly.

First of all bleed plentifully, and keep the horse for some time to an opening diet of scalded bran, and sometimes scalded barley, lessening the quantity of his hay. After two days repeat the bleeding, but in a smaller degree. If the horse has a cold, it will be proper to give him pectoral drinks, proper for that disorder. *See* Cold.

But if no symptom of a cold appear it will be necessary, after bleeding and a spare diet, to give him two or three

purges, not only to remove the plethora or fulneſs, but to attenuate and thin his blood, for which the following is recommended:

"Take of the fineſt ſuccotrine aloes, an ounce and a quarter; freſh jallap, two drams; ſalt of tartar, three drams; native cinnabar, or the cinnabar of antimony, half an ounce; make it into a ball with a ſufficient quantity of ſyrup of roſes or marſhmallows; adding twenty or thirty drops of chemical oil of anniſeeds, making the whole into a ball, rolling it in liquorice-powder."

The purge may be made ſtronger or weaker by increaſing or diminiſhing the jallap. Let this be repeated two or three times, and the horſe will probably recover, without a relapſe. Powder of antimony, or its preparations, as the liver, the *crocus metallorum*, its cinnabar, or the native cinnabar, mixed with equal parts of gum guiacum, may be alſo given in ounce doſes, for three or four weeks, to mend his blood, and take off its ſizineſs. Nor ſhould exerciſe, as ſoon as the horſe is able to bear it, be omitted.

When a horſe drops down ſuddenly with hard riding, or violent driving, it in many reſpects reſembles an apoplexy, and all the organs of the head are affected as in an apoplexy; but as this proceeds only from the extraordinary rarefaction of the blood, and its rapid motion, whereby the ſmall veſſels of the brain, heart, and lungs, are ſo extremely diſtended as to cauſe an univerſal preſſure on the origin of the nerves; the horſe by this means loſes all ſenſe and motion, and generally falls ſuddenly, eſpecially upon any ſudden ſtop; becauſe when the bodily motion ceaſes, the circulation of the blood in the veins is not accelerated in proportion to its influx from the arteries, which ſoon produces a ſuffocation and a falling down, without ſenſe or motion. Inſtances of this kind are not uncommon, eſpecially in very hot weather, when the external heat adds greatly to the blood's motion and rarefaction. But as we ſuppoſe in this caſe, little or no fault in the blood, except, perhaps, a plethora, or weakneſs of the veſſels, the quickeſt and readieſt remedy is bleeding; and unleſs the horſe dies with the violence of the fall, which ſometimes happens, or by burſting the ſmall veſſels of the brain or lungs, or happens through polipuſes in the heart or principal veins, he will ſoon riſe of himſelf, or without much help, and may be preſerved from ſuch accidents for the future, by better uſage. *Gibſon on the Diſeaſes of Horſes.*

APPETITE, a certain painful or uneaſy ſenſation, always accompanied with a deſire to eat or drink.

Horſes, more than moſt other creatures, are ſubject to diſeaſes of the ſtomach, particularly to a *want of appetite*, and a *vitiated*, or *voracious appetite*.

Want of APPETITE is when a horſe feeds poorly, and is apt to mangle his hay, or leave it in the rack, and the ſame time gathers little fleſh, and his dung habitually ſoft, and of a pale colour.

Theſe are evident ſigns of a relaxed conſtitution, wherein the weakneſs of the ſtomach and guts may have a very great ſhare. This habitual weakneſs may be either natural and hereditary, or may be cauſed by ſome previous ill management; ſuch as too much ſcalded bran, or too much hot meat of any kind, which relaxes the tone of the ſtomach or guts, and in the end produces a weak digeſtion, and conſequently a loſs of appetite.

The beſt method to harden and recover ſuch horſes, is to give them much gentle exerciſe in the open air, eſpecially in dry weather; never to load their ſtomachs with large feeds, and to keep them as much as poſſible to a dry diet, indulging them now and then with a handful of beans among their oats; but in caſe the horſe grows weak, and requires the help of phyſic, a few laxative purges like the following, ſhould be given.

"Take ſuccotrine aloes, ſix drams; rhubarb in fine powder, two drams; ſaffron dried and powdered, one dram: make it into a ſtiff ball, with a ſufficient quantity of ſyrup of roſes, and add two drams of the elixir proprietatis, prepared with oil of ſulphur by the bell."

This purge will work very gently, and bring the horſe to a better appetite, and ſtrengthen his digeſtion. It may be repeated once a week, or once in ten days, and after the operation of each purge,

"Take a large handful of the raſpings or ſhavings of guaiacum, pomegranate bark, and balauſtines bruiſed, of each an ounce; galangals and liquorice root ſliced, of each half an ounce: let theſe be boiled in ſix quarts of ſmith's forge-water, to three pints; and while it is warm, infuſe in the decoction two drams of ſaffron, and half an ounce of diaſcordium."

Let this be divided into two drinks, and give one after the purge has done working, and the other after two day's intermiſſion; in cold weather the drinks ſhould be warmed before they are adminiſtered: the ſame may be complied with after the laſt purge, and repeated as often as may be neceſſary, continuing to give the horſe conſtant exerciſe in the open free air; and this will be the likelieſt method to ſtrengthen ſuch horſes, as are of weak relaxed conſtitutions.

But where ſuch a habit is contracted by too much feeding, eſpecially on hot ſcalded diet, which is often the caſe of young horſes kept up for ſale, the beſt way is to bleed and purge ſuch horſes, and at the ſame time to rowel them in the belly; for this ſort of feeding eaſily occaſions horſes to be lax, that have no natural diſpoſition to it; for when they grow ſuddenly fat by ſuch management, the ſecretions from the guts become greaſy, which always cauſes weakneſs and relaxation in them, and often forms a proper nidus for the breeding of vermin; all which may be eaſily remedied by purging in the firſt place, and afterwards by proper exerciſe, and a clean diet.

As for thoſe horſes that are of a hot fiery diſpoſition, and loſe their appetites by their heat and fretting, it is a caſe that cannot eaſily be remedied, becauſe of the natural inflammatory diſpoſition of their blood; the only method is to keep them to a cool diet while they are young, and, in country places, to let them run abroad, eſpecially where they have ſtables and warm ranges, to keep them from the inclemency of the weather in winter; for theſe ſort of horſes are always tender, being, for the moſt part, extremely thin ſkinned, and their blood of a thin texture, and eaſily put in motion. For the ſame reaſon, the beſt way, in ſummer, is to bring them up in the day time, and only let them run abroad in the night, they being more hunted with the flies than any other, which keeps them continually upon the fret, and hinders them from thriving. When ſuch horſes live till they are full aged, their heat and fierineſs often abates, ſo that they grow more uſeful; but while they are young, they are more ſubject to inward impoſtumations than horſes of a cooler temperament; and theſe often kill them ſuddenly, or bring them into lingering conſumptive maladies, which in ſome meaſure may be prevented by the above method. *Gibſon on the Diſeaſes of Horſes.*

Vitiated, or *Voracious* APPETITE, is that where the animal is always craving for meat. *See* FOUL-FEEDING.

APPLE-TREE, a fruit-tree ſo well known in this country, that any deſcription of it would be ſuperfluous.

There are a great variety of apples, ſome of which have been introduced from France; but three only of thoſe foreign ſorts are much eſteemed in England, viz. the French rennet, the rennet-griſe, and the violet apple; the other being early fruit, which do not keep long. Beſides, their fleſh is generally mealy, ſo that they do not deſerve to be propagated, as we have many better fruits in England.

The firſt apple which is brought to the London markets is the codlin; a fruit too well known to need any deſcription.

The next is the Margaret apple: this fruit is not ſo long as the codlin, and of a middle ſize; the ſide next the ſun changes to a fair red when ripe, the other ſide is of a pale yellow green; the fruit is firm, and of a quick pleaſant taſte, but does not keep long.

The ſummer pearmain is an oblong fruit, ſtriped with red next the ſun; the fleſh is ſoft, and in a ſhort time mealy; ſo that it is not greatly eſteemed.

The Kentiſh fill-baſket is a ſpecies of codling, of a large ſize, and longer ſhaped than the codlin. This ripens a little later in the ſeaſon, and is generally uſed for baking, &c.

The tranſparent apple. This was brought to England about the year 1724, and was eſteemed a curioſity: it came from Peterſburgh, where it is affirmed to be ſo tranſparent, that the kernels may be perfectly ſeen, when the apple is held to the light; but, in this country, it is a mealy inſipid fruit, ſo as not to be worth propagating.

Loan's pearmain, is a beautiful fruit to the ſight, of a middling ſize; the ſide next the ſun is of a beautiful red, and the other ſide ſtriped with the ſame colour; the fleſh is vinous; but as it ſoon grows mealy, it is not greatly eſteemed.

The quince-apple. This is a ſmall fruit, ſeldom larger than the golden-pippin, but longer, and reſembles the quince in ſhape, eſpecially towards the ſtalk; the ſide next the ſun is of a ruſſet colour, on the other ſide inclining to yellow. This is an excellent apple for about three weeks in September, but it will not keep much longer.

The golden-rennet is a fruit ſo well known in England as to need no deſcription. This ripens about Michaelmas, and for about a month is a very good fruit, either for eating raw, or baking.

The aromatic pippin is alſo a very good apple. It is about the ſize of a nonpareil, but a little longer; the ſide next the ſun is of a bright ruſſet colour: the fleſh has an aromatic flavour: it ripens in October.

The Hertfordſhire pearmain, by ſome called the winter pearmain. This is a good ſized fruit, rather long than round, of a fine red next the ſun, and ſtriped with the ſame colour on the other ſide; the fleſh is juicy, and ſtews well, but is not eſteemed for eating by any nice palates. This is fit for uſe in November and December.

The Kentiſh pippin is a large handſome fruit, of an oblong figure; the ſkin is of a pale green colour; the fleſh is full of juice, which is of a quick acid flavour. This is a very good kitchen fruit, and will keep till February.

The Holland pippin is larger than the former; the fruit is ſomewhat longer, the ſkin of a darker green, and the fleſh firm and juicy. This is a very good kitchen fruit, and will keep late in the ſeaſon.

The monſtrous rennet is a very large apple, of an oblong ſhape, turning red towards the ſun, but of a dark green on the other ſide; the fleſh is apt to be mealy, and is therefore not much valued by thoſe that are curious, and only preſerved for the magnitude of the fruit.

The embroidered apple is a pretty large fruit, ſomewhat ſhaped like the pearmain; but the ſtripes of red are very broad, from whence the gardeners have given it this title. It is a middling fruit, and commonly uſed as a kitchen apple, though there are many better.

The royal ruſſet, by ſome called the leather-coat ruſſet, on account of the deep ruſſet colour of the ſkin. This is a large fair fruit, of an oblong figure, broad towards the baſe; the fleſh is inclinable to yellow. This is one of the beſt kitchen apples we have, and the trees are very great bearers; they grow large and handſome, and the fruit is in uſe from October till April; it is alſo a pleaſant fruit to eat.

Wheeler's ruſſet is an apple of a middling ſize, flat and round; the ſtalk is ſlender; the ſide next the ſun of a light ruſſet colour, the other ſide inclining to a pale yellow when ripe; the fleſh is firm, and the juice has a quick acid flavour; but it is an excellent kitchen fruit, and will keep a long time.

Pile's ruſſet is not quite ſo large as the former, but is of an oval figure, of a ruſſet colour towards the ſun, and of a dark green on the other ſide. It is a very firm fruit, of a ſharp acid flavour; but is much eſtemed for baking, and will keep ſound till April or later, if well preſerved.

The nonpareil is a fruit pretty generally known in England, though there is another apple frequently ſold in the markets for it, which is what the French call *haute-bonne*. This is a larger fruit than the nonpareil, more inclining to yellow, the ruſſet colour brighter, it is earlier ripe, and ſooner gone. This is not ſo flat as the true nonpareil, nor is the juice ſo ſharp, though it is a good apple in its ſeaſon; but the nonpareil is ſeldom ripe before Chriſtmas, and, when well preſerved, will keep till May perfectly ſound. This is juſtly eſteemed one of the beſt apples yet known.

The golden pippin is a fruit peculiar to England. There are few countries abroad where this ſucceeds well, nor do the trees produce ſo good fruit in many parts of England as could be wiſhed. This is in ſome meaſure owing to their being grafted on free ſtocks, which enlarges the fruit, but renders it leſs valuable; becauſe the fleſh is not ſo firm, nor the flavour ſo quick; it is alſo apt to be dry and mealy. This ſhould therefore always be grafted upon the crab-ſtock, which will not canker like the others; and though the fruit will not be ſo fair to the ſight, yet it will be better flavoured.

Beſides the above variety of apples, there are a great many more; but theſe will be ſufficient to furniſh the table and kitchen during the whole ſeaſon of fruits. And with regard to the apples chiefly preferred for making cyder, they will be enumerated under that article. *See* CYDER.

All ſorts of apples are propagated by grafting, or budding upon the ſtocks of the ſame kind, for they will not take on any other ſort of fruit-tree. In the nurſeries there are three ſorts of ſtocks generally uſed to graft apples upon; the firſt are called free-ſtocks, which are raiſed from the kernels of all ſorts of apples indifferently, and theſe are alſo by ſome called crab-ſtocks; for all thoſe trees which are produced from ſeeds, before they are grafted, are termed crabs, without any diſtinction; but ſuch ſtocks as are raiſed from the kernels of crabs preſſed for verjuice, ſhould be preferred. For it is very certain, that by frequent grafting ſome ſorts of apples upon free-ſtocks, the fruits have been rendered larger, but leſs firm, poignant, and of ſhorter duration.

The ſecond ſort of ſtocks is the Dutch creeper; theſe are deſigned to ſtint the growth of the trees, and keep them within compaſs for dwarfs, or eſpaliers.

The third ſort is the paradiſe apple, which is a very low ſhrub, and therefore only proper for trees which are kept in pots by way of curioſity, for theſe do not continue long.

Some perſons have made uſe of codlin ſtocks for grafting of apples, in order to ſtint their growth; but as theſe are commonly propagated by ſuckers, it is not adviſable to uſe them. Nor are the codlin trees raiſed from ſuckers equal to thoſe grafted upon crab ſtocks; for the fruit of the latter will be firmer, laſt longer, and have a ſharper flavour. The trees ſo propagated will alſo laſt much longer ſound, and never put out ſuckers, as the codlins always do, which, if not conſtantly taken off, will weaken the trees, and cauſe them to canker; nor is it only from their roots, but alſo from the knots of the ſtems, that a great number of ſtrong ſhoots are produced, which fill the trees with uſeleſs ſhoots, and render them unſightly, and the fruit ſmall and crumpled.

The method of raiſing ſtocks from the kernels of crabs, or apples, is, to procure them where they are preſſed for verjuice, or cyder; and after they are cleared from the pulp, they may be ſown upon a bed of light earth, covering them over about half an inch thick with the ſame light earth; theſe kernels may be ſown in November or December, where the ground is dry, but in wet ground it will be better to defer it till February; but then the ſeeds muſt be preſerved in dry ſand, and kept out of the reach of vermin; for if mice or rats can get to them, they will devour the ſeeds: there ſhould alſo be care taken of the ſeeds, when ſown, to protect them from thoſe vermin, by ſetting traps, &c. to take them. In the ſpring, when the plants begin to appear, they muſt be conſtantly kept clear from weeds, which, if ſuffered to grow, will ſoon overtop the plants, and ſpoil their growth; if theſe thrive well, ſome of them will be fit to tranſplant into the nurſery the October following; for the ſooner theſe ſeedling plants are removed from the ſeed bed, the leſs danger there will be of their ſhooting down tap-roots, which, in fruit trees, ſhould always be prevented. The ground where theſe young ſtocks are to be planted, ſhould be carefully digged, cleanſed from the roots of all bad weeds, and laid level; then the ſtocks ſhould be planted in rows three feet aſunder, and the plants one foot diſtant in the rows, cloſing the earth pretty faſt to their roots; when the ſtocks are tranſplanted out of the feed bed, the firſt autumn after ſowing, they muſt not be headed; but ſuch as are inclined to ſhoot downward, the tap-root muſt be ſhortened, in order to force out horizontal roots. If the ground is pretty good in which theſe ſtocks are planted, and the weeds conſtantly cleared away, the ſtocks will make great progreſs; ſo that thoſe which are intended for dwarfs, may be grafted the ſpring twelve months after they are planted out of the feed beds; but thoſe which are deſigned for ſtandards, will require two or three years more growth, before they are fit to graft, by which time they will be upwards of ſix feet high. The other neceſſary work to be obſerved while theſe trees remain in the nurſery, the reader will find under the article NURSERY.

If theſe trees are deſigned for eſpaliers in the kitchen garden, and there be a proper extent of ground, it will be proper to plant not only ſuch ſorts as are adapted to the uſe of the table, but alſo a ſufficient number of trees to ſupply the kitchen; but where the kitchen garden is ſmall, the latter muſt be ſupplied from ſtandard trees, either from the orchard, or wherever they are planted; but as many of theſe kitchen apples are large, and hang late in the autumn upon the trees, they will be much more expoſed to the ſtrong winds on ſtandard trees, than in eſpaliers, whereby many of the fruit will be blown down before they are ripe, and others ſo bruiſed as to prevent their keeping: the planting of them therefore in eſpaliers, where it can be done, ſhould always be preferred.

The diſtance between theſe trees ſhould not be leſs than twenty-five or thirty feet, for ſuch ſorts as are of moderate growth, if grafted upon crab or free-ſtocks; but the larger growing ſorts ſhould not be allowed leſs room than thirty-five feet, which will be found full near enough, if the ground is good, and the trees properly trained; for as the branches of theſe trees ſhould not be ſhortened, but trained at their full length, ſo in a few years they will be found to meet. Indeed, at the firſt planting, the diſtance will appear ſo great to thoſe perſons who have not obſerved the vigorous growth of theſe trees, that they will ſuppoſe they never can extend their branches ſo far as to cover the eſpalier; but if ſuch perſons will but obſerve the growth of ſtandard trees of the ſame kinds, and remark how wide their branches are extended on every ſide, they will be ſoon convinced, that as theſe eſpalier trees are allowed to ſpread on two ſides only, the progreſs muſt conſequently be greater, as the whole nouriſhment of the roots will be employed in theſe ſide branches, than where there is a greater number of branches on every ſide of the tree, which are to be ſupplied with the ſame nouriſhment.

The trees ſhould not be more than two years growth from the graft, but thoſe of one year ſhould be preferred: be careful that their ſtocks are young, ſound, and ſmooth, free from canker, which have been cut down in the nurſery. When they are taken up, all the ſmall fibres ſhould be entirely cut off from their roots, which, if left on, will turn mouldy and decay, and by that means obſtruct the new fibres in their growth; the extreme parts of the roots muſt be ſhortened, and all bruiſed roots cut off; and if there are any miſplaced roots, which croſs each other, they ſhould alſo be cut away. As to the pruning the head of theſe trees, there needs be nothing more done, than to cut off any branches, which are ſo ſituated, as that they cannot be trained to the line of the eſpalier; in the planting there muſt be care taken not to place their roots too deep in the ground, eſpecially if the ſoil be moiſt, but rather raiſe them on a little hill, which will be neceſſary to allow for the raiſing of the borders afterwards. The beſt ſeaſon for planting theſe trees in all ſoils that are not very moiſt, is, from October to the middle, or latter end of November, according as the ſeaſon continues mild; but ſo ſoon as the leaves fall they may be removed with great ſafety. After the trees are planted, it will be proper to place down a ſtake to each tree, to which the branches ſhould be faſtened, to prevent the wind from ſhaking or looſening their roots, whi h will deſtroy the young fibres; for when theſe trees are planted very early in the autumn, they will ſoon puſh out a great number of new fibres, which, being very tender, are eaſily broken, and the trees thereby greatly injured. If the winter ſhould prove ſevere, it will be proper to lay ſome rotten dung, tanner's bark, or ſome ſort of mulch, about their roots, to prevent the froſt from penetrating the ground, which might damage theſe tender fibres; but the mulch ſhould not be laid before the froſt begins; for if it be laid over the roots ſoon after the trees are planted (as is often practiſed) it will prevent the moiſture from entering the ground, and do much hurt to the trees.

The following ſpring, before the trees begin to puſh, two or three ſhort ſtakes ſhould be driven down on each ſide of the tree, to which the branches ſhould be faſtened down as horizontally as poſſible, never cutting them down, as is by ſome practiſed, for there will be no danger of their putting out branches enough to furniſh the eſpalier, when the trees are once well eſtabliſhed in their quarters.

In the pruning of theſe trees, the chief point is never to ſhorten any of their branches, unleſs there be an abſolute want of ſhoots to fill the places of the eſpalier; for where the knife is much uſed, it only multiplies uſeleſs ſhoots, and prevents their fruiting; ſo that the beſt method of managing theſe trees is, to go over them three or four times in the growing ſeaſon, and rub off all ſuch ſhoots as are irregularly produced, and train the others down to the ſtakes, in the poſition they are to remain; if this be carefully performed in ſummer, there will be little left to be done in the winter; and by bending their ſhoots from time to time as they are produced, there will be no occaſion to uſe force to bring them down, nor any danger of breaking the branches. The diſtance theſe branches ſhould be trained from each other, for the largeſt ſorts of fruits, ſhould be about ſeven or eight inches, and for the ſmaller five or ſix. If theſe plain inſtructions are followed, it will ſave much unneceſſary labour of pruning, and the trees will, at all times, make a handſome appearance; whereas, when they are ſuffered to grow rude in ſummer, there will be much difficulty in bringing down their ſhoots without breaking, eſpecially if they are grown ſtubborn. All the ſorts of apple trees produce their fruit upon curſons, or ſpurs; ſo that theſe ſhould never be cut off, for they will continue fruitful a great number of years. *Miller's Gard. Dict.*

For the method of making the eſpaliers, ſee the article ESPALIER.

And for the method of planting ſtandard trees in orchards, ſee ORCHARD.

APRICOT-TREE, a fruit tree now well known in the Engliſh gardens.

There are about ſeven varieties of apricots cultivated in the Engliſh gardens, viz. 1. The maſculine apricot. 2. The orange apricot. 3. The Algier apricot. 4. The Roman apricot. 5. The Turkey apricot. 6. The Breda apricot. 7. The Bruſſels apricot.

The maſculine is the firſt ripe of all the apricots; it is a ſmall roundiſh fruit, of a red colour towards the ſun; as it ripens the colour fades to a greeniſh yellow on the other ſide. The tree is very apt to be covered with flowers; but as they come out very early in the ſpring, they are frequently deſtroyed by the cold, unleſs the trees are covered to protect them.

The orange is the next ripe apricot; this fruit is much larger than the former, and, as it ripens, changes to a deep yellow colour. The fleſh of this is dry, and not high flavoured; it is fitter for tarts, than for the table.

The Algier is the next in ſeaſon; this is of an oval ſhape, a little compreſſed on the ſides; it turns to a pale yellow, or ſtraw colour, when ripe; the fleſh is dry, and not high flavoured: this, and what is by ſome perſons called the common apricot, are often confounded.

The Roman is the next ripe apricot; this is a larger fruit than the former, and not compreſſed on the ſides; the colour is deeper, and not ſo dry as the former.

The Turkey apricot is yet larger than either of the former, and of a globular figure; they turn to a deeper yellow than the former; the fleſh is firmer, and of an higher flavour than either of the former.

The Breda apricot (as it is called from its being brought from thence into England) was originally brought from Africa:

Africa: this is a large, roundiſh fruit, changing into a deep yellow, when ripe; the fleſh is ſoft, full of juice, and of a deep orange colour on the inſide; the ſtone is rounder and larger than that of the other ſorts: this is the beſt apricot we have; and, when ripened on a ſtandard, is preferable to all other kinds.

The Bruſſels is the lateſt ripe of all the apricots; for, when it is planted againſt a wall, it is generally the beginning of Auguſt before it is ripe, unleſs when it is planted to a full ſouth aſpect; which is what ſhould not be practiſed, becauſe the fruit is never well taſted which grows in a warm expoſure. This fruit is of a middling ſize, rather inclining to an oval figure; red on the ſide next the ſun, with many dark ſpots, and of a greeniſh yellow on the other ſide; the fleſh is firm, and of an high flavour; the fruit often cracks before it is ripe.

Moſt people train theſe trees up to ſtems of ſix or ſeven feet high, or bud them upon ſtocks of that height; but this is a practice that ſhould not be recommended, becauſe the higher the heads of theſe trees are, the more they are expoſed to the cutting winds in the ſpring, which too frequently deſtroy the bloſſoms; and the fruit is alſo more liable to be blown down in ſummer, eſpecially if there ſhould happen to be much wind at the time they are ripe; which, by falling from a great height, will be bruiſed and ſpoiled; therefore half ſtandards, of about two and a half, or three feet in the ſtem ſhould be preferred to thoſe which are much taller.

Theſe fruits are all propagated by budding them on plum ſtocks, and will readily take upon almoſt any ſort of plum, provided the ſtock be free and thriving (except the Bruſſels kind, which is uſually budded on a ſort of ſtock, commonly called the St. Julian, which better ſuits the tree, as being generally planted for ſtandards, than any other ſort of plum will.) The manner of raiſing the ſtocks, and budding theſe trees, are treated of under their particular articles.

Theſe trees are all (except the two laſt ſorts) planted againſt walls, and ſhould have an eaſt or weſt aſpect; for, if they are planted full ſouth, the great heat cauſes them to be mealy before they are well eatable. The borders under theſe walls ſhould be ſix feet wide at leaſt, and, if it were more, the better; but they ſhould never be made ſo deep, as is the general cuſtom; for, if the earth be two feet deep, or two and a half at moſt, it is enough.

If your ground is a wet cold loam or clay, you ſhould raiſe your borders as much above the level of the ſurface as it will admit, laying ſome ſtones or rubbiſh in the bottom, to prevent the roots from running downwards; but, if you plant upon a chalk or gravel, it will be better to raiſe the borders to a proper thickneſs with good loamy earth than to ſink the borders by removing the chalk or gravel.

The beſt ſoil to be uſed for theſe and all other ſorts of fruit trees, is freſh untried earth, from a paſture ground, taken about ten inches deep, with the turf, and laid to rot and mellow at leaſt twelve months before it is uſed; and this muſt be kept often turned, to ſweeten and imbibe the nitrous particles of the air.

Your borders being thus prepared, make choice of ſuch trees as are but of one year's growth from budding; and, if your ſoil is dry, or of a middling temper, you ſhould prefer October for the beſt ſeaſon for planting, eſpecially having, at that time, a greater choice of trees from the nurſeries, before they have been picked and drawn over by other people. The manner of preparing theſe trees for planting being the ſame in common as other fruit trees, we refer the reader to the article Peaches.

But do not cut off any part of the head at that time, unleſs there are any ſtrong fore-right ſhoots which will not come to the wall, which may be taken quite away.

Your trees being thus prepared, you muſt mark out the diſtances they are to ſtand, which, in a good ſtrong ſoil, or againſt a low wall, ſhould be twenty feet, or more: but, in a moderate ſoil, and againſt taller walls, eighteen feet is a good reaſonable diſtance; then make an hole where each tree is to ſtand, and place its ſtem about four inches from the wall, inclining the head thereto: and, after having fixed the tree in the ground, nail the branches to the wall, to prevent their ſhaking. In this ſtate let it remain till the middle of March, when, if the weather is good, you muſt unnail the branches of your trees, ſo as not to diſturb the roots, and, being provided with a ſharp knife, put your foot cloſe to the ſtem of the tree; and, having placed your left-hand to the bottom of the tree, to prevent its being diſturbed, with your right-hand cut off the head of the tree, if it has but one ſtem, or where it may have two or more ſhoots, each of them muſt be ſhortened to about four or five eyes above the bud, ſo that the ſloping ſide may be towards the wall.

In the ſpring, if the weather proves dry, you muſt, now-and-then, give your trees a gentle refreſhing with water all over their head, which will greatly help them; and alſo lay ſome turf, or other mulch, round their roots, to prevent their drying during the ſummer-ſeaſon: as new branches are produced, obſerve to nail them to the wall in an horizontal poſition; and ſuch ſhoots as are produced fore-right, muſt be intirely diſplaced. This muſt be repeated, as often as is neceſſary, to prevent their hanging from the wall; but by no means ſtop any of their ſhoots in ſummer.

At Michaelmas, when the trees have done growing, you muſt unnail their branches, and ſhorten them in proportion to their ſtrength; a vigorous branch may be left eight or nine inches long, but a weak one ſhould not be left above five or ſix.

When you have ſhortened the ſhoots, be ſure to nail them as horizontally as poſſible; for upon this it is that the future good of the tree chiefly depends.

The ſecond ſummer obſerve, as in the firſt, to diſplace all fore-right ſhoots, as they are produced, nailing in the other cloſe to the wall horizontally, ſo that the middle of the tree may be kept open; and never ſhorten any of the ſhoots in ſummer, unleſs to furniſh branches to fill vacant places on the wall; and never do this later than April. At Michaelmas ſhorten theſe ſhoots, as was directed for the firſt year; the ſtrong ones may be left nine or ten inches, and the weak, ſix or ſeven at moſt.

The following year's management will be nearly the ſame with this; but only obſerve, that apricots produce their bloſſom-buds, not only upon the laſt year's wood, but alſo upon the curſons or ſpurs, which are produced from the two year's wood: great care ſhould therefore be had in the ſummer management, not to hurt or diſplace theſe: obſerve alſo to ſhorten your branches at the winter pruning, ſo as to furniſh freſh wood in every part of the tree.

Theſe few rules, well executed, together with a little obſervation and care, will be ſufficient; and, to pretend to preſcribe particular directions for all the different accidents, or manners of treating fruits, would be impoſſible; the reader will find what has been ſaid, if duly attended to, ſufficient.

The Bruſſels and Breda apricots, being, for the moſt part, planted for ſtandards, will require very little pruning or management; only obſerve to take out all the dead wood, or ſuch branches as croſs each other; this muſt be done early in autumn, or in the ſpring, after the cold weather is paſt, that the part may not canker where the inciſion is made. *Miller's Gard. Dict.*

APRIL, the fourth month of the civil year, conſiſting of thirty days.

This month is the beſt month, if the weather be dry, to ſow barley and white oats, to deſtroy weeds, and alſo to fallow land.

Fell the timber you intend to bark, if the ſpring be forward: cleanſe and rid your coppices, and preſerve them from cattle: keep geeſe and ſwine out of commons and paſtures, and water new planted trees, if the weather prove dry.

Pick up ſtones on the new ſown land: ſow hemp and flax.

Cleanſe ditches, and get in your manure that lies in the ſtreets or lanes, or lay it in heaps.

Set oſiers, willows, and other aquatics, before they are too forward, and alſo ſlips of roſemary or lavender.

You may throughout this month ſow clover graſs, St. Foyn, and all French and other graſſes, or hays: plant

plant madder, and be selling of your winter fed cattle. *Mortimer's Husbandry.*

AQUATICS, or *aquatic* plants, such plants and trees as grow in water.

Thus, the willow, osier, water-cresses, brook-limes, &c. are aquatics.

ARABLE *land*, such land as is tilled, or cultivated for the production of corn.

ARAIRE, the name of a small plough used in Provence and Languedoc, in France.

It consists of a ground wrist, *a*, *b*, (Plate I. Fig. 3.) from three to four feet long, ending in a point towards *b*. The under part of this wrist, instead of being flat, is formed into a ridge, which extends the whole length of it.

This ground wrist, at the end *a*, terminates in a strong tenon fixed in a large mortise, formed at the extremity *d* of the beam *d e*, and is besides fastened to the beam by two iron uprights *f g*, which have a head at *g*, and going through the beam are keyed at *f*: the distance between the under part of the beam about *f*, and the upper part of the ground wrist towards *g*, is about fifteen inches. Instead of these uprights there is sometimes put a piece of sharpened wood or iron, as represented by the pricked line *h g*, which serves instead of a coulter.

On the upper part of the ground wrist is fixed a large iron share *d b* (Fig. 4). the part *d i*, is received into the same mortise of the extremity *d* (Fig. 3.) in which the tenon of the ground wrist is fastened; and the wings of the share *k l* (Fig. 4.) rest upon the iron uprights *f g* (Fig. 3.)

On the hindermost part of this plough is a single lever *m d* (Fig. 3.) which serves for a handle: at the end *d*, where it is bent, it enters, as well as the ground wrist and share, into the great mortise *d*, at the end of the beam; and the whole is secured with wedges. The handle sometimes consts of two pieces lapped one over the other, as at *n*, to lengthen or shorten it, according to the height of the ploughman.

By means of the wedges just mentioned, the angle which the ground wrist forms with the beam, may be altered at pleasure, which makes it plough more or less deep. At the hinder parts of the ground wrists are two earth boards, fastend at *o*, by a strong wooden pin, which passes through both the boards and the ground wrist.

The beam *d*, *f*, *e*, which is from eight to ten feet long, has an iron bolt at the end *e*, which enters with great ease into a large mortise made at the extremity *g*, of the piece of wood *q* 5 *r*, intended to pass between the oxen, and to which their harness is to be fastened. When a single horse is used in the plough, a shaft is substituted instead of the piece of wood *q* 5 *r*, and fastened to the end of the beam *e*, by an iron ringlet.

It is evident that this plough goes a greater or less depth, according as the draught is more or less raised. The ploughman, as has been already observed, can alter the angle which the ground wrist forms with the beam, by means of the wedges he drives into the mortise of the beam, which receives both the ground wrist and handle. But these directions not being sufficiently exact, it is necessary that the ploughman should lean on the handle *m*, when it cuts too deep, and raise it when it makes too shallow a furrow: this labour is so constant, that were the plough to work in a strong soil, the ploughman could not support it. The two little earth boards *p p*, turn over to the right and left the earth that has been loosened by the share; but this is not done so regularly, as when there is but one earth board, which throws the earth into the furrows before made, as fast as it comes out of that which the plough is forming: it is however certain, that the ground wrist being ridged, the ploughman always rests it on one side, which occasions the greater part of the earth to be thrown one way.

These ploughs having no coulters, the earth is not cut vertically at all: for neither the piece of sharpened wood, nor the sheath which joins the ground wrist to the beam, and which is placed a little before the small iron bars *f*, *g*, can be esteemed a coulter. The bar represented by the pricked line *h g*, may serve instead of a coulter, but it must then be made of iron; and in this case the coulter would be very improperly situated, for it should by rights be before the share.

These ploughs are very convenient to use among trees, or in vineyards: they may also serve to stir the ground in the intervals between the rows of saintfoin and lucerne; but then should be rather called cultivators, than ploughs. *Du Hamel's Elemens d'Agriculture.*

ARCHIMEDES's *screw*, a kind of spiral pump, for raising water, so called from Archimedes, its inventor.

It consists of a long cylinder, with a hollow pipe, tube, or groove coiled round it, as represented on Plate I. Fig. 5. where A B shews the cylinder, and C D the tube open at each end. It is placed in an oblique position to the horizon, with the lower end in the water to be raised, and the other supported by the pivot below the winch J K, by which the tube and cylinder are turned round.

As soon as the screw is immersed in the water, it immediately rises therein by the orifice C, to the level of the surface of the water E F; and if the point of the spiral tube, which in the beginning of the motion is coincident with the surface of the water, happens not to be on the lower side of the cylinder, the water will, upon the motion of the screw, move on the spiral tube, till it comes to the point which is on the other side, and coincident with the surface of the water; when it is arrived at that point, as suppose at O, it cannot afterwards possess any part of the spiral, but that which is upon the lowest part of the cylinder; for it cannot move from O towards H or G, because they are situated higher above the horizon; and since this will constantly be the case, after the water in the spiral has obtained the point O, it is plain that it must always be on the under part of the cylinder.

But because the cylinder is in motion, every part of the spiral screw from O to D, will, by degrees, succeed to every part thereof from O to D, as it comes on the lower side; that is, it must ascend on the lower part of the cylinder through all the length of the pipe, till it comes to the orifice at D, where it will run out, as having nothing farther to support it.

This engine may be very useful in raising water, foul with sand, &c. as the leathers of pumps will be soon destroyed by these particles. And it was principally this reason that induced the ingenious Mr. Smeaton to erect a machine of this kind in the gardens of her royal highness the princess dowager of Wales at Kew, where it is worked by horses, and supplies all the ponds, &c. in that extensive garden with water. A machine of this kind, turned by a wind-mill, might be of great use in draining lands in several parts of England, as it is not subject to be out of order, and might be made to raise a very large quantity of water to a small height. We shall describe several other contrivances for this purpose when we come to treat of draining of lands, there being many very curious and useful engines of this kind deposited in the machine room of the society for the encouragement of arts, &c. *See the article* DRAINING *of* LANDS.

ARDERS, fallowings, or plowings of land.

ARK, a large chest to put corn or fruit in, like the bin of a buttery.

ARLES, or EARLES, earnest; thus an arles-penny, signifies an earnest penny.

AROMATIC, an epithet applied to such plants, and other bodies, as yield a fine fragrant smell, and have a warm spicy taste.

ARPENT, the French name for an acre. *See* ACRE.

We have already observed under the article *acre*, that the French arpent contains 100 perches of twenty-two French square feet, which is equal to about one acre and three quarters of a rood English measure. But it may be necessary to add here, that the French have three different arpents, distinguished by the epithets *little*, *middle*, and *great* arpent.

The little ARPENT contains 100 perches of eighteen feet and a half square; consequently its superficial measure is 32,400 French feet, equal to 34,603 feet, or three rood, seven perches, and twenty-seven feet English measure.

The middle ARPENT, confifts alfo of 100 perches, twenty feet fquare, which make 40,000 French feet fuperficial meafure; equal to 42,720 feet, or three rood, thirty-fix perches, and 149 feet Englifh meafure.

The great ARPENT, contains ten perches of twenty-two fquare perches. *See the article* ACRE.

ARTICHOKE, a plant well known in the Englifh gardens, where there are two forts cultivated, namely, the globe artichoke, and the French artichoke.

The globe artichoke is much the better plant. This hath large heads, with brown fcales, which turn inward: the flefhy part at the bottom of the fcales is very thick, and therefore preferred to the French artichoke, whofe ftalks generally grow higher; but the head fmaller, and of a more conical form, than thofe of the globe. The fcales alfo are narrower, of a greener colour, and frequently turned outward. The flefhy part, which is eaten, is not near fo thick, and hath a difagreeable perfumed tafte. This fpecies was almoft wholly deftroyed in the Englifh gardens during the hard froft in 1739-40.

The manner of propagating this plant is from flips or fuckers taken from the old roots, in February or March, which, if planted in a good foil, will produce large fair fruit the autumn following.

About the beginning of March, according to the goodnefs of the feafon, or forwardnefs of the old artichoke ftocks, will be the proper time of dreffing them, which muft be thus performed: with your fpade remove all the earth from about your ftock, down below the part from whence the young fhoots are produced, clearing the earth from between the fhoots, fo as to be able to judge of the goodnefs of each, with their proper pofition upon the ftock; then make choice of two of the cleareft, ftraiteft, and moft promifing plants that are produced from the under part of the ftock, which you are to let remain for a crop; then with your thumb force off all the other plants and buds, clofe to the head of the ftock, from whence they are produced, being very careful not to leave any of the buds, and with your fpade draw the earth about the two plants which are left, and with your hands clofe it faft to each of them, feparating them as far afunder as they can conveniently be placed without breaking them, obferving to crop off the tops of the leaves, which hang down, with your hands: your ground being levelled between the ftocks, you may fow thereon a fmall crop of fpinage, which will be taken off before the archichokes will cover the ground; and be fure to keep them clear from weeds; and towards the latter end of April, or the beginning of May, when your plants begin to fhew their fruit, you muft carefully look over your ftocks, and draw up all young plants from them, which may have been produced fince their dreffing, and cut off all fuckers which are produced from the ftems of the artichokes, leaving only the principal head, by which means your fruit will be larger: when your artichokes are fit to gather, you muft break, or cut them down clofe to the furface of the ground, that your ftocks may make ftrong frefh fhoots by the middle of November, which is the feafon for earthing, or, as the gardeners term it, landing them up: which is thus done:

Cut off all the young fhoots quite clofe to the furface of the ground; then dig between every ftock, raifing all the earth between each row of ftocks into a ridge, as is done in the common method of trenching ground, fo as that the row of artichokes may be exactly in the middle of each ridge; this will be fufficient to guard them againft froft: and I would here recommend it to the public, as infinitely preferable to long dung, which is by the unfkilful often ufed to cover the roots, and is the occafion of their fruit being fmall, and almoft without any bottoms to them. Obferve, that, although I have mentioned November as the feafon for earthing them, yet, if the weather proves mild, it may be deferred till any time in December.

When you have thus earthed them up, you have nothing more to do till February or March, by which time they will have grown through the ridge of the earth; and, when the weather is proper, muft be dreffed as was before directed.

When you have a mind to make a new plantation of artichokes, after having digged in and buried fome very rotten dung in the ground you have allotted for that purpofe, make choice of fuch of your plants, taken from your old ftocks, as are clear, found, and not woody, having fome fibres at the bottom; then with your knife cut off that knobbed woody part, which joined them to the ftock; and if that cuts crifp and tender, it is a fign of its goodnefs; but if tough and ftringy, throw it away as good for nothing: then cut off the large outfide leaves of the plants, intended for fetting, pretty low, that the middle or heart leaves may be above them.

Your plants being thus prepared (if the weather be very dry, or the plants have been any time taken from the ftocks, it will be convenient to fet them upright in a tub of water for three or four hours before they are planted, which will greatly refrefh them) you muft then proceed to planting, which muft be done by ranging a line acrofs the ground, in order to their being placed exactly in a row, and, with a meafure-ftick, plant them at two feet diftance from each other in the rows, and, if defigned for a full crop, five feet diftance from row to row: your plants muft be fet about four inches deep, and the earth clofed very faft to their roots; obferving, if the feafon proves dry, to keep them watered two or three times a week, until they are gowing, after which they do not require any.

Thefe plants in a kindly feafon, or on a moift foil, will produce the largeft and beft artichokes fome time in Auguft and September, after all thofe from the old ftocks are paft; fo that if you intend to continue your artichokes through the whole feafon, you muft make a new plantation every year, otherwife you cannot poffibly have fruit longer than two or three months.

Thofe artichokes which are planted in a moift rich foil, will always produce the largeft and beft fruit; fo that where fuch a foil can be obtained, it will be proper to make a frefh plantation every fpring, to fucceed the old ftocks, and fupply the table in autumn. But the roots will not live through the winter in a very moift foil; fo that your ftocks which you intend fhould remain to fupply the table early, and to furnifh plants, fhould be in a drier fituation. You fhould always obferve to plant artichokes in an open fpot of ground, not under the drip of trees, where they will draw up very tall, and produce only fmall infignificant fruit. *Miller's Gard. Dict.*

That ingenious cultivator M. de Chateauvieux, has raifed excellent artichokes in the open field, without dunging the ground, or even watering the plants, merely by a thorough ftirring of the earth, according to the principles of the new hufbandry. "Artichokes, fays that ingenious gentleman, planted at the beginning of May, produced, in September, their firft fruit, which was, in general, from twelve to fifteen inches in circumference. Their leaves entirely covered the beds fix feet wide."

Jerufalem ARTICHOKE, a fpecies of the fun flower, of the perennial kind, propagated in many gardens for the roots, which are efteemed by fome people; but they are watery and windy, which hath brought them almoft into difufe.

Thefe are propagated by planting the fmaller roots, or the larger ones cut into pieces, obferving to preferve a bud to each feparate piece, either in the fpring or autumn, allowing them a good diftance, for their roots will multiply greatly: the autumn following, when their ftems decay, the roots may be taken up for ufe. Thefe plants fhould be cultivated in fome remote corner of the garden, for they are very unfightly while growing, and their roots are apt to over-run whatever grows near them; nor can they be eafily deftroyed, when they are once well fixed in a garden. *Miller's Gard. Dict.*

ARTIFICIAL GRASSES, fuch as are introduced into the field with great care, and cultivated afterwards with great diligence. Such as burnet, clover, lucern, faintfoin, ray-grafs, fpurry, &c. *See the method of cultivating each under its proper article.*

ARTIFICIAL PASTURES, fuch lands as are properly cultivated and fown with the above plants, or any other that yield a great deal of fodder for cattle.

ASCARIDES,

ASCARIDES, ſmall worms common in horſes, reſembling needles, ſome of them white, and ſome of an azure colour, with flattiſh heads. They are often called needle-worms by the farriers.

Theſe worms are very troubleſome, and hard to be rooted out, and expoſe horſes to frequent gripes, and other fretting uneaſy diſorders in their guts. They breed at all times of the year, and often when one brood is deſtroyed another ſucceeds. They are not mortal; but when a horſe is peſtered with this ſort of vermin, though he will go through his buſineſs tolerably well, and ſometimes feed heartily, yet he always looks lean and jaded; his hair ſtares as if he was ſurfeited, and nothing he eats makes him thrive; he oftens ſtrikes his hind-feet againſt his belly, which ſhews where his grievance lies, and is ſometimes griped, but without the violent ſymptoms that attend a cholic, or ſtrangury, for he never rolls or tumbles, but only ſhews uneaſineſs, and generally lays himſelf down quietly on his belly for a little while, and then gets up and falls a feeding; but the ſureſt ſign is when he voids them with his dung.

Theſe ſmall worms ſometimes come away in great numbers with a purge, and ſome horſes get clear of them by purges only; but this does not often happen; for the horſes that breed aſcarides are, above all others, ſubject to ſlime and wormy matter. They ſeem to have their lodgment about the beginning of the ſmall guts, near the ſtomach, among the concocted aliment or chyle, both from their colour, the ſymptoms of the gripes, and the ſudden fits of ſickneſs theſe horſes are often ſeized with, which ſometimes make them abruptly leave off their food, for a few minutes, and fall greedily to it again as ſoon as the ſick fit is over. They are ſeldom ſeen, except when a horſe has had a purge given, or when he falls into a natural purging, which thoſe horſes are often ſubject to, and then they come away in very great numbers, with much ſlime and naſtineſs. They not only make a horſe grow lean, and look ſurfeited; but in opening his mouth, one may perceive a more than ordinary languid whiteneſs, and a ſickly ſmell, from the want of thoſe due ſupplies of blood and nouriſhment, which give a livelineſs to the colour that is always perceivable in ſound vigorous horſes; ſo that whatever be the primary cauſe, theſe worms ſeem, in a great meaſure, to proceed from a vitiated appetite, and a weak digeſtion, which renders them the more difficult to be removed; for which reaſon recourſe muſt be firſt had to mercurials, and after theſe, to ſuch things as are proper to ſtrengthen the ſtomach, promote digeſtion, and give a better tone to the ſolids.

To a horſe, therefore, that is troubled with theſe ſmall white, or azure coloured worms, the following method may be obſerved:

"Take of calomel that has been often ſublimed and well prepared, two drams; diapente half an ounce; make it into a ball, with a ſufficient quantity of conſerve of wormwood, or of rue, and give it in the morning, keeping the horſe from meat and water four hours before, and four hours after taking it."

The next morning adminiſter the following purge, taking great care to keep the horſe from wet, or from any thing that may expoſe him to catch cold.

"Take Barbadoes, or plantation aloes, one ounce; ſalt of tartar, two drams; freſh ginger grated, a dram and a half; oil of amber a middling ſpoonful: make the whole into a ball with flour or liquorice powder."

This purge may be worked off in the ſtable with warm water, which is much the ſafeſt way when mercurials are given. The calomel ball and purge may be repeated in ſix or eight days; and again in ſix or eight days more.

When a horſe has gone through a courſe of theſe mercurials purges, let the following drink be given two or three times a week, and continued till the horſe begins to thrive and look healthful.

"Take rue, camomile flowers, and horehound, of each a handful; galangals, bruiſed in a mortar, three drams; liquorice root, ſliced, two drams: boil it in a quart or three pints of forge-water five or ſix minutes, in a covered veſſel, and keep it covered till cold: then ſtrain it through a piece of coarſe canvas, and give it in the morning upon an empty ſtomach." *Gibſon on the Diſeaſes of Horſes.*

ASH, or ASH-TREE. There are ſeveral ſpecies of the aſh-tree cultivated by curious perſons for the ſake of variety; but what deſerves attention in a work of this kind, is the common aſh, called by botaniſts, *fraxinus foliolis ſerratis, floribus apetalis*; and is ſo well known as to need no deſcription.

This tree propagates itſelf in plenty by the ſeeds which ſcatter in the autumn; ſo that when the ſeeds happen to fall in places where cattle do not come, there will be plenty of plants come up in the ſpring; but when any perſon is deſirous of raiſing a quantity of the trees, the ſeeds ſhould be ſown as ſoon as they are ripe, and then the plants will come up the following ſpring; but if the ſeeds are kept out of the ground till ſpring, the plants will not come up till the year after; the ground therefore ſhould be kept clean all the ſummer where they are ſown, and not diſturbed, leſt the ſeeds ſhould be turned out of the ground, or buried too deep to grow.

When the plants are come up, they muſt be kept clean from weeds during the ſummer; and, if they make good progreſs in the ſeed-bed, they will be fit to tranſplant by the following autumn; ſome ground ſhould, therefore, be prepared to receive them; and as ſoon as their leaves begin to fall, they ſhould be tranſplanted. In taking of them up care ſhould be taken not to break or tear off their roots; to prevent which they ſhould be taken up with a ſpade, and not drawn up, as is frequently practiſed; for as many of the plants which riſe firſt from ſeeds will out-ſtrip the others in their growth, ſo it is frequently practiſed, to draw up the largeſt plants, and leave the former to grow a year longer, before they are tranſplanted; and to avoid hurting thoſe that are left, the others are drawn out by hand, and thereby many of their roots are torn off, or broken. It is, therefore, much the better way to take all up, little or big, together, and tranſplant them out, placing the large ones together in rows, and the ſmall ones by themſelves. The rows ſhould be three feet aſunder, and the plants a foot and a half diſtance in the rows. In this nurſery they ſhould remain two years, by which time they will be ſtrong enough to plant where they are to remain, for the younger they are planted out the larger they will grow; ſo that where they are deſigned for uſe, they ſhould be planted very young; nor ſhould the ground where they are raiſed be better than that where they are deſigned to grow. For when any plants are raiſed in good land, and afterwards planted into worſe, they very rarely thrive; ſo that it is much the better method to make the nurſery upon a part of the ſame land, where the trees are deſigned to be planted, and then a ſufficient number of the trees may be left ſtanding upon the ground, and theſe will outſtrip thoſe which are removed, and grow to a larger ſize.

Where people live in the neighbourhood of aſh-trees, they may ſupply themſelves with plenty of ſelf-ſown plants, provided cattle are not ſuffered to graze on the land; for if cattle can come at them, they will eat off the young plants, and not ſuffer them to grow; but where the ſeeds fall in hedges, and are protected by buſhes, the plants will come up and thrive: in theſe hedges the trees are frequently permitted to grow till they have deſtroyed the hedge, for there is ſcarce any tree ſo hurtful to all kinds of vegetables as the aſh, which robs every plant of its nouriſhment within the reach of its roots, and ſhould therefore never be ſuffered to grow in hedge-rows; for they not only kill the hedge, but impoveriſh corn, or whatever is ſown near them. Nor ſhould any aſh-trees be permitted to grow near paſture grounds, for if any of the cows eat of the leaves or ſhoots of the aſh, all the butter that is made of their milk will be rank, and of little or no value. In all good dairy countries therefore they never ſuffer any aſh-trees to grow.

If the wood of theſe trees be rightly managed, it will turn greatly to the advantage of its owner; for by the under wood, which will be fit to cut every eight or ten years, there will be a continual income more than ſufficient to pay the rent of the ground, and all other charges; and ſtill there will be a ſtock preſerved for timber, which

which in a few years, will be worth forty or fifty ſhillings per acre.

This timber is of excellent uſe to the wheelwrights and cartwrights for ploughs, axle-trees, fellies of wheels, harrows, oars, blocks for pullies, and many other purpoſes.

The beſt ſeaſon for felling theſe trees is from November to February; for if it be done either too early in the autumn, or too early in the ſpring, the timber will be ſubject to be infeſted with worms, and other inſects: but for lopping of pollards the ſpring is preferable for all ſoft wood. *Miller's Gard. Dict.*

ASHES, the earthy particles of combuſtible ſubſtances remaining after they have been burnt.

If the aſhes are produced from vegetable bodies, they contain a conſiderable quantity of fixed ſalt, blended with the earthy particles, and from theſe particles, the alcaline ſalts, called pot-aſh, pearl-aſh, &c. are extracted.

Aſhes of all ſorts contain in them a very rich fertile ſalt, and are the beſt manure of any to lay upon cold lands, eſpecially if kept dry, and the rain doth not waſh away their ſalts. One load of dry aſhes will go as far as two not kept ſo. But as rain water diminiſhes their ſalts, ſo the moiſtening them with chamber-lie, or ſoap-ſuds, will add greatly to their ſtrength. Two load of theſe aſhes will manure an acre of land better than ſix load of thoſe that are expoſed to the rain, and that are not ordered ſo, which is the common allowance for an acre, though ſome lands require more, and ſome leſs. That the aſhes of any ſort of vegetables are very advantageous to land, is what is experienced in moſt places of England, by the improvement that is made by burning of fern, ſtubble, ſtraw, heath, furze, ſedge, bean-ſtalks, &c. *Mortimer's Huſbandry.*

Coal ASHES from their calcarious quality, are ſingularly beneficial to ſtiff and ſour land, for which purpoſe they are ſucceſsfully uſed in the neighbourhood of ſome great cities, where coal is burnt for fuel. They open clayey grounds, and correct their bad qualities. The gardeners and farmers about London know their value, and make a very profitable uſe of them, particularly to bring into order thoſe grounds which have been dug for brick earth. After ſpreading theſe aſhes upon the clay bottom, they either ſow horſe-beans, or ſet the early Spaniſh, and ſometimes the Windſor-bean in thoſe ſpots; or elſe they lay ſuch lands down with rye-graſs, which generally ſucceeds very well. Mr. Bradley blaming the people of Staffordſhire, and the counties adjoining, where there are coal-pits, for not improving their heavy grounds around thoſe pits, by manuring them with coal aſhes, which might be eaſily burnt out of the waſte coals, ſays, "that wherever there are plenty of coal-pits, there can be no want of good profitable land." *Bradley's Huſbandry.*

Mr. Mortimer agrees entirely with Mr. Bradley, eſteeming ſea-coal aſhes as the beſt manure of any for cold lands, the moſt laſting, and the fitteſt to kill worms. Their ſharp and drying quality opens the pores of ſtiff ſoils, and diſcharges a great deal of their viſcous quality. Mr. Worlidge looks upon them as an excellent compoſt when mixed with horſe dung; he adds, that they are a great curer of moſs and ruſhes in moſt grounds. *Worlidge's Huſbandry.*

Kiln ASHES, made of ſtraw, furze, &c. are a good manure for almoſt any kind of ſoil. In the weſt of England farmers ſift them over their corn and graſs; but this muſt not be done in windy weather, becauſe they are ſo very light that they would be eaſily blown away. They ſucceed beſt when laid on juſt before rain or ſnow. *Mills's Huſbandry, vol.* I.

Peat ASHES are likewiſe a very good manure. Mr. Miller is of opinion, that they are greatly bettered by being mixed with lime before they are laid on the land.

Mr. Ellis has rightly obſerved, that there is a conſiderable difference between the aſhes of lean peat, and thoſe produced by the fatter kind. If barley, ſays he, be ſown ſo late as the beginning of May, lean peat aſhes in particular may be applied over it, or harrowed in with the grain; but aſhes burnt from fat black peat, ſuch as is dug at Newbury, are of ſo ſulphureous a nature, that farmers are afraid to lay them on their barley; nor do they dreſs their wheat with them till the ſpring is advanced, and then they are ſown over it.

The earth of which this rich manure is made, is taken from a black mooriſh ground, with a narrow wood ſcoop, which brings it out like a long brick. Theſe pieces of ſwampy earth are laid on the ground to dry in the ſummer; after which they ſell for eight ſhillings a waggon load, for fuel. But when they are to be uſed for manure, after being dried, they are burnt in heaps of ten, twenty, or thirty loads, laying on more peat upon the outſides, as the fire increaſes within, to keep it from having too much vent.

The great uſe of theſe aſhes was diſcovered about fifty years ago; but they ſoon fell into diſrepute, owing to the injudicious management of people, who imprudently laid on too great quantities of them at a time, by which means the corn was burnt. Afterwards they found that ſix, or at moſt ten buſhels, were ſufficient to be ſown over an acre of wheat, peaſe, turnips, clover, rape-ſeed, or ſaintfoin, as early as could conveniently be done. But ſtill many are afraid to ſow them over barley, leſt a dry ſeaſon ſhould enſue, and burn it up: for theſe aſhes are thought to contain three times as much ſulphur as there is in coal aſhes. This is reaſonably ſuppoſed from their very ſtrong ſulphureous ſmell; their ſparkling and jumping when ſtirred while burning, and their drying up corn by their too great heat. Theſe peat aſhes, as likewiſe thoſe of wood or coal, will help to keep off the ſlug from peaſe and other grains, by the ſalt and ſulphur contained in them, and conduce very much to their preſervation in cold wet ſeaſons. But no danger of over-heating need be feared from the aſhes of that peat which grows, as turf, over ſandy bottoms, as great quantities do on Leighton-heath in Bedfordſhire; for theſe are as much too lean, as the others are too rank. *Ellis's Modern Huſbandman, vol.* II.

We muſt not here omit the account the ingenious Mr. du Hamel has given of a kind of peat aſhes made in France, as the ſame kind of earth with that from whence they are burnt, may be doubtleſs found in many parts England, if farmers would give themſelves the trouble to ſearch for it.

This peat is a blackiſh earth, reſembling the ſoil of ſome meadows. When burnt it emits a thick, diſagreeable ſulphureous vapour. A certain degree of moiſture helps to make it burn, though even then it waſtes but ſlowly. After it has once taken fire it burns of itſelf, but without producing any flame. It is of ſo cauſtic a nature, that it would ſtrip off the ſkin of the hands and feet of the men who knead it, if they did not take proper precautions againſt that inconvenience. Its aſhes retain this cauſtic quality; for the hands of thoſe peaſants who ſtrew them are often hurt by it, if the air be at all damp. This earth, in its natural poſition runs in veins of different ſizes; ſometimes ſeven or eight feet thick, and thirty or forty feet long; and ſometimes they extend four or five hundred feet; after which the vein often fails at once, and perhaps is not found again till two or three miles off. Theſe veins generally lie pretty near the ſurface of the earth, ſeldom deeper than twelve or fifteen feet.

This earth is found only in marſhy places, which muſt ſometimes be drained before it can be come at. It ſhews itſelf by a ſlimy ſkin over the adjacent waters.

Three pounds of this earth being diſtilled in a retort, produced fifteen ounces of a bituminous oil, reſembling that extracted from pit-coal; and the reſiduum yielded, when waſhed, about half a pound of vitriol.

The method of preparing this earth, in order to render it fit for fertilizing land, is as follows: water is thrown over it, and two or three men knead it with their feet, till they bring it to the conſiſtence of a paſte, which is then made into cakes ſeven or eight inches in diameter. Theſe cakes are laid by to dry, though not to ſuch a degree but that there ſtill remains a little moiſture in them, that being neceſſary to facilitate their burning.

The cakes thus prepared are piled up in the form of a pyramid, with ſufficient ſpaces between them for the fire to penetrate; and under this pyramid, which is built upon a kind of hearth, a little ſtraw and bruſh-wood is laid

laid to set them on fire. Two or three days after their ashes are spread with a rake, that they may cool. Some veins of this earth yield white ashes, but they are not so good as those of a reddish hue.

From fifty to seventy pounds of these ashes are spread upon each acre of land in April or May; and in about a week's time the blades of corn, or grass, if it be pasture ground, assume a new verdure, and appear surprisingly strong, even in the coldest soils.

Some of these bituminous earths are better than others. Care must be taken to begin to rake out the ashes of each pyramid as soon as the greater part of it is burnt; for they would lose a great deal of their virtue, if left on the fire till all that is inflammable be consumed: nor would the fire go out in less than a fortnight or three weeks, if they were not scraped away as they are formed.

It would be needless to mention, that a greater quantity of the ashes of an inferior quality must be used, than of those that are stronger, and consequently better; but it may not be amiss to observe, that, in general, wet lands require more than dry soils. The effects of this manure will be manifest for two or three years. It might be dangerous to renew it every year. *Traitté de la Culture de Terres, tom.* V. *pag.* 226.

Pot ASHES are the refuse or ashes remaining after the salt, called pot ashes, is extracted from them.

These ashes are of great service to most sorts of land; but as they have been in a great measure deprived of their salts, it is necessary to lay them on much thicker than other ashes. A bushel and a half of these may be used for a bushel of fresh ashes: but they should always be mixed with some other light ingredient, which may be used in any quantity, if laid on very stiff land. If the land be not over stiff, they may be laid upon it with less mixture. *Bradley's Husbandry.*

Soap ASHES are a composition of wood ashes and lime, remaining after the soap-makers have drawn off their lye.

They are an excellent manure, and were first used by the Flemings with very great success. Two loads of these ashes are sufficient for an acre of arable land; and by the assistance of this manure the ground will not only yield a large crop, but may be sown yearly, without leaving it fallow at any time. They should be laid on the ground in the beginning of winter, that the rain may more easily dissolve and wash them in. Sir Hugh Platt tells us, that by manuring a piece of barren land at Bishop's-hall in Middlesex, in the year 1594, he obtained an excellent crop of summer barley; that he measured the stalk and ear of one of these plants, and found it to be an ell and three inches in length, from the ground to the summit of the ear. We have given a figure of this ear of summer barley in its natural size, on Plate III. Fig. I. *Platt's Jewel-house of Art and Nature.*

A writer in the *Museum Rusticum* declares, that he has for many years past received great benefit by using soap ashes as a manure, with which he almost constantly dresses his wheat lands; but never uses it alone, on account of its hot burning quality.

"My method, adds he, is to make a large heap of dung and earth, that is two loads of earth to one of dung, placed in alternate layers to rot. After this has undergone a strong fermentation, I cause the whole heap to be turned and well mixed, leaving it some time longer to mellow.

"I then procure the soap ashes, and mix them with the compost, in the proportion of one load of ashes to ten of the compost, leaving, for some time, the whole to mellow together.

"When wheat seed-time comes, about the latter end of September, I cause about ten cart loads of this rich compost to be laid in little heaps on each acre of the land I intend to sow with wheat: this manure is immediately spread, and, sowing my wheat broad cast, I plough it in together with the compost.

"The advantage resulting from this practice, on stiff soils, are many; and particularly, if the farmer is the least careful in preparing his tilth, he will have a clean crop, free from smut or weeds; a matter of no small consequence to him.

"I have tried this manure on lighter lands, and find it answer extremely well, provided it has lain a considerable time in the compost heap, to mellow and abate its natural heat; but it agrees best by far with clayey soils, and in such is well worthy of being recommended as an excellent dressing for a wheat crop." *Museum Rust. vol.* IV. *pag.* 339.

Turf ASHES, the ashes procured by burning turfs, or the parings of the surface of heathy and moorish land. *See the article* BURN-BAKING.

These parings, or turfs, are cut in a dry season, and set up to dry thoroughly, leaning one against another; and, when dry, are piled into small heaps or piles, about a quarter or half a load, in each, carried up exactly square to a certain height, and then drawn up gradually in a pyramidical manner, so as to throw off any accidental showers. In a very dry season even the covering of these piles may be carried home, and stacked or housed indiscriminately with the rest; but in a wetter season it is usual to separate and dry those topmost turfs, if the weather allows, and to stack them separately, to be used on the tops of fires, when large, as dampers. A stout labourer will, in a day, cut two waggon loads of these turfs. The women and children can set them up to dry, and the women can pile them up.

These ashes (in the moors of Yorkshire, where, as the Rev. Mr. Comber informs us they are greatly used, the principal firing being turfs) are carried out daily, or once in two or three days, to the dunghill; and the farmer takes the opportunity of his first leisure towards the end of the year, to carry them out to his meadow land, on which he lays them thicker or thinner, as he has more or less land which he apprehends to want them, or more or less of them. The first rains wash them in, and the next summer never fails to shew their good effect.

It will be easily imagined, that as these ashes are much finer, or more pulverized than those of coals, so they more insinuate themselves into the soil, but are, in their effects, much less lasting. However, as every year brings a considerable supply, the farmer is less concerned that they are not a lasting manure.

In the moors of Yorkshire, the farmer is so sensible of the efficacy of these ashes, that it is become a proverb among them, "The better fire, the richer farmer." In consequence of this principle, the farmer endeavours to procure all the ashes he can from the cottagers who have no land. And hence a happy connection arises; for the poor cottager finding the article of carriage the chief part of the expence of his fuel, is wise enough to bargain with the farmer to bring him home such a quantity of his turfs in consequence of his ashes.

Some farmers lay these ashes on their ground in the spring; and, if showers follow, they will have their effect in the summer crop, though not so great as if they had been laid on at the end of the year. It must however be remarked, that he who lays on his ashes in the spring, lays on what has been very lately made in the winter; and he who lays on at the latter end of the year, lays on what has been evaporating during the whole summer; so that it is not easy to say which method is the better. *Museum Rusticum, vol.* V. *pag.* 311.

ASPARAGUS, *sparagus*, or *sperage*, corruptly called *sparrow-grass*, a plant well known in the English gardens. Mr. Miller has enumerated ten species of this plant; but that generally cultivated is the garden asparagus, called by botanists, *asparagus caule herbaceo erecto, foliis setaceis, stipulis paribus.*

The garden asparagus is propagated by sowing of the seed; in the procuring of which, you should be particularly careful to get it from some person of integrity; or, if you have any opportunity, save it yourself, or in some other neighbouring garden. In order to which a sufficient number of the fairest buds should be marked early in the spring. These buds will, many of them, produce great numbers of red berries; which should be suffered to remain upon the branches until the latter end of September, when the haulm will begin to decay; then cut off the branches, and strip the berries into

into a tub, where they may lie in an heap to ſweat for three weeks; by which means the outer huſks will be rotten: then fill the tub with water, and break all the huſks, by ſqueezing them between your hands. Theſe huſks will all ſwim upon the water, but the ſeed will ſink to the bottom; ſo that, by pouring off the water gently, the huſks will be carried along with it; and by putting freſh water two or three times, and ſtirring your ſeed about, you will make it entirely clean; then ſpread your ſeed upon a mat, and expoſe it to the ſun and air in dry weather, until it is perfectly dry; when you may put it into a bag, and hang it up in a dry place till the beginning of February; at which time, you muſt prepare a bed of good, rich earth, made very level, whereon you muſt ſow you ſeed (but not too thick, which will cauſe your plants to be ſmall) and, having trod your ſeed into the ground, rake it over ſmooth.

In the following ſummer keep it diligently cleared from weeds, which will greatly add to the ſtrength of your plants; and, towards the latter end of October, when the haulm is quite withered, you may ſpread a little rotten dung over the ſurface of the ground, about an inch thick; which will preſerve the young buds from being hurt by the froſts, &c.

The ſpring following your plants will be fit to plant out for good (for I would never chuſe plants of more than one year's growth, having very often experienced them to take much better than older, and to produce finer roots) you muſt therefore prepare your ground by trenching it well, burying therein a good quantity of rotten dung at the bottom of each trench, that it may lie at leaſt ſix inches below the ſurface of the ground: then level your whole plot very exactly, taking out all large ſtones; but this ſhould be done not long before you intend to plant your aſparagus; in which you muſt be governed according to the nature of your ſoil, or the ſeaſon; for if your ſoil is dry, and the ſeaſon forward, you may plant early in March; but, in a very wet ſoil, it is better to wait till the middle of April; which is about the ſeaſon that the plants are beginning to ſhoot. I know many people have adviſed the planting of aſparagus at Michaelmas; but this I have experienced to be very wrong; for in two different years I was obliged to tranſplant large quantities at that ſeaſon; but I had better have thrown away the plants; for, upon examination, in the ſpring, I found moſt of the roots were grown mouldy, and decaying: and, I am ſure, not one in five of them ſucceeded; and thoſe which did, were ſo weak, as not to be worth their ſtanding.

The ſeaſon being now come, you muſt, with a narrow pronged dung-fork, carefully fork up your roots, ſhaking them out of the earth, and ſeparating them from each other; obſerving to lay their heads even, for the more convenient planting them; which muſt be performed in this manner: your plot of ground being levelled, you muſt begin at one ſide thereof, ranging a line very tight croſs the piece; by which you muſt throw out a trench exactly ſtraight, and about ſix inches deep; into which you muſt lay your roots, ſpreading them with your fingers, and placing them upright againſt the back of the trench, that the buds may ſtand forward, and be about two inches below the ſurface of the ground, and at twelve inches diſtance from each other; then, with a rake, draw the earth into the trench again, laying it very level, which will preſerve the roots in their right poſition: then remove your line a foot farther back, and make another trench in like manner, laying therein your plants, as before directed, and continuing the ſame diſtance row from row; only obſerving, between every four rows, to leave the diſtance of two feet and a half, for an alley to go between the beds, to cut the aſparagus, &c.

Your plot of ground being finiſhed and levelled, you may ſow thereon a ſmall crop of onions, which will not hurt your aſparagus; and tread in your ſeeds, raking your ground level.

There are ſome perſons who plant the ſeed of aſparagus in the place where the roots are to remain; which is a good method, if it be performed with care. The way is this: after the ground has been well drenched and dunged, they lay it level, and draw a line acroſs the ground (in the ſame manner as is practiſed for planting of the young plants) then, with a dibble, make holes at a foot diſtance; into each of which you muſt drop two ſeeds, for fear one ſhould miſcarry: theſe holes ſhould not be more than half an inch deep: cover the ſeeds, by ſtriking the earth in upon it; and go on, removing the line a foot back for another row; and, after four rows are finiſhed, leave a ſpace for an alley between the beds, if it is deſigned to ſtand for the natural ſeaſon of cutting; but, if it is to be taken up for hot-beds, there may be ſix rows planted in each bed; and the diſtance in the rows need not be more than nine inches. This ſhould be performed by the middle of February, becauſe the ſeeds lie long in the ground: but, if onions are intended to be ſown upon the ground, that may be performed a fortnight or three weeks after, provided the ground is not ſtirred ſo deep as to diſturb the aſparagus-ſeeds, in raking the onion ſeed into the ground.

As the roots of aſparagus always ſend forth many long fibres, which run deep into the ground; ſo, when the ſeeds are ſown where they are to remain, theſe roots will not be broken or injured, as thoſe muſt be which are tranſplanted; therefore they will ſhoot deeper into the ground, and make much greater progreſs; and the fibres will puſh out on every ſide; which will cauſe the crown of the root to be in the center; whereas, in tranſplanting, the roots are made flat againſt the ſide of the trench.

When your aſparagus is come up, and the onions have raiſed their ſeed-leaves upright, (which will be in three weeks or a month after planting) you muſt, with a ſmall hoe, cut up all the weeds, and thin your crop of onions, where they may have come up in bunches; but this muſt be done carefully, and in dry weather, that the weeds may die as faſt as they are cut up, being careful not to injure the young ſhoots of aſparagus. This work muſt be repeated about three times; which, if well done, and the ſeaſon not too wet, will keep the ground clear from weeds, until the onions are fit to be pulled up, which is commonly in Auguſt; and is known, when their greens fall down, and begin to wither. When you have drawn off your onions, you muſt clean your ground well from weeds; which will keep it clean till you earth your beds, which muſt be done in October, when the haulm begins to decay; for if you cut off the haulm, while green, the roots will ſhoot freſh again, which will greatly weaken them. This young haulm ſhould be cut off with a knife, leaving the ſtems two or three inches above ground; which will be a guide to you to diſtinguiſh the beds from the alleys; then, with an hoe, clear off the weeds into the alleys, and dig up the alleys, burying the weeds in the bottom; and throw the earth upon the beds, ſo that the beds may be about five inches above the level of the alleys: then you may plant a row of coleworts in the middle of the alleys; but do not ſow or plant any thing upon the beds, which would greatly weaken the roots: nor would I ever adviſe the planting of beans in the alleys (as is the practice of many) for it greatly damages the two outſide rows of the aſparagus. In this manner it muſt remain till ſpring, when you muſt hoe over the beds, to deſtroy all young weeds; then rake them ſmooth, and obſerve, all the ſucceeding ſummer, to keep them clear from weeds; and in October dig up the alleys again, as was before directed, earthing the beds, &c.

The ſecond ſpring after planting, you may begin to cut ſome of your aſparagus, though it will be much better to ſtay until the third; therefore now you muſt fork up your beds with a flat pronged fork, made on purpoſe, which is commonly called an aſparagus fork: this muſt be done before the buds ſhoot in the ſpring, and with care, leſt you fork too deep, and bruiſe the head of the root; then rake the beds over ſmooth, juſt before the buds appear above ground; which will deſtroy all young weeds, and keep your beds clean much longer, than if left unraked, or done ſo ſoon as forked: and, when your buds appear about four or five inches above-ground, you may then cut them; but it ſhould be done ſparingly, only taking the large buds, and ſuffering the ſmall to run up to ſtrengthen the roots; for, the more you cut, the greater will be the increaſe of buds; but they will be ſmaller, and the roots ſooner decay. When you cut a bud, you muſt open the ground with your knife (which ſhould be very narrow and long in the blade, and filled with teeth like a ſaw) to ſee whether

whether any more young buds are coming up close by it, which might be either broken or bruised in cutting the other; then, with your knife, saw it off about three inches under-ground: This may appear a troublesome affair, to people unacquainted with the practical part; but those who are employed in cutting asparagus, will perform a great deal of this work in a short time; but care in doing it is absolutely necessary to be observed by all who cut asparagus.

The manner of dressing your asparagus-beds is every year the same as directed for the second; viz. keeping them from weeds, digging the alleys in October, and forking the beds towards the end of March, &c. only observe, every other year, to lay a little rotten dung (from a melon or cucumber-bed) all over your beds, burying some in your alleys also, at the time for digging them up. This will preserve the ground in heart to maintain your roots in vigour; and by this management, a plat of good asparagus may be continued for ten or twelve years in cutting, and will produce good buds, especially if it be not cut too long each season; for when it is not left to run up pretty early in June, the roots will be greatly weakened, so that the buds will be smaller: therefore in those families where asparagus is required late in the season, a few beds should be set apart for that purpose, which will be much better than to injure the whole plantation, by cutting it too long.

The quantity of ground necessary to be planted with asparagus, to supply a small family, should be at least five or six rods; less than that will not do: for if you cannot cut one hundred at a time, it will scarcely be worth while; for you must be obliged to keep it after it is cut two or three days, to furnish enough for one mess; but for a larger family, twelve rods of ground should be planted, which, if a good crop, will furnish two or three hundred each day in the height of the season. *Miller's Gard. Dict.*

Asparagus-*fork*, a flat pronged fork, made on purpose to fork up the beds of asparagus.

ASPECT, among gardeners, the same with exposure. *See the articles* Exposure.

ASPEN-TREE, a species of the poplar, and called by botanists, *populus foliis subrotundis dentato angulatis utrinque glabris.* Poplar-tree with roundish leaves, having an angular indenture, and smooth on both sides.

The leaves of this tree stand upon long slender foot-stalks, so as to be shaken by the least wind, from whence it has been called the trembling poplar, or aspen-tree.

The method of cultivating this tree is the same in every respect as that of the abele-tree. *See* Abele-Tree.

ASS, a creature well known in most parts of Europe, and proves very useful in many respects, if taken proper care of.

The horse is trained up, great care is taken of him, he is instructed and exercised; while the poor ass is left to the brutality of the meanest servants, and the wantonness of children, that so far from improving, he must be a loser by his education: and indeed had he not a large fund of good qualities, the manner in which he is treated is sufficient to exhaust them. He is the sport, the but, and the drudge of the vulgar; who, without the least thought or concern, drive him along with a cudgel, beating, overloading, and tiring him. We do not remember, that, if there were no horses, the ass would be considered, both with regard to himself and us, as the most useful, most beautiful, and most distinguished of animals. Instead of being the first, he is now the second; and from this accident alone he is held in no estimation. It is the comparison that degrades him: he is considered, not in himself, but relatively to the horse. We forget that he is an ass; that he has all the qualities of his nature, all the gifts annexed to his species; and think only on the figure and qualities of the horse which are wanting in him, and which it would be improper for him to have.

By his natural temper he is as humble, as patient, and as quiet, as the horse is proud, fiery, and impetuous; he bears with firmness, and perhaps with courage, blows and chastisements. He is sober, both with regard to the quantity and quality of his food, contenting himself with the most harsh and disagreeable herbs, which the horse, and other animals, will not touch. In water he is very nice, drinking only of that which is perfectly clear, and at brooks with which he is acquainted. *Buffon's Histoire Naturelle, tom.* IV.

The ass, though a contemptible creature, is very serviceable to many that are not able to buy or keep horses; especially where they live near heaths or commons, the barreness of which will keep them, being contented with any trash, dry leaves, stalks, thistles, briars, chaff, and any sort of straw is excellent food for them; they require very little looking after, and will sustain labour, hunger, and thirst, beyond most creatures. They are seldom or never sick; and endure longer than any other creature. They may be made use of to plough light lands, to carry burdens, to draw in mills, for which they are very excellent, to fetch water, or any other odd things. They are very useful for their milk, which is an excellent restorative in consumptions, and other weaknesses: but they would be of much more advantage were they used, as they are in foreign countries, for the breeding of mules. *See the article* Mule.

The she-ass, if you have any regard to their breed, should be covered between the months of March and June. The best age to breed from is from three years old to ten, and you should let the young ass suck two years, and not work them till they are three years old.

Those are reckoned the best shaped that are well squared, have large eyes, wide nostrils, long necks, broad breasts, high shoulders, a great back, short tail, the hair sleek and of a blackish colour: their skins make the most durable shoes of any sort of leather. *Mortimer's Husbandry, vol.* I. *pag.* 222.

ATMOSPHERE, the vast body, or collection of air which surrounds the earth to a very considerable height.

Clouds, which are precipitated in drops of rain for the service of mankind, do not consist wholly of watery particles; for besides aqueous vapours, and what these contain, there are raised from the surface of the earth into the air, sulphureous and saline particles, which are also carried up into the clouds, and mixed with the aqueous vapours. Here we have a mixture of all such substances, as it were, in their extremely small parts, floating in the air together, and the effects of these sulphureous and saline particles, thus mingled with aqueous vapours, are sometimes very sensible, especially in thunder and lightning; when the sulphureous and nitrous particles taking fire, by the motion arising from heat, break out with the violence of flashes and noise, very much resembling the effects of gunpowder.

Another proof that there are nitrous particles raised into the air, we have in the nourishment which rain, replete with these ingredients, gives to plants, more than any other water; and also from the collection of nitre, or saltpetre, in heaps of earth, out of which these principles derived from rain are known to be extracted, if these heaps of earth be exposed to the air, so as to keep the wet weather from spoiling the operation. It is also a convincing argument, that these nutritive ingredients are of consequence in vegetation, by plants in water refusing to grow in droughty weather, notwithstanding they have such plenty of moisture; from their being absolutely at a stand when rain has been long a stranger to the earth, they are plainly seen to go forward with the business of vegetation, like those plants which have been deprived of motion or growth, when the fine showers descend, and continue to do so for some time.

Here then, in both cases of the plants in a pond, there is water, but there are only in one these vegetative principles, which give motion to the plants, and consequently those ingredients are absolutely necessary to vegetation; and therefore we may conclude, that water, when properly dilated by fermentation at the roots, is only an assistant to plants, in applying those necessary principles, or helping to conduct them through the tubular interstices of the fibres, or to float the nitrous particles through the whole system of the operation in motion, or growth of vegetables, and not the food itself, or any sort of nourishment when divested of those principles. Whether, therefore, the system of exceeding fine fibres, or or tubes of a plant at a ftand in a pond, in a very droughty feafon, admits that water undilated, for want of nutritive, or fermenting principles, into its body, during the great want of rain; or whether it abfolutely refufes to imbibe, or cannot attract, for want of a finer divifion of its parts, any of it, as there are in it no nutritive ingredients, does not feem to admit of any doubt in favour of the latter queftion, which, if true in nature, may poffibly be of fervice in the growth of fome forts of plants, and perhaps fave much trouble in attempting to force others forwards with fome fort of water.

Since it is plain, that there is a vaft quantity of nitrous, fulphureous, and bituminous matter all over the furface of the earth, and that plants and animals abound with volatile falts, we need not wonder that the heat of the fun fills the air with fuch fine particles, and all forts of unctuous exhalations, by firft expanding them, after which they rife till they meet with air and other mixtures of the fame fpecific gravity. What are ufually called *ignes fatui*, feem to confift of a more unctuous fubftance than other exhalations, for we find their oily particles are eafily fixed, but not fo foon fpent as thofe of fulphur and nitre. Shooting ftars are improperly fo called, becaufe they are nothing more than exhalations kindled in the air; and if a long train of fubftances take fire at once, it is commonly termed a *dart*; and if there be many, and they continue in the fame place, they are then called *beams*.

Thus we plainly fee how full the atmofphere is of thefe rich ingredients for the bufinefs of vegetation; and becaufe they are of fuch vaft confequence to the growth of plants, we will enumerate the fources of them upon the frame of the globe; from whence the fun and wind borrow them, in order to difperfe them properly in the air, that they may intimately mix, and defcend with the rain drops, and fo be conveyed to the mouths of the fibrous tubes of plants with the greateft care and fkill; from thefe ingredients firft leaving the furface of the earth, through the whole procefs of their various motions, configurations, and combinations, till they are prepared in the moft exquifite manner to be received into the bowels of vegetables, which we plainly fee ftand in great need of them, as without their friendly affiftance, or fome compofitions of dung to refemble them, they are unable from water and earth alone to get forward to maturity.

Salts are of various kinds, but all have a fharp pungent tafte, though not all alike; and of thefe fome are dug out of the earth like ftone out of a quarry; others are made by art, by letting the fea-water into fhallow pits on the fhore, and continue there till the aqueous particles are exhaled by the fun and wind, and then the falt remains at the bottom. The falt is in its nature the fame in both cafes; for the faline particles are not made by art in the combination of ingredients to imitate it; they are only feparated from the watery particles wherein they floated. The qualities of this excellent ingredient in vegetation are, that it eafily diffolves, and melts readily in the open air, if it be refined from all heterogeneous matter; when the water wherewith it is entangled is any ways drawn off, there remains a grofs fediment, but the finer parts are carried away with it; this fediment is the only part the fire cannot melt, but reduces it to a calx.

This facility of the finer parts fwimming, as they are fpecifically lighter than water, contributes to the benefit of plants; or rather thefe fine faline particles are of the fame fpecific gravity with the water; that they may intimately mix with it, and be carried in thofe vapours through all the neceffary ftages, till they return to the earth again. This quality of melting and diffolving in water and air, fets the finer parts at liberty, and prepares them to take wing with the common exhalations. And yet the fediment, or groffer parts, which are left behind, have their excellent ufes in helping the embrios of plants to fend out their fibrous tubes, in fearch after more refined particles, which either adhere to the fuperficies of the particles of earth, or are contained in their internal pores.

Nitre, of which there are feveral forts, natural and artificial, the former refining itfelf, and the latter refined by art, is a kind of falt, which eafily takes fire, but like fea-falt is eafily reducible to a calx. The vapours, or particles of nitre, when they defcend for the ufe of plants, are found to contain abundance of fpirits; for the nitre, as a falt, is impregnated with them, which render it volatile, and the fluid extracted from it is very fharp and corrofive. The calx to which nitre is reducible, as well as the calx of common falt, has its excellent ufe in vegetation; and when it is reduced by fire to this ftate, it then takes the name of fixed falt, or rather the afhes of falts: the benefit of this calcination to land is manifeft from the afhes of burnt vegetables, and other natural bodies reducible to a calx: for the rich principles, or food, if we may call it fo, of vegetables, are contained more or lefs in all bodies, whofe parts can be thus feparated, as is evident from the operations in chemiftry, which reduce bodies to their component parts, by the help of fire.

Sulphur is a liquid clammy fubftance, whofe parts are foon feparated, and rife up into the air with other vapours, and foon occafions violent motions in the atmofphere, and becomes entombed in the aqueous particles, and is with the rain brought down to the plants. Bitumen is pretty much of the fame nature with fulphur, and with it is found in great plenty in moft bodies, but in the moft remarkable manner, and in the greateft quantities, in pit-coal; yet not in equal quantities, as fome coals burn better than others, and confequently may contain more or lefs of thefe principles, which are apt to burn. Naptha is a kind of bitumen, and the only difference is, that it takes fire fooner than bitumen is obferved to do, and is not fo eafily quenched; and this facility of admitting the heating particles, which throw thefe inflammatory bodies into a fpeedy motion internally, is of great ufe in the different degrees of the plant's growth.

Maltha feems to be a fpecies of naptha; its properties, as they appear to common obfervation, are, that if it touches any thing, it fticks fo faft to it, as not eafily to be feparated; and water thrown on it in moderate quantities, does but the more inflame it, and earth alone is able to quench it. This valuable ingredient, when it defcends in the drops of rain, adheres very intimately to the internal parts of the foil, both in the fuperficies and the concave parts of the pores; and other defcents of rain increafe the motion of the internal parts of the particles of maltha, and thereby promote a fine dilatation in the tubular interftices of the fibres of plants, and duly contribute to the acceleration of that motion in them, which is neceffary to the different ftages of their growth and nourifhment. Before the fine parts of the maltha are in readinefs, or duly prepared by moifture, and their well regulated fermentation, and while it is waiting for the defcent of more rain, it is divefted of all internal motion, and confined as a prifoner, till the other requifites to the plant's welfare are properly affembled, and ready to perform their offices.

Thefe are the chief materials which give motion to plants, and of which the latter are found to confift, when they are analized, unfolded, or feparated into their component parts by chemiftry. The profeffors of that art call the volatile fpirits, fulphur, and faline particles, the active principles; becaufe thefe, when duly prepared, and exactly applied to the mouths of the fibres, become the fole agents, and by their continual motion, caufe the whole action of the plant.

The vapours thus raifed from the furface of the earth, become the original matter of all meteors, or heterogeneous fubftances, fit for the production of the vegetable world; and confequently an inftrument in the wife appointment of Divine Providence, for the prefervation of man, and all fubordinate animals. When thefe heterogeneous vapours are thus lifted up above the earth, one degree of cold condenfes them into larger globules, which then becoming fpecifically heavier than the atmofphere, fall in drops of rain, and bring down all thofe treafures entombed in them. A greater degree of cold produces a coagulation of the heterogeneous vapours, which fhoot like

like falts into various forms, united into certain angles, and make the flakes of fnow, which ftill contain the nutritive principles.

A third, or ftill greater degree of cold, combines the vapours into a harder fubftance, wherein the valuable ingredients are intombed, and they defcend in what we call hail; but if the cold condenfes the vapours before they rife high above the furface of the earth, they will be unable to afcend, but will hover about, and fill the lower part of the atmofphere with what is ufually called a fog, or mift; and if the cold be ftill more intenfe, the mift is frozen to every twig and blade of grafs in form of a white incruftation, which is called rime. When the air in the day-time is warm, and the vapours buoyed up in it are too fine to be then vifible, they will be condenfed by the coolnefs of the evening, and defcend on the vegetables in the form of dew: and if the evening of fuch a fine day be cold enough to freeze, then inftead of a dew, the furface of the ground will be covered with what is commonly called a white froft. Thefe are the various ways appointed to bring down again upon the earth the treafures that were taken from it, in order to be prepared and properly fpread over the globe, by methods and contrivances equally beautiful and furprizing; and all this for the fupply of needy man, who is, when thefe bleffings are for a confiderable time withheld from him, turned to deftruction.

But amongft the riches of the atmofphere for the production of vegetables, we muft not forget the confequences which the air itfelf is of to them, as we have already obferved under the article air. *See* AIR. *Randall's Semi-Virgilian Hufbandry.*

AVENUE, a walk planted on each fide with trees, leading to an houfe, wood, &c.

The Englifh elm will do in all grounds, except fuch as are very wet and fhallow; and this is preferred to all other trees, becaufe it will bear cutting, heading, or lopping in any manner, better than moft others. The rough or fmooth Dutch elm is approved by fome, becaufe of its quick growth; this is a tree that will bear removing very well; it is alfo green almoft as foon as any plant whatever in fpring, and continues fo as long any, and it makes an incomparable hedge, and is preferable to all other trees for lofty efpaliers. The lime is valued for its regular growth, and fine fhade: the horfe chefnut is proper for all places that are not too much expofed to rough winds. The common chefnut will do very well in a good foil, and rifes to a confiderable height, when planted fomewhat clofe, though, when it ftands fingle, it is rather inclined to fpread than grow tall. The beech is a beautiful tree, and naturally grows well with us in its wild ftate, but it is lefs to be chofen for avenues than the before-mentioned, becaufe it does not bear tranfplanting well, but is very fubject to mifcarry. Laftly, the abele is fit for any foil, and is the quickeft grower of any foreft-tree. It feldom fails in tranfplanting, and fucceeds very well in wet foils, in which the others are apt to fail. The oak is but little ufed for avenues, becaufe of its flow growth.

The old method of planting avenues was with regular rows of trees, and this has been always kept till of late; but we have now a much more magnificent way of planting avenues: this is by fetting the trees in clumps or platoons, making the opening much wider than before, and placing the clumps of trees about three hundred feet diftant from an one other. In each of thefe clumps there fhould be planted either feven or nine trees; but it is to be obferved, that this is only to be practifed where the avenue is to be of fome confiderable length, for, in fhort walks, this will not appear fo fightly as fingle rows of trees. The avenues made by clumps are fitteft of all for parks. The trees in each clump fhould be planted thirty feet afunder, and a trench fhould be thrown up round the whole clump, to prevent the deer from coming to the trees to bark them. *Miller's Gard. Dict.*

AVER, a general name for a labouring beaft of any kind.

AVERAGE, a term ufed by the farmers of many parts of England for the breaking up of corn fields; otherwifed called eddifh, or roughings.

AVER-CORN, a name formerly given to the corn conveyed to the lord's granaries by his tenants.

AVER-LAND, the land ploughed by the tenants for the ufe of their lord.

AUGUST, the eighth month of the civil year.

This month returns the countryman's expences into his pockets, and encourages him to another year's adventure. If it proves dry, warm, and free from high winds, it faves a great deal of the hufbandman's expence.

You may yet twifallow, alfo lay on your compoft or foil, as well on your lands intended either for barley or wheat.

Carry wood, or other fuel home, before winter approaches, and renders the roads deep and heavy.

Provide good feed, and well picked, againft feed-time.

Put your ewes and cows you do not like to fatten.

This is generally the principal harveft-month for all forts of grain, therefore make the beft ufe of good weather while you have it.

About the end of this month you may mow your after-grafs, and alfo clover, faintfoin, and other French grafs. Geld lambs, and make the fecond return of your fat fheep and cattle. *Mortimer's Hufbandry, vol.* II.

AUGRE, an inftrument much ufed by carpenters, wheelrights, &c. for boring large round holes. It confifts of a wooden handle and an iron blade, terminated with a fteel bit.

A common augre may be very ufefully applied to try the nature of the under foil, and layers of earth, in order to know what may be expected from them, with regard to the vegetation of plants. In order to this three augres will be neceffary; the firft of them about three feet long; the fecond fix; and the third ten. Their diameters fhould be near an inch, and their bits large, and capable of bringing up part of the foil they pierce. An iron handle fhould be fixed crofs-ways to wring it into the earth; from whence the inftrument muft be drawn up, as often as it has pierced a new depth of about fix inches, in order to cleanfe the bit, and examine the foil. But the borer, an inftrument invented by the marquis de Tourbilli, is much better adapted to this operation. *See the article* BORER.

AVIARY, a place fet apart for the feeding and propagating birds. An aviary fhould be fufficiently large as to allow the birds a confiderable freedom of flight; and turfed, to avoid the appearance of foulnefs on the floor.

AUMBRY, *Ambry*, or *Aumery*, a pantry, or cupboard to fet victuals in.

AURICULA, the name of a plant, which has of late years been cultivated with extraordinary care and pains by the curious in gardening, being highly efteemed for its producing a very beautiful flower, which is diverfified of a greater variety of colours, and exhibits more properties to complete the idea of the fancy of a florift, than any other fpecies of the flowery tribe.

The characters of a good auricula are the following: 1. The ftem of the flower fhould be lofty and ftrong. 2. The foot-ftalk of the fingle flower fhould be fhort, that the umbel may be regular and clofe. 3. The pipe, or neck of each flower fhould be fhort, and the flowers large, and regularly fpread, being no ways inclinable to cup. 4. The colours fhould be very bright, and well mixed. 5. The eye of the flower fhould be large, round, and of a good white or yellow; and the tube, or neck, not too wide.

In order to obtain good auriculas from feeds, you muft make choice of the beft flowers you have; which fhould be expofed to the open air, that they may have the benefit of fhowers, without which they feldom produce good feeds. The time of their ripening is in June or July, which you may eafily know by the feed-veffel turning to a brown colour, and opening; you muft therefore be careful left the feeds be fcattered out of the veffel, for it will not be all fit to gather at the fame time.

The general time for fowing this feed is in Auguft, but if it be fown before Chriftmas it will be time enough.

The beft foil for this feed is good frefh fandy mould, mixed with very rotten neats dung, or very rotten dung from

from the bottom of an old hot-bed: with this you ſhould fill your pots or boxes in which you intend to ſow your ſeeds; and having levelled the ſurface of the earth very ſmooth, ſow your ſeeds thereon, covering it very lightly with rotten willow mould, taken out of the ſtems of decayed hollow willow-trees; then cover the box, &c. with a net or wire, to prevent the cats, fowls, &c. from ſcratching out, or burying your ſeeds too deep. Let theſe boxes, &c. be placed ſo as to receive only the morning ſun, during the winter ſeaſon; but in the beginning of March remove them where they may have ſcarce any ſun, for your plants will now ſoon begin to appear; and if expoſed to one whole day's ſun, would be all deſtroyed.

During the ſummer ſeaſon, refreſh them often with water in dry weather, but never give them too great great quantities at once. In the month of July following, your young auriculas will be large enough to tranſplant, at which time you muſt prepare a bed or boxes, filled with the above-mentioned ſoil, in which you may plant them at about three inches diſtant; and, if in beds, you muſt ſhade them every day, till they are thoroughly rooted, as alſo in very hot dry weather; but if they are in baſkets or boxes, they may be removed into a ſhady place.

When the ſeedling auriculas are planted in beds, there ſhould be ſome rotten neat's dung laid about ten inches under the ſurface, and beaten down cloſe and ſmooth: this will prevent the worms from drawing the young plants out of the earth, which they generally do where this is not practiſed. This dung ſhould be laid about a foot thick, which will entirely prevent the worms getting through it, until the plants are well eſtabliſhed in the beds; and the roots of the auriculas will ſtrike down into the dung by the ſpring, which will make their flowers ſtronger than uſual: theſe beds ſhould be expoſed to the eaſt, and ſcreened from the ſouth ſun.

The ſpring following many of theſe flowers will ſhew; when you may ſelect ſuch of them as have good properties, which ſhould each of them be removed into a ſeparate pot of the ſame prepared earth, and preſerved until the next ſeaſon, at which time you will be able to form a judgment of the goodneſs of the flower; but thoſe that produce plain coloured, or ſmall flowers, ſhould be taken out and planted in borders, in the outparts of the garden; and the others which do not produce their flowers the ſame year, may be taken up, and tranſplanted into a freſh bed, to remain till you ſee how they will prove.

The manner of propagating theſe flowers when obtained, is from off-ſets, or ſlips, taken from the old roots in April, when the flowers are in bloom: theſe off-ſets muſt be planted into ſmall pots filled with the ſame ſort of earth, as was before directed for the ſeedlings; and during the ſummer ſeaſon ſhould be ſet in a ſhady place, and muſt be often, but very gently, refreſhed with water. In the autumn and winter they muſt be ſheltered from violent rains. The ſpring following theſe young plants will produce flowers, though weak; ſoon after they are paſt flowering, you muſt put them into large pots, and the ſecond year they will blow in perfection. *Miller's Gard. Dict.*

AWMS, the beard of wheat or barley. The word is, in ſome parts of England, pronounced *ails*.

AXIS, or *axle-tree*, of a waggon, cart, &c. is the ſtrong piece of wood or iron, which ſupports the carriage, and round the extremities of which the wheels turn. *See the articles* CART *and* WAGGON.

B.

BACK-SINEW, in a horſe, is that ſtrong ſinew extending along the hinder part of the ſhank from the knee to the heel, into which it is inſerted.

The back-ſinew is ſo very ſubject to be hurt or ſtrained, that it is conſidered as one of the moſt common and uſual accidents that happens to a horſe; it generally proceeds from hard riding upon dry grounds, and from other cauſes, where the roads are ſtony and hard, and ſometimes where they are poachy.

It is eaſily perceived by the ſwelling of the ſinew, which ſometimes extends from the knee down to the heel; and when it is ſo, a horſe does not care to ſet his foot even upon the ground; but, for the moſt part, in his ſtanding, ſets it before the other.

The uſual way of curing this malady, is with cold charges, which often ſucceed very well, if often renewed; ſome uſe curriers ſhavings bound round the knee with a bandage, and this alſo anſwers very well in ſome caſes; but there is nothing either ſo ready or efficacious as vinegar or verjuice mixed with bole, being often in a day ſoaked well into the ſinew warm; and if any thing of the lameneſs or ſwelling remains after this, and after the heat and inflammation is gone off, a mild bliſter, that has nothing corroſive in it beſides the cauſtic ſalt of the flies, will, generally ſpeaking, effectuate a cure, and bring the ſinew fine.

When hot and relaxing oils mixed together are uſed to the back-ſinew, which many practitioners are fond of, becauſe they ſometimes ſucceed in horſes that have their ſinews ſtrong and rigid, yet they are apt to engender wind-galls of a bad kind, or make the veins on each ſide the ſinew to be full and gorged; and horſes have been known to be lame for two or three years together with theſe varixes in the veins. Bliſtering in this caſe has very little or no effect, firing through the vein till the blood comes being only ſufficient to remove that weakneſs. After the firing, the whole leg from the knee down to the heel, and all the hollow places on both ſides, muſt be charged with a good ſtrengthening plaiſter, which will perfect the cure, eſpecially if the horſe be turned to graſs for a month or five weeks, or, in the winter, if he run a little while in a ſmooth yard, where he has good dry litter. *Gibſon on the Diſeaſes of Horſes.*

BACON, the fleſh of a hog dried in the ſmoke.

A writer in the *Muſeum Ruſticum*, vol. III. pag. 234, has given us the following method of making bacon in Somerſetſhire.

The ſeaſon for killing hogs for bacon is between September and Chriſtmas. When you kill a large hog for bacon, lay the ſides in the ſalting-troughs, and ſprinkle them pretty heavily with bay-ſalt: then leave them twenty-

twenty-four hours to drain away the blood, and fome of the over abounding juices.

After this take them out, wipe them very dry, and throw away the drainings. Then take fome frefh bay-falt, and heating it well in a large iron frying-pan, rub the meat very well with it; repeating this work every day for four days, and turning the fides every other day.

If the hog be large, keep the fides in brine (turning them ten times) for three weeks; after which take them out, and let them be thoroughly well dried in the ufual manner: if they are not fully dried, they will neither keep fo well, nor eat fo fine.

BADGER, the name of an animal, common in many parts of England; and called by feveral names, as a gray, a brock, a borefon, or a baufon.

Badgers are almoft as pernicious a creature to the hufbandman as the fox, though not fo fubtile, nor can they fo eafily catch their prey; but for what they can catch, as new fallen lambs, young pigs and poultry, they are as bad. The way to catch them is with a fpringe, or a fteel trap, or to dig a pit acrofs their path five feet deep, and about four feet long, making it narrow at the top and bottom, and wide in the middle. This muft be covered with fome fmall fticks and leaves, fo as that the badger may fall in when he comes upon it. Some hunt them into their holes in a moon-fhine night, and then dig them out. *Mortimer's Hufbandry, vol.* I. *pag.* 314.

BAG, a name given by farriers to a medicine for recovering a horfe's appetite when loft. It is done in this manner: they take an ounce of affa fœtida, and an equal quantity of the powder of favin; thefe ingredients they put into a bag, which they faften to the horfe's bit, keeping him bridled for two hours, two or three times a day: as foon as the bag is taken off, he will immediately eat. The fame bag will ferve a long time.

BAKING *of land.* If fome forts of ftiff and binding land be fown dry, and a fcudd of rain falls before the earth has time to fettle, it is obferved that the cruft of fuch land will bake, fo that the corn cannot come through, to the great damage of the crop; this evil does not happen if fuch a fcudd of rain be followed by cool cloudy weather, and not hot fun-fhine; for then the earth will not lie fo hollow as to be baked. The beft way to prevent this is, to roll it immediately after fowing, which faftens the earth together, whereby the fun has not that power of piercing into it, and confequently not of baking it.

Land of this kind fhould, therefore, be fown as often as poffible with winter corn, fuch as wheat and vetches; for though, if wet follows the fowing, the fun is not ftrong enough at that time of the year to fcorch the ground up, and bind it; and it is obferved, that this fort of ground has been always lucky for vetches, probably for the above reafon. *Lifle's Obfervations in Hufbandry, vol.* I. *pag.* 26.

BALK, a piece of land which has been either cafually overflipped, or not turned up in ploughing; or carefully left untouched by the plough, for a boundary between lands, or fome other ufe.

BALK, alfo fignifies the fummer-beam, or dorman of a houfe.

BALKS, or *bawks*, implies poles laid over a ftable, or other building, for a roof.

BALM. *See the article* BAUM.

BANDS, a fmall parcel of the longeft wheat taken from the grips, and twifted together at the ear ends, for binding the wheat into fheaves.

The bands fhould be laid in the morning, that they may not crack; for the ftraw will not twift after the fun is up, but will be brittle, and break off below the ears. The turning of three or four of the ftubble or bottom ends of the ftraw to the ears of the band, helps greatly to add to its ftrength and toughnefs.

The bands for binding up the fheaves fhould not be fpread but in fair weather, becaufe being preffed down by the grip or two which it is neceffary to lay upon them to keep them in their places, and prevent their being untwifted by the fun, they will grow fooner than any other part of the corn, if rain fhould come; for they cannot dry on account of their lying undermoft. But though the bands muft always be made while the morning dew is upon them, the fheaves ought by no means to be bound up wet: if they are, they will certainly grow mouldy.

Farmers do not always attend fufficiently to the binding up of their fheaves, but fuffer the reapers, for difpatch, to tie the bands juft underneath their ears, inftead of binding them at the other end; the confequence of which is, that they will hardly hold together to be flung into the cart, and will certainly be in great danger of falling to pieces before they are thrafhed.

If a little rain be forefeen in harveft time, it is beft to bind the grips into fheaves as faft as they are made; becaufe fmall fhowers will wet the fingle grips fo much, that they cannot be bound up, and thefe fhowers may be the fore-runners of greater rains. The fheaves being bound will foon dry after fuch wet. But if a hard rain is forefeen, the beft method is not to bind the wheat into fheaves, becaufe they will then be wet to the bands, and muft be opened again. Mr. Lifle tells us, that one of his neighbours to whom this happened, unfheafed fome of his wheat to dry it, and opened it and turned it fo often, that the ears broke off, whereby he loft half his corn; caution therefore ought to be ufed in this cafe, left by curing one evil we create a worfe. *Lifle's Obfervations in Hufbandry, vol.* I. *pag.* 333.

BANDS *of a faddle* are two pieces of iron, flat, and three fingers broad, nailed upon the bows of a faddle, one on each fide, contrived to hold the bows in the fituation that makes the form of a faddle.

BANE, in fheep, the fame with rot. *See the article* ROT.

BANGLE-EARS, an imperfection in a horfe, which may be remedied in the following manner: place his ears as you would have them ftand, and then with two little boards, or pieces of trenchers, three fingers broad, having two long ftrings faftened to them, bind the ears fo faft in the places where they ftand, that they cannot ftir; then behind the head, and the root of the ears, you will fee a great deal of empty, wrinkled fkin, which you muft pull up with your finger and thumb, and clip away with a pair of fharp sciffars all the empty fkin clofe by the head; then with a needle and red filk, ftitch the two oufides of the fkin together, and heal the wound with a mixture of honey and turpentine: when this is done, take away the fplints that hold up the ears, and in a little time they will keep the place where you fixed them without alteration.

BANK, a heap of earth piled up to keep out the water of a river, lake, or the fea.

Sloping banks are the beft fecurity againft the incroachments of the fea, of rivers, or of lakes; making proper allowance for the weight of water, and violence of the waves. Thefe banks fhould be raifed about two feet above the level of the water at the higheft tides, and their ftrength fhould be proportioned to the force of the water intended to be fenced off. When a river is too much confined, it fwells confiderably upon a flood, and confequently requires banks of greater height and ftrength than would otherwife be neceffary; though it will fometimes break even thefe, and carry all before it, if a fufficient fpace be not allowed for the increafe of its water: but when fuch a fpace is left, the waters fpread, and feldom rife more than two or three feet above their ufual level. In fome cafes a breadth of fifteen or eighteen feet, on each fide may do; but in others, fifty, eighty, or an hundred feet, or perhaps fo many yards, according to the largenefs of the river, muft be left open for that purpofe. It is beft to err on the fafe fide; efpecially as the ground that is left between the banks and the river will be far from being loft; for it will afford good grazing in the dry feafons of the year, and may be planted with ofiers, and willows, and other trees of that kind; but thefe fhould never be planted upon the banks, left the winds fpoil and tear them, by fhaking the trees, and loofening their roots.

In the ifle of Ely, it is common to fee great banks diftant one or two hundred yards on each fide from the channel of the river; and when they are fo made, they are always fafe: but where the diftance between the banks is narrow, there, and there only, the banks are in in danger of being broken down, and the country of being overflowed.

If a confiderable body of water is to be guarded againft, dig a trench ten or twelve feet wide, and two or three deep, or more, according to the height of the bank required. Lay all the foil that is taken out of this trench, on that fide of it which lies towards the water, and leave a fpace of two or three feet between the trench, and the foot of the bank. Let the bank be made with an eafy flope of fifteen or eighteen feet in length towards the water, allowing the flope two and a half, or three feet fall to one in height; but the infide flope need not be more than eight or nine feet, which is a foot and a half flope to one foot perpendicular. The bank thus raifed five or fix feet high, according as the floods require, will be two feet wide at the top, where it fhould be well flatted, that people may walk upon it. Let it then be covered with gravel dug out of the channel of the water, by which means the river will be deepened, and the bank rendered ftronger; and to add to the latter, fow it very thick with grafs-feed. This will be found much better than turfing it with fods taken from off the trench, or fome neighbouring ground; becaufe the fods are apt to fhrink, open, and part from one another in dry weather, and are then liable to be wafhed away with the next flood; whereas in this much cheaper way, a clofe covering of grafs, even long enough to mow, will be formed in a month or two: far fitter than fods to break the furface of the bank; for any tolerable foil may be very foon brought to have a coat of grafs, by only raking it fine, and fowing it with grafs-feeds. In a week or ten days in the fpring, or fummer, the grafs will be up, and grow to fuch a height in a month or fix weeks, as to be fit for mowing.

Some have attempted to guard againft inundations by building walls of ftone and lime, where the materials are in plenty. The great danger here is their being undermined, and that chiefly by the water's ftriking with force againft the bottom, upon meeting with refiftance from the wall. But this may be eafily guarded againft by laying a row of flat ftones lower than the bottom of the river; for the water ftriking againft thefe ftones, turns off without any danger to the foundation.

The broad trench within the bank, befides affording materials for making the bank and flopes, is attended with the farther advantage of ferving for a drain to the inland ground. Thefe trenches fhould always be carried as far as the banks, particularly when thefe are intended to fence off a rifing tide; and in the loweft part of the ground a fluice with a valve, flap-door, or flood-gate fhould be placed in the bank, where it will both difcharge the inland water, when the tide is out, and prevent its flowing in. The feafon of the year freeft from floods fhould be chofen for making thefe banks, that the bank may have time to fettle and grow firm before the heavy rains come on. It is alfo advifable to be as expeditious as poffible in this work. For if it be begun in a dry fummer, and finifhed in a month or two, there will be little danger of being interrupted by extraordinary floods or violent ftorms, either of which might do more harm in one day, than could be repaired in a fortnight.

The exact dimenfions of the bank, and of the ditch within it, cannot be precifely afcertained by any general rule; becaufe both tides and floods rife to different heights, and have different force, in different places and circumftances. The ftrength above-mentioned may be fufficient for banks in common cafes; but in others, where a great body of water, or a powerful tide is to be oppofed, they may be, as the memoirs of the Berne Society (*tom.* II. *part* II. *pag.* 262) advife, four feet or more wide at the top, with a bafis proportioned to their height, as three and a half are to one; or, if it be defired to make them ftill more folid, as four to one; fo that if the bank be four feet and a half high, its bafis in the former cafe will be fourteen feet wide, and in the latter eighteen.

The Dublin Society for the advancement of agriculture informs us (Numb. XVII. *for April* 1737) that "Lord Limerick has recovered between four and five hundred acres of very rich falt marfh, at Dundalk in Ireland, and effectually fecured them from the fea, by fuch banks as are above defcribed; and by the fame method many hundred thoufand acres have been recovered from the fea in Cambridgefhire, Lincolnfhire, and other parts of England; not to mention the low lands of Holland; which are indeed fecured againft the violence of the fea by no other means.

"If there be a neceffity for making banks on a ftrand where nothing but fand can be met with, thofe banks fhould be large, and the flope very broad and extended; and if grafs-feed will not grow on them, let fea-weeds be planted. Thefe with fticking furze, ftraw, or loppings of trees, will help to keep the banks together."

But a better method, and more effectual, is given by Dr. Hales in the Philofophical Tranfactions, from the experience of Dr. Wark, a clergyman in Scotland. The method confifts in fixing to the bottom of the channel, a breadth of furze proportioned to the force it is to refift. The fand or flime, as either abounds, will foon fettle among the branches of the furze; and when the firft bed of the furze is thus interwoven or covered, another bed of furze is to be laid on as before, and fo on, till the bank is raifed to a fufficient height. Dr. Wark affures us, that by this fimple method a bank was made near Holy-ifland fo ftrong, that it became a bar againft the fea itfelf.

"It fometimes happens, that the fea flows in through a narrow gut or paffage, by which the inland waters are difcharged, and then extends itfelf, and covers a great deal of ground. When this happens, if the inland waters cannot be diverted into another courfe, fince a paffage muft be left for their difcharge; let a ftrong fluice be fixed in the loweft part of the channel, with large piers of ftone, running out for its fupport, and a ftrong foundation of wood or broad ftones for the water to run over.* When this is done, let the banks of fand, or other foil near at hand, be made in the manner already mentioned, on each fide of the fluice.

"The reafon why it is advifed, in places where a fluice is to be made, to begin the work by this rather than by the bank, is, that while the tides have liberty to flow in and out at a great breadth, the fluice may be made in any part of the channel without being much incommoded by the tide; whereas if it be deferrred till the banks on each fide are made, the force of the tide, when confined to a narrow paffage, will tear up all before it, and render the building of the fluice impracticable: and upon the fame account, the banks fhould be begun at the loweft part of the channel, and carried on from thence to the upper grounds.

"If, by any accident, the waters fhould fwell fo high as to overflow and tear the banks, farther mifchief may be prevented by fixing with all expedition, a fail-cloth, or fheet of linen at the bottom of the bank, where the flood breaks in; for if this be done in time, the water will flow over the cloth, without wafhing away the bank.

"In every improvement, the expence fhould be particularly confidered. That of making banks in this method is fmall. In low grounds the foil is foft, and dug with eafe, and all the work may be done with the fpade and fhovel, without pick-axes, which muft be ufed in upland ground; and the materials are on the fpot. All the charge will be often more than repaid by the firft years improved crop of grafs, and the fafety of the meadows. The produce of fucceeding years will amount much higher, and the hufbandman will be out of all danger for the future of having his lands overflowed and fpoiled. Farmers have frequently fuftained more damage from the hay deftroyed in one feafon by floods, than the whole value of what it would have coft them to inclofe and bank their meadows, and free them from all hazards."

BANNOCK, an oat-cake kneaded with water only, and baked in the embers.

BANQUET, is that fmall part of the branch of the bridle that is under the eye, which being rounded like a fmall rod, gathers and joins the extremities of the bit to the branch, and that in fuch a manner, that the banquet is not feen, but covered by the cap, or that part of the bit which is next the branch.

To BAR *a vein*, implies an operation in farriery performed in the following manner: they open the ſkin above and below the place where the operation is to be performed, and after freeing the vein from the ſurrounding parts, they tie it at thoſe openings with two ligatures; after which they open the vein between the ligatures in order to diſcharge the blood. This operation is performed upon the veins of a horſe's leg, and other parts of his body, in order to ſtop the courſe, and leſſen the quantity of malignant humours that prevail there.

BARB, a general name for horſes imported from Barbary.

The cheſt of the barb is long and ſlender, riſes beautifully from the withers, his mane little, his head well ſhaped, ſmall, and lean; his ſhoulders flat and ſlender; his withers narrow and plump; his back ſtrait and ſhort; his flanks and ſides round, and not bellying out; his haunches firm and well ſhaped; his croup generally ſomewhat long, and his tail placed pretty high; his thigh well ſhaped, and ſeldom flat; his legs handſome, well ſhaped, and without long hair at the paſtern joint; his foot well made, but his paſtern often long.

Barbs are of all colours, but generally brown. They are ſomething negligent in their goings; but, properly encouraged, ſhew an amazing ſwiftneſs and vigour: they are very light and fit for running; and ſeem of all others the fitteſt to breed from. It were, however, to be wiſhed that they were a little taller, the largeſt rarely exceeding fourteen hands; and one of fourteen hands and an inch, is very extraordinary. Experience has, however, ſhewn, that in England, France, &c. they get colts larger than themſelves. Among the barbs, thoſe from the kingdom of Morocco are accounted the beſt, except the mountain barbs. Thoſe of the reſt of Mauritania are inferior to them, as are alſo thoſe of Turkey, Perſia, and Armenia. All horſes from a hot climate have a ſmoother coat than others. *Buffon's Hiſtoire Naturelle, tom.* IV.

BARBELS, or *barbs*, are excreſſences or knots of ſuperfluous fleſh, growing under the tongue, and may be ſeen by drawing it aſide.

They are cured by cutting them cloſe off, and waſhing the wounded part with brandy, or ſalt and water. *Bartlet's Farriery, pag.* 262.

BARBERY, or pipperidge-buſh, a ſhrub that grows naturally in the hedges in many parts of England; it is alſo cultivated in gardens for its fruit, which is pickled, and uſed for garniſhing diſhes. This ſhrub riſes with many ſtalks from the root, to the height of eight or ten feet. The flowers appear in May, and the fruit ripens in September.

Theſe ſhrubs are propagated either by ſuckers, of which there are plenty about the old roots, or by layers.

The beſt time for laying down the branches, is in the autumn, when their leaves begin to fall; the young ſhoots of the ſame year are the beſt for this purpoſe. Theſe will be rooted by the next autumn, when they may be taken off, and planted where they are deſigned to remain. *Miller's Gard. Dict.*

A fooliſh ſuperſtition has for many ages prevailed among the farmers in many parts of England, namely, that a field of corn will always be blaſted, if a barbery-ſhrub grows in any one of the hedges that ſurround it. But theſe ridiculous notions are now pretty well baniſhed from the generality of our huſbandmen, and it is hoped the reſt will ſoon follow their example.

BARBS. *See the article* BARBELS.

BARG, a horſe-way up a ſteep hill.

BARING *of trees. See the article* ABLAQUEATION.

BARK, the exterior part of trees, ſerving them for a ſkin or covering.

Dr. Agricola ſays, that the bark of a tree may be compared to the ſkin of an animal, which is deſigned for the preſervation of the inward parts. It is generally of a ſpongy texture, and communicates with the pith, by a multiplicity of ſmall fibres paſſing between the capillary tubes, of which the wood conſiſts; ſo that the roots having imbibed the proper nutriment of the tree, it is carried up by the warmth of the ſun, through the fine arterial veſſels of the tree to the top of it; and being there condenſed by the cold, it returns by its own gravity down by the veſſels which lie between the wood and the inner bark, which perform the office of veins; and as it paſſes by leaves ſuch part of its juices as the texture of the bark will receive, and requires for its ſupport.

Some are of opinion, that the ſoft whitiſh rind, or ſubſtance which lies between the inner bark and the wood, performs the office of veins; and ſome call this a third bark, ſuppoſing it to differ from the other only in having its fibres cloſer; adding that this is the part which contains the liquid ſap, gums, &c. found in plants during the ſpring and ſummer months, and which hardening by degrees, is imperceptibly conveyed into the woody part of the tree, forming every year a new circle of wood between the bark and the trunk. Theſe circles are not equally thick, that circumſtance depending on the fertility of the year.

The bark of trees in general, and eſpecially that of the oak, contains a very rich ſalt, extremely uſeful in vegetation. One load of oak bark laid in a heap and rotted, after the tanners have uſed it for dreſſing their leather, will do more ſervice to ſtiff cold land, and its effects will laſt longer, than two loads of the richeſt dung. Mr. Miller ſays it is much better for cold, ſtrong land, than for light, hot ground, if it be uſed alone, as taken from the tan-yard; becauſe it is of a warm nature, and will looſen and ſeparate the earth ſo effectually, that, by only uſing it two or three times, a ſtrong ſoil, not eaſy to be wrought, will be rendered perfectly light and looſe: but by mixing it with earth of a nature contrary to that which it is intended to correct, and in a proportion ſuited to the nature of the ſoil it is to be laid on, it will prove a fine manure for almoſt any land; its ſalts being ſuch as will always fertilize the ground. Mr. Mortimer aſſerts, that it will alter and change the very nature of the ſoil, and turn it into a very rich black mould. *Mortimer's Huſbandry, vol.* I. *p.* 121.

It neceſſarily abounds in vegetable parts, derived from the tree to which it once belonged; and cannot but be ſtrongly impregnated with animal juices, as it lies a long time in the tan-vats, with the ſkins and hides of animals: circumſtances which muſt render it ſingularly beneficial to all poor lands.

If laid on graſs, it ſhould be ſpread ſoon after Michaelmas, that the winter rains may waſh it into the ground: for if it be laid on in the ſpring, it will be apt to burn the graſs, and, inſtead of improving, will do it a conſiderable injury for that ſeaſon. When uſed for corn land it ſhould be ſpread before the laſt ploughing, that it may be turned down for the fibres of the corn to reach it in the ſpring; for if it lies too near the ſurface, it will forward the growth of the corn in winter; and in the ſpring, when the nouriſhment is chiefly wanted to encourage the growth of the plants, it will be ſo nearly conſumed, that the corn will receive very little advantage from it.

Mr. Bradley tells us, that he adviſed a gentleman to whom a conſiderable quantity of bark was left upon the extirpation of the leaſe of a tan-yard, to lay ſome of it upon a piece of ſtubborn four land, which he did with ſuch ſucceſs, that his product was admired by all the gardeners and farmers in the neighbourhood. For ſuch ground, he thinks it ſhould be mixed with a ſandy ſoil; and that one third of bark to two thirds of ſand, will be a very ſufficient proportion for clays; laying on about one hundred and fifty cart loads upon an acre. *Bradley's Huſbandry, pag.* 90.

All barks or rinds of trees, though not of ſo high a value as that of the oak, which is the ſort principally uſed by tanners, muſt of neceſſity enrich either corn or paſture ground, if broken into ſmall pieces, and laid upon it. They muſt needs be much richer than the mould or earth, uſually found in the bodies of old, large, hollow, willow-trees, though this is juſtly eſteemed very efficacious. *Worlidge's Huſbandry, pag.* 84.

For the manner of making hot-beds with tanner's bark, *ſee the article* TAN.

BARK-BOUND, a diſeaſe common to fruit-trees, and may be cured by making a ſlit through the bark, from the top of the tree to the bottom, in February or March; and if the gaping be pretty conſiderable, fill up the

the rift with cow-dung. *Mortimer's Husbandry, vol.* II. *pag.* 85.

BARKING *of trees*, the operation of ftripping off the bark or rind, particularly that of the oak, for the ufe of tanners.

It is neceffary in our climate to perform this operation in the month of May, becaufe at that feafon only, the bark is, by the great quantity of fap, feparated from the wood. This alfo renders it neceffary to fell the trees in that month; but by this method the timber is much lefs valuable than it would be if felled after the fall of the leaf.

BARLEY, a fpecies of grain well known in England, and of which Mr. Miller has enumerated four fpecies.

1. The fpring barley, which has a double row of beards or awms ftanding erect. This is the fort principally cultivated in England, and of which the farmers make two forts, viz. the common, and the rath-ripe barley: but thefe two forts are in reality the fame; for the rath-ripe is only an alteration of the common barley, occafioned by being long cultivated upon warm gravelly lands. The feeds of this, when fown in cold or ftrong land, will, the firft year, ripen near a fortnight earlier than the feeds taken from ftrong land, and therefore the farmers in the vales generally purchafe their feed barley from the warm lands; for if faved in the vales two or three years, it will become full as late in repening as the common barley of their own product: on the other hand, the farmers on the warm land are alfo obliged to procure their feed barley from the ftrong land, otherwife their grain would degenerate in bulk or fulnefs, which, by this change, is prevented. This fort of barley is eafily diftinguifhed by the two orders of beards or awms, which ftand erect; the rind is alfo much thinner, and therefore efteemed better for making malt.

2. The long-eared barley, which is cultivated in many parts of England, and is an exceeding good fort; but fome farmers object to this barley, becaufe they fay the ears being long and heavy, it is more apt to lodge. This fort of barley hath its grains regularly ranged in a double row, lying over each other, like the tiles on a houfe, or the fcales of fifh. It has no beards or awms; but its rind is very thin, and therefore efteemed for making malt.

3. The fprat barley, called alfo Battledore, Fulham, and Patney barley, from the great quantities cultivated in the neighbourhoods of thofe places, has fhorter and broader ears than either of the former forts; the awms or beards are longer, which tend greatly to preferve it from the bird, and the grains placed clofer together. This feldom grows fo tall as the other fpecies; the ftraw is alfo coarfer, and therefore not fo good fodder for cattle.

4. The winter barley, called alfo fquare-barley, bear-barley, or big, is feldom cultivated in the fouthern parts of England; but in the northern counties, and in Scotland it is the general fort fown, as being much hardier than the other fpecies. There are two forts of this barley, the one with four rowsof grains, and the other with fix, the latter of which is commonly diftinguifhed by the name of barley-big. The grain is large and plump, but the rind or chaff of it being thicker than that of either of the preceding forts, it is lefs efteemed for making malt, and therefore not cultivated in the fouthern parts of England, where the forts which are fo much better for that purpofe thrive fo well.

Both the four and fix rowed barley are generally fown in the autumn, nearly at the fame time with wheat, not only in temperate climates, but alfo in very cold countries; their hardinefs being fuch as to bear the winter's frofts, even in the mountainous parts of the northern regions. In hot countries they are fown in January, February, and March.

All the other forts are fown in the fpring of the year in a dry time; in fome very light land barley is fown early in March, but, in ftrong clay foils, not till April, and fometimes not till the beginning of May; but when it is fown fo late, if the feafon does not prove very favourable, it is very late in autumn before it is fit to mow, unlefs it be the rath-ripe fort, which is often ripe in nine weeks from the time of fowing: though Mr. Lifle is of opinion, that this, in particular, ought to be fown early, for otherwife it will grow very thin. He likewife thinks, that it fhould be fown on better ground than the other barley, becaufe as it ripens in a fhorter time it may be naturally fuppofed to exhauft the nutritive juices of the earth fafter than other corn. But it is faid by others, that thefe nutritive juices in almoft any tolerable foil, will probably hold out long enough to feed a crop of fo fhort a ftanding as this is, though they might not fuffice for corn which fhould remain longer upon the ground; and it is added, that about Patney in Wiltfhire, they fow the pooreft fandy ground with rath-ripe barley. *Lifle's Hufbandry, vol.* I. *pag.* 271.

Mr. Lifle adds, that he himfelf in the year 1707, fowed in Hampfhire, rath-ripe barley in very poor white ground, and fome of the fame corn in good ftrong clay land. No rain fell to bring it up till June; after which there were frequent fhowers, and plenty of rain till harveft. His rath-ripe barley in the poor land was miferably bent, broken in the ftraw, and harled, or fallen down. In the ftrong clay land, the fame corn fuffered the fame injuries, though in a lefs degree: but the ftraw and leaves of the rath-ripe barley in both places blighted, and were full of black fpecks; their ears were thin, and their colour was loft; while the plants of late-ripe barley in an adjacent field were free from thefe fpots, and ftood upright with good ftrength. From this experiment he infers, that fince the clay land in the hilly country of Hampfhire, though in good heart, cannot, even in a moift year, fufficiently feed the ftraw of rath-ripe barley, fo as to enable it to ftand upright, but fuffers it to be languid and withering, this fort of corn is not proper for fuch places, and that it is better to fow late-ripe barley, even though three or four horfes extraordinary be provided againft fowing time, in order to get the corn into the ground a week before May begins. *Lifle's Hufbandry, vol.* I. *pag.* 272.

Another important obfervation made on the fame occafion, by the fame judicious farmer, was, that one half of the feed which fell deep came up without rain, while the reft did not fprout till after the rain came. The half which came up firft, could not, by reafon of the weaknefs of the ftems, wait for the ripening of the latter edge-grown corn, in the fame field; but its ftraw bent, broke, and was entangled, and the ears buried themfelves among the broad clover fown with the barley, fo that he was forced to cut it; not being able to ftay a week or ten days longer for the edge-grown corn to ripen: whereas the late-ripe barley ftood fo upright in its ftraw, that the corn which came up firft would ftay ten days for the edge-grown corn.

The fame gentleman had another evident proof, in the year 1706, that the ftraw of the rath-ripe barley is thinner and weaker than that of the late-ripe. All his rath-ripe barley, of which he fowed fifty acres in different forts of ground, and fome of it fide by fide with late-ripe barley, crumpled down in the ftraw, while the late-ripe barley of the fame forwardnefs and growth, ftood upright.

Upon the whole, Mr. Lifle, after obferving farther, that, if the ground be good, and the year a feeding one, rath-ripe barley is apt to run rank, and to fall while very green in the ear, which occafions the grain not to fill; concludes, in regard to this fort of corn, that it fhould always be fown early, that the land fhould not have a north expofure, and that the foil in which it is planted fhould be pretty good, either naturally fuch, or rendered fo by art; "for we know, fays he, that the poorer the ground is, the weaker and poorer the ftraw will be in all forts of corn; and if the rath-ripe barley has by nature a weaker and thinner ftraw than the late-ripe barley, and on that account is apter to crumple, to bend down, and to break in the ftraw before it is ripe; much more will it be apt to do fo, when the ftraw is made much thinner and weaker than naturally it would be, by the poverty of the ground it is fown in. It is very evident to me, that rath-ripe barley ought not to be fown on poor ground, and much lefs fo in cafe it lies declivous from the fun towards the north." *Lifle's Hufb. vol.* I. *p.* 273, 274.

The

The middle-ripe barley, as Mr. Liſle calls it, meaning the common ſpring barley, bears late ſowing, even upon ground declivous from the ſun, better than the rath-ripe ſort; but not near ſo well as the late-ripe, or common long-eared barley; nor will its ſtalk ſtand ſo long. Mr. Liſle was convinced from experience, that late-ripe barley will endure being ſowed when the ground is wetter than will do for the rath-ripe ſort, and that a bottom ground, or vale pent in between two hills, though ſhaded by one of them from the ſun, will, by means of the warmth and cloſeneſs of the air, often ripen corn as faſt as the ground that lies declivous to the ſun. In a field which he ſowed with the common ſpring barley, the loweſt part of which laid on a flat, ripened regularly, and even ſooner than another part of the ſame field which lay upon the ſide of a hill declivous to the ſun: but on that ſide of the ſame hill which ſloped from the ſun, the corn was more edge-grown, lay backward, and neither looked ſo white, nor was it ſo ripe. *Liſle's Huſbandry, vol.* i. *p.* 275.

The land which lies both very dry and healthy, and in which both mellowneſs and lightneſs are joined to a proper ſtrength of ſoil, is that which produces the beſt body, and thinneſt rinded barley; qualities which always recommend this grain, eſpecially to the maltſters. Such generally is the barley of the growth of the hilly countries. But poverty of ſoil is by no means requiſite in land, in order to its producing a plump and thin rinded barley: though it is allowed, that poor land which lies dry and warm, will bear better corn of this kind, than rich land in a cold and wet ſituation: for barley does not ſtand ſo much in need of ſtrength in the land, as of the healthineſs and warmneſs of the ſoil; though both are beſt where they can be had. *Liſle's Huſb. vol.* i. *p.* 281.

With regard to the choice of ſeed-barley, it is neceſſary to obſerve, that the beſt grain for ſowing is that which is not blackiſh at the tail, nor has a deep redneſs, but is of a pale lively yellow colour, intermixed with a bright whitiſh caſt, and if the rind be a little ſhrivelled, it will be ſo much the better; for that ſlight ſhrivelling occaſioned by its having ſweated in the mow, is a ſure indication that its coat is thin. The huſk of thick rind barley being too ſtiff to ſhrink, will lie ſmooth and hollow, even when the inſide flour has ſhrunk from it.

The neceſſity of a change of ſeed from time to time, by ſowing that of the growth of a different ſoil, is no where more evident than in the culture of this grain, which otherwiſe becomes coarſer and coarſer every year. But at all times in this, as well as in all other grain, the utmoſt care ſhould be taken that the ſeed be full bodied.

Mr. Liſle tells us, that in order to be ſatisfied of this, he took out of a heap of barley ſixty grains, of different ſizes, viz. twenty of the biggeſt, twenty of the middle ſize, and twenty of the ſmalleſt corns. Twenty of each ſort of theſe grains he planted in three pots, each filled with the ſame ſort of mould, which was very rich. In eight or nine days time, thirteen of the fulleſt bodied grains were come up, nine of the middle ſized, and only five of the ſmalleſt, and the plants of the plumpeſt corn exceeded thoſe of the others, both in colour and breadth of blade. In three days after, he found nineteen blades of the largeſt ſort come up, ſeventeen of the middle ſize, and thirteen of the ſmalleſt; and in three days more, the blades of the beſt and of the middle ſort were all come up, while only ſeventeen of the worſt had ſprouted, with ſuch manifeſt diſadvantage in colour and ſtrength in theſe laſt, as plainly ſhewed that many of them would not have come up at all in poor ground. *Liſle's Huſb. vol.* i. *p.* 283.

It is natural to ſuppoſe that barley will, like wheat, be benefited by being ſteeped before it be ſown: for as rain cannot be depended upon ſoon after the ſowing of ſpring corn, there is ſurely an equal reaſon for extending the practice of theſe ſorts of grain, as well as to thoſe which are ſown in the autumn. Liming indeed may hurt barley, if hot weather ſhould ſoon follow after the ſowing; but a little ſprinkling of ſoot bids fair for improving it, at leaſt it will prevent the inſects from preying upon the ſeed. The Rev. Mr. Elliot informs us, that a farmer, who was obliged to attend other buſineſs in the courſe of the morning, ſowed oats at break of day, and harrowed them in before ſun-riſing. The conſequence was, that the corn thus early ſown, out-ſtripped the other oats ſown on the ſame day after the ſun was up, had larger ears, and appeared every way better, though the ſpot in which they grew was the worſt part of the field. If the dew, when buried with the corn had this effect, it is reaſonable to ſuppoſe that a much greater would have been produced, had the ſeed been ſown in the evening, left all night to have been ſoftened with the dew, and then harrowed in, in the morning. *Elliot's Eſſays on Field Huſbandry, p.* 29.

Mr. Liſle alſo tells us, that a maltſter in Hampſhire having taken lands in the beginning of May, and no barley being to be had, he, by the perſuaſion of his malting-ſervant, made uſe of barley he had wetted, and was juſt well chitted or ſprouted; this corn came up well, and produced as good a crop as any ſown that year. *Liſle's Huſbandry, vol.* i. *p.* 284.

Barley is generally ſown either after a fallow, or on an erſh or ſecond crop. If after a fallow, the land muſt be ploughed at leaſt three times; and at the firſt ploughing, it ſhould be laid in ſmall ridges, and in that manner remain during the winter for the froſt to mellow it: but if another ploughing can be given it in January, or in the beginning of February, the ground will be ſtill much better broken and prepared. In March theſe ridges are ſplit, the ground is well harrowed, and laid as ſmooth as can be, and, if poſſible, it is ploughed again the ſame day, in order to ſow. But in ſtrong wet lands, the beſt way is to lay it round, and make deep furrows to receive the water.

Some at the time of twifallowing in June, make the land very fine, and ſow it with turneps, which they feed with ſheep in the winter; and in March they plough it up, and order it as before: but others, who take this method of ſowing turneps, give it only one ploughing in March, juſt before they ſow.

Thoſe who ſow barley upon an erſh, after wheat, plough up the wheat ſtubble in as dry weather as they can, as ſoon as the time of ſowing wheat is over, which is generally about the beginning of October, and lay three ridges into one, if they have dung to ſpread upon it: but if they have not, they plough it in ſmall ridges, as before directed, that it may be the drier, and be the better mellowed by the froſt: they then plough it up again in March, and order it as before. Some farmers injudiciouſly ſow their barley after oats, in which caſe, neither of theſe three ploughings ought by any means to be neglected; and the land will be in much better order if the firſt of them be given in October: or, if the harveſt be early, the weather dry, and the huſbandman can poſſibly find time to do it, he will improve his ground ſtill more, by ploughing it up before he ſows his wheat, juſt as harveſt is in: this will be half as good as a ſummer's fallow. But all years will not admit of this practice. *Mortimer's Huſbandry, vol.* i. *p.* 131.

Some ſow their barley on ſmall ridges, and others on broad lands; the latter cannot be laid too round.

Mr. Mortimer relates, that a farmer in Eſſex, who lived near a market-town, from whence he had good quantities of dung, uſed to ſow his land with barley and clover; reaped the corn at harveſt, fed the clover all the winter, and from ſpring till the middle of July, when he fallowed his ground. In the next ſpring he ſowed it again with barley and clover, and repeated every year this method, by which he had large crops. His land was a rich light mould, ſomewhat inclining to a gravelly bottom. *Mortimer's Huſbandry, vol.* i. *p.* 132.

A correſpondent of the editors of the *Muſeum Ruſticum* obſerves, that a few years ago he ſowed twenty-five acres of land, in fine tilth, with broad clover and barley; but the ſpring being backward and cold, and the ſummer wet, the clover got too forward, and overpowered the barley. At harveſt they were both cut together; and the clover being full of juice, occaſioned its being a tedious time before the barley could be houſed. When he got it into the barn, the men complained much of its threſhing ſo badly, that they could not undertake to do it unleſs he would double the price to them: as this could not be afforded, he ordered them to give it only a light beating, leaving the under corn in the ſtraw, together with the clover, for the cattle.

By this means he loſt half his crop by the clover; and what barley could be obtained was lean, and thin-bodied, fetching but a very indifferent price at market.

As this was not the firft lofs of the fame kind he had experienced, he was determined, if poffible, to find out fome remedy; and accordingly applied to a very intelligent farmer in the neighbourhood, who advifed him to fow his clover, for the future, a month after the barley, by which means it would not prove too rank. This advice he accordingly followed, and found it to anfwer extremely well; and has therefore, to his great advantage, continued the practice ever fince. He adds, that there is no danger of the clover failing, though the feafon fhould prove dry; and that the feed is to be fcattered on the ground without any farther care, there being no occafion to harrow or roll it; for the fmall blades of the barley will keep moifture enough in the land to fupply the fmall wants of the clover during its infant growth, and when the barley is off, it will thrive furprizingly. *Mufeum Rufticum, vol.* iii. *p.* 315.

It has been already obferved, that the ufual time of fowing is in March, April, or the beginning of May. It is generally thought moft advifable to fow light lands the earlieft, and to embrace the firft dry feafon that offers for doing it; dry weather being beft for moft fummer corn. Clayey grounds, and lands fubject to weeds, are thought to produce the beft crops when fowed late. Mr. Mortimer fays, that barley will do well when fown even about the middle of May, if the feed has been properly fteeped. *Mortimer's Hufb. vol.* i. *p.* 132.

The common method is to fow the barley feed with a broad-caft at two fowings; the firft being harrowed in once, the fecond is harrowed until the feed is buried; the common allowance of feed is four bufhels to an acre: but if the farmers could be prevailed upon to alter this practice, they would foon find their account in it; for if a third part of that quantity be fown, there will be a much greater produce, and the corn will be much lefs liable to lodge, as I (fays Mr. Miller) have many times experienced; for when corn, or any other vegetables ftand very clofe, the ftalks are drawn up weak, and thence incapable of refifting the force of the winds, or fupporting themfelves under heavy rains: but when they are at a proper diftance, their ftalks will be more than twice the fize of the other, and therefore are feldom laid. I have frequently obferved in fields where there has been a foot-path through their middle, that the corn, which has ftood thin on each fide of the path, hath ftood upright, when all the reft on both fides has been laid flat on the ground; and whoever will give himfelf the trouble to examine thefe roots near the path, will find them tiller out (*i. e.* have a greater number of ftalks) to more than four times the quantity of the other parts of the field. I have feen experiments made by fowing barley in rows acrofs divers parts of the fame field, and the grains fown thin in the rows, fo that the roots were three or four inches afunder in the rows, and the rows a foot diftant; the intermediate fpaces of the fame field were at the fame time fown broad-caft in the ufual way; the fuccefs was this: the roots which ftood thin in the rows tillered out from ten or twelve, to upwards of thirty ftalks on each root, the ftalks were ftronger, the ears longer, and the grains larger than any of thofe fown in the common way; and when thofe parts of the field, where the corn was fown in the ufual way, has been lodged, thefe parts fown thin have fupported their upright pofition againft wind and rain, though the rows have been made not only lengthways, but acrofs the lands, in feveral pofitions; fo that there could be no alteration in regard to the goodnefs of the land, or the fituation of the corn: where therefore fuch experiments have been made, and always attended with equal fuccefs, there can be no room to doubt which of the two methods is moft eligible, fince if the crops were only fuppofed to be equal in both, the faving two thirds of the corn fown is a very great advantage, and deferves a national confideration, as fuch a faving, in fcarce times, might be of very great benefit to the public. This faving of feed-corn muft be underftood to regard fuch as is fown broad-caft; for if it be fown in drills, an eighth part of the feed ufually fown will be fufficient for an acre of land, and the produce will be greater; for all forts of corn are naturally inclined to fend out feveral ftalks from each root, which they rarely fail to do where the roots are at a proper diftance, and have room; nor do ftalks grow in this cafe near fo tall, but are much ftronger than when they are near together, when they rarely have more than two or three ftalks; whereas thofe roots which have proper room, feldom have lefs than ten or twelve. I have had eighty ftalks upon one root of barley, which were ftrong, produced long ears, and the grain was better filled than any I ever faw grow in the common method of hufbandry, and the land on which this grew was not very rich; but I have frequently obferved on the fides of hot-beds in the kitchen gardens, where barley-ftraw has been ufed for covering the beds, that fome of the grains left in the ears have dropped out and grown, the roots have produced from thirty to fixty ftalks each, and thofe have been four or five times larger than the ftalks ever arrive at in the common way; but to this I know it will be objected, that although upon rich ground in a garden, thefe roots of corn may probably have fo many ftalks, yet in poor land they will not have fuch produce: therefore unlefs a greater quantity of feeds be fown, the crop will not be worth ftanding, which is one of the greateft fallacies that can be imagined; for to fuppofe that poor land can nourifh more than twice the number of roots in the fame fpace as rich land, is fuch an abfurdity, as one could hardly fuppofe any perfon of common underftanding guilty of; and yet fo it is: for the general practice is to allow a greater quantity of feed to poor land, than for richer ground, not confidering that where the roots ftand fo clofe, they will deprive each other of their nourifhment, and confequently ftarve themfelves, which is always the cafe when the roots ftand clofe, which any perfon may at firft fight obferve in any part of the fields where the corn happens to fcatter when they are fowing it; or in places where by harrowing, the feed is drawn in heaps, thofe patches will ftarve, and never grow to a third part of the fize as the other parts of the fame field; and yet, common as this is, it is little noticed by farmers, otherwife they furely would not continue their old cuftom of fowing. I have made many experiments for feveral years in the pooreft land, and have always found that all crops, which were fown or planted at a greater diftance than ufual, have fucceeded beft upon fuch land; and I am convinced if farmers could be prevailed upon to quit their prejudices, and make trial of this method of fowing their corn thin, they would foon fee the advantage of this hufbandry. *Miller's Gard. Dict.*

It is a common practice in fome parts to fcatter the dung of pigeons, poultry, &c. over barley and other corn, after the corn is fown; but if this method be purfued, care fhould be taken to fcatter the dung immediately; becaufe then the fhoot will eafily make its way through: but when laid on later, it burns up, and eats the blades of the young plants. *Mortimer's Hufbandry, vol.* i. *p.* 133.

It too often happens from unfavourable weather, and an extremely dry fpring, that it is impoffible by the common method to break the clods, and prepare the ground fufficiently for fowing barley; in which cafe it has been the ufual method to break the clods with a large beetle, called, from its ufe, a clotting-beetle. But this being a very chargeable and tedious method of preparing land, induced the ingenious Mr. Randall of York, to conftruct an inftrument, which he calls a fpiky roller, by the affiftance of which a large quantity of land may, in fuch a dry feafon, be foon reduced to an exceeding fine tilth, with very little trouble. The reader will find a full account of this ufeful inftrument, the manner of making and ufing it, together with a figure of the roller, under the article Spiky Roller.

After the barley is fown and harrowed in, the ground fhould be rolled after the firft fhower of rain, to break the clods and lay the earth fmooth; which will render it better to mow the barley, and alfo caufe the earth to be clofer to the roots of the corn, which will be of great fervice to it in dry weather.

And alfo when the barley has been up three weeks or a month, it will be a very good method to roll it over with a weighty roller, which will again prefs the earth clofe to the roots of the corn, and thereby prevent the fun and air from penetrating the ground, which will be of fingular fervice in dry feafons; and this rolling of it before it ftalks, will caufe it to tiller out into a greater number of ftalks; fo that if the plants fhould be thin, this will caufe them to fpread fo as to fill the ground, and likewife ftrengthen the ftalks. *Miller's Gard. Dict.*

If the corn grows too rank as it is ſometimes thought to do in a wet ſpring, mowing is then much better than feeding it; becauſe the ſcythe takes off only the rank tops, but the ſheep feed upon all indifferently: nor ſhould they even in any caſe be left upon it too long, becauſe being particularly fond of the ſweet end of the ſtalk next the root, they will bite ſo cloſe as to injure the future growth of the plant.

Barley is ripe when the red roan, as the farmers call it, meaning a reddiſh colour on the ear, is gone off, when the ears droop, and fall, as it were, double againſt the ſtraw, and the ſtalks have loſt their verdure. If it be full of weeds it muſt lie in the ſwarth till they are dry. It is not apt to ſhed; but in wet weather it will be apt to ſprout or grow muſty; and therefore every fair day after rain it ſhould be ſhook up and turned; and when it is tolerably dry, let it be made up into cocks; but be ſure never to houſe it till thoroughly dry, leſt it mow-burn, which will make it malt worſe than if it had ſpired in the field. The common produce of barley is two or three quarters upon an acre. *Mortimer's Huſbandry, vol.* i. *p.* 133.

Mr. Liſle ſays that poor thin barley and oats ſhould be cut a little ſooner than if the ſame plants were ſtrong and vigorous; for that the ſtraw, when the plants are full ripe, will not ſtand againſt the ſcythe. In this caſe the barley, in particular, muſt lie in ſwarth till it is thoroughly dry. Some of his barley, which lay out in ſwarth five or ſix days in very fine weather, though both blighted and edge-grown, grew plump, and acquired very near as good a colour as the beſt. He reckons ſhort ſcythes the beſt for mowing lodged or crumpled corn, becauſe they miſs the feweſt plants; and obſerves that a bow upon the ſcythe, which will carry the ſwarth away before it, is preferable to a cradle, the fingers of which would be pulled to pieces by the intangled corn, in drawing back the ſcythe. *Liſle's Huſbandry, vol.* i. *p.* 335.

Mr. Du Hamel tells us, that a farmer at Acou, obſerving that the chief hopes of more than common ſucceſs by means of the new huſbandry, were founded on the frequent ſtirring of the ground while the corn was in it, and on allowing each plant ſufficient ſpace to extend its roots, and thereby collect the more nouriſhment, tried an experiment which appeared to him very proper to diſcover whether the effect would anſwer. He carefully cultivated a grain of barley, which grew by chance in his vineyard. This plant, ſaid he, ſtands diſtant from any other; it can extend its roots every way; it is in a rich ſoil, and cannot want for food: by joining frequent culture to theſe advantages, this plant of barley, according to the principles of the new huſbandry, ought to yield a ſurprizing increaſe. His reaſoning was juſt, and the experiment confirmed it; for this ſingle grain of barley produced two hundred ears, and about thirty ſtalks which had no ears. Some of the ſtalks were four feet high, and moſt of them three. Mr. Du Hamel counted twenty-four grains in a middling ear. Thus one grain, planted in a good ſoil, and well cultivated, produced 4800 grains; and the ſtraw of this ſingle plant of barley made of itſelf a ſheaf. *Tranſlation of Du Hamel's Huſb. p.* 113.

We have already obſerved, under the article SOAP ASHES, that Sir Hugh Platt, by ſpreading that manure over his land, had a ſurprizing crop of barley, the plants of which were of a prodigious ſize. An ear of this barley is delineated in its natural ſize, Plate III. Fig. 1.

BARM, yeaſt, or the thick cruſt that riſes on the ſurface of beer, while it is fermenting.

BARN, a covered place or houſe for laying up any ſort of grain, hay, or ſtraw.

Every farm ſhould be furniſhed with barns proportioned to the quantity of corn it produces, which will be a great advantage to the farmer. The barns ſhould have a dry ſituation, and be properly placed in the farm-yard, but not quite contiguous to the houſe for fear of fire.

A barn is uſually made of wooden frames covered with planks of oak, or built of brick or ſtone, which ever the country affords in the greater plenty; and in either caſe there ſhould be ſuch vent-holes, or openings, in its ſides or walls, as to afford free admittance to the air, in order to prevent the mouldineſs that would otherwiſe from the leaſt dampneſs lodging in the corn. The gable ends may be always of brick or ſtone, for the ſake of greater ſolidity, and the whole may be roofed with thatch or tiles, as is moſt convenient. The ſize of the barn ſhould be proportioned to the crop uſually produced by the land to which it belongs. Two large folding doors ſhould face each other, one in each ſide of the building, for the convenience of carrying in or out a waggon-load of corn in ſheaves; and theſe doors ſhould be of the ſame breadth with the threſhing-floor to afford the more light and air; the former for the threſhers, and the latter for winnowing. Over the threſhing-floor, and a little above the reach of the flail, poles are often laid a-croſs from one beam to another, to form a kind of upper floor, upon which the threſher may throw his ſtraw or haulm, to make an immediate clearing, till he has time to ſtow it more properly elſewhere: and on the outſide, over the great doors, it will be right to form a large penthouſe, made to project ſufficiently to cover a load of corn, in caſe a ſudden ſtorm ſhould come on before it can be houſed; and alſo to ſhelter the poultry in the farm-yard, in great heat, or bad weather.

It is moſt adviſable, and indeed moſt commonly practiſed in countries which abound in corn, to have a ſeparate barn for wheat, another for ſpring-corn, ſuch as barley and oats, and a third for peas, tares, lentils, clover, ſaintfoins, &c.

Some art, which muſt be the reſult of practice, is neceſſary in placing and piling up the ſheaves in barns. But it may not be uſeleſs to obſerve, that it is always neceſſary to preſs them as cloſe to the walls of the barn as poſſible, ſo as not to afford the leaſt room for rats, or other vermin to creep in between them: for if they once get admittance they will ſoon penetrate further, lodge themſelves in the mow, and do prodigious damage to the corn. Where this misfortune happens, the only remedy is to take down the mow, kill the vermin, and pile it up a-new.

But the floor, or threſhing place, is the principal part of every barn, and therefore the greateſt care ought to be taken in making it. In order to this, the ſurface of the intended threſhing place is dug away to the depth of about ſix inches, and the earth thus taken out, after being well cleared of ſtones, is mixed with the ſtrongeſt clay that can be procured, and with the dung of cows or oxen. This mixture is then worked together with water, till it is of the conſiſtence of ſtiff mortar, and the compoſt thus made is ſpread as ſmooth as poſſible with a trowel, upon the ſpot from whence the earth was taken. As it cracks in drying, it muſt be beaten down with great force; or rolled with a heavy roller till all the crevices are filled up; and this muſt be continued till it is quite ſolid, hard, and firm.

The beſt barn-floor, both for threſhing and for keeping corn, is that which is drieſt, ſmootheſt, moſt completely ſolid, and conſequently freeſt from cracks and holes, in which inſects and vermin may ſhelter themſelves, and even breed. The ancients were remarkably careful in this reſpect, as we learn from Cato, Varro, and Columella, the laſt of which excellent huſbandman relates particularly the great pains they took, firſt to dig up the ground to ſome depth, in order to moiſten it with freſh lees of oil, but not with any that had ſalt in them; then to mix it thoroughly with chaff, and ram it down as cloſe as poſſible; afterwards as it dried, to ſtop all the cracks and crevices that appeared; to continue beating it down with great force, to render it quite level; and, laſtly, to ſtrew it again with chaff, which they trod in, and then left it to be completely dried by the ſun. All theſe writers agree, that the lees of oil, thus uſed, prevent the growth of weeds in theſe floors, and contribute to preſerve the corn from being plundered by the mice and ants. Their barns were always ſeated high, and as dry as poſſible.

A floor made in the above manner muſt be greatly preferable to either ſtone, or the earthen floors, too common in many parts of England, and from which ſuch dampneſs has been communicated to the corn, as has rendered wheat, for example, ſixpence a buſhel the worſe, either for keeping or exporting.

Boarded threſhing-floors, made of ſound, thick, well ſeaſoned planks of oak, are excellent for ſervice, will laſt a long time, and may be converted into good floorings for rooms, by planing them down, after they are become two uneven for the purpose originally intended.

BARNACLES, horse-twitchers, or brakes, are a sort of instruments used by farriers to put upon horses noses, when they will not stand quietly, to be shod, blooded, or dressed.

There are several sorts of barnacles, the common sort are rollers of wood, bound together, with the horse's nose between them. Another sort have handles, and are therefore termed pincers, to distinguish them from the foregoing. And a third sort are held together at the top by a ring inclosing buttons, having the top buttons held by an iron pin riveting through them.

BARREN CORN, a name given to a distemper in corn, by M. Aimen, who first observed it. The ears of wheat or rye, the species most subject to this distemper, which are thus affected, are long, lean, and white; in some the stamina, or small threads in the middle of the flower, are dry, transparent, and horned; the female organs are small, whiter, and less velvetty, than in healthy ears: in others, the filaments are swelled, the apices, or knobs on the tops of the stamina, void of dust, or farina, and the stigmata badly unfolded. The stigmata of all the blossoms of an ear are sometimes dried and parched; at other times the apices are swelled.

M. Aimens thinks, with Theophrastus, that these accidents happen to such plants as grow with most vigour. Then, says he, the sap, which is powerfully conveyed into the leaves and other parts of the plant, prevents the organs of fructification from unfolding themselves.

He also imagines that frost may cause this accident, by particularly effecting the female organs: and he thinks, that a hot gleam of sun-shine coming after a hard shower may have the same effect. If this be the case, the distemper in question may be ranked with the parched and shrivelled corn, or perhaps with the empty-eared corn. Lastly, the same naturalist observes, that insects are sometimes, though very rarely, the cause of this distemper.

Barren Earth, a name given by some to the under stratum of earth, or that which lies below the stratum frequently turned up, and cultivated for the nourishment of plants.

This notion of the under stratum of earth being dead or barren, and will destroy every vegetable planted in it, seems to be founded on a mistake; for every kind of earth, whether it be upon or under the surface, is certainly capable of giving nourishment to plants, provided it be for some time exposed to the influence of the air, frosts, &c. in order to enable it to dispense its nutritive qualities. An earth seemingly barren dug out of a deep pit, will, if spread on the surface, and properly stirred and exposed, be soon in a condition of bearing plants, and even much more so than the earth, which having been long at the surface, is almost exhausted, by the number of vegetables it has successively nourished. The notion of any earth being barren, merely because it is placed at a distance from the surface, is by the most intelligent naturalists exploded: its particles may perhaps want a proper arrangement, but it always possesses the vegetative quality. This opinion has been confirmed by repeated experiments; and a very remarkable one of this kind is related by a correspondent of the editors of the *Museum Rusticum*, *vol.* i. *p.* 100. &c. where the writer tells us, that he planted a quantity of potatoes in a piece of what was called dead barren earth, the upper bed having been taken away and spread on the adjacent land. Yet in this spot of ground dug two spits deep by the help of spades and mattocks, and the earth broke as fine as possible, he had a prodigious crop of remarkably fine potatoes; though the earth had not been exposed to the influence of the atmosphere above two months, it being dug in February, and the potatoes planted the latter end of March.

Barren Springs, a name given by husbandmen to such springs whose waters are injurious to land.

Most waters that flow from coal-mines, or through beds of sulphureous minerals, have this pernicious quality, destroying vegetables, instead of nourishing them. They have a harsh and brackish taste, are generally of a reddish colour, and deposit a reddish sediment in the channel through which they flow. They are much better when they have run some distance, than at their first breaking out on the surface of the earth. *Mortimer's Husbandry*, *vol.* i. *p.* 20.

BARS, the fleshy rows that run a-cross a horse's mouth, reaching almost to the palate. They are very distinguishable in young horses.

BARTH, a warm place, or pasture, for calves or lambs.

BARTON, *or* Barken, the yard of a house.

BASIL, the name of a plant, of which there are several species; but that which bears the largest leaves, especially if they are of a purplish colour, are reputed the best.

They are all annual and very tender plants, and must therefore be raised on a moderate hot-bed from seeds sown in March. When the plants are come up, they should be transplanted into another moderate hot-bed, observing to water and shade them until they have taken root; after which they should have plenty of air in mild weather, otherwise they will draw up very weak. In May they should be taken up with a ball of earth to their roots, and transplanted either into pots or borders, observing to shade them until they have taken root; after which, they will require no farther care, but to clear them from weeds, and refresh them with water in dry weather. Though these plants are only propagated from seeds, yet if you have any particular sort which you are desirous to increase, you may take off cuttings any time in May or June, and plant them on a moderate hot-bed, observing to water and shade them for about ten days; in which time they will take root, and in three weeks time be fit to remove, either into pots or borders, with the seedling plants. In September these plants will perfect their seeds, when those sorts which appear the most distinct should have their seeds preserved separate, for sowing the following spring. *Miller's Gard. Dict.*

BASON, a reservoir, or place for holding water either for the use or ornament of a garden.

In making basons, particular regard must be had to the soil of the garden; for in loose sandy land great care will be necessary in making the clay walls so as to hold water; but where the soil is loomy, or inclining to clay, there will be little difficulty in making basons, nor need the clay-wall be so thick. Where the ground is loose, the clay-walls at the bottom should not be less than two feet thick, and those on the sides one and an half. The clay should be well wrought over and trod when it is taken from the pit, before it is used in building the wall. The true sign of good clay is, that it be close and firm, without any mixture of sand, and that it be tenacious and fat in handling. It should be well worked before the clay is brought to the place, for if the clay be too long exposed to the sun and air, it will be less proper for use, especially if it be laid in small parcels.

The best time of the year for making basons is in autumn, when the sun is declining, and the weather temperate; for in the spring of the year, the drying east and north-east winds generally blow; so that the clay-walls, if not very carefully covered as fast as they are made, often crack in many places, so that the water finds a passage through them. The same inconveniency happens from the violent heat of the sun in summer; for when the clay dries very fast, it will be very difficult, if not impossible, to prevent its cracking.

When the ground where the bason is to be made, is dug out level, the clay must be brought in, and laid very carefully in the bottom, observing that no dirt or small stones be mixed with it; some water must also from time to time be thrown on the clay, while the men are treading it closely with their naked feet; after which it must be very well rammed. When the bottom is finished with clay, a layer of coarse gravel about four or five inches thick should be laid over it, which will greatly tend to secure the clay bottom, and render the water clear. But where the bason is large, so that the clay bottom is long in making, it should be covered with moist litter, to prevent its drying, which may be taken off when the whole is finished to lay on the gravel; but if part of the side walls be finished before this is done, it will be the better; because there may then be some water let into the bason, as soon as the gravel is laid, which will prevent the clay from cracking. After this the walls round the fides of the bafon muft be carried up with the fame care as above directed for the bottom, obferving alfo to cover the clay with litter while the work is carrying on, and afterwards to lay it with coarfe gravel; and as the walls are finifhed round, the water may be let in to fecure the walls from drying or cracking.

When the whole is finifhed, a ftratum of gravel four or five inches thick fhould be laid upon the clay, then a thin ftratum of good earth, and the whole covered with turf. The fand will prevent the grafs from rooting into the clay, and alfo keep out the froft. The turf on the fide of the bafon fhould be laid as far down as the water is apt to fall, that no part of the clay may be wholly expofed to the weather.

No trees or fhrubs fhould be fuffered to grow near a bafon, for their roots will penetrate through the clay walls, and occafion fiffures, through which the water will find an eafy paffage.

In fome countries where clay cannot be eafily procured, the walls of thefe bafons are frequently made with chalk, beaten into a foft powder, and made into a fort of mortar, with which the walls are made by ramming and working it very hard and firm. Thefe bafons hold water very well, if never fuffered to be dry any length of time; for whenever that happens the fun and winds by drying the chalk, caufe it to crack, and thefe cracks commonly extend through the thicknefs of the walls, fo as to let out the water.

Others build the walls of their bafons with bricks laid in terrafs, which is a good method for fuch places where the ground is loofe and fandy; becaufe the walls, when well built, will fupport the loofe earth from falling, or fettling away from the fides; but where terrafs is ufed, the walls fhould not be long dry and expofed; for the heat is apt to crack the terrafs.

Some make a cement of powdered tile and lime, two parts of the former to one of the latter, being very careful in the mixing of it not to add too much water, but to labour it well in beating, which is a principal thing to be obferved. With this cement they cover the furface of the walls of their bafons about two inches thick, laying on the plaifter, and being very careful that no fticks, ftraws, or ftones, are mixed with it: this plaiftering is generally performed in dry weather, and as foon as it is finifhed, it is rubbed over with linfeed oil, or bullocks blood, and the water let into the bafon as foon as poffible. This cement has the property of hardening under water, fo as to be equal to ftone, and will continue as long found.

But whatever the materials are made ufe of in building the walls, great care muft be taken to render them fo ftrong, as to enable them to refift the weight of the water; where, therefore, the ground about the bafon is not very folid, the walls fhould be thicker, and fupported on the backfide by buttreffes of the fame materials, placed at proper diftances: or, if the walls are made of clay, planks fupported by ftrong timbers, at proper diftances, fhould be placed fo as to fuftain them; otherwife there will be great danger of their being broken down, efpecially where the bafons are large enough for the waves driven by the wind to dafh forcibly againft the banks. *Miller's Gard. Dict.*

BASTARD *Alkanet*, called alfo *baftard gromill*, or *falfarn*, a weed common among corn, efpecially rye. It may be eafily known by its red roots, which yield a red tincture, and are ufed by the young girls in Sweden to colour their cheeks. From the root ufually rifes a fingle ftem about a foot high, rough, and branching out at the top. The flowers are fmall and white, furrounded with five long, narrow, hairy leaves, forming what the botanifts call the empalement of the flower cup, and fucceeded by four white rough feeds. *See a figure of this plant on* Plate III. Fig. 2.

BAVINS, brufh-faggots, or faggots made with the brufh-wood at length.

BAUM, a plant very common in the Englifh gardens. It is raifed either from feeds, or propagated by flips from its roots, which are perennial, though its ftalks are annual. The feeds fhould be fowed in the fpring; but the flips planted in October, that they may have time to get ftrength before the frofts come on. The roots alfo of this plant may be parted into fmall pieces, with three or four buds to each. Thefe fhould be planted about two feet afunder in beds of common garden earth, where they will foon fpread fo as to meet each other. The only culture they require is to water them till they have taken root, to keep the plant clean from weeds, and to cut off the dry ftalks in autumn; ftiring the ground between the roots. *Miller's Gard. Dict.*

BAUSON, the fame with badger. *See* BADGER.

BAY, a colour in horfes, fo called from its refembling the colour of a dried bay-leaf.

There are various degrees of this colour from the lighteft bay to the dark, which approaches nearly to the brown, but is always more gay and fhining. The bright bay is an exceeding beautiful colour, becaufe a bright bay horfe has generally a reddifh dafh, with a gilded afpect, his main and tail black, with a black or dark lift down his back. The middle colours of bay have alfo frequently the black lift, with black main and tail. And the dark bays have almoft always their knees and pafterns black; and we meet with feveral forts of bays, that have their whole limbs black from their knees and hocks downwards. The bays that have no lift down their backs, are, for the moft part, black over their reins, which goes off by an imperceptible gradation from dark to light towards the belly and flanks. Some of thefe incline to a brown, and are more or lefs dappled. The bay is one of the beft colours, and horfes of all the different kinds of bays are commonly good, unlefs when accidens happen to fpoil them while they are colts. *Gibfon on Horfes, vol.* I. *pag.* 44.

BAY *of a barn*, that part where the mow is placed. Hence fuch barns as have the threfhing-floor in the middle, and a fpace for a mow on each fide, are called barns of two bays, &c.

BAYARD, a bay horfe.

BAY-SALT, is falt made from fea-water by the heat of the fun only, without the affiftance of fire. The cryftals of this falt are much larger than thofe of the common falt, occafioned by the gentle evaporation of the watry particles; whence the cryftals have a fufficient time to fhoot, which they have not in the common method. From this circumftance bay-falt becomes much better for falting meat, &c. than the common.

BEANS, a fort of pulfe well known, and of which there are two fpecies, diftinguifhed by the names of the garden-bean, and the horfe-bean.

Garden-BEANS. There are feveral varieties of garden-beans, diftinguifhed among gardeners by different names, viz.

The Mazagan bean is the firft and beft fort of early beans at prefent known; they are brought from a Portuguefe fettlement of the fame name on the coaft of Africa. The feeds of this fort are fmaller than the horfe-bean, and as the Portuguefe are but flovenly gardeners, there is commonly a great number of bad feeds among them. If this fort be fown in October, under a warm hedge, pale, or wall, and carefully earthed up when the plants are advanced, they will be fit for the table by the beginning of May: the ftems of this fort are very flender, and therefore fhould be fupported by ftrings clofe to the hedge, or pale, to preferve them from the morning frofts, which are fometimes fevere in the fpring, and retards their growth: thefe beans bear plentifully; but they ripen nearly together, fo that there are feldom more than two gatherings from the fame plants. If the feeds of this fort are fowed two years in England, the feeds will become much larger, and not ripen fo foon, which is called a degeneracy.

The next fort is the early Portugal bean, which appears to be the Mazagan faved in Portugal; this is the moft common fort ufed by gardeners for their firft crop, but they are not near fo well tafted as the Mazagan.

The next is the fmall Spanifh bean; this will come in foon after the Portugal fort, and being a better tafted bean, fhould be preferred.

Then comes the broad Spanifh, which is a little later than the other; but coming in before the common forts, and being a good bearer, is frequently planted.

The

The Sandwich bean comes soon after the Spanish, and is almost as large as the Windsor-bean; but being hardier, is commonly sown a month sooner. It is a plentiful bearer.

The Toker bean, as it is generally called, comes about the same time with the Sandwich, and being a great bearer, is now frequently planted.

The white and black blossom-beans are also by some persons much esteemed; the beans of the former are, when boiled, almost as green as pease, and being a sweet bean, renders it more valuable: both these sorts are very apt to degenerate, if their seeds are not saved with great care.

The Windsor-bean is allowed to be the best of all the sorts for the table: when these are planted on a good soil, and are allowed sufficient room, their seeds will be very large, and in great plenty; and when they are gathered young, are the sweetest and best tasted of all the sorts; but the seeds of these should be carefully saved by pulling out such of the plants as are not perfectly right, and afterwards by sorting out all the good from the bad beans when they are out of the pods. This sort of bean is seldom planted before Christmas, because it will not bear the frost so well as many of the other sorts; it is, therefore, generally planted for the great crop to come in June or July.

Those beans which are planted early in October, will come up by the beginning or middle of November; and as soon as they are two inches above the ground, the earth should be carefully drawn up with a hoe to their stems, and this must be two or three times repeated, as the beans advance in height, which will protect their stems from the frost. If the winter should prove severe, it will be very proper to cover the beans with pease haulm, fern, or some other light covering, which will secure them from the injury of the frost: but this covering must be constantly taken off in mild weather, otherwise the beans will draw up so tall and weak as to come to little; and if the surface of the border be covered with tanner's bark, it will prevent the frost from penetrating into the ground to the roots of the beans, and be of great service to protect them from the injury they might otherwise receive.

In the spring, when the beans are advanced to be a foot high, they should be fastened up to the hedge with packthread, so as to draw them as close as possible; which will secure them from being injured by the morning frosts, which are often so severe in April, as to lay those beans flat on the ground, which are not thus guarded: at this time all suckers which come out from the roots should be very carefully taken off, for these will retard the growth of the bean, and prevent their coming early. When the blossoms begin to open toward the bottom of the stalks, the top of the stem should be pinched off, which will cause those first pods to stand, and thereby bring them forward. If these rules are observed, and the ground kept clean from weeds, or other plants, there will be little danger of their failing.

But lest the first crop should be destroyed by frost, it will be absolutely necessary to plant more about three weeks after the first, and so to repeat planting more every three weeks, or a month, till February; but those which are planted towards the end of November, or the beginning of December, may be planted on sloping banks, at a distance from the hedges; for if the weather should prove mild, these will not appear above-ground before Christmas; therefore will not be in so much danger as the first and second planting, especially if the surface of the ground is covered with tan to keep the frost out of the ground. The same directions which are before given will be sufficient for the management of these; but only it must be observed, that the larger beans should be planted at a greater distance than the small ones; as also, that those which are first planted must be put closer together, to allow for some miscarrying; therefore when a single row is planted, the beans may be put two inches asunder, and those of the third and fourth planting may be allowed three inches; and when they are planted in rows across a bank, the rows should be three feet asunder; but the Windsor-beans should have a foot more space between the rows, and the beans in the rows should be planted five or six inches asunder.

In the management of the later crop of beans, the principal care should be to keep them free from weeds and other plants, which would draw away their nourishment; to keep earthing them up, and when they are in blossom, to pinch off their tops, which, if suffered to grow, will draw the nourishment from the lower blossoms, and thereby prevent the pods from setting, so that only the upper parts of the stems will be fruitful. Another thing also should be observed in planting of the succeeding crops, namely, to make choice of moist, strong land, for the later crops; for if they are planted on dry ground, they rarely come to much, unless the summer proves wet.

These later crops should be successively planted about a fortnight after each other, from February to the middle of May, after which time it is generally too late to plant, unless the land be very strong and moist; for in warm, dry, light land, all the later crops of beans, are infested by black insects, which cover all the upper part of their stems, and soon cause them to decay.

When the seeds of the beans are designed to be saved, a sufficient number of rows should be set apart for that purpose, according to the quantity desired; these should be managed in the same way as those which are designed for the table; but none of the beans should be gathered. When the seed is ripe the stalks should be pulled up, and set upright against a hedge to dry, observing to turn them every third day, that they may dry equally; they may then be threshed out and cleaned for use, or otherwise stacked up in a barn, till there is more leisure for threshing them out; and afterwards the seed should be drawn over, to take out all those that are not fair, preserving the best for sowing, and the ordinary for feeding cattle.

It is a very good method to change the seeds of all sorts of beans, and not to sow and save the seeds long in the same ground, for they do not succeed so well; if, therefore, the land be strong where they are to be planted, it will be the best way to procure seeds from a lighter ground, and so *vice versa*; for by this means the crops will be larger, the beans fairer, and not so liable to degenerate. *Miller's Gard. Dict.*

Some few trials has been lately made in France to raise garden beans in open fields, on the principles of the new husbandry; and the result of these experiments sufficiently indicate that very large crops may be procured by that method, if properly practised. M. Du Hamel tells us, that M. Eyma planted, in December 1755, in a field near Bourdeaux, the common sort of garden beans, in a middling soil not dunged, but thoroughly ploughed a foot deep. The rows were two feet asunder, and the plants a foot distant from one another. These beans, which every one thought too thinly sown, being assisted by frequent hoeings, yielded a greater crop than any in the common way. When they began to ripen, M. Eyma gave the spaces between them a good ploughing, and on the twenty-third of June sowed in each of them a row of red kidney-beans, which came up very well. In a fortnight after he plucked up the garden beans, and gave the ground on which they stood a slight hoeing. These kidney-beans proved the finest he ever saw. He repeated the same experiment in 1756, and was rewarded with such success as surpassed his warmest expectations. *Traité de la Culture des Terres, tom.* V. *page* 81.

Horse BEANS, delight in a strong moist soil, and an open exposure, for they never thrive well on dry warm land, or in small enclosures, where they must, and are frequently attacked by the black dolphin fly: these insects are often in such quantities as to cover the stems of the beans entirely, especially all the upper part of them; and whenever this happens, the beans seldom come to good; but in open fields where the soil is strong, and the plants have room, this rarely happens.

These beans are usually sown on land which is fresh broken up, because they are of use to break and pulverise the ground, as also to destroy weeds; so that the land is rendered much better for corn, after a crop of beans, than it would have been before, especially if they are sown and managed according to the new husbandry, with a drill plough, and the horse-hoe used to stir the ground between the rows of beans, which will prevent the growth of weeds, and pulverize the ground, whereby a much greater crop of beans may, with more certainty, be expected, and the land will be better prepared for whatever crop it is designed for after.

The season for sowing beans is from the middle of February to the end of March, according to the nature of the soil; the strongest wet soil should always be last sown. The usual quantity of beans sown on an acre of land, is about three bushels, tho' this is double the quantity that need be sown, especially according to the new husbandry; but it will be necessary first to set down the practice according to the old husbandry, and then give directions for their management according to the new. The method of sowing is after the plough, in the bottom of the furrows; but then the furrows should not be more than five, or, at most, six inches deep. If the land be newly broken up, it is usual to plough it early in the autumn, and let it lie in ridges till after Christmas; then to plough it in small furrows, and lay the ground very smooth. These two ploughings will break the ground fine enough for beans, and the third ploughing is to sow the beans, when the furrows should be made shallow, as before mentioned.

Most people set their beans too close; for as some lay the beans in the furrows after the plough, and others lay them before the plough, and plough them in; so by both methods the beans are as close as the furrows are made, which is much too near; for when they are on strong good land, they are generally drawn up to a very great height, and are not so apt to pod as when they have more room, and are of a lower growth. The better way, therefore, is to make the furrows three feet asunder, or more, which will cause them to branch out into many stalks, and bear in greater plenty than when they are closer; by this method less than half the quantity of beans will be sufficient for an acre of land, and the air being admitted between the rows, the beans will ripen much earlier, and more equally than in the common way. *Miller's Gard. Dict.*

It has been already observed, that the black dolphin fly often destroys a crop of beans, and to prevent which, a correspondent of the editors of the *Museum Rusticum* proposes, that when these destructive insects are first seen on the tops of the beans, one or more persons, provided each with a scymeter or hanger, should be sent in the field, and strike off the heads of the beans. He adds, that by this means a crop has been often saved, this fly being seldom known to rise again when it once falls with the bean-top to the ground. *Museum Rusticum, vol.* III. *pag.* 233.

Another correspondent in the above work says, that as soon as the beans have got six leaves, the sheep should be turned in to feed among them; for they will eat up all the young weeds, even the melilot, without touching the beans. He adds, that the sheep may be kept every day among the beans till they are in blossom; but they must not be suffered to lie down. *Museum Rusticum, vol.* III. *pag.* 339.

When beans are intended to be planted according to the new husbandry, the ground should be four times ploughed before the beans are set, which will break the clods, and render it much better for planting. Then use a drill plough, to which a hopper is fixed for setting the beans, the drills should be made at three feet asunder, and the spring of the hopper set so as to scatter the beans at three inches distant in the drills. By this method less than one bushel of seed will plant an acre of land. When the beans are up, if the ground be stirred between the rows with a horse plough, it will destroy all the young weeds; and when the beans are advanced about three or four inches high, the ground should be again ploughed between the rows, and the earth laid up to the beans; and if a third ploughing, about five or six weeks after be given, the ground will be kept clean from weeds, and the beans will stalk out, and produce a much greater crop than in the common way. *Miller's Gard. Dict.*

A correspondent of the editors of the *Museum Rusticum*, has given the following method of cultivating beans in the vale of Aylesbury.

" First, says he, I plough two furrows on each outside of the land, but sow no beans in them: I afterwards drill, with an instrument hereafter described, the three next furrows: then I plough two furrows without drilling any beans in them, and so on, sowing three, and leaving two for intervals, till the land is finished.

" When the beans are about two or three inches high, I plough two furrows up each interval, turning the furrows from the beans, so as to make a ridge in the middle of each interval. I have a little plough on purpose for this use, about half the size of a common plough, which is drawn by one horse.

" This work should be done after a rain. This year, 1764, on the fifteenth of May we had rain. I therefore went to plough in the intervals on the eighteenth, and continued at plough till all were finished. On the eighth of June we had rain again. On the ninth of June I went to harrow the intervals with the triangular harrow hereafter described. About a week after that we had more rain. I then went to harrow again, going up the interval I went down before, and down that which I went up. This is what we call cross-tining. Thus my land is laid quite smooth, kept clear from weeds, and the beans have a fine loose mould to strike their fibres into; and it is by far the cheapest way of weeding beans.

Proportions of the above Drill (see Plate III. Fig. 3.)

" Diameter of the iron wheel twenty inches.

" Length of the box from A to B, twenty inches.

" Breadth of the box from B to C, ten inches.

" Depth of the Box from C to D, five inches and a half.

" Diameter of the cylinder of wood upon the iron axis of the wheel, four inches. This cylinder turns out the beans regularly.

" Length of the cylinder two inches and a half. On this cylinder are twenty-one holes, a quarter of an inch deep, and half an inch in diameter.

" E is a tongue, which drops upon the cylinder, and plays up easily: the tongue is half an inch thick, and three quarters wide. When a larger bean than ordinary comes, it will throw the tongue up, which naturally recovers its place again; and so the work goes on well and even. The tongue is represented separately with its notch at E: the notch does not go quite through it; it falls exactly on the holes of the cylinder.

" A lid takes off to put the beans into the box, and buttons down at F."

The triangular Harrow *described* (see Plate III. Fig. 4.)

" From A to B eighteen inches.

" The tines are nine inches a-part.

" The three tines in the cross-bar are only three inches and a half a-part.

" E, a cock which plays upon a pin, in which are three holes to hang the whipple tree in. If you put it into the upper hole the tines bear very heavy upon the ground: I generally use the middle hole." *Museum Rusticum, vol.* III. *pag.* 26.

When the beans are ripe they are reaped with a hook, as is generally practised for pease; and after having lain a few days on the ground, they are turned, and this must be repeated several times, until they are dry enough to stack; but the best method is to tie them in small bundles, and set them upright; for then they will not be in so much danger to suffer by wet, as when they lie on the ground; and they will be more handy to carry and stack, than if they were loose.

The common produce is from twenty to twenty-five bushels on an acre of land. *Miller's Gard. Dict.*

In the stiff, strong land, of the vale of Aylesbury, they annually sow a great many acres of horse-beans, all which they usually mow with a bare scythe, in swarth, as they call it; that is, they mow beans towards the beans; and each mower has a boy, who follows him with a fork,

fork, and lays the beans in wads. Their reaſon for mowing them in ſwarth, is on account of the largeneſs of their crops, and the beans leaning inwards: it is only when they have a thin crop, that they venture to mow them againſt their bending (this they call throating;) for ſhould they do it in common, it would break the hearts of the mowers, being as hard work again as the other.

When they mow in ſwarth, the workmen always keep the points of their ſcythes downwards, or they would ſtrip of great quantities of the beans.

In Hertfordſhire alſo, ſome farmers mow their beans with a ſcythe, and a three ribbed ſtrong cradle: this cuts a great deal in a day, lays the beans in regular rows, and ſaves the expence of a wa der; but in Buckinghamſhire they cannot uſe a cradle, their crops being in general ſo heavy, that the workmen could not carry over the ſwarth. *Muſeum Ruſticum, vol.* I. *page* 275.

The beans ſhould lie in the mow to ſweat, before they are threſhed out; for as the haulm is very large, and ſucculent, ſo it is very apt to give and grow moiſt; but there is no danger of the beans receiving damage, if they are ſtacked tolerably dry; becauſe the pods will preſerve the beans from injury; and they will be much eaſier to threſh after they have ſweat in the mow than before; and after they have once ſweated and are dry again, they never after give.

By the new huſbandry the produce has exceeded that of the old by more than ten buſhels an acre; for if the beans cultivated in the common method are obſervéd when they are in pod, it will be found that more than half way of their ſtems have no beans on them; for by ſtanding cloſe, they are drawn up very tall, ſo the tops of the ſtalks only produce, and all the lower part is naked; whereas in the new method, they bear almoſt to the ground; and as the joints of the ſtems are ſhorter, ſo the beans grow cloſer together. *Miller's Gard. Dict.*

Beans are a part of the diet of horſes, but chiefly uſed in mixture with bran or chaff, and by ſome upon the road, with oats; but they are moſtly given to coach-horſes and others that are conſtantly in draught. They afford the ſtrongeſt nouriſhment of all other grain, and will enable horſes to go through a great deal of heavy labour; but in ſome ſeaſons they breed a kind of vermin, which the farmers call a red bug, and is reckoned dangerous, and therefore the beſt way at ſuch times is to have them well dried and ſplit, which may, in ſome meaſure, deſtroy the malignity that is engendered in them. *Gibſon on Horſes, vol.* I. *pag.* 171.

Whoever has frequented the corn markets in London cannot but know that old horſe-beans ſell from ten to fifteen, and even more, per cent. dearer than new corn: becauſe new beans will, by their abundant crudity, give a horſe the gripes, and other diſorders equally fatal. To prevent ſuch conſequences, and at the ſame time ſave the difference between the expence of old and new corn, a correſpondent of the editors of the *Muſeum Ruſticum*, tells us that he made the following experiment.

He purchaſed a quantity of new beans, and filled a large tub with them, pumping in as much water as was neceſſary to wet them: after ſoaking about ten hours he drew off the water, and laid the beans in a heap on the floor. In this manner he ſuffered them to continue till they began to heat, when he ſpread them out thinner, moving them often with a malt ſhovel, and letting them lie in beds till the germ ſwelled and became turged. Then he carried them to a malt-kiln, and dried them gradually; and gave part of them to his horſes, as ſoon as cold.

By this preparation he aſſures us new beans will agree as well with cattle as any old corn that can be procured at the market.

The greateſt nicety in the operation is to prevent the beans from ſprouting, or malting, which would injure them, and not to dry them by too quick a heat. *Muſeum Ruſticum, vol.* I. *pag.* 327.

Kidney BEANS, called alſo *French beans.* There are a vaſt number of varieties of this plant brought from America, which it would be tedious, as well as ſuperfluous, to enumerate; eſpecially as ſome of the old ſorts are preferable to any of the new for the kitchen garden. There is, however, one ſort which deſerves to be particularly mentioned, and which has been long cultivated in the Engliſh gardens for the beauty of its ſcarlet flowers, from whence it is called the ſcarlet bean. This ſort hath twiſting ſtalks, which, if properly ſupported, will riſe to the height of twelve or fourteen feet; the leaves are ſmaller than thoſe of the common kidney-bean. The flowers grow in large ſpikes, and are much larger than thoſe of the common ſort; and of a deep ſcarlet colour; the pods are large and rough, and the ſeeds are purple marked with black. This ſort requires no other treatment than the common ſort, but the ſtalks ſhould have tall ſtakes put down by them to twine round, otherwiſe they will fall on the ground, which will ſoon cauſe them to rot. Although this ſort be chiefly cultivated for the beauty of its flowers, yet Mr. Miller recommends it as the beſt ſort for the table; and adds, that whoever makes trial of this, will, he is perſuaded, prefer it to all other kinds yet known.

The beſt ſorts for the table are the ſcarlet bloſſom bean, juſt mentioned, and a white bean of a ſmall ſize and ſhape, which appears to be only a variety of the ſcarlet, as it differs in no other reſpect, than the beauty of the flowers and ſeeds, being equal in ſize and flavour. And next to theſe is the large Dutch kidney-bean, which grows as tall as either of theſe, and muſt therefore be ſupported by ſtakes, otherwiſe their ſtalks will trail upon the ground and ſpoil. The ſort with ſcarlet flowers is preferable to this in goodneſs, and is alſo hardier; and though it will not come ſo early as ſome of the dwarf kinds, yet it will continue bearing till the froſt puts a ſtop to it in autumn, ſo that it is much preferable to either of them; for the pods of this ſort when old, are ſeldom ſtringy, and have a better flavour than the young pods of theſe ſorts, and will alſo boil greener.

There are two or three ſorts of kidney-beans cultivated with erect ſtalks, which want no ſupport, as they do not put out any twining ſtalk. Theſe are much cultivated by the gardeners for that reaſon, as alſo for their producing a great plenty of pods; but they are inferior in goodneſs to the others.

All ſorts of kidney-beans are propagated by ſeeds, which are too tender to be ſown in open air before the middle of April; for if the weather ſhould be cold and wet after they are in the ground, they will rot; or if the morning froſt ſhould happen after the plants are come up, they will be deſtroyed. The beſt way therefore to have early kidney-beans, where there is no conveniency of frames for raiſing them, is to ſow the ſeeds in rows, pretty cloſe, upon a moderate hot-bed, the latter end of March, or beginning of April. If the heat of the bed be ſufficient to bring up the plants, it will be enough; this bed ſhould be arched over with hoops, that it may be covered over with mats every night, or in bad weather. In this bed the plants may ſtand till they have put out their trifoliate leaves, when they ſhould be carefully taken up, and tranſplanted in warm borders near hedges, pales, or walls. If the ſeaſon proves dry at the time of removing them, the plants ſhould be gently watered to forward their taking new root, and afterwards managed in the ſame manner with thoſe ſown in the full ground. Theſe tranſplanted beans will not grow ſo ſtrong as thoſe which are not removed, nor will they continue bearing ſo long; but they will come a fortnight earlier than thoſe which are ſown in the full ground.

The firſt crop intended for the full ground, ſhould be put in about the middle of April; but theſe ſhould have a warm ſituation, and a dry ſoil, otherwiſe the ſeeds will rot in the ground; or if the weather ſhould prove ſo favourable as to bring up the plants, yet there will be danger of their being killed by morning froſts, which frequently happen in the beginning of May.

The ſecond crop ſhould be ſown about the middle of May. Theſe will come into bearing before the early kinds are over, and if they are of the ſcarlet ſort, will continue fruitful till the froſt deſtroys the plants in autumn, and theſe will be good as long as they laſt. The manner of planting them is to draw ſhallow furrows with a hoe, at about three feet diſtance from each other, into which you ſhould drop the ſeeds about two inches aſunder; then, with the head of a rake, draw the earth over them, ſo as to cover them about an inch deep.

If the ſeaſon be favourable, the plants will begin to appear in about a week's time after ſowing, and ſoon after will raiſe their heads upright; therefore when the ſtems are advanced above-ground, you ſhould gently draw a little earth up to them, obſerving to do it when the ground is dry, which will preſerve them from being injured by ſharp winds; but you ſhould be careful not to draw any of the earth over their ſeed leaves. After this they will require no further care, but to keep them clear from weeds, until they produce fruit, when the pods ſhould be carefully gathered two or three times a week; for if they are permitted to remain upon the plants a little too long, the beans would be too large for for eating, and the plants would be greatly weakened thereby.

The large ſorts of kidney-beans muſt be planted at a greater diſtance, row from row; for as theſe grow very tall, ſo if the rows are not at a farther diſtance, the ſun and air will be excluded from the middle rows, therefore theſe ſhould not be leſs than four feet and a half diſtance, row from row; and when the plants are about four inches high, the poles ſhould be thruſt into the ground by the ſide of the plants, to which they will faſten themſelves, and climb to the height of eight or ten feet, and bear plenty of fruit from the ground upward. The Dutch and French preſerve great quantities of the large Dutch beans for winter uſe, which they ſtew, and render agreeable, with gravy and other ſauces.

The beſt way of ſaving the ſeeds of theſe plants, is to let a few rows of them remain ungathered in the height of the ſeaſon; for if you gather from the plants for ſome time, and afterwards leave the remainder for ſeed, their pods will not be near ſo long and handſome, nor will the ſeed be ſo good. In autumn, when you find they are ripe, you ſhould, in a dry ſeaſon, pull up the plants, and ſpread them abroad to dry; after which you may threſh out the ſeed, and preſerve it in a dry place for uſe. *Miller's Gard. Dict.*

BEAR, or *bere*, a ſpecies of barley, called alſo winter barley, ſquare barley, and big.

This grain is chiefly cultivated in Scotland, the northern parts of England, and Ireland. It yields a very large return, but is not eſteemed ſo good for malting as the common barley, for which reaſon it is very little cultivated in the ſouthern parts of England. *See* BARLEY.

BEARD, the ſame with awm. *See* AWMS.

BEARD *of a horſe*, a name given to the hairs ſcattered on his under lip to the place where the curb of the bridle reſts.

BEARDED *oat-graſs*, the ſame with wild oats. *See the article Wild* OATS.

BEAR'S EAR, the Engliſh name for the plant generally called auricula. *See* AURICULA.

BEC, a ſmall brook, a rivulet, a little ſtream of water.

BEDS, a name given by many writers on the new huſbandry to the ſpaces occupied by the rows of corn; to diſtinguiſh them from the intervals, or open ſpaces between theſe beds, which they term alleys. *See* ALLEY.

Yellow ladies BEDSTRAW, *cheeſe-rennet*, *maid's-hair*, or *petty mugwort*, a weed very common in moiſt meadows and paſture grounds. Its ſlender ſtalks riſe to about a foot in height. The leaves come out in whorls, eight or nine together. They are long, narrow, and of a green colour. Two little branches generally come out near the top of the ſtalk, ſupporting a conſiderable number of ſmall yellow flowers, conſiſting of one petal, divided into four parts, and ſucceeded by two large kidney ſhaped ſeeds.

BEE, a ſmall and well known inſect, famous for its induſtry.

This uſeful and laborious inſect is divided by two ligaments into three parts or portions, the head, the breaſt, and the belly. The head is armed with two jaws and a trunk; the former of which play like two jaws opening and ſhutting to the right and left. The trunk is long and taper, and, at the ſame time, extremely pliant and flexible, being deſtined by nature for the inſect to probe to the bottom of the flowers through all the impediments of their chives and foliage; and drain them of their treaſured ſweets: but were this trunk to be always extended it would prove incommodious, and be liable to be injured by a thouſand accidents; it is therefore of ſuch a ſtructure, that, after the performance of its neceſſary functions, it may be contracted, or rather folded up; and beſides this, it is fortified againſt all injures by four ſtrong ſcales, two of which cloſely ſheathe it, and the two others, whoſe cavities and dimenſions are larger, encompaſs the whole. From the middle part or breaſt of the bee grow the legs, which are ſix in number: and at the extremity of the paws are two little hooks, diſcernible by the microſcope, which appear like ſickles, with their points oppoſite to each other. The wings are four, two greater and two ſmaller, which not only ſerve to tranſport them through the air, but, by the noiſe they make, to give notice of their departure and arrival, and to animate them mutually to their ſeveral labours. The hairs with which the whole body is covered, are of ſingular uſe in retaining the ſmall duſt that falls from the chives of the flowers, of which the wax is formed, as will be obſerved hereafter. The belly of the bee conſiſts of ſix rings, which ſlide over one another, and may therefore be lengthened or contracted at pleaſure; and the inſide of this part of the body contains the inteſtines, the bag of honey, the bag of poiſon, and the ſting. The office of the inteſtines is the ſame as in other animals. The bag of honey is tranſparent as cryſtal, containing the ſweet juices extracted from flowers, which the bee diſcharges into the cells of the magazine for the ſupport of the community in winter. The bag of poiſon hangs at the root of the ſting, through the cavity of which, as through a pipe, the bee ejects ſome drops of this venomous liquor into the wound, and ſo renders the pain more exceſſive. The mechaniſm of the ſting is admirable, being compoſed of two darts, incloſed within a ſheath that tapers into a fine point, near which is an opening to let out the poiſon. The two darts are ejected through another aperture, which, being armed with ſeveral ſharp beards like thoſe of fiſh-hooks, are not eaſily drawn back again by the bee; and indeed ſhe never diſengages them if the wounded party happens to ſtart and put her into confuſion; but if one can have patience to continue calm and unmoved, ſhe clinches thoſe lateral points round the ſhaft of the dart, by which means ſhe recovers her weapons, and gives leſs pain to the perſon ſtung. The liquor which at the ſame time ſhe infuſes into the wound, cauſes a fermentation, attended with a ſwelling, which continues ſeveral days; but that may be prevented by immediately pulling out the ſting, and enlarging the puncture, to let the venomous matter have room to eſcape.

Let us now conſider the generation, polity, and labours of theſe inſects, the true knowledge of which is very much owing to the modern invention of glaſs-hives, through which all the ſecrets of the community are laid open to a curious obſerver. Any perſon who carefully examines a hive at different ſeaſons of the year, will diſtinguiſh three ſorts of bees; of which the far greater number are the common working bees, who do all the buſineſs of the hive, and ſeem to be neither male nor female. The working bee is repreſented at C (Plate III. Fig. 5.) The ſecond ſort, called drones, are the males, and ſomewhat larger than the former (as A, Fig. 6.) they have no ſting, nor even ſtir from the hive, but live upon the honey prepared by the others. The third ſort is a much larger and longer bodied bee, of which there are often but one in every ſwarm or colony of young bees, who are from time to time detached from the hive in ſearch of another habitation. This large bee is what the ancients called the king, from the reſpect they always ſaw paid to it by the other bees; but being the female, the moderns more properly give the title of queen, or mother of the ſwarm. *See* Plate III. Fig. 7. B.

When

When thefe induftrious infects begin their works, it is obferved they divide themfelves into four parties, one of which is deftined to the fields to provide materials for the ftructure; the fecond works upon thofe materials, and forms them into a rough fketch of the dimenfions and partitions of the cells; the third examines and adjufts the angles, removes the fuperfluous wax, polifhes the work, and gives it its neceffary perfection; and the fourth is employed in bringing provifions to the labourers that build them, becaufe polifhing is not fo laborious. They begin their work at the top of the hive, continuing downwards to the bottom, and from one fide to another; and to make it the more folid they ufe a fort of tempered wax, refembling glue. The form of the cells of the honey-comb is hexagonal, which figure, befides what is common with a fquare and equilateral triangle, has the advantage of including a greater fpace within the fame furface.

The expedition of the bees in their labour is almoft incredible; for notwithftanding the elegance and juft proportions of the work, they are fo indefatigable, that they will, in one day, finifh a honey-comb a foot long, and fix inches broad, capable of receiving three thoufand bees.

It is not eafy to know, particularly, the manner in which they employ themfelves at this work, on account of the number of bees then in motion, by which means the eye can hardly diftinguifh any thing but confufion. We have however been able to obferve the following particulars: fome bees, bearing in each of their talons a little piece of wax, are feen running to the places where their companions are at work upon the combs; at their arrival they faften the wax to the work by means of the fame talons, which they apply fometimes to the right, and fometimes to the left. Each bee is employed but a fhort time on this work, when another takes its place.

While a part of the bees are at work in conftructing the cells, others are employed in perfecting thofe that are newly modelled, finifhing the angles, fides, and bafes, in fo exquifite a manner, and with fuch remarkable delicacy, that three or four of thefe fides laid upon one another, are not thicker than a leaf of common paper; and becaufe the entrance of the cell, which is adapted to the fize of the bee, would, on account of this delicacy, be fubject to break, they ftrengthen the entrance of each cell with a border of wax.

We have already obferved, that the bees which build the cells work but a little while at a time; but it is different with regard to thofe that polifh them, for they work a long while, and with great expedition, never intermitting their labour, unlefs it be to carry out of the cell the particles of wax taken off in polifhing: and, to prevent this wax from being loft, other bees ftand ready to receive it from the polifhers, and carry it to fome other part in order to its being employed.

Each comb has two rows of cells oppofite to each other, which have their common bafes. The thicknefs of each comb is fomething lefs than an inch; and, confequently, the depth of each cell about five lines; but at the fame time the breadth of each is little more than two.

All the combs are conftructed with cells of this fize, except a fmall number of others in fome particular parts of the hive, which are larger, and appropriated to the lodging eggs, that afterwards become drones, or male bees.

There are alfo, in fome parts of the hive, three or four cells bigger than the others, and conftructed in a different manner. They are of a fpheroidical figure, open in the inferior part, and attached to the extremeties of the combs.

When the cells are completed, the queen takes poffeffion of thofe fhe likes beft to depofite her eggs in, and the reft are left to be filled with honey. She lays one egg in each cell, and fometimes more than an hundred of thofe eggs in a day; but what is ftill more remarkable, fhe lays thofe eggs which are to produce common bees in cells of the common fhape and fize, thofe that are to become drones or males, in the cells of a larger fize, and depofites thofe which are to become females, like herfelf, in the fpheroidical cells already defcribed.

Thefe eggs, after lying fome time in the cells, are hatched into maggots, and fed with honey ten or twelve days, after which the other bees clofe up the cells with a thin piece of wax; and under this covering they become gradually transformed into bees, in the manner as filk-worms are into butterflies. Having undergone this change, the young bees pierce through their waxen doors, wipe off the humidity from their little wings, take their flight into the fields, rob the flowers of their fweets, and are perfectly acquainted with every neceffary circumftance of their future conduct. As to the males or drones, which are deftined only to propagate their fpecies, they live very comfortably for about three months after they are hatched; but when that time is over, and the females are impregnated, the common bees either kill them, or drive them from the hive, as burdenfome to the community, and not a drone is to be found till the next feafon.

The method in which the bees collect their wax and honey deferves to be a little explained. At the bottom of all flowers there are certain glands which contain more or lefs honey, that is, the moft exalted particles of the fugary juices of the plant. Thefe juices the bee fucks up with her probofcis or trunk above-mentioned, and draws it into her mouth; and when it has thus taken a fufficient quantity into her ftomach, returns to the hive, and difcharges the honey into the common magazine.

When the cells prepared to receive it are full, the bees clofe up fome with wax till they have occafion for the honey; the reft they leave open, to which all the members of the fociety refort, and take their repaft with a very inftructive moderation.

It is an excellent obfervation of a modern author, that the hive is a fchool to which numbers of people ought to be fent; prudence, induftry, benevolence, public fpiritednefs, œconomy, neatnefs, and temperance, are all vifible among the bees. Thefe little animals are actuated by a focial fpirit, which forms them into a body politic, intimately united, and perfectly happy. They all labour for the general advantage; they are all fubmiffive to the laws and regulations of the community: having no particular intereft, no diftinction but thofe which nature or the neceffities of their young have introduced amongft them. We never fee them diffatisfied with their condition, or inclinable to abandon the hive in difguft, or find themfelves flaves or neceffitous: on the contrary, they think themfelves in perfect freedom, and perfect affluence; and fuch indeed is their real condition. They are free, becaufe they only depend on the laws; they are happy, becaufe the concurrence of their feveral labours inevitably produces abundance, which contributes to the riches of each individual. Let us compare human focieties with this, and they will appear altogether monftrous. Neceffity, reafon, and philofophy, have eftablifhed them for the commendable purpofes of mutual aid and benefits: but a fpirit of felfifhnefs deftroys all; and one half of mankind, to load themfelves with fuperfluities, leave the other deftitute of common neceffaries.

Wax is compofed of the farina, or duft, formed on the apices of flowers. This the bees collect, and with their fore-feet and jaws, roll up into little balls, which they convey, one at a time, to the feet of their middle legs, and from thence to the middle joints of their hind legs, where there is a fmall cavity like a fpoon to receive it. Thefe balls are not, however, true wax, but the fubftance or bafis of it: to reduce this crude fubftance into wax, it muft firft be digefted in the body of the bee.

After the bees have brought home this crude fubftance, they eat it by degrees; or, at other times, three or four bees come and eafe the loaded bee by eating each of them a fhare, the loaded bee giving them a hint fo to do. Hunger is not the motive of their thus eating the balls of waxy matter, efpecially when a fwarm is firft hived; but it is their defire to provide a fpeedy fupply of real wax for making the combs. At other times, when

when there is no immediate want of wax, the bees lay this matter up in repositories, to keep it in store.

When this waxy matter is swallowed, it is, by the digestive powers of the bee, converted into real wax, which the bees again disgorge as they work it up into combs; for it is only while thus soft and pliant from the stomach that they can fabricate it properly. That the wax thus employed is taken from their stomachs, appears from their making a considerable quantity of comb soon after they are hived, and even on any tree or shrub where they have rested but a short while before their being hived, though no balls were visible on their legs, excepting those of a few which may be just returned from the field.

Bees collect crude wax also for food; for if this was not the case, there would be no want of wax after the combs are made: but they are observed, even in old hives, to return in great numbers loaded with such matter, which is deposited in particular cells, and is known by the name of *bee-bread*. We may guess that they consume a great deal of this substance in food, by the quantity collected, which, by computation, may in some hives amount to an hundred weight in a season, whilst the real wax in such an hive does not perhaps exceed two pounds.

But besides the three substances, honey, wax, and bee-bread, already mentioned, there is another with which the bees close every crevice in their hives, and which is called propolis. It is a kind of resin easy to be rolled out, much more tenacious than wax, and more easily fixed. It does not seem to require any preparation, being a real resin, which they collect from trees, and employ as they find it. It grows very hard in the hive, but may be softened by heat. It is dissoluble in spirit of wine. It commonly diffuses a very agreeable smell when heated. Its outward colour is of a reddish brown; its inside resembles wax, and is a little yellowish. When the bees make use of it, it is soft and pliable; but it hardens daily, and becomes in time harder than wax. This propolis serves also for another purpose, which is, that when a snail, slug, or any other creature too large to be carried out by the bees, has been slain in the hive, they case it over with this substance, and thereby prevent the bad effects of the putrid smell arising from dead bodies.

When the hive is become too much crowded, by the addition of the young brood, a part of the bees think of finding themselves a more commodious habitation, and with that view single out the most forward of the young queens. A new swarm is therefore constantly composed of one queen at least, and of several thousand working bees, as well as of some hundreds of drones. The working bees are some old, some young.

Scarce has the colony arrived at its new habitation, when the working bees labour with the utmost diligence, to procure materials for food and building. Their principal aim is not only to have cells in which they may deposit their honey; a stronger motive seems to animate them. They seem to know that their queen is in haste to lay her eggs. Their industry is such, that in twenty-four hours they will have made combs twenty inches long, and wide in proportion. They make more wax during the first fortnight, if the season is favourable, than they do during all the rest of the year. Other bees are at the same time busy in stopping all the holes and crevices they find in their new hive, in order to guard against the entrance of insects which covet their honey, their wax, or themselves; and also to exclude the cold air; for it is indispensably necessary that they be lodged warm.

When the bees first settle in swarming, indeed when they at any time rest themselves, there is something very particular in their method of taking their repose. It is done, by collecting themselves in a heap, and hanging to each other by their feet. They sometimes extend these heaps to a considerable length. It would seem probable to us, that the bees from which the others hang, must have a considerable weight suspended to them. All that can be said is, that the bees must find this to be a situation agreeable to themselves. They may perhaps have a method of distending themselves with air, thereby to lessen their specific gravity; in the same manner as fishes do, in order to alter their gravity, compared with water.

When a swarm divides into two or more bands, which settle separately, this division is a sure sign that there are two or more queens among them. One of these clusters is generally larger than the other. The bees of the smaller cluster, or clusters, detach themselves by little and little, till at last the whole, together with the queen, or queens, unite with the larger cluster. As soon as the bees are hived and settled, the supernumerary queen, or queens, must be sacrificed to the peace and tranquility of the hive. This execution generally raises a considerable commotion in the hive, and several other bees, as well as the queen or queens, lose their lives. Their bodies may be observed on the ground, near the hive. The queen that is chosen is of a more reddish colour than those which are destroyed: so that fruitfulness seems to be a great motive of preference in bees; for the nearer they are to the time of laying their eggs, the bigger, larger, and more shining are their bodies.

For three or four nights before a swarm sallies forth, there is in the hive a peculiar humming noise, of which authors give very different descriptions, probably owing to the strength of imagination in each. Every sound among bees arises from their striking their wings against the air: their wings being their sole organ of sound, if we may be allowed the expression. By moving their wings more or less forcibly and swiftly, they beat the air, and form the varied confused sounds which we call humming. The noise which foretels their swarming is easily distinguished by those who are accustomed to it, and is more especially observed before the casts, or second and following swarms. The hive appears so full of bees, that part of them hang in clusters on the outside; and the drones are perceived flying about in greater numbers than usual. But the most certain sign, and which indicates this event to be on that day, is, that the bees refrain from flying into the fields, though the season seems inviting. Just before they take their flight, there is an uncommon silence in the hive, and this continues for some time: but as soon as one breaks forth, they all follow, and are instantly on the wing. They seldom swarm before the sun has warmed the air; that is, not before ten in the morning, and seldom later than three in the afternoon: and the time of the year in which they most generally swarm, is from the middle of May to the end of June; but sometimes sooner or later, according as the season is more or less favourable. The earliest swarms do not always prove the best, especially if they are so early as the end of April or beginning of May: for the weather often is afterwards so wet and cold, that they are frequently in danger of being destroyed, or greatly reduced, by famine. Though swarms which issue forth so late as July are not in danger of a present famine; yet they scarcely have time and opportunity to lay in a sufficient store for the winter. Towards the season of swarming, the door of the hive should be enlarged, to give the bees the greater freedom to issue out; and it should likewise remain so for young swarms, during the first fortnight or three weeks, to allow the freer entrance to the bees, at that time extremely busy in collecting their necessary stores. The entrance should afterwards be gradually lessened, to prevent the otherwise easy access of enemies, of which there is great danger, especially as the autumn advances.

Hives continue sometimes to send forth swarms till the old hive becomes too much weakened, and part of it is empty. It is probable, that the prolific young queens prompt the bees to swarm thus frequently: for it is certain that if there is not a young mother qualified to bring forth a numerous progeny, though there be ever so great a number of bees, they will all remain, and die rather than quit the hive.

Whenever the bees of a swarm fly too high, they are made to descend lower, and disposed to settle, by throwing among them handfuls of sand or dust: probably the bees mistake this for rain. It is usual at the same time to beat on a kettle or frying-pan; perhaps from its being observed that the noise of thunder prompts such bees as are in the fields to return home. Precautions of this kind are the more neceſſary, if, as Dr. Warder, in his True Amazons, obſerves, "the bees always provide a place for their habitation before they ſwarm; either in ſome hollow tree, or in the hollow part of ſome old building, or in ſome deſerted hive, which the ſwarm have already prepared, by cleaning out whatever may be offenſive to their cleanly nature." Of this he gives an inſtance; and concludes, that "though they provide themſelveswith a houſe before they ſwarm, and take much pains about it; yet if you are early enough in your taking the ſwarm, and they find themſelves at unawares in a convenient houſe, they have no mind generally to leave it: but if they riſe again the ſame or next day, be ſure hive them not in the ſame hive again, for it is plain they have ſome diſlike to it."

As ſoon as the ſwarm is ſettled, the bees which compoſe it ſhould be got into a hive with all convenient ſpeed, to prevent their taking wing again. If they ſettle on a ſmall branch of a tree, eaſy to be come at, it may be cut off, and laid upon a cloth; the hive being ready immediately to put over them. If the branch cannot be conveniently cut, the bees may be ſwept from off it into a hive. Lodge but the queen in the hive, and the reſt will ſoon follow. If the bees muſt be conſiderably diſturbed, in order to get them into a hive, the moſt adviſable way is to let them remain in the place where they have pitched, till the evening, when there is leſs danger of their taking wing. If it be obſerved that they ſtill hover about the place they firſt alighted upon, the branches there may be rubbed with rue, or elder leaves, or any other thing diſtaſteful to them, to prevent their returning to it.

The hive employed on this occaſion ſhould be cleaned with the utmoſt care, and its inſide be rubbed very hard with a coarſe cloth, to get off the looſe ſtraws, or other impurities, which might coſt them a great deal of time and labour to gnaw away. It may then be rubbed with fragrant herbs or flowers, the ſmell of which is agreeable to the bees, or with honey.

The hive ſhould not be immediately ſet on the ſtool where it is to remain, but ſhould be kept near the place at which the bees ſettled, till the evening, leſt ſome ſtragglers ſhould be loſt. It ſhould be ſhaded, either with boughs, or with a cloth, that the too great heat of the ſun may not annoy the bees.

We ſometimes ſee a ſwarm of bees, after having left their hive, and even alighted upon a tree, return to their firſt abode. This never happens but when the young queen did not come forth with them, for want of ſtrength, or perhaps courage to truſt to her wings for the firſt time; or poſſibly from a conſciouſneſs of her not being impregnated.

Bees are not apt to ſting when they ſwarm; therefore it is not neceſſary then to take much extraordinary precaution againſt them. It is however adviſable for thoſe who are not accuſtomed to them, to cover their face and hands.

A ſecond ſwarm ſcarcely is, and much leſs are the ſubſequent ones, worth keeping ſingle; becauſe, being few in number, they cannot allow ſo large a proportion of working bees to go abroad in ſearch of ſtore, as more numerous ſwarms can, after having appointed a proper number for the various works to be done within. For this reaſon it is adviſable to unite two or more of theſe laſt or latter ſwarms into one hive, ſo as to procure a ſufficient number of bees in one hive. Bees ſometimes ſwarm ſo often, that the mother-hive is too much weakened. In this caſe, the ſwarms ſhould be reſtored back; and this ſhould alſo be done when a ſwarm produces a ſwarm the firſt ſummer, as it ſometimes does. The beſt way, indeed, is to prevent ſuch ſwarming, by giving the bees more room: though this, again, will not anſwer where there is a young pregnant queen; ſhe well knowing that her life is the forfeit of her remaining at home.

The uſual method of uniting ſwarms is very eaſy. Spread a cloth at night upon the ground cloſe to the hive in which the two caſts or ſwarms are to be united; lay a ſtick a-croſs this cloth; then fetch the hive with the new ſwarm, ſet it over the ſtick, give a ſmart ſtroke on the top of the hive, and all the bees will drop down upon the cloth, in a cluſter. This done, throw aſide the empty hive, take the other from off the ſtool, and ſet this laſt over the bees, who will ſoon aſcend into it, mix with thoſe already there, and become one and the ſame family. Others, inſtead of ſtriking the bees down upon the cloth, place with its bottom upmoſt the hive in which the united ſwarms are to live, and ſtrike the bees of the other hive down into it. The former of theſe hives is then reſtored to its natural ſituation, and the bees of both hives ſoon unite. If ſome bees ſtill adhere to the other hive, they may be bruſhed off on the cloth, and they will ſoon join their brethren. Or one may take the following method, which gives leſs diſturbance to the bees. Set with its mouth upmoſt the hive into which the young ſwarm has been put, and ſet upon it the other hive. The bees in the lower hive, finding themſelves in an inverted ſituation, will ſoon aſcend into the upper.

Though all writers acknowledge, that one of the queens is conſtantly ſlain on theſe occaſions, and generally a conſiderable number of the working bees; yet none of them, Columella excepted, has propoſed the eaſy remedy of killing the queen of the latter caſt or ſwarm before the union is made; a means by which the lives of the working bees may be preſerved. This may be done, either by intoxicating them, and then picking her out, or by ſearching her out when the bees are beaten down upon the cloth; for this being done in the night, to prevent the battle which might otherwiſe enſue, there will be no great difficulty in finding her.

A large ſwarm may weigh eight pounds, and ſo gradually leſs, to one pound: conſequently a very good one may weigh five or ſix pounds. All ſuch as weigh leſs than four pounds ſhould be ſtrengthened, by uniting to each of them a leſs numerous ſwarm. The ſize of the hive ſhould be proportioned to the number of the bees; and, as a general rule, it ſhould be rather under than over-ſized, becauſe bees require to be kept warmer than a large hive will admit of.

Columella directs, that the apiary, or bee-garden, face the ſouth, in a place neither too hot, nor too much expoſed to the cold; that it be in a valley, in order that the loaded bees may with the greater eaſe deſcend to their homes; that it be near the manſion-houſe, on account of the conveniency of watching them, but ſo ſituated as not to be expoſed to noiſome ſmells, or to the din of men or cattle; that it may be ſurrounded with a wall, which however ſhould not riſe above three feet high; that, if poſſible, a running ſtream be near them, or, if that cannot be, that water be brought near them in troughs, with pebbles or ſmall ſtones in the water, for the bees to reſt on whilſt they drink; or that the water be confined within gently declining banks, in order that the bees may have ſafe acceſs to it; they not being able to produce either combs, honey, or food for their maggots, without water. That the neighbourhood of rivers or baſons of water with high banks be avoided, becauſe winds may whirl the bees into them, and they cannot eaſily get on ſhore from thence to dry themſelves; and that the garden in which the apiary ſtands be well furniſhed with ſuch plants as afford the bees plenty of good paſture. The trees in this garden ſhould be of the dwarf kind, and their heads buſhy, in order that the ſwarms which ſettle on them may be the more eaſily hived.

The proprietor ſhould be particularly attentive that the bees have alſo in their neighbourhood ſuch plants as yield them plenty of food. Columella enumerates many of theſe fitted to a warm climate: among them he mentions thyme, the oak, the pine, the ſweet ſmelling cedar, and all fruit trees. Experience has taught us, that furze, broom, muſtard, clover, heath, buck-wheat, &c. are excellent for this purpoſe. Pliny recommends broom, in particular, as a plant exceedingly grateful, and very profitable to bees; and Mr. Bradley ſpeaks highly of the advantages which ariſe from the planting of it for the food of theſe uſeful inſects. *See the article* BROOM.

Plantations of muſtard, of the flowers of which bees are extremely fond, may be kept in bloom for ſeveral weeks running.

Great improvements may alfo certainly be made in the effential article of providing plenty of pafture for bees, whenever this fubject fhall be more carefully attended to than it, unfortunately, has hitherto been. A rich corn country is well known to be a barren defart to them during the moft confiderable part of the year; and therefore the practice of other nations, in fhifting the places of abode of their bees, well deferves our imitation.

Columella informs us, that, as few places are fo happily fituated as to afford the bees proper pafture both in the beginning of the feafon and alfo in the autumn, it was the advice of Celcus, that after the vernal paftures are confumed, the bees fhould be tranfported to places abounding with autumnal flowers; as was practifed by conveying the bees from Achaia to Attica, from Eubœa and the Cyclad iflands to Scyrus, and alfo in Sicily, where they were brought to Hybla from other parts of the ifland. He likewife directs, that the hives be carefully examined before they are removed from one place to another, and to take out fuch combs as appear old, loofe, or have moths in them, referving only thofe that are found, in order that the hive may be ftored with combs collected from the beft flowers.

M. Maillet, in his curious defcription of Egypt, relates, that "fpite of the ignorance and rufticity which have got poffeffion of that country, there yet remain in it feveral footfteps of the induftry and fkill of the antient Egyptians. One of their moft admirable contrivances is, their fending their bees annually into diftant countries, in order to procure them fuftenance there, at a time when they could not find any at home; and their afterwards bringing them back, like fhepherds who fhould travel with their flocks, and make them feed as they go. It was obferved by the antient inhabitants of Lower Egypt, that all plants bloffomed, and the fruits of the earth ripened, above fix weeks earlier in Upper Egypt, than with them. They applied this remark to their bees; and the means then made ufe of by them, to enable thefe ufeful induftrious infects to reap advantage from the more forward ftate of nature there, were exactly the fame as are now practifed, for the like purpofe, in that country. About the end of October, all fuch inhabitants of the Lower Egypt as have hives of bees, embark them on the Nile, and convey them upon that river quite into Upper Egypt; obferving to time it fo that they arrive there juft when the inundation is withdrawn, the lands have been fown, and the flowers begin to bud. The hives thus fent are marked and numbered by their refpective owners, and placed pyramidically in boats prepared for the purpofe. After they have remained fome days at their fartheft ftation, and are fuppofed to have gathered all the wax and honey they could find in the fields within two or three leagues around; their conductors convey them, in the fame boats, two or three leagues lower down, and there leave the laborious infects fo long time as is neceffary for them to collect all the riches of this fpot. Thus, the nearer they come to the place of their more permanent abode, they find the productions of the earth, and the plants which afford them food, forward in proportion. In fine, about the beginning of February, after having travelled through the whole length of Egypt, gathering all the rich produce of the delightful banks of the Nile, they arrive at the mouth of that river, towards the ocean; from whence they fet out, and from whence they are now returned to their feveral homes: for care is taken to keep an exact regifter of every diftrict from whence the hives were fent in the beginning of the feafon, of their numbers, of the names of the perfons who fent them, and likewife of the mark or number of the boat in which they were placed."

The author of the Natural Hiftory of Bees gives the following account of what is practifed in this way in France; an example well worth our imitation in many parts of this kingdom. "M. Proutaut, fays he, keeps a great number of hives. His fituation is one of thofe in which flowers become rare or fcarce very foon, and where few or none are feen after the corn is ripened. He then fends his bees into Beauce, or the Gatinois, in cafe it has rained in thofe parts. This is a journey of about twenty miles, which he makes them take. But if he concludes that the bees could not meet, in either of thofe counties, wherewith to employ themfelves advantageoufly, he then has them carried into Sologne, about the beginning of Auguft; as knowing that they will there meet with a great many fields of buck-wheat in flower, which will continue fo till about the end of September. His method of tranfporting them is thus. His firft care is, to examine thofe hives, fome of whofe honey-combs might be broken or feparated by the jolting of the vehicle: they are made faft one to the other, and againft the fides of the hive, by means of fmall fticks, which may be difpofed differently as occafion will point out. This being done, every hive is fet upon a packing-cloth, or fomething like it, the threads of which are very wide: the fides of this cloth are then turned up, and laid on the outfide of each hive, in which ftate they are tied together with a piece of fmall pack-thread wound feveral times round the hive. As many hives as a cart built for that purpofe will hold, are afterwards placed in this vehicle. The hives are fet two and two, the whole length of the cart. Over thefe are placed others; which make, as it were, a fecond ftory or bed of hives. Thofe which are ftored with combs fhould always be turned topfy-turvy. It is for the fake of their combs, and to fix them the better, that they are difpofed in this manner; for fuch as have but a fmall quantity of combs in them, are placed in their natural fituation. Care is taken in this ftowage, not to let one hive ftop up another; it being effentially neceffary for the bees to have air; and it is for this reafon they are wrapped up in a coarfe cloth, the threads of which were wove very wide, in order that the air may have a free paffage, and leffen the heat which thefe infects raife in their hives; efpecially when they move about very tumultuoufly, as often happens in thefe carts. Thofe ufed for this purpofe in Yévre, hold from thirty to forty-eight hives. As foon as all are thus ftowed, the caravans fet out. If the feafon is fultry, they travel only in the night; but a proper advantage is made of cool days. You will imagine that they do not ride poft. The horfes muft not be permitted even to trot; they are led flowly, and through the fmootheft roads. When there are not combs in the hives fufficient to fupport the bees during their journey, the owner takes the earlieft opportunity of refting them wherever they can collect wax. The hives are taken out of the cart, then fet upon the ground, and after removing the cloth from over them, the bees go forth in fearch of food. The firft field they come to ferves them as an inn. In the evening, as foon as they are all returned, the hives are fhut up; and being placed again in the cart, they proceed in their journey. When the caravan is arrived at the journey's end, the hives are diftributed in the gardens; or in fields adjacent to the houfes of different peafants, who, for a very fmall reward, undertake to look after them. Thus it is that, in fuch fpots as do not abound in flowers at all feafons, means are found to fupply the bees with food during the whole year."

Thefe inftances of the great advantages which attend fhifting of bees in fearch of pafture, afford an excellent leffon to many places in this kingdom: they direct particularly the inhabitants of the rich vales, where the harveft for bees ends early, to remove their flocks to places which abound in heath, this plant continuing in bloom during a confiderable part of the autumn, and yielding great plenty of food to bees. Thofe in the neighbourhood of hills and mountains will fave the bees a great deal of labour, by taking alfo the advantage of fhifting their places of abode.

We come now to explain the moft inhuman method commonly practifed of taking bees, which confifts in wantonly deftroying the whole fwarm, in order to enjoy the fruits of their labours.

Were we to kill the hen for her egg, the cow for her milk, or the fheep for the fleece it bears, every one would inftantly fee how much we fhould act contrary to our own intereft: and yet this is practifed every year in regard to bees. Would it not argue more wifdom in us to be contented with taking away only a portion of their wax and honey, as is the practice of many countries?

The

The common method here is, that when thofe which are doomed for flaughter have been marked out (which is generally done in September) a hole is dug near the hive, and a ftick, at the end of which is a rag that has been dipped in melted brimftone, being ftuck in that hole, the rag is fet on fire, the hive is immediately fet over it, and the earth is inftantly thrown up all around, fo that none of the fmoak can efcape. In a quarter of an hour, all the bees are feemingly dead; and they will foon after be irrecoverably fo, by being buried in the earth that is returned back into the hole: I fay, they will foon be abfolutely killed by this laft means; becaufe it has been found, by experiment, that all the bees which have been affected only by the fume of the brimftone, recover again, excepting fuch as have been finged or hurt by the flame. Hence it is evident, that the fume of brimftone might be ufed for intoxicating the bees, with fome few precautions. The heavieft and the lighteft hives are alike treated in this manner; the former, becaufe they yield the moft profit, with an immediate return; and the latter, becaufe they would not be able to furvive the winter. Thofe hives which weigh from fifteen to twenty pounds, are thought to be the fitteft for keeping.

The practice of the ancients was, however, very different from this: they were content to fhare with thefe induftrious infects, the produce of their labours; and fome very laudable attempts have been made in our own country, to attain the defirable end of getting the honey and wax without deftroying the bees. John Geddy, Efq; publifhed in the year 1665, his invention of boxes for preferving the lives of bees. Thefe were improved by Jofeph Warder, phyfician, at Croydon, who at the fame time embellifhed his account of the ftructure and ufe of thefe boxes, with feveral other curious circumftances concerning bees, in his work intituled, The true Amazons, or the Monarchy of Bees. Two very worthy clergymen, the reverend Mr. John Thorley of Oxford, and the reverend Mr. Stephen White, M. A. rector of Holton in Suffolk, have brought the method of preferving the lives of bees to ftill greater perfection. We fhall relate the opinions and practice of each, beginning with Mr. Thorley, who lived many years before Mr. White, and add to their accounts the beft improvements that have been lately made in foreign countries.

Mr. Thorley, in his Enquiry into the Nature, Order, and Government of Bees, thinks colonies preferable to hives, for the following reafons. Firft, the more certain prefervation of very many thoufands of thefe noble and ufeful creatures: Secondly, their greater ftrength (which confifts in numbers) and confequently their greater fafety from robbers: Thirdly, their greater wealth, arifing from the united labours of the greater number. He tells us, that he has in fome fummers taken two boxes filled with honey from one colony; and yet fufficient ftore has been left for their maintenance during the winter, each box weighing forty pounds. Add to thefe advantages, the pleafures of viewing them; with the greateft fafety, at all feafons, even in their bufieft time of gathering, and their requiring a much lefs attendance in fwarming time. The bees thus managed are alfo more effectually fecured from wet and cold, from mice and other vermin.

His boxes are made of deal, which, being fpungy, fucks up the breath of the bees fooner than a more folid wood would do. Yellow dram-deal, thoroughly feafoned, is the beft.

An octagon, being nearer to a fphere, is better than a fquare form; for as the bees, in winter, lie in a round body near the center of the hive, a due heat is then conveyed to all the out-parts, and the honey is kept from candying.

The dimenfions which Mr. Thorley, after many years experience, recommends for the boxes, are ten inches deep, and twelve or fourteen inches broad, in the infide. He has tried boxes containing a bufhel or more, but found them not to anfwer the defign like thofe of a leffer fize.

The top of the box fhould be made of an entire board, a full inch thick after it has been planed, and it fhould project on all fides at leaft an inch beyond the dimenfions of the box. In the middle of this top there muft be a hole five inches fquare, for a communication between the boxes; and this hole fhould be covered with a fliding fhutter, of deal or elm, running eafily in a groove over the back window. The eight pannels, nine inches deep, and three quarters of an inch thick when planed, are to be let into the top fo far as to keep them in their proper places; to be fecured at the corners with plates of brafs, and to be cramped with wires at the bottom, to keep them firm: for the heat in fummer will try their ftrength. There fhould be a glafs window behind, fixed in a frame, with a thin deal cover, two fmall brafs hinges, and a button to faften it. This window will be fufficient for infpecting the progrefs of the bees. Two brafs handles, one on each fide, are neceffary, to lift up the box: thefe fhould be fixed in with two thin plates of iron, near three inches long, fo as to turn up and down, and put three inches below the top-board, which is nailed clofe down with fprigs to the other parts of the box.

Thofe who chufe a frame within, to which the bees may faften their combs, need only ufe a couple of deal fticks of an inch fquare, placed acrofs the box, and fupported by two pins of brafs; one an inch and a half below the top, and the other two inches below it; by which means the combs will quickly find a reft. One thing more, which perfects the work, is a paffage four or five inches long, and lefs than half an inch deep, for the bees to go in and out at the bottom of the box.

Mr. Thorley, fon to the above-mentioned clergyman, has improved his father's method of managing bees; and having been convinced from near fixty years experience, that his bee-hives would be productive of much greater profit to the owners of bees, and alfo render that cruel and ungenerous practice of deftroying thefe animals not only unneceffary, but pernicious, prefented a bee-hive of this conftruction to the Society of Arts, &c. in the Strand, who readily purchafed another of his hives filled with honey, &c. that they might be infpected by the curious, and brought into univerfal ufe; and from this bee-hive the view on Plate III. Fig. 8, was drawn. The fociety, perfuaded that the invention would prove of the greateft advantage to this country, publifhed a premium of two hundred pounds, in order to introduce Mr. Thorley's, or fome other method of a fimilar kind, whereby much larger quantities of honey and wax might be procured, and, at the fame time, the lives of thefe laborious and ufeful infects preferved.

The bottom part, marked *a*, is an octangular bee-box, made of deal boards, about an inch in thicknefs, the cover of which is about 17 inches in diameter, but the internal part only 15½, and its height 10 inches. In the middle of the cover of this octangular box is a hole, which may be opened or fhut at pleafure, by means of a flider *d*. In one of the pannels is a pane of glafs, covered with a wooden door, *e*. The entrance, *f*, at the bottom of the box is about three inches and a half broad, and half an inch high. Two flips of deal, about half an inch fquare, crofs each other in the center of the box, and are faftened to the pannels by means of fmalls fcrews. To thefe flips the bees faften their combs.

In this octangular box the bees are hived, after fwarming in the ufual manner, and there fuffered to continue till they have built their combs, and filled them with honey, which may be known from opening the door, and viewing their works through the glafs pane, or by the weight of the hive. When the bee-mafter finds his laborious infects have filled their habitation, he is to place a common bee-hive of ftraw, reprefented at *b*, made either flat at the top, or in the common form, on the octangular box, and draw out the flider, by which a communication will be opened between the box and the ftraw hive; the confequence of which will be, that thofe laborious infects will fill this hive alfo with the product of their labours. When the bee-mafter finds the ftraw hive is well filled, he may pufh in the flider, and take it away, placing another immediately in its room, and then drawing out the flider. Thefe indefatigable creatures will then fill the new hive in the fame manner.

manner. By proceeding in this method, Mr. Thorley assured the society that he had taken three successive hives, filled with honey and wax, from one single hive, during the same summer; and that after he had laid his insects under so large a contribution, the food still remaining in the octangular box was abundantly sufficient for their support during the winter. He added, that if this method was pursued in every part of the kingdom, instead of that cruel method of putting the creatures to death, he was persuaded, from long experience, that wax would be collected in such plenty that candles might be made with it, and sold as cheap as those of tallow are at present.

Mr. Thorley has also added another part to his bee-hive, which cannot fail of affording the highest entertainment to a curious and inquisitive mind. It consists of a glass receiver, represented at D, eighteen inches in height, eight inches in diameter at the bottom, and in the greatest part thirteen. This receiver has a hole at the top, about an inch in diameter, through which a square piece of deal E is extended to nearly the bottom of the vessel, having two cross bars to which the bees fasten their combs. When the bees have filled their straw hive, (which must have a hole in the center, covered with a piece of tin) Mr. Thorley places the glass *e* upon the top of the straw hive, and draws out the piece of tin: the bees, now finding their habitation enlarged, pursue their labours with such alacrity, that they fill this glass hive likewise with their stores. And as this receptacle is wholly transparent, the curious observer may entertain himself with viewing the whole progress of their works. One of the hives, now deposited at the society's rooms in the Strand, is filled with the produce of the labours of those insects; and the glass-hive is supposed to contain about thirty-eight pounds of honey.

It will, however, be necessary to cover the glass with an empty hive of straw, or at least with a cloth, which may be easily removed when you inspect your bees, lest too much light prevent your insects from working.

When the glass is completely filled, slide a tin-plate between it and the hive or box, so as to cover the passage, and in half an hour the glass may be taken off with safety. What few bees remain in it, will readily go to their companions. He then very obligingly offers his service and farther information to any gentleman or lady whose curiosity may incline them to inspect his apiary. He has added a glass window to his straw hives, in order to see what progress the bees make; which is of some importance, especially if one hive is to be taken away whilst the season still continues favourable for their collecting of honey: for when the combs are filled with honey, the cells are sealed up, and the bees forsake them, and reside mostly in the hive in which their works are chiefly carried on. Observing also, that the bees were apt to extend their combs through the passage of communication into the upper hive, whether glass or other, which rendered it necessary to divide the comb when the upper hive was taken away, he now puts in that passage a wire screen, or netting, the meshes of which are large enough for a loaded bee to go easily thro' them. This prevents the joining of the combs from one box to the other, and consequently obviates the necessity of cutting them, and of spilling some honey, which, running down amongst a crowd of bees, used before to incommode them much; it being difficult for them to clear their wings of it.

The reverend Mr. Stephen White, rector of Holton in Suffolk, informs us, that his fondness for these little animals soon put him upon endeavouring, if possible, to save them from *fire* and *brimstone*; that he thought he had reason to be content to share their labours for the present, and great reason to rejoice if he could at any time preserve their lives, to work for him another year; and that the main drift of his observations and experiments has therefore been, to discover an easy and cheap method, suited to the abilities of the common people, of taking away so much honey as can be spared, without destroying or starving the bees; and by the same means to encourage seasonable swarms.

In his directions how to make the bee-boxes of his inventing, he tells us, speaking of the manner of constructing a single one, that it may be made of deal or any other well seasoned boards which are not apt to warp or split. The boards should be near an inch thick: the figure of the box square, and its height and breadth nine inches and five eighths, every way measuring within. With these dimensions it will contain near a peck and an half. The front part must have a door cut in the middle of the bottom edge, three inches wide, and near half an inch in height, which will give free liberty to the bees to pass through, yet not be large enough for their enemy the mouse to enter. In the back part you must cut a hole with a rabbit in it, in which you are to fix a pane of the clearest and best crown-glass, about five inches in length, and three in breadth, and fasten it with putty: let the top of the glass be placed as high as the roof within-side, that you may see the upper part of the combs, where the bees with their riches are mostly placed. You will, by this means, be better able to judge of their state and strength, than if your glass was fixed in the middle. The glass must be covered with a thin piece of board, by way of shutter, which may be made to hang by a string, or turn upon a nail, or slide sideways between two mouldings. Such as are desirous of seeing more of the bees works, may make the glass as large as the box will admit, without weakening it too much; or they may add a pane of glass on the top, which must likewise be covered with a shutter, fastened down with pegs to prevent accidents.

The side of the box which is to be joined to another box of the same form and dimensions, as it will not be exposed to the external air, may be made of a piece of slit deal not half an inch thick. This he calls the side of communication, because it is not to be wholly inclosed: a space is to be left at the bottom the whole breadth of the box, and a little more than an inch in height, and a hole or passage is to be made at top, three inches long, and more than half an inch wide. Through these the bees are to have a communication from one box to the other. The lower communication being on the floor, our labourers, with their burthens, may readily and easily ascend into either of the boxes. The upper communication is only intended as a passage between the boxes, resembling the little holes, or narrow passes, which may be observed in the combs formed by our sagacious architects, to save time and shorten the way when they have occasion to pass from one comb to another; just as, in populous cities, there are narrow lanes and alleys, passing transversly from one large street to another.

In the next place you are to provide a loose board, half an inch thick, and large enough to cover the side where you have made the communication. You are likewise to have in readiness several little iron staples, an inch and half long, with the two points or ends bended down more than half an inch. The use of these will be seen presently.

You have now only to fix two sticks crossing the box from side to side, and crossing each other, to be a stay to the combs; one about three inches from the bottom, the other the same distance from the top; and when you have painted the whole, to make it more durable, your box is finished.

The judicious bee-master will here observe, that the form of the box now described is as plain as is possible for it to be. It is little more than five square pieces of board nailed together; so that a poor cottager, who has but ingenuity enough to saw a board into the given dimensions, and to drive a nail, may make his own boxes well enough, without the help or expence of a carpenter.

No directions are necessary for making the other box, which must be of the same form and dimensions. The two boxes differ from each other only in this, that the side of communication of the one must be on your right-hand; of the other on your left. Plate III. Fig. 9. represents two of these boxes, with their openings of communication, ready to join to each other.

Mr. White's manner of hiving a swarm into one or both of these boxes, is thus.

You are to take the loose board, and fasten it to one of the boxes, so as to stop the communications. This may be done by three of the staples before mentioned; one on the top of the box near the front, the two others on the back, near the top and near the bottom. Let one end of the staple be thrust into a gimlet-hole made in the box, so that the other end may go as tight as can be over the loose board, to keep it from slipping when it is handled. The next morning, after the bees have been hived in this box, the other box should be added, and the loose board should be taken away. This will prevent a great deal of labour to the bees, and some to the proprietor.

Be careful to fasten the shutter so close to the glass, that no light may enter through it; for the bees seem to look upon such light, as a hole or breach in their house, and on that account may not so well like their new habitation. But the principal thing to be observed at this time, is to cover the box, as soon as the bees are hived, with a linnen cloth thrown loosely over it, or with green boughs, to protect it from the piercing heat of the sun. Boxes will admit the heat much sooner than straw hives; and if the bees find their house too hot for them, they will be wise enough to leave it. If the swarm be larger than usual, instead of fastening the loose board to one box, you may join two boxes together with three staples, leaving the communication open from one to the other, and then hive your bees into both. In all other respects, they are to be hived in boxes after the same manner as in common hives; which being well known, it were needless here to give particular directions concerning it.

The door of the second box should be carefully stopped up, and be kept constantly closed, in order that the bees may not have any entrance but through the first box.

When the boxes are set in the places where they are to remain, they must be screened from the summer's sun, because the wood will otherwise be heated to a greater degree than either the bees or their works can bear; and they should likewise be screened from the winter's sun, because the warmth of this will draw the bees from that lethargic state which is natural to them, as well as to many other insects, in the winter season. For this purpose, and also to shelter the boxes from rain, our ingenious clergyman has contrived the following frame.

Plate III. Fig. 10. represents the front of a frame for twelve colonies. *a*, *a*, are two cells of oak, lying flat on the ground, more than four feet long. In these cells you are to fix four oaken posts, about the thickness of such as are used for drying linnen.

The two posts *b*, *b*, in the front, are about six feet two inches above the cells: the other two standing backward, five feet eight inches.

You are next to nail some boards of slit deal horizontally from one of the fore-posts to the other, to screen the bees from the sun. Let these boards be seven feet seven inches in length, and nailed to the inside of the posts, and be well seasoned, that they may not shrink or gape in the joints.

c, *c*, are two splines of deal, to keep the boards even, and strengthen them.

Plate III. Fig. 11. represents the back of the frame. *d*, *d*, *d*, *d*, are four strong boards of the same length with the frame, on which you are to place the boxes. Let the upper side of them be very smooth and even, that the boxes may stand true upon them: or it may be still more advisable, to place under every pair of boxes a smooth thin board, as long as the boxes, and about a quarter of an inch wider. The bees will soon fasten the boxes to this board, in such manner, that you may move or weigh the boxes and board together, without breaking the wax or resin, which for many reasons ought to be avoided. These floors must be supported by pieces of wood, or bearers *e*, *e*, &c. which are nailed from post to post at each end. They are likewise to be well nailed to the frame, to keep them from sinking with the weight of the boxes.

f represents the roof, which projects backward about seven or eight inches beyond the boxes, to shelter them from rain.

You have now only to cut niches or holes in the frame, over against each mouth or entrance into the boxes, at *b*, *b*, *b*, in Fig. 10. Let these niches be near four inches long; and under each you must nail a small piece of wood for the bees to alight upon.

The morning or evening sun will shine upon one or both ends of the frame, let its aspect be what it will: but you may prevent its over-heating the boxes, by a loose board set up between the posts, and kept in by two or three pegs.

The same gentleman, with great humanity, observes, that no true lover of bees ever lighted the fatal match without concern; and that it is evidently more to our advantage, to spare the lives of our bees, and be content with part of their stores, than to kill and take possession of the whole.

About the latter end of August, says he, by a little inspection through your glasses, you may easily discover which of your colonies you may lay under contribution. Such as have filled a box and a half with their works, will pretty readily yield you the half box. But you are not to depend upon the quantity of combs, without examining how they are stored with honey. The bees should, according to him, have eight or nine pounds left them, by way of wages for their summer's work.

The most proper time for this business is the middle of the day: and as you stand behind the frame, you will need no armour, except a pair of gloves. The operation itself is very simple, and easily performed, thus: open the mouth of the box you intend to take; then, with a thin knife, cut through the resin with which the bees have joined the boxes to each other, till you find that you have separated them; and after this thrust a sheet of tin gently in between the boxes. The communication being hereby stopped, the bees in the fullest box, where it most likely the queen is, will be a little disturbed at the operation; but those in the other box, where we suppose the queen is not, will run to and fro in the utmost hurry and confusion, and send forth a mournful cry, easily distinguished from their other notes. They will issue out at the newly opened door; not in a body, as when they swarm, nor with such calm and chearful activity as when they go forth to their labours; but by one or two at a time, with a wild flutter, and visible rage and disorder. This, however, is soon over; for as soon as they get abroad, and spy their fellows, they fly to them instantly, and join them at the mouth of the other box. By this means, in an hour or two, for they go out slowly, you will have a box of pure honey, without a living bee in it to molest you; and likewise without dead bees, which, when you burn them, are often mixed with your honey, and both waste and damage it.

Mr. White acknowledges, that he has sometimes found this method fail, when the mouth of the box to be taken away has not been constantly and carefully closed; the bees will, in this case, get acquainted with it as an entrance, and when you open the mouth in order to their leaving this box, many of them will be apt to return, and, the communication being stopped, will, in a short time, carry away all the honey from this to the other box; so much do they abhor a separation. When this happens, he has recourse to the following expedient, which he thinks infallible. He takes a piece of deal, a little larger than will cover the mouth of the box, and cuts in it a square nich somewhat more than half an inch wide. In this nich he hangs a little trap door, made of a thin piece of tin, turning upon a pin, with another pin crossing the nich a little lower, so as to prevent the hanging door from opening both ways. This being placed close to the mouth, the bees which want to get out will easily thrust open the door outwards, but cannot open it the other way, to get in again; so must, and will readily, make to the other box, leaving this in about the space of two hours, with all its store, justly due to the tender hearted bee-master, as a ransom for their lives.

What lead Mr. White to prefer collateral boxes to those before in use, was, to use his own words, his "compassion for the poor bees, who, after traversing the fields, return home weary and heavy laden, and must perhaps deposit their burden up two pair of stairs, or in the garret. The lower room, it is likely, is not yet furnished with stairs; for, as is well known, our little architects lay the foundation of their structures at the top, and build down-

downward. In this case, the weary little labourer is to drag her load up the sides of the walls; and when she has done this, she will travel, many times, backward and forward, as I have frequently seen, along the roof, before she finds the door, or passage into the second story; and here again she is perplexed with a like puzzling labyrinth, before she gets into the third. What a waste is here of that precious time which our bees value so much, and which they employ so well? and what an expence of strength and spirits, on which their support and sustenance depends? In the collateral boxes, the rooms are all on the ground floor: and because I know my bees are wise enough to value convenience more than state, I have made them of such a moderate, though decent, height, that the bees have much less way to climb to the top of them, than they have to the crown of a common hive."

Mr. White is confident that the expence of his boxes, and of the frame above described, will not, if a reasonable allowance be made for their duration, prove greater, in the end, than the charge of straw hives, and of the frames that are made, in most places, for their reception: to which he adds, that a great part of this expence may be saved, if the bee-master can spare a place within any of his buildings, especially if they be boarded, where he may fix his stools for the boxes to stand on, making holes at proper distances for the bees to work out at: nor need he be very solicitous concerning the aspect or height of his buildings; for bees have been known to thrive well, and get a large quantity of honey, though placed almost at the top of a high turret in Trinity-college, and on the north side of it.

M. Vicat, a very ingenious lady in Swisserland, published, in the memoirs of the Berne society for the year 1764, very judicious observations on bees and hives, particularly those which are added one to another in the manner above described. Her remarks well deserve our attention; and therefore we shall give here her own account of them.

On the ninth of June 1761, this lady bought an hive of bees, in a straw hive. The combs were emptied of their honey, and thereby rendered the more liable to be attacked by the moth. She placed it in a little garden in the heart of the city of Lausanne. She soon discovered there were moths in it, and that the bees had lice on them; which determined her to place a glass hive over the straw one, and to shut up the opening into the lower hive. She frequently looked into the glass hive, to see what passed in it. The bees never stopped in it, and it served only as a thoroughfare to the straw hive. The bees, though very laborious and numerous, could not defend themselves against the moths, which multiplied daily: on the eighteenth of July her bees were reduced to little more than three hundred. Finding their number decrease every day, she suspected that some accident had happened to the queen, which upon examination she found to be true; as she also did, that these moths may soon destroy the most numerous hive. They had mouldered away the wax, and had united the three middle combs, by their galleries, to such a degree, that they appeared but as one mass. Upon turning up the hive, to see what condition it was in, she found the sides covered with white and hard cocoons, which would soon produce moths. They were in such quantity as to fill the crown of her hat.

It appears to her that the moths are most ready to attack hives which have swarmed oftener than once; because in them the combs, in which the young bees were reared, being empty, serve for both shelter and food to their maggots, which feed only on wax. For the same reason, late swarms, and hives in which there is not much honey, are equally exposed to these insects. Such hives should therefore be cleaned at least once a week. If moths are found on the stool of the hive, it should be cleaned every morning. In order to do this the more easily, without disturbing the bees, or running the hazard of being stung by them, she caused a large square hole to be made in the stools on which her bees stand, with a slider underneath, fitted to it. By this means she preserved another hive, which she had placed in the same garden on the same day, June nine, 1761: and though it was a swarm put into a new straw hive, she observed moths in it by the end of July. She calls this hive Numb. 1.

When she secured this hive for the winter, she put it into a dry room; but the air there being too mild, the bees consumed almost their whole store. She drew the slider often; for the disaster which had happened to her other hive rendered her now more attentive, and she generally found a quantity of moths on it. The combs became mouldy, which she endeavoured to wipe off with soft brown paper, and rubbed it off the sides of the hive with a napkin. So many bees died during the winter, that the hive became very weak in comparison to what it was in the autumn. About the middle of March, she placed it in a little garden surrounded with houses.

She placed near the former a swarm of June 1761, which had been kept in a hive of Mr. Paltau's construction, and had stood the preceding summer in the country, and the winter in a green-house in town, where the air was constantly kept temperate. Few of these bees died. She calls this hive Numb. 2.

That she might judge of the strength of these hives, she counted the bees which entered into each of them in a quarter of an hour, taking the same hour of a fine day. She repeated this during several weeks, and found that about six hundred and sixty entered in Numb. 2, and two hundred, or sometimes two hundred and twenty, in the same time, into Numb. 1.

In May, the numbers of bees were so much increased, that it was no longer possible to count them. Numb. 1. was now as well stocked with bees as Numb. 2. She had been particularly careful of the former, and had fed them with honey in rainy weather. She had cleaned the slider every morning, and often found on it even four moths at a time. She thinks that the bees can easily pull them out of their holes before their galleries have been strengthened with cross threads, and cemented with the crumbs of wax, or their excrements. The bees do not always carry them out of the hive, but sometimes leave them on the stool, where the little maggots soon weave a case to conceal themselves in; as she has known them do in a few hours. She found the greatest number of them at about four or five o'clock in the morning.

She resolved to place over Numb. 1. a glass hive, to give the bees an opportunity of working in it. With this view, she cut some rounds off the top of the straw hive, so as to make an opening of four inches, upon which she put a piece of board with a corresponding opening of four inches; and on the twenty-fifth of March 1762, a glass hive was placed over it. She shut up the mouth of the straw hive, in order to oblige the bees to enter by an opening under the glass hive, which she covered, lest the cold might incommode or even kill her bees, which were few in number. Though they increased so much by May as to be equal with Numb. 2. yet the bees never stopped in the glass hive. She judged from this, that they would rather descend, if she gave them a convenient habitation below. She therefore placed under the straw hive a box, which had an opening in it of eight inches, for the bees to pass through. They soon extended their works downward, so that in a fortnight they almost filled the box with combs. On the eighth of July she took away the glass hive; and though it had hitherto served them only as a passage, they were much disconcerted when it was removed: for after she had filled up the opeing in the top of the straw hive with flax and rue, the loaded bees continued for several day to fly round it, though the rue was disagreeable to them, before they would enter by the opening in the box, which was the only one they now had.

It is very remarkable, that the bees made no combs in the glass hive, though they were so fond of entering by it; and yet they descended into the box as soon as it was placed under them. We might have imagined it to be easiest for them to enter below, at the bottom of the box; but instead of so doing, they entered by the glass hive, passed through the straw hive full of combs, and carried their load down into the box. This gave her the first hint, that it was most advisable to put the additional hive into which we would have the bees to work, under the full one, and she has since found it succeed accordingly.

On the twentieth of July, she found that the bees of Numb. 1. had cast out so great a quantity of their young brood,

brood, that ſhe gathered ſome handfuls of it about the hive. The bees continuing to do the ſame next day, ſhe determined to take away the ſtraw hive the day after. For this purpoſe, ſhe choſe eight o'clock in the morning, which ſhe had obſerved to be the time when the greateſt number of bees were gone into the fields. She began by looſening the ſtraw hive from the board on which it reſted, and to which the bees had faſtened it with propolis. She then took the wadding out of the hole in the top of the ſtraw hive; near to which ſome linnen rags were kept ſmoking, and this ſmoke was blown into the hive by a pair of bellows. As ſoon as ſhe judged that moſt of the bees had been forced down into the box, ſhe cauſed a ſtrong iron wire to be drawn through between the hive and the board it reſted on, thereby to cut tranſverſely all the combs which were extended from the hive into the box through the hole of communication. The hive was then taken up with all the combs but one, which ſeparated from the middle of the hive. She carried this comb, with two fingers of each hand, to a table at ſome diſtance, on which the hive had been placed bottom up. The comb which ſhe carried was almoſt covered with bees; and as it fell from the middle of the hive, where the queen generally reſides, ſhe ſearched for her, and found her on the firſt round of the hive, ſcarce able to crawl, being daubed with honey which had flowed from the combs cut through. She waſhed her in a glaſs of water; but finding that this did not entirely carry off the honey which ſtill adhered to her wings, ſhe waſhed her a ſecond time, and put her among ſeveral bees which had alſo been waſhed, but had recovered ſtrength enough to aſſiſt their queen. They immediately ſet themſelves to dry and aſſiſt her. She kept her thus for half an hour, in the preſence of ſeveral curious perſons, who had often ſought in vain for her. As ſoon as ſhe thought her able to make uſe of her legs and wings, ſhe carried her to the ſtool on which the box remained, now to become the only habitation of the bees. Here ſhe was again bruſhed and licked during an hour, by bees which were in great numbers on the forepart of the box, and at laſt ſhe entered.

A farmer with whom this lady kept ſome bees in the country had an old ſtraw hive, which he intended to deſtroy in order to come at their honey and wax. She propoſed to him to follow the ſame ſteps as ſhe had taken with her's, which he agreed to, knowing that he could not loſe any thing by it. Having been taught by experience, ſhe adviſed him to put a box under the hive, rather than a hive over it. As ſhe had obſerved that her own bees had ſo obſtinately adhered to their former paſſage, ſhe adviſed him to place the box at a ſmall diſtance from the place where the hive had ſtood, that the whole might be the newer to them. They ſet to work heartily on the third of July; and by the ſixteenth of Auguſt they had lain in ſo much proviſion, that ſhe determined to take off the hive in the ſame manner as ſhe had done her own. The honey did not run ſo much, becauſe the weather was not ſo hot.

Whatever pains are taken to drive the bees out of the hive by means of ſmoke, many ſtill remain in it. In order to preſerve theſe bees, ſhe found that the beſt way was to ſweep them with the wing of a fowl into a tub of water, as faſt as the combs were taken out. This practice was attended with ſeveral advantages. It prevented the people being ſtung, it cleared the bees of any honey that might have dropped on them, and it made many of their lice fall off them.

In order to take them out of the water, ſhe cauſed a thin linnen cloth to be ſpread over the mouth of an empty tub, in ſuch manner that it hung every where over the brim, and was held by one perſon, whilſt another poured the water, in which the bees were, gradually through it. The bees remained on the cloth. It is eſſential that the quantity of water be large in proportion to the number of bees, and that they be quite ſenſeleſs before they are taken out. If the firſt water taſtes of honey, they ſhould be bathed in a ſecond quantity. M. de Réaumur loſt many bees by not attending to this precaution. When the bees have been ſufficiently bathed, madam Vicat ſpreads them on whited-brown paper, which, with the warm air, ſoon dries them.

It was ſome time before this lady could find the queen of the farmer's hive. The country people who ſaw this operation, were ſtruck with great compaſſion on ſeeing ſo many bees laid out, as it were, upon the table; for they thought them quite dead, and could not believe her when ſhe aſſured them that they would all return to life. By the time ſhe had found the queen, many of the bees had ſo far recovered, as to take care of her. Madam Vicat obſerved on her crocelet a louſe, which ſhe ſtruck off with a pin. She ſaw a ſecond on the hind part of her head; but it ſtuck ſo faſt that ſhe could not remove it; nor was ſhe much ſolicitous about it, becauſe the queen ſeemed to to be in good plight. All the bees were placed on the ſtool before the box; and ſhe was informed next day, that they had all ſoon returned to their companions. Having obſerved in the combs ſome cells which had young in them, ſhe put an additional height under the box, in which ſhe placed the combs with the young in them: and remarking on the twentieth of Auguſt, that there were ſeveral moths under the laſt addition, in which the combs with young were placed, ſhe judged it not to be right to preſerve ſuch combs for the future. Experience has ſince confirmed her in this opinion.

It is generally alledged, that the moths get ſo much the upper hand in the hives by the fourth year, that it is neceſſary to deſtroy the bees on the third year, in order to get the then remaining honey and wax; for that all would otherwiſe fall a prey to the moths. Madam Vicat has now ſhewn, that hives may be preſerved from moths without condemning to the fire thoſe precious labourers, the bees; a practice as barbarous as it is ſenſeleſs; a practice which was ſtrictly forbidden by a Grand Duke of Tuſcany, under the penalty of ſevere puniſhment, as we are informed by M. de Réaumur. If care is not taken, even three years will be too long a time to allow; for the moths will frequently deſtroy a hive the very firſt year.

The lice which ſtick to bees are not generally thought to be prejudicial to them; and this may be true when there are but few of thoſe vermin; but when every bee in a hive has two, or perhaps three lice upon it, as is often the caſe, we may believe that the bees are greatly incommoded by them: indeed we may be aſſured of it, by their uſing every means in their power, though ineffectually, to get rid of them. M. de Réaumur declares, that he cannot think well of a hive in which the greateſt number of bees have lice on them.

Madam Vicat had a hive near a chair in her garden, in which ſhe uſed to ſit at work for hours. She one day ſaw many bees endeavouring to rid themſelves of theſe troubleſome enemies, and endeavoured, but to little purpoſe, to aſſiſt them, by killing the lice with her ſciſſars. Recollecting that tobacco is a poiſon to many inſects, ſhe immediately ſtrewed a little Morocco tobacco over ſome bees which had lice on them. The lice fell off inſtantly, as dead. In order to be aſſured that tobacco did not hurt the bees, ſhe confined ſome which were louſy, under a glaſs placed on paper ſtrewed with tobacco. After the bees had paſſed ſeveral times over the tobacco, the lice fell off them dead. She left the bees in the glaſs three hours, and at the end of that time they appeared vigorous and well.

Mr. Thorley tells us, that the beſt time to plant colonies of bees, is either in ſpring with new ſtocks full of bees, or in ſummer with ſwarms. If ſwarms are uſed, procure, if poſſible, two of the ſame day; hive them either in two boxes, or in a hive and a box; at night place them in the bee-houſe, one over the other, and, with a knife and a little lime and hair, ſtop cloſe the mouth of the hive, or upper-box, ſo that not a bee may be able to go in or out, but at the front door. This done, you will, in a week or ten days, with pleaſure ſee the combs appear in the boxes; but if it be an hive, nothing can be ſeen till the bees have wrought down into the box. Never plant a colony with a ſingle ſwarm, as Mr. Thorley ſays he has ſometimes done, but with little ſucceſs.

When the ſecond box, or the box under the hive, appears full of bees and combs, it is time to raiſe your colony. This ſhould be done in the duſk of the evening, and in the following manner.

Place your empty box, with the ſliding ſhutter drawn back, behind the houſe, near the colony that is to be raiſed, and at nearly the height of the floor; then lifting

ing up the colony with what expedition you can, let the empty box be put in the place where it is to ftand, and the colony upon it, and fhut up the mouth of the then upper box, with lime and hair as before directed.

When, by the help of the windows in the back of the boxes, you find the middle box full of combs, and a quantity of honey fealed up in it, the loweft box half full of combs, and few bees in the uppermoft box, proceed thus.

About five o'clock in the afternoon, drive clofe, with a mallet, the fliding fhutter under the hive or box that is to be taken from the colony. If the combs are new, the fhutter may be forced home without a mallet; but be fure it be clofe that no bees may afcend into the hive or box to be removed. After this, fhut clofe he doors of your houfe, and leave the bees thus cut off from the reft of their companions for the fpace of half an hour or more. In this time, having loft their queen, they will fill themfelves with honey, and be impatient to be fet at liberty.

If, in this interval, you examine the box or boxes beneath, and obferve all to be quiet in them, you may be confident that the queen is there, and in fafety. Hereupon raife the back part of the hive or box fo far, by a piece of wood flipped under it, as to give the prifoners room to come out, and they will return to their fellows: then lifting the box from off the colony, and turning it bottom upmoft, cover it with a cloth all night; and the next morning, when this cloth is removed, the bees that may have remained in it will return to the colony. Thus you have a hive or box of honey, and all your bees fafe.

Mr. Thorley adds, that the method he has purfued with great fuccefs for many years, and which he recommends to the public, as the moft effectual for preferving bees in common hives, is incorporation, or uniting two ftocks into one, by the help of a peculiar fume or opiate, which will put them intirely in your power for a time, to divide and difpofe of at pleafure. But as that dominion over them will be of fhort duration, you muft be expeditious in this bufinefs.

The queen is immediately to be fearched for, and killed. Hives which have fwarmed twice, and are confequently reduced in their numbers, are the fitteft to be joined together, as this will greatly ftrengthen and improve them. If a hive which you would take is both rich in honey, and full of bees, it is but dividing the bees into two parts, and putting them into two boxes, inftead of one. Examine whether the ftock to which you intend to join the bees of another, have honey enough in it to maintain the bees of both: it fhould weigh full twenty pounds.

The narcotic, or ftupefying fume, is made with the *fungus maximus* or *pulverulentus*, the large mufhroom, commonly known by the name bunt, puckfift, or frogcheefe. It is as big as a man's head, or bigger: when ripe, it is of a brown colour, turns to powder, and is exceeding light. Put one of thefe pucks into a large paper, prefs it therein to two-thirds, or near half the bulk of its former fize, and tie it up very clofe; then put it into an oven fome time after the houfhold bread has been drawn, and let it remain there all night: when it is dry enough to hold fire, it is fit for ufe. The manner of ufing it is thus:

Cut off a piece of the puck, as large as a hen's egg, and fix it in the end of a fmall ftick flit for that purpofe, and fharpened at the other end, which place fo that the puck may hang near the middle of an empty hive. This hive muft be fet with the mouth upward, in a pail or bucket, which fhall hold it fteady, near the ftock you intend to take. This done, fet fire to the puck, and immediately place the ftock of bees over it, tying a cloth round the hives, that no fmoke may come forth. In a minute's time, or little more, you will hear the bees fall like drops of hail into the empty hive. You may then beat the top of the full hive gently with your hand, to get as many of them as you can: after this, loofing the cloth, lift the hive off to a table, knock it feveral times againft the table, feveral more bees will tumble out, and perhaps the queen among them. She often is one of the laft that falls. If fhe is not there, fearch for her among the main body in the empty hive, fpreading them for this purpofe on a table.

You muft proceed in the fame manner with the other hive, with the bees of which thefe are to be united. One of the queens being fecured, you muft put the bees of both hives together, mingle them thoroughly, and drop them among the combs of the hive which they are intended to inhabit. When they are all in, cover it with a packing or coarfe cloth, which will admit air, and let them remain fhut up all that night, and the next day. You will foon be fenfible that they are awaked from this fleep.

The fecond night after their union, in the dufk of the evening, gently remove the cloth from off the mouth of the hive, (take care of yourfelf) and the bees will immediately fally forth with a great noife; but being too late, they will foon return; then inferting two pieces of tobacco-pipes to let in air, keep them confined for three or four days, after which the door may be left open.

Providence has ordained that infects which feed on leaves, flowers, and green fucculent plants, are in an infenfible or torpid ftate from the time that the winter's cold has deprived them of the means of fubfiftence. Thus the bees, during winter, are in fo lethargic a ftate, that little food fupports them: but as the weather is very changeable, and every warm or funny day revives them, and prompts them to return to exercife, food becomes neceffary on thefe occafions. Mr. White very judicioufly obferves, that a greater degree of cold than is commonly imagined to be proper for bees, is favourable to them in winter. If a fharp froft, fays that experienced gentleman, continues for two or three months, without intermiffion, you may obferve, through your glafs, that the bees are all this time clofely linked together in clufters between the combs. If they are not altogether without motion, yet it is certain they ftir not from their places, while the cold continues, and therefore eat not at all.

A colony of bees therefore placed on the north-fide of a building will wafte much lefs of their provifions, than others which ftand in the fun; for coming feldom forth, they eat little; and yet in the fpring are as forward to work and fwarm, as thofe which had twice as much honey in the preceding autumn. The owner fhould however examine their ftate in the winter, and if he finds that inftead of being cluftered between the combs, they fall down in numbers on the ftool or bottom of the hive, the hive fhould be immediately carried to a warmer place, where they foon recover.

Moft writers on bees have obferved, that thefe infects are fubject to a kind of purging in the fpring, which is often fatal to the whole hive. Madam Vicat afcribes this diftemper to the honey being candied in the hive by the cold. But Columella defcribes it as an annual diftemper which feizes them in the fpring, when the fpurge bloffoms, and the elm difclofes its feeds; for that the bees, being allured by the firft flowers, feed fo greedily upon them, that they furfeit themfelves therewith, and die of a loofenefs, if they are not fpeedily relieved. He relates Hyginus's advifing, in this cafe, to cover the bees with afhes of the fig-tree; and affirms, that, being enlivened by the warmth of thefe afhes, the bees will revive in two hours, and go into a hive brought to them. Columella advifes giving them rofemary and honey diluted with water. Ariftomachus feems to have prefcribed the moft effectual cure, namely, to take away all the vitiated combs, that is, all the combs in which there are open cells appearing to contain candied honey.

The authors of the *Maifon Ruftique*, impute this purging to the bees feeding on pure honey, which does not form a food fufficiently fubftantial for them, unlefs they have bee-bread to eat at the fame time; and advife giving them a honey-comb taken from another hive, the cells of which are filled with crude wax or bee-bread.

The common practice is to feed them in the autumn, giving them as much honey as will bring the whole weight of the hive to near twenty pounds. To this end, the honey is diluted with water, and then put into an empty comb, fplit reeds, or, as Columella directs, upon clean wool, which the bees will fuck perfectly dry.

The following directions given for this purpofe in the *Maifon Ruftique*, feem to be very judicious. Repleni£h the weak hives in September, with fuch a portion of combs

combs full of honey, taken from other hives, as ſhall be judged to be a ſufficient ſupply for them. In order to do this, turn up the weak hive, after taking the precaution of defending yourſelf with the ſmoke of rags, cut out the empty combs, and put the full ones in their place, where ſecure them with pieces of wood run acroſs, in ſuch manner that they may not fall down when the hive is returned to its place. The bees will ſoon fix them more effectually. If this method be thought too troubleſome, ſet under the hive a plate of liquid honey, unmixed with water, with ſtraws laid acroſs it, and over theſe a paper pierced full of holes, through which the bees will ſuck the honey, without daubing themſelves. This ſhould be done in cloudy or rainy weather, when the bees ſtir leaſt abroad; and the hive ſhould be covered, to protect the bees from robbers, who might be allured to it by the ſmell of honey.

Another circumſtance which may render it very neceſſary to feed the bees, is, when ſeveral days of bad weather enſue immediately after they have ſwarmed; for then, being deſtitute of every ſupply beyond what they carried with them, they may be in great danger of being ſtarved. In this caſe honey ſhould be given them in proportion to the duration of the bad weather.

But it is not enough to know how to manage bees in all ſeaſons; it will be alſo requiſite to know how to defend them from their enemies; among which hornets and waſps, and eſpecially the ſpecies of waſps which are ſcarcely larger than bees, are very formidable; for they ſeize a bee loaded with honey. If this robbery is committed near the mouth of the hive, they carry off the bee to a place of greater ſafety. Their neſts ſhould therefore be carefully deſtroyed, by pouring plenty of boiling water into them; for this is by much the ſafeſt method.

The field-mouſe is an enemy to be carefully guarded againſt as ſoon as the cold begins to approach: for if it enters at that ſeaſon, it makes dreadful havock. At firſt it deſtroys the loweſt parts of the combs; but as the weather grows colder, and the bees more torpid, it aſcends up the hive, and ſeizes on the richeſt treaſure: nor does the evil end here: for other bees, ſmelling the honey ſpilt by the mouſe, fall upon the hive, and rob it of what remained; or as ſoon as the warm weather returns, and the bees ſtir about, they are ſometimes ſo diſguſted at the havock made by the mouſe, that they deſert the hive. The only way to guard againſt this, is to prevent its entering into a hive. Whilſt the bees continue in their vigorous ſtate, it dares not attack them: therefore, as ſoon as the cold approaches, the entrance to the hives ſhould be leſſened.

Bees may themſelves be reckoned enemies to bees: for they ſometimes wage cruel wars againſt each other. Their fighting and plundering one another ought chiefly to be imputed, as Mr. Thorley obſerves, either to their perfect abhorrence of ſloth and idleneſs, or to their inſatiable thirſt for honey: for when, in ſpring or autumn, the weather is fair, but no honey can be collected from plants, and is to be found only in the hives of other bees, they will venture their lives to get it there.

Dr. Warder aſſigns another cauſe of their fighting, which is, the neceſſity that the bees are reduced to when their own hive has been plundered, at a ſeaſon when it is too late for them to repair the loſs by any induſtry in the fields.

Sometimes one of the queens is killed in battle. In this caſe, the bees of both hives unite as ſoon as her death is generally known among them. All then become one people: the vanquiſhed go off with the robbers, richly laden with their own ſpoils, and return every day, with their new aſſociates, to pillage their old habitation. This cauſes a throng unuſual for the ſeaſon, at the door of the hive they are plundering; and if the owner lifts it up at night, when all are gone home, he will find it empty of inhabitants; though there perhaps will remain in it ſome honey, which he takes as his property.

When two ſwarms take flight at the ſame time, they ſometimes quarrel, and great numbers are deſtroyed on both ſides, till one of the queens is ſlain. This ends the conteſt, and the bees of both ſides unite under the ſurviving ſovereign.

Robbers make their attacks chiefly in the latter end of July, and the month of Auguſt. They appear to act with caution at firſt, and to procure themſelves an entrance by ſtealth; not pitching boldly like the native bees, and then entering at once in at the door. If they are encouraged by ſucceſs, they return in greater parties, ſometimes all the bees of a hive, and endeavour to force that entrance which they ſought before with ſo much caution. They come in ſuch numbers, as frequently to make thoſe who are not acquainted with theſe ſcenes, miſtake them for new ſwarms: but the number of dead bees ſtrewed on the ground, ſoon convince them of this error. Columella adviſes to kill the queen, if poſſible; but the moſt effectual way to prevent the loſs of bees, as well as of honey, occaſioned by theſe robberies, is, early in the autumn, to leſſen the entrance into the hive, as before directed, ſo as to leave room for only two or three bees to paſs a-breaſt.

In the third claſs of enemies to bees is a ſmall caterpillar, termed the wax-worm, or wax-moth, becauſe of the havock it makes on wax. It is tender in its frame, unarmed and defenceleſs; and yet can ſubſiſt itſelf in the midſt, and at the coſt, of the moſt numerous hive. A few of theſe little caterpillars will deſtroy and break to pieces the combs of a hive, build up new edifices for lodging themſelves in it, and finally force the bees to quit the place.

This inſect is of the ſpecies of the falſe-moth, and is extremely nimble. It is enough for it to get into a hive unawares. It runs ſo very ſwiftly, that it paſſes unperceived, and ſlides into ſome narrow place between the combs, perhaps inacceſſible to bees, there to lay its eggs in ſecurity. This done, it makes its eſcape as well as it can. From each of theſe eggs proceeds a caterpillar, which eſcapes certain death merely by its extreme ſmallneſs, and the quickneſs with which it ſpins and enwraps itſelf in a covering ſufficient to ſecure it from all harm. This covering, or tube, is glued to the wax which the caterpillar feeds on, and this inſect lengthens the tube as it eats the wax, till at laſt it ſhuts itſelf up, in order to be transformed into a chryſalis. Several caterpillars, and conſequently ſeveral moths, muſt proceed from the eggs which the males and females engender. Probably the bees deſtroy great numbers of the moths: however, if a ſingle female has an opportunity to lay her eggs, ſhe is ſo exceedingly prolific, that this ſecond brood may quite overſpread the hive. If one of the impregnated females eſcapes out of the hive by means of her great nimbleneſs, ſhe ſeeks out another hive, in which ſhe ſpreads the ſame ſource of miſchief.

The only method of deſtroying theſe pernicious inſects is to take away the infected hive; and after clearing it from the moths, reſtore it to the proper owners, who will now work with greater diligence and reſolution.

The next particular neceſſary to be known, is how to ſeparate the honey from the wax. In order to this, the combs ſhould be laid in a place perfectly ſecure from the acceſs of bees; for otherwiſe the bees would not only carry off much honey, but alſo be extremely troubleſome, by ſtinging the people at work. It is proper to burn cow-dung, or rotten hay, at the doors and windows of this place; becauſe the ſmell of the ſmoke ariſing from thence is ſo diſagreeable to the bees, that it will drive them away. If any bees remain in the comb, they ſhould be bruſhed off with the wing of a fowl into a tub of water, and being afterwards dried in another place, they will fly back to their hive. If the combs are taken out of the hive before the end of autumn, there are generally young bees in them. The parts of the combs in which theſe are ſhould be laid aſide, for they would give a bad taſte to the honey. The bee-bread muſt alſo be ſeparated, and both ſhould be melted with the wax.

Before the combs are laid to drain out their honey, they ſhould be carefully cleaned of every ſort of filth, or inſects. The cruſt with which the bees cover the honey in them ſhould then be pared off with a ſharp, thin, broad knife, and the combs themſelves ſhould be divided through

through the middle, in such manner as to render the cells open at both ends, that the honey may flow the more freely out of them. The combs should be laid in this state on sieves, or some other contrivance, which will afford the honey a free passage. It will run quite clear; and the honey thus obtained should be kept by itself, as being the purest and best.

The combs which are but partly filled, and also those that were full and have done running, are broken by hand, and the honey in them is squeezed out. Some put the broken combs into a strong bag, and then use a press to squeeze the honey out of them; and even warm the broken combs with the help of fire: but neither of these last consider that, in both these ways, much of the wax passes through the bag with the honey, and that the wax being of greater value than the honey, the owner sustains a loss in that respect, besides that his honey becomes the less valuable, in proportion to its being less pure. It is true, that great part of the wax thus mixed with the honey soon rises to the surface, and may be taken off, especially after the honey is grown hard.

The makers of mead need not be extremely solicitous about separating the honey so very perfectly from the wax, because, by washing the wax in cold water, the honey will dissolve in the water, and the wax being strained from it by running the water through a coarse cloth, neither bad taste nor impurity will be communicated by it to the water, which may afterwards be used for making mead. The wax that has been skimmed off the honey separated by pressure, should be washed in the same manner; because, by this means, no part of the wax will be lost.

The goodness and flavour of honey depend on the fragrance of the plants from which the bees collect it: and hence it is that the honey of different places is held in different degrees of estimation. That which is made early in the year is also preferred to what is collected in the latter end of the season.

In order to obtain the wax in a pure state, what remains of the combs after separating the honey, together with the combs which contain bee-bread and young bees or maggots, is put into a copper with a sufficient quantity of clean water, which is made to boil over a slow fire, and stirred frequently with a stick. When the wax is melted, it is run through bags, which are put into a press, to separate the wax perfectly. The wax runs from the press into a vessel placed underneath, with some water in it, to prevent the wax from sticking to it. What remains after the pressure may be again boiled in water, in order to obtain more wax from it: and this should be repeated by slow boilings, rather than by boiling it strongly at once.

When all the wax is thus separated from the dregs, it is again melted in water, over a very gentle fire, and skimmed clean whilst any scum arises. It is then poured into vessels suited to give it the desired form, after previously putting into them a little water, to keep the wax from sticking to them. These vessels are then carried into a place where the wax may cool gradually. It is found that, the larger the cakes of wax are, the better the wax keeps, and the higher price it brings; also, that the more gentle it has been boiled, the better it likewise is: for too hasty boiling renders it hard, and this increases the difficulty of bleaching it. Whatever filth sticks to the bottom of the cake is scraped off with a knife.

We shall conclude this article with a few directions for purchasing bees; which should always be done in the spring, as the dangers of the winter are then over. The summer is an improper time for buying them, because the heat of the weather then softens the wax, and thereby renders the combs liable to break, if they are not very well secured. The honey too, being then thinner than at other times, is more apt to run out of the cells, which is attended with a double disadvantage, namely, the loss of the honey, and the daubing of the bees, whereby many of them may be destroyed. A first and strong swarm may indeed be be carried away in the night after it has been hived.

The hive should be full of combs, and well stored with bees. The purchaser should examine the wax, in order to know the age of the hive. The combs of a year old are white; those of two years are dark coloured, or yellow; and where the combs are black, the hive should be rejected; because old hives are most apt to be infected with the moth, and most liable to other accidents. For this reason, the state of the combs should be examined as high up as possible; because the lower parts of the combs may have been cut off, and renewed in the preceding summer. It sometimes, though rarely, happens, that two queens continue to govern separately in the same hive; and in this case a large comb forms the barrier. Such hives should be rejected, because there is not in them that harmony which is necessary for the success of the bees.

In order to judge of the state of the hive, it may be raised a little in the evening, so as to admit a more than usual degree of cold; for this will drive the bees to the top of the hive, and so benumb them, that the next morning there will be no danger of their stinging. If any such danger does appear, a pot of lighted charcoal, with some linnen rags upon it, may be got ready, and held under the hive whilst it is pulled back in order to be examined.

We may also judge of the thriving state of the hive by the following appearances. Bees which are in good condition will get into the fields early in the morning, return loaded, enter boldly, and not come out of the hive in bad weather; for when they do, this indicates that they are in great want of provisions. They are alert on the least disturbance; they preserve their hive free from all filth, or dead nymphs or bees; they are ready to assist the bees which return loaded from the fields, and to defend the hive against every enemy that dares to approach: they make a continual humming noise, which increases on the least touch. Indeed, by the loudness of the humming, we may judge of the strength and progress of the hive, and therefore this should be frequently noticed, to enable us to form the better judgment of the present state the bees are in. *Columella, lib. IX. Maison Rustique, tom. I. Memoires, &c. de la Societé de Berne: Anné* 1764. *Réamur's Memoires pour servir à l'Histoire Naturelle des Insects, tom. V. Thorley's Enquiry into the Nature, &c. of Bees. Warder's Monarchy of Bees. White's collateral Bee-Boxes. Mill's Essay on the Management of Bees.*

BEECH, the name of a well known tree, and of which some planters suppose there are two distinct species; calling the one the mountain or wild beech, and the other the common beech. They also say, that the wood of the former is whiter than that of the latter; but Mr. Miller assures us that there is only one species of this tree, and that the difference in the colour of the wood arises from the difference in the soils.

This tree is propagated by sowing the mast, which may be done at any time from October to February, only observing to secure the seeds from vermin when early sown; and, if this be carefully done, the sooner they are sown after they are fully ripe, the better: a small spot of ground will be sufficient for raising a great number of these trees from seed; for if the plants are come up very thick, the strongest of them should be drawn out the autumn following, that those left may have room to grow; so that a seed-bed, carefully managed, will afford a three year's draught of young plants, which should be planted in a nursery, and, if designed for timber trees, at three feet distant row from row, and eighteen inches asunder in the rows.

But if they are designed for hedges, to which the tree is very well adapted, the distance need not be so great; two feet row from row, and one foot in the rows, will be sufficient. In this nursery they may remain two or three years, observing to dig up the ground between the roots, at least once a year, that their tender roots may the better extend themselves every way: but be careful not to cut or bruise their roots, which is injurious to all young trees; nor should you ever dig the ground in summer, when the earth is hot and dry; for by letting in the rays of the sun to the roots, the young trees are often destroyed.

This tree will grow to a considerable stature, though the soil be stoney and barren, as also upon the declivities of hills and chalky mountains, where they will resist the wind

wind better than moſt other trees; but then the nurſeries for the young trees ought to be made upon the ſame ſoil; for if they are raiſed on good ground, and in a warm expoſure, and afterwards tranſplanted into a bleak, barren ſituation, they ſeldom thrive. The nurſery ſhould therefore be made upon the ſame ſoil, where the plantation is intended, and the plants drawn annually to extend the plantation.

The tree is very proper to form large hedges to ſurround plantations, or wilderneſs quarters; and may be kept in a regular figure, if ſheared twice a year; eſpecially if they ſhoot ſtrong; in which caſe if they are neglected but a ſeaſon or two, it will be very difficult to reduce them again.

The ſhade of this tree is very injurious to moſt ſorts of plants which grow near it, but is generally believed to be very ſalubrious to human bodies.

It delights in a chalky or ſtony ground, where it generally grows very faſt; the bark of the trees in ſuch land is clear and ſmooth, and although the timber is not ſo valuable as that of many other trees, yet as it will thrive on ſuch ſoils, and in ſuch ſituations where few better trees will grow, the planting of them ſhould be encouraged, eſpecially as the trees afford an agreeable ſhade, and the leaves make a fine appearance in ſummer, and continue green as long in autumn as any of the deciduous trees; therefore in parks, and other plantations for pleaſure, this tree deſerves to be cultivated among thoſe of the firſt claſs, eſpecially where the ſoil is adapted to it. *Miller's Gard. Dict.*

The timber is of great uſe to turners for making trenchers, diſhes, trays, &c. and alſo to carpenters for making ſtools, bedſteads, &c. Shipwrights likewiſe often uſe it for the keels of ſhips; and it is eſteemed the beſt wood for firing. The thin lamina, or ſcale of the wood, commonly called paſte-board, is uſed in making band-boxes, hat-caſes, &c.

Beech wood is well known to be ſubject to worms, which ſoon deſtroy it. This worm is ſuppoſed to feed upon the ſap remaining in the wood after it is cut into ſcantlings, and worked up for uſe. If therefore the ſap can, by any means, be extracted, the wood will be much leſs ſubject to decay. Upon this principle, a correſpondent of the authors of the *Muſeum Ruſticum* greatly improved the wood, by laying it a reaſonable time in a pond, and afterwards drying it in the ſhade; by which means the timber when applied to uſe, was at leaſt as good, and as durable as elm. He adds, that by boiling the wood intended for ſmaller works, ſuch as bowls, trenchers, chairs, &c. two or three hours in a copper filled with water, all the ſap will be extracted, the wood will work pleaſanter, be more beautiful when finiſhed, and laſt, without compariſon, longer. *Muſeum Ruſticum, vol.* II. *pag.* 135.

BEECH *maſt*, the ſeed of the beech-tree.

This maſt is very good for feeding ſwine; ſo that in ſome counties of England, where there are large woods of beech-trees, the hogs are fed for months together on the maſt only. They thrive prodigiouſly on this food only, ſo that many porkers are killed in a year fatted with beech-maſt, without the aſſiſtance of any other food. It is, however, the better way to take them up, and give them either pollard, barley-meal, or peaſe, for a month or five weeks, when they will be fit for the tub.

But beech-maſt, like acorns, are apt to give the hogs a diſtemper called the garget; which may be effectually prevented, if a few peaſe or beans moiſtened with water, and ſprinkled over with antimony finely powdered, be given them every other day for a fortnight or three weeks. *Muſeum Ruſticum, vol.* I. *pag.* 474.

BEES-NEST, or *birds-neſt*, the ſame with wild carrot. *See the article Wild* CARROT.

BEER, a common and well known liquor, made of malt and hops, and uſed in various parts of Europe, particularly in thoſe where the vine will not flouriſh, and where cider is ſcarce. *See the article* BREWING.

The grounds, or ſettlings of beer, &c. form a very rich manure.

BEESTINGS, the firſt milk taken from a cow after calving.

If this milk be not taken away clean from the cow upon her firſt calving, it will often make the cow's milk to dry away. Nor ſhould the beeſtings be given to the calf, as it is very apt to ſurfeit. *Liſle's Huſbandry, vol.* II. *pag.* 143.

BEET, the name of a plant commonly cultivated in gardens, and of which there are two ſpecies, commonly diſtinguiſhed by the names of white and red beet: the former is cultivated for its leaves, and the latter for its roots.

The roots of the white beet ſeldom grow larger than a man's thumb; the ſpikes of the flowers come out from the wings of the leaves, which are long, and have many narrow leaves placed between the flowers. The lower leaves are thick and ſucculent, and their foot-ſtalks are broad. The varieties of this ſort are, the white beet, the green beet, and the Swiſs, or chard beet; but theſe will all vary from one to the other by culture.

It is commonly ſown by itſelf, and not mixed with other crops, the beginning of March, upon an open ſpot of ground, not too moiſt. When the plants have put out four leaves, the ground ſhould be hoed, as is practiſed for carrots, carefully cutting up all the weeds, and alſo the plants where they are too near each other, leaving them at leaſt ſix inches aſunder. In three weeks or a month's time, the ground ſhould be a ſecond time hoed over, to cut up the weeds, and then ſet the plants at a greater diſtance; for by this time they will be paſt danger, ſo ſhould not be left nearer than eight or ten inches, if regard is had to the goodneſs of the leaves; and if it is of the Swiſs kind, with broad leaves, the plants muſt not be nearer than a foot: in ſix weeks after, the ground ſhould be hoed over a third time; which, if properly done, will deſtroy all the weeds; ſo that after this, the plants will ſpread and prevent the weeds from growing, therefore will want but little cleaning for a conſiderable time, and the leaves will ſoon be fit for uſe, when the outer larger leaves ſhould be firſt gathered; leaving the ſmall inner leaves to grow larger; ſo that a ſmall ſpot of ground will ſupply a moderate family, and furniſh a new ſupply of leaves the whole year, provided the plants are not permitted to run up to ſeed, for after that their leaves will not be good. *Miller's Gard. Dict.*

M. de Chateauvieux tells us, that of this plant, cultivated according to the principles of the new huſbandry, produced leaves three or four inches broader than thoſe of the ſame kind of plants in his kitchen garden. By this method of culture it will yield an amazing quantity of leaves, which being very pleaſant to the taſte, will prove good food for cattle; and Mr. Roque has found by experience, that cows fed with them give a large quantity of milk. This plant, according to Mr. Roque's obſervations, grows above an inch a day, and is beſt ſown in March. A buſhel is enough for an acre, and will not coſt above ten ſhillings. It thrives beſt in a deep, rich, light ſoil: the ſtalks are very rich and ſucculent, and therefore the cows ſhould eat it green

The red beet hath large thick ſucculent leaves, which are for the moſt part of a dark green, or purple colour. The roots of this are large, and of a deep red colour, on which their goodneſs depends; for the larger theſe roots grow, the tenderer they will be; and the deeper their colour, the more they are eſteemed. The varieties of this are, the common red beet, the turnip-rooted red beet, and the green leaved red beet.

It is frequently ſown with carrots, parſnips, or onions, by the kitchen gardeners near London, who draw up their carrots or onions when they are young, whereby the beets will have room to grow, when the other crops are gathered; but where the crops are not timely removed from them, it will be a better method to ſow them ſeparately. This ſort requires a deep light ſoil, for as their roots run deep in the ground, ſo in ſhallow ground, they will be ſhort and ſtringy. The ſeeds ſhould be ſown in March, and muſt be treated in the ſame manner as the white beet; but the plants ſhould not be left nearer than a foot diſtance, or in good land a foot and an half, for the leaves will cover the ground at that diſtance. The roots will be fit for uſe in the autumn, and continue good all the winter; but in the ſpring, when they begin to ſhoot, they will be hard and ſtringy. *Miller's Gard. Dict.*

That attentive cultivator M. de Chateauvieux raiſed the red beet according to the principles of the new huſbandry; and on digging up the roots on the twenty-fifth of October, he found them all nearly of the ſame ſize, which was from five to ſix inches in diameter towards the top, or thickeſt part. Theſe roots ſeem to promiſe fair for being an excellent food for cattle, and would be well worth the trial, as they will produce a very large increaſe, and are eaſily cultivated.

BEETLE, a wooden inſtrument in the form of a mallet, but much larger, uſed in driving piles, wedges, hedge-ſtakes, &c.

BEETLE, is alſo the name of a flying inſect, of which there are a great variety of ſpecies; but they have all of them caſes over their wings to defend them from hard bodies, which they often meet with when they dig holes in the ground, or gnaw rotten wood with their teeth, to make themſelves houſes or neſts. When they fly they fill the air with a humming noiſe, and, perhaps, greater than that of any other inſect. There are different ſorts of beetles, ſome being large with horns, and others ſmall, and without horns.

BEEVES, a general name for oxen, or black cattle in general.

BEHEN, a ſpecies of chickweed, frequently called ſpattling-poppy. *See* CHICKWEED.

BENT-*graſs*, a ſpecies of graſs common in paſture grounds; there are ſeveral ſorts of this graſs, particularly that called fine bent, for the gathering the ſeeds of which the ſociety offered a premium. We have given a figure of one of the ſpecies of bent-graſs, on Plate III. Fig. 11.

BERE, or *bear*, a ſpecies of barley. *See the article* BARLEY.

BERNE-MACHINE, the name of an engine for rooting up trees, invented by Peter Sommer, a native of Berne in Switzerland.

A model of this machine was ſent by the Berne Society to the Society for the Encouragement of Arts in London, and from this model the drawing on Plate IV. Fig. 1. was made. The engine conſiſts of three principal parts, the beam, the ram, and the lever. The beam A B C, of which only one ſide is ſeen in the figure, is compoſed of two ſtout planks of oak of three inches thick at leaſt, and ſeparated by two tranſverſe pieces of the ſame wood at A and C, about three inches thick. Theſe planks are bored through with correſponding holes, as repreſented in the figure, to receive iron pins, upon which the lever acts between the two ſides of the beam, and which are ſhifted higher and higher, as the tree is raiſed, or rather puſhed out of its place. The ſides are well ſecured at top and bottom, by ſtrong iron hoops.

The iron pins on which the lever reſts, ſhould be an inch and a quarter, and the holes through which they paſs, an inch and a half in diameter. The poſition of theſe holes is ſufficiently indicated by the figure.

The foot of the beam, when the machine is in action, is ſecured by ſtakes repreſented at G, driven into the earth.

The ram D, which is made of oak, elm, or ſome other ſtrong wood, is capped with three ſtrong iron ſpikes, repreſented at *f*, which take faſt hold of the tree. This ram is ſix or eight inches ſquare, and a ſlit is cut lengthwiſe through the middle of it, from its lower end at K, to the firſt ferule *a*, in order to allow room for the chain *g b*, to play round the pulley K, which ſhould be four inches thick, and nine inches in diameter. This ram is raiſed by means of the chain *g b*, which ſhould be about ten feet long, with links four inches and three quarters in length, and an inch thick. One end of this chain is faſtened to the top of the beam at C, while the other, after paſſing through the lower part of the ram, and over the pulley K, terminates in a ring or link repreſented Fig. 3. the two ears *m*, *n*, of which ſerve to keep it in a true poſition between the two planks of the beam. In this ring the hook P is inſerted.

The hook is repreſented in profile, Fig. 2. where F is the part that takes hold of the ring. But it muſt be obſerved, that the parts of this machine, repreſented in Fig. 2, 3. are drawn on a ſcale twice as large as the whole engine, Fig. 1.

The hook F, Fig. 2. ſhould be made of very tough iron, as well as the handle D, and the arch E *e*. This handle ſhould be two inches thick at *z*, where it joins to the hook, and the thickneſs gradually leſſen by degrees up to the arch, which need not be more than half an inch thick.

On each ſide of the pin *z*, is a ſemi-circular notch, *x*, *y*, which reſts alternately on the pins, when the machine is worked. The hole D, and the arch *E e*, ſerve to fix a long lever of wood E F, Fig. 1. by means of two iron pins; and by this contrivance the lever is either raiſed or depreſſed at pleaſure, in order to render the working of the machine eaſy in whatever part of the beam the lever may be placed: for without this contrivance the extremity of the lever E F, would, when the handle *d* F was near the top of the beam C, be much higher than men ſtanding upon the ground could reach. It muſt, however, be remembered that the lever is often ſhortened by this contrivance, and conſequently its power leſſened.

The machine is worked in the following method: it is placed againſt a tree, in the manner repreſented in the figure, ſo that the iron ſpikes at *f* may have hold of the tree, and the end of the beam A be ſupported by ſtakes repreſented at G. The iron handle, Fig. 2. is placed in the opening between the two planks of the beam, and the wooden lever fixed to it by means of the iron pins already mentioned. The hook F takes hold of the chain, and one of the iron pins is thruſt into the outer row of holes, by which means the outer notch *x* will reſt on the pin, which will be now the center of motion; and the end of the lever E, Fig. 1. being preſſed downwards, the other notch *y*, Fig. 2. will be raiſed, and at the ſame time the chain, and conſequently the ram. The other iron pin is now to be thruſt into the hole in the inner row, next above that which was before the center of motion, and the end of the lever E, Fig. 1. elevated, or puſhed upwards, the latter pin on which the notch *y* reſts, now becoming the center of motion. By this alternate motion of the lever, and ſhifting the pins, the chain is drawn upwards over the pulley K, and conſequently the whole force of the engine exerted againſt the tree. There is a ſmall wheel at L, in order to leſſen the friction of that part of the machine.

From this account the reader will very eaſily perceive that the machine is nothing more than a ſingle pulley, compounded with a lever of the firſt and ſecond order; and therefore its power may be eaſily computed from the nature of the pulley and lever.

It muſt, however, be remembered, that as the puſh of the engine is given in an oblique direction, it will exert a greater or leſſer force againſt the horizontal roots of the tree in proportion to the angle formed by the machine with the plane of the horizon; and that the angle of 45° is the maximum, or that when the machine will exert its greateſt force againſt the horizontal roots of the tree.

M. N. E. Tſcharner, ſecretary to the Berne Society, obſerves, in a letter ſent to the Society for the Encouragement of Arts, &c. in London, and dated Berne, Jan. 10th 1763, that by repeating experiments with this machine he has found that the chain *g b*, is ſo far from giving an additional power, that it hinders the play and effect of the engine by its friction; and that when the ram preſſes ſtrongly againſt the beams, the chain is ſqueezed between the beams ſo as to render the upper holes uſeleſs, and prevents the machine from being worked out to its full length; in conſequence of which it is obliged to be removed from its firſt place, and fixed again anew; which neceſſarily occaſions a loſs of time. He alſo found that the ram was too ſhort. He has therefore taken away the chain, and lengthened the ram four feet.

The inconvenience of the chain was immediately ſeen by the Society for the Encouragement of Arts, and therefore the machine at large made by their directions, was conſtructed without it. The ram moved between the two cheeks of the beam, and was puſhed up by the alternate

alternate motion of the lever. And that the force of the machine might not be lessened by the removal of the chain, the lever was made of twice the length of that in the Berne model.

It will be very readily granted, that an engine constructed in this manner will be very useful in saving the labour of men; though very inadequate to the task intended, that of throwing down trees. For it sufficiently appeared from experiments made by the committee of mechanics, that trees above sixteeen inches diameter, especially if oaks or elms, cannot be thrown down with this engine, without the assistance of cutting their roots.

BEVERAGE, drink, liquor to be drank.

BIENNIAL *plants*, such as continue two years.

BIG, the same with bear, or square barley. *See the article* BARLEY.

BIGGE, a pap, or teat.

BILL, an edged tool used by husbandmen in cutting bushes, &c. It is a kind of hatchet with a hooked point, and a handle either shorter or longer, according to the various uses for which it is intended.

BIN, or BINN, a place where corn, &c. is deposited.

BIND-WEED, called by some *with-wind*, a troublesome weed, of which there are two species, the smaller and the greater.

The first, or smaller bind-weed, commonly called gravel bind-weed, is very common upon dry banks, and in gravelly ground in most parts of England, and is generally a sign of gravel lying near the surface. Its roots penetrate very deep into the ground, whence it is in some countries called devil's guts. It is a very troublesome weed both in gardens and fields.

The second or greater bind-weed, is also a troublesome weed; but in an open clear spot of ground, where the plants are constantly hoed down for three or four months, they may be effectually destroyed; for when the stalks are broken or cut, a milky juice flows out, by which the roots are soon exhausted, and decay; but as every part of the root will grow, this circumstance renders it a troublesome weed to destroy, where its roots are intermixed with those of other plants. *Miller's Gard. Dict.*

Mr. Lisle, after observing that he believes bind-weed propagates itself in pasture grounds chiefly by its seeds, and by its roots in arable land, because it seems to flower too late in corn to seed before the corn is cut, thinks the reason why it is most apt to multiply in clayey soils, is because such ground being, in the common practice, ploughed only in winter months, after wheat, for other crops as barley, pease, or oats, and not till about September for winter vetches; this tillage cannot destroy the roots or seeds of weeds like the summer fallows for wheat; but, on the contrary, promotes their increase, particularly from the off-sets, or joints of the roots. "I have known, says he, in this case, clay land folded for barley, and particularly that part of it which, waiting for the folds going over it last, was latest fallowed, bring up such an increase of with-wind, that, though the spring and summer had been very dry, every stem of barley had a with-wind round it. As the fold brought up a crop of this corn, it brought up with each plant its enemy, which would eat it out, pull it down before it could ripen, and threby prevent the filling of the grain. The crop is also greatly hazarded here, after it is cut, from the danger it must run by laying in swarth, till this weed is withered before it can be carted. Again, near the end of the first summer, after the first year of a crop of hop-clover, which I fed, that is about the beginning of August, I fallowed the ground for wheat, then dunged the fallows, and sowed the wheat before Michaelmas. I had a very good crop of wheat; but a with-weed came up to every plant; so that had it been a wet and cold summer, instead of a hot and dry one, as it chanced to be, my corn would have been pulled down and lodged while green in the ear, and in the milk, and could not then have filled in body and flour, but must have been of the nature of blighted corn. The increase of the with-wind here was, without doubt, occasioned by laying down this ground only to one summer feed after the hop-clover was sown, when it had borne three or four crops of summer corn after its wheat crop; for by the winter ploughings, as I intimated before, the off-sets of the roots of weeds, and their seeds, were propagated. I could not conveniently destroy these roots or seeds by giving the ground a seasonable summer fallow in the beginning of June; because I should then have lost the fruits of my hop-clover crop, by ploughing it in at the beginning of the first summer: though this would have contributed much to the killing of the with-wind: whereas, by delaying the fallowing three months longer, viz. to the beginning of August, when the sun had lost its strength to burn up the roots and malt the seeds, and it was too late for the ground to lie long to a fallow, the dung laid on the fallows gave new life to the roots and seeds. *Lisle's Husbandry, vol.* II. *pag.* 303.

BINN. *See* BIN.

BIRCH, the name of a tree so well known as to need no description. This tree is not much esteemed for its wood, but however it may be cultivated to advantage upon barren land, where better trees will not thrive; for there is no ground so bad, but this tree will thrive in it; for it will grow in moist springy land, or in dry gravel or sand, where there is little surface: so that upon ground which produced nothing but moss, these trees have succeeded so well, as to be fit to cut in ten years after planting, when they have been sold for near ten pounds per acre standing, and the after-produce have been considerably increased. And as many of the woods near London, which were chiefly stocked with these trees, have been of late years grubbed up, so the value of these plantations have advanced in proportion. Therefore those persons who are possessed of such poor land, cannot employ it better, than by planting it with these trees, especially as the expence of doing it is not great.

The best method to cultivate this tree, is to furnish yourself with young plants from the woods, where they naturally grow, and are generally found there in great plenty; but in places where there are no young plants to be procured near, they may be raised from seeds, which should be carefully gathered in the autumn, as soon as the scales under which they are lodged begin to open, otherwise they will soon fall out and be lost: the seeds are small, so should not be buried deep in the ground. The autumn is the best season to sow them; and in a shady situation, the plants will thrive better than when they are exposed to the full sun; for in all places where there are any large trees, their seeds fall, and the plants come up well without care; so that if the young plants are not destroyed by cattle, there is generally plenty of them, in all the woods where there are any of these trees. These wild plants should be carefully taken up, not to injure the roots. The ground where they are to be planted, will require no preparation; all that is necessary to be done, is to loosen the ground with a spade or mattock, in the places where the plants are to stand, making holes to receive their roots, covering them again when the plants are placed, closing the earth hard to their roots. If the plants are young, and have not much top, they will require no pruning; but where they have bushy heads, they should be shortened, to prevent their being shaken and displaced by the wind. When the plants have taken root, they will require no other care, but to cut down the great weeds which would over-hang the plants, being careful not to cut or injure the young trees. This need not to be repeated oftener than twice in a summer the two first years, after which time the plants will be strong enough to keep down the weeds, or at least be out of danger from them.

These may be planted any time from the middle of October, till the middle of March, when the ground is not frozen; but in dry land the autumn is the best season, and the spring for moist. The distance which they should be planted, is four feet square, that they may soon cover the ground, and by standing close they will draw each other up; for in situations where they are much exposed, if they are not pretty close, they will not thrive so well.

If the plants take kindly to the ground, they will be fit to cut in about ten years; and afterwards they may be cut every seventh or eighth year, if they are designed for the

broom-

broom-makers only; but where they are intended for hoops, they ſhould not be cut oftener than every twelfth year.

The broom-makers are conſtant cuſtomers for birch, in all places within twenty miles of London, or where it is near water-carriage: in other parts the hoop-benders are the purchaſers; but the larger trees are often bought by the turners, and the wood is uſed for making ox-yokes, and other inſtruments of huſbandry.

In ſome of the northern parts of Europe, the wood of this tree is greatly uſed for making of carriages and wheels, being hard and of long duration. In France it is generally uſed for making wooden ſhoes. It likewiſe makes very good fuel.

In ſome places theſe trees are tapped in the ſpring, and the ſap drawn out to make birch wine, which has been recommended for the ſtone and gravel, as is alſo the ſap unfermented. The bark of the birch-tree is almoſt incorruptible. In Sweden the houſes are covered with it, where it laſts many years. It frequently happens, that the wood is entirely rotten, and the bark perfectly ſound and good. *Miller's Gard. Dict.*

The beſt method of obtaining the ſap of the birch-tree for making wine, &c. is to bore a hole ſlanting upwards with a middle-ſized augre to a moderate depth in the tree, and to faſten a bottle to the orifice, by which means a large quantity of the ſap may be ſpeedily procured. Or many gallons in a day may be gathered from the boughs of the trees by cutting them off, leaving their ends fit to go into the mouths of bottles, and ſo by hanging many bottles on ſeveral boughs, the liquor will diſtill into them very plentifully.

The ſeaſon for this work is from the end of February to the end of March, whilſt the ſap riſes, and before the leaves ſhoot out from the tree; for when the ſap is forward, and the leaves begin to appear, the juice, by a long digeſtion in the branch, grows thick and coloured, which before was thin and limpid. Nor will the ſap diſtil either in the night, or in cold weather while the north and eaſt winds blow; but very well and freely, when the ſouth-weſt winds blow, or the ſun ſhines warm.

The liquor is beſt that proceeds from the branches, having had a longer time in the tree, and thereby better digeſted, and acquiring more of its flavour than if it had been extracted from the trunk. *Mortimer's Huſbandry, vol.* ii. *p.* 406.

In order to have enough of this liquor to ſet about making wine with it, many trees ſhould be tapped at the ſame time, ſo that a ſufficient quantity of ſap may be obtained in a few days; for it will not keep long, without a tendency to putrefaction. To prevent this, ſome authors adviſe ſetting that which is firſt drawn in bottles, or other proper veſſels, in the ſun, till the reſt be ready, and to put into it a hard toaſt of rye-bread cut thin, to make it ferment. But as it is neceſſary to mix with this juice either ſugar or raiſins, in order to give it a body, to enable it to undergo a regular fermentation, which alone can render it fit for keeping, and for want of which it is that this wine is ſo apt to burſt the bottles into which it is put, that firſt fermentation will certainly be found hurtful. When therefore the huſbandman has not a ſufficient number of trees to obtain ſap enough for his purpoſe in two or three days, the moſt adviſable way will be to put the ſap into very ſweet veſſels, and place them in a cool cellar; for it will keep there perfectly ſound, for a much longer time, eſpecially if it be covered with oil, or bunged up cloſe.

The proportion of ſugar may be varied according to the taſte and intention of the brewer: but, in general, a pound of ſugar is thought to be the proper allowance for a gallon of this liquor. The ſap and ſugar muſt be thoroughly united by a heat juſt ſufficient to make them boil; but the long boiling, which is generally adviſed, can anſwer no good purpoſe: on the contrary, it will render the liquor leſs diſpoſed to ferment kindly, and likewiſe deprive it of a conſiderable part of the peculiar fragrance and flavour of the tree from whence it was taken. It ſhould therefore be carefully remembered, that the ſole purpoſe of boiling this liquor is, to make a thorough diſſolution of the ſurgar in it. Some people ſubſtitute honey inſtead of ſugar; in this caſe a quart of honey is eſteemed equal to a pound of ſugar. With regard to various ſpices ordered by different writers, they muſt be left to the taſte and option of the maker.

It is generally found neceſſary in order to ferment this liquor, to put into it a little yeaſt, a bit of dough, or a thin toaſt of leavened bread; after which it is treated in all reſpects like other vinous liquors. See the articles FERMENTATION, and WINE.

It is ſaid, that in the North, where large birch and plane trees are frequent, their ſap is obtained in ſuch plenty as to be uſed for brewing, inſtead of water, and that it makes equally ſtrong beer with much leſs malt. Dr. Tong, in the Philoſophical Tranſactions, N° 46. ſays, that one buſhel of malt brewed with this liquor will make as good ale, as four buſhels with common water. He thinks the ſap of the ſycamore the beſt for brewing; becauſe it is very ſweet, and, at the ſame time, very wholeſome.

BIRD-GRASS, *or* FOWL-MEADOW-GRASS, a very excellent graſs imported from Virginia, by the late Peter Wych, Eſq; and has been cultivated with ſucceſs by Mr. Roque. The Rev. Dr. Elliot of New-England, in his Eſſays on Field-Huſbandry, tells us, that it acquired this odd name from its being brought into a piece of poor meadow at Dedham, by ducks and other wild water-fowl. We have given a figure of this valuable graſs on Plate IV. Fig. 4.

As Mr. Roque is the only perſon that has ſucceſsfully cultivated this ſpecies of graſs, we ſhall give our readers his own account of it, which he ſent in a letter to the Society for the Encouragement of Arts, &c.

"In the month of March, 1764, I received from the late Peter Wych, Eſq; the chairman of the committee of agriculture in the Society for the Encouragement of Arts, &c. an ounce and a half of the ſeed of a ſpecies of graſs called bird-graſs. He obtained it from Virginia, where it grows, though it is not a native graſs. The intention of putting it into my hands was, in order that I ſhould cultivate it, and be thence able to form a judgment whether it might have any peculiar properties not found in our graſſes, that would render it an advantageous article of culture here. He had, himſelf, conceived a very high opinion of it, by the information he had gained concerning it, from the country whence it came; and intended, as ſoon as he ſhould have due proof from experiment, of what he hoped, to bring it before the Society for the Encouragement of Arts, &c. who had, with public-ſpirited zeal, entered very minutely into the conſideration of the means of improving paſtures. Being very ſolicitous to acquit myſelf of the truſt, I carefully preſerved this little treaſure till the month of April, which I thought might be a fit time to ſow it. Not being acquainted with the particular nature of this graſs, I prepared the ground for it, in the ſame manner I ſhould have done for a flower-bed: raking it with a wooden rake. I did this as I was willing by every means to ſecure its coming up: but ſuch care would not have appeared in the leaſt neceſſary, had I known its great hardineſs, and force of vegetating power, as I have done ſince.

"At the time I expected the bird-graſs to riſe from my ſeed, I found the weeds and common graſs coming up very thick: ſo that I could not diſtinguiſh the deſired kind from theſe intruders; particularly the poa-graſs. Being a ſtranger, as I before ſaid, to the appearance of the bird-graſs, I thought it the beſt way to weed out the other graſs and herbs which I knew, and to let what I could not diſtinguiſh to be ſo, remain in the ground: and my eagerneſs was ſo great to perceive whether the bird-graſs was come up, that I went almoſt every hour to look after it. I diſcovered it at laſt, in about a month from the time of its being ſown, by its having a deeper green hue than is commonly ſeen in our graſſes: and I tranſplanted it as ſoon as I imagined it would bear moving, into ſome of the ſame kind of ground, as that on which it had been raiſed: having firſt turned it up and cleared it from weeds. The ſize of this piece of ground was about twenty rods: part of it a little gravelly, and the other part of it moory land. I ſoon perceived the bird-graſs grew better on the gravelly than on the moory part of the ground. That on the gravelly being of a better colour and ſweeter than that on the moory; which was pale and yellow. And with reſpect to the moory ground itſelf, one part was moiſter than

than the other, and the bird-grafs grew better on the drier fide than on the wet. The grafs, however, looked well all the fummer, and in the month of September following, I began to gather the feed, and proceeded in it till October. The quantity of the feed was above twelve pounds.

"The firft year the grafs did not grow to above two feet and an half high: but the fecond it rofe to be four feet high. On the 14th of June of that year, being 1765, I meafured out ten rods of this grafs, and cut it. Three days after I weighed the product of this ten rod, herb and feed together; and they amounted to twelve hundred pounds. The tenth of Auguft following, the fame grafs was again grown to the height of two feet eight inches, and was a fecond time fit to cut for hay: but I did not cut it; becaufe I wanted a fecond crop of feed: which I obtained in the beginning of October; and it proved a much greater crop than the former. About this time a good deal of rain fell, which occafioned me no fmall fhare of trouble in drying the grafs, and turning the little cocks. I then firft remarked that fhoots were made from almoft every joint, in confequence of the moifture; but from fome more than others: and of thefe many were of a finger's length. Had I not fuffered this grafs to ftand, that I might have the feed, I am fatisfied I could have mowed it thrice in the year; but wanting to collect as great a quantity as I could of the feed, I have not yet actually tried that experiment. I am very confident, however, that this kind of grafs may be brought to afford eight tons of hay per acre in the year: and any perfon who may entertain doubts of the reafonablenefs of this fuppofition, may have them cleared up by ocular proof, if they will take the trouble to call on me; as great numbers of gentlemen have already done, to their entire fatisfaction in this point. The latter end of May, and the beginning of June, will be a proper time for fuch infpection; as this grafs, being a forward kind, will be fit to cut at that feafon.

"This grafs has a peculiar quality, different from what is found in any other kind I ever knew before; which is, that it hath very fhort joints, and that every joint fends out fhoots, which ftrike root whenever they touch the ground. On taking a full-grown plant of the grafs out of the ground, it will be found, moreover, capable of being divided into twenty fmaller roots or off-fets, proper to be again planted: and thefe off-fets, though taken thus from the root, even in the beginning of July, will bear feed the fame year. If, likewife, when this grafs is ready to be mowed, there fhould happen to be much rain, no damage will enfue on waiting a month for fair weather. Becaufe, as this grafs is conftantly fending out fhoots at every joint, it always keeps frefh; and does not wither, nor root at the bottom, as other graffes do: but, on the contrary, it continues green, even till the feed is ripe: which is certainly a very fingular property, and of great confequence.

"The goodnefs of this kind of grafs may alfo be very obviously inferred from the following particular. When I firft fowed it, which was in the month of April, 1764, I had, as I have above declared, only one ounce and a half of feed: but betwixt that time and the prefent, I have found fuch a furprizing increafe, that I have collected from the fucceffive crops of this ounce and a half, as much feed as has fown two hundred and fifty acres of land; and have befides, as much by me at prefent, as will fow one hundred acres more.

"I fhall not dwell any longer on the commendation of this grafs, than only to fay, that it has every quality requifite to make good hay. That it is eafily propagated, and from a very fmall portion of feed. That it is not fubject to rot, or fail in patches, as moft other kinds of grafs do. That it is a beautiful green at all times, and confequently affords a moft pleafing verdure, when fown in fight of any houfe, or made part of any profpect. And, laftly, that the produce of hay from it is extremely great, being much more than any other kind of true grafs will yield. Of the truth of all this many perfons can witnefs, who have, on feeing the real trials refpecting it, given the greateft encomiums on it: I fhall therefore proceed now to offer fome directions for its culture.

"The ground on which the feed of this kind of grafs is intended to be fown, is to be prepared in the manner that is proper for lucern: that is, it fhould be well ploughed and harrowed; and cleared, as much as poffible, from all weeds, in the fame way as is done for barley. When the ground is well mellowed and fweetened, the feed may be fown: the quantity of which may be about one pound and a half per acre; and the time of doing it, from March to April.

"Before the bird-grafs feed be fown, it will be proper to fow as much barley or oats, as will afford half a crop: and fuch barley or oats being harrowed in, the pound and half of bird-grafs feed fhould be fown over it: after which, in general cafes, the ground is only to be rolled the firft opportunity when it is dry. But if the foil be fandy or dry, it may be proper to give it a very light harrowing.

"This kind of grafs cannot be well fown without fome corn. Becaufe it is of fo fine and delicate a nature, at its firft coming up, that the weeds would overpower and choak it at that time: or a great expence would be neceffary for clearing them away by hand. But when this grafs is fo mature, as to be in the ftate of a pafture, or fit to cut, it grows fo clofe and thick, that if a handful of money was thrown up over it, none would, when fallen, I am certain, reach the ground.

"As to the nature of the foil proper for the culture of bird-grafs, almoft every kind will do very well for it; except, as has been obferved before, fuch as is too wet or moory; and this is one of the good properties of this grafs, becaufe few kinds flourifh much on dry gravelly ground.

"This is a juft account of the obfervations and experiments I have hitherto made on this valuable grafs; and they feem fufficient to juftify me, in endeavouring to render it known to the public, as an object worthy their attention."

BIRD'S-NEST, the name of a weed otherwife called wild carrot. *See Wild* CARROT.

BISHOP, a little fpotted beetle, commonly called the lady-cow, or lady-bird.

BISHOPING, a cant term made ufe of by horfe-jockies, implying the unfair practices they make ufe of to conceal the age of an old horfe, or the ill properties of a bad one.

BIT, *or* BITT, the iron part of a bridle, put into a horfe's mouth.

BLACK, a colour in horfes, efteemed very beautiful, efpecially when they are of a jet fhining black, and well marked, without having too much white: for as a great deal of white, efpecially when it fpreads round their eyes, and a great way up their legs, adds nothing to their beauty, fo neither does it add any thing to their goodnefs. The Englifh black horfes have more white about them than the black horfes of any other country. The Spanifh, Arabian, Dutch, and Danifh horfes, feldom have much; though a ftar or blaze, and fometimes a white muzzle, and one or more of the feet tipped with white, always looks beautiful and lively, and is fo far from being a diminution of the goodnefs of a horfe, that moft think it an addition, from an opinion that horfes without marks are generally ftubborn and ill-conditioned. Some black horfes have brown muzzles, are brownifh on their flanks, and between their hips. Thefe are often called black browns, as they are not a perfect black, but approach near to the colour of a tawny black hound; fome are of a lighter colour about their muzzles, and are called mealy-mouthed horfes; and of thefe fort are the pigeon-eyed horfes, which have a white circle round their eye-lids, and their fundaments often white. Thofe that partake moft of the brown, are generally the ftrongeft in conftitution. *Gibfon on Horfes, vol.* i. *p.* 46.

BLACK-GRASS, a fpecies of grafs in America, of which the following account is given by the late Dr. Elliot of New-England.

"We have, fays that worthy writer, in a letter to Mr. Mills, an excellent fort of grafs in our falt marfhes. It thrives beft, and grows largeft, in thofe meadows which border on tide-rivers, and have the greateft mixture of frefh-water. Where the water is very falt it is not apt to fix and fpread; but will remain fhort and poor. It is very tender, and cuts as eafily as garden cives, grows thicker and taller than the common falt-marfh grafs, and affords from two to three tons of hay to the acre: but it is a flow grower, after it has been cut. Its feeds are fmall, like thofe of tobacco. The colour of this grafs is a very deep green,

green, which renders it fo confpicuoufly different from every other kind, that it is univerfally known by the name of black grafs.

"This fpecies introduced itfelf long fince the fettlement of New England. Our firft planters knew nothing of it; nor has it yet travelled very far fouth-weft. Its firft appearance in this colony was on a marfh at Saybrook, to which an old boat was brought down Connecticut river, by a great flood, and there caft up. This inclined me to think, that it was originally an inland grafs, which happened to fuit with fuch falt marfhes as are well fupplied with frefh water; and what confirms me in this opinion is, that a perfon in the town of Killingworth, where I refide, having cleared a fwamp far diftant from falt water, and afterwards fent into this frefh meadow, cattle, which had been foddered with hay of the black grafs, had there in a fhort time (undoubtedly by means of its feeds carried thither in the dung of thefe cattle) a fine growth of this very grafs, which has fince not only eftablifhed itfelf, fpread, extended, and, like a conqueror, beaten out the natural grafs; but looks as flourifhing in that frefh meadow, as any growing on a falt marfh.

"I have a large tract of peat meadow, in which no grafs feeds will grow. I defign to try the feeds of this black grafs in that dead frefh meadow, fince the other forts which I have tried do not fucceed. What encourages me to do this, is my having introduced it into a once ufelefs, worthlefs morafs, worfe indeed than nothing, though of confiderable extent, for I was obliged to be at the expence of fencing it, for the fake of other land. It was quite over-run with reeds, bufhes, and brakes.

"Between this land of mine and a creek of falt water, intervened three meadow lots belonging to other perfons. I obtained leave of the owners to cut a ditch fix feet wide through their ground, and carried this ditch to the upper end of my land, where feveral crofs ditches were then dug, to invite in, and retain the falt water. The gaping mouths of thefe numerous ditches foon occafioned a ftrong indraught of falt water, and, in time, converted the main ditch into a proper tide creek. The falt water thus introduced has done wonders. It has not only killed the trees, bufhes, brakes, and levelled great inequalities, but has alfo introduced the black grafs, and thereby rendered an acre of that land, which was not worth any thing before, now worth thirty-five pounds of our currency.

"The falt water in its paffage through my neighbours grounds has alfo done them great fervice, by introducing this black grafs; and all this with fmall expence." *Mills's Hufbandry, vol.* III. *pag.* 416.

To this account of the black grafs given by doctor Elliot, we fhall add the following, tranfmitted in a letter from that gentleman's fon-in-law, the reverend doctor Gale.

"Its (the black grafs) early fpring and growth, its lively green, its great produce, the preference given to it by cattle, when diftributed promifcuoufly with falt grafs for their food; its rendering the turf of mirey, loofe, dirty meadows, firm and folid, and its extraordinary quality when improved for pafture in the fpring and fummer, raifed its reputation, and endeavours were ufed to propagate it: but it proved very fullen and uncertain in its growth; growing only where it lifted, from the feed promifcuoufly fhed, and wafted about by the tide which overflowed the meadows.

"It is obferved to grow and flourifh well near the banks of rivers, which admit the falt water, and even in flat or low meadows, which are in fome meafure overflowed every tide by the falt water: but thefe low meadows muft alfo be of that kind only, where there is a courfe of frefh water when the tide is out: fo that a mixture of both frefh and falt water feems to be neceffary for its prolific vegetation.

"It grows largeft and beft in reedy and rufhy coves, or arms of the falt meadows, which are a little higher than the general level of the falt marfh, which are not commonly overflowed by the flux and reflux of the tides, which lie at fome diftance from falt creeks or courfes of falt water, and which are watered by frefh fprings rifing from the banks, or adjoining uplands.

"I have feen feveral fuch meadows which flourifh remarkably with this fort of grafs, though but lately brought under culture: I am credibly informed, that eight acres of fuch a cove produced this year thirty-two tons of black grafs in an adjoining townfhip.

"The black grafs is not near fo much impregnated with falt as the common grafs is, when both of them grow together; and the dew which adheres to the black grafs is frefh, when that on falt grafs is highly impregnated with falt.

"It thrives beft on a clay or ftrong loam. The natural turf fhould be broken, and the feed, after being mixed with frefh cow-dung, fhould be fpread, and faftened in by treading, that it may not be carried off by the water: or it may be propagated by tranfplanting the turf taken from a black grafs meadow, by which means it will be made to fpread a pace.

"It will alfo grow where falt water never reaches. I have feen it growing on moift upland, and the turf has been fo firm, that it was hard work for fix oxen to plough through it."

We fhall only add, that the above gentleman has juft fent the Society for the Encouragements of Arts, &c. a confiderable quantity of the feed of this black grafs; and that they have diftributed it to a number of gentlemen, in order to their fowing it on proper foils; fo that there is great reafon to hope that this valuable grafs will foon be as well known in England, as it is now in America.

BLACK-LAND, a name given to a particular fort of clayey foil, which is rather a grey than a true black. But however pale it may be when dry, it always blackens by means of rain; and when ploughed up at thofe feafons, it fticks to the plough fhare; and the more it is wrought, the muddier and dufkier coloured it appears.

Thefe forts of lands when fomewhat fat, yet porous, light, and fufficiently tenacious, are good both for corn and grafs; but as they are moftly in bottoms, fo the wetnefs of them often fpoil them for corn; but where they are dry, they are extraordinary fruitful, efpecially for barley; they will bear alfo good wheat upon an erch crop: but if they are fo very rich, that you fear lodging of the corn, you may, if a deep mould, plant them with liquorice, or fow them with hemp, woad, cole, rape-feed, madder, or fome other rich commodity, that beft agrees with fuch land; and afterwards with corn, when fome of the fertility is abated. The natural produce of thefe lands is commonly thiftles, docks, and all forts of rank weeds and grafs. It will bear excellent clover. The beft manure is chalk, lime, dung, &c. *Mortimer's Hufbandry, vol.* I. *pag.* 75.

BLACK-LEGS, a name given in Leicefterfhire to a difeafe frequent among the calves and fheep. In Staffordfhire they call it the wood-evil.

It is a white jelly, and fometimes a bloody jelly, fettling in their legs, from whence it has its name of black-legs, and often in the neck between the fkin and flefh, which will make them carry their necks awry. If it falls on the joints they overcome it; but of in their bowels they die, nor is there any cure. *Lifle's Hufbandry, vol.* II. *pag.* 134.

BLACK OATS, a fpecies of oats greatly cultivated in the northern parts of England, being efteemed a very hearty food for horfes. *See the article* OATS.

BLACK THORN, a fpecies of bufhes well known, and much ufed in making fences, &c.

It is not reckoned quite fo good for fences as the white thorn, becaufe it is apt to run more into the ground, and is not fo certain of growing; but then the bufhes are much the beft, and moft lafting of any for dead hedges, or to mend gaps: nor are cattle fo apt to crop them as the other. They will grow on the fame fort of foil with the white thorn; but the richer the mould is, the more they will profper. *Mortimer's Hufbandry, vol.* I. *pag.* 5.

BLADE, the fpire of grafs, or green fhoots of corn.

BLADE, alfo fignifies the fharp or ftriking part of a weapon or inftrument.

BLAIN, a difeafe to which cattle are fubject in the fpring of the year. Some think it is occafioned by a little red worm which the cattle lick up. It often occafions a bladder as large as a hen's egg under the tongue, and when this happens, the beaft may be cured by breaking the bladder, and rubbing it with falt.

Others impute the difeafe to a fudden rifing of the blood, and may be known by the beaft's eyes running with water; and as the diftemper advances, its eyes will fwell, and, if bled under the rump, the blood will feel hot. In this cafe the following drench is recommended. Take a pennyworth of Englifh liquorice, and an equal quantity of Englifh anifeeds, turmeric, long pepper, horfe-fpice or diapente, all ground fine, and juft boiled up in a quart of ftrong beer; but if the heat of the blood indicates that the diftemper proceeds from a hot caufe, the horfe-fpice fhould be omitted. It is added, that if the bladder cannot be found under the tongue, the bum-gut fhould be raked, where it will be found in the back. If a knife be run through the ear of a beaft near the root, it will, according to the report of experienced graziers, prove a certain cure in this diftemper, provided it be done before the beaft falls. *Lifle's Hufbandry, vol.* II. *pag.* 127.

BLANCHING, an operation performed on certain fallets, roots, &c. fuch as cellery and endives, to render them fairer and fitter for the table.

One method of blanching confifts in tying the leaves up clofe; this is practifed on cabbages, lettuces, &c. in the fummer, which makes them fit for ufe confiderably fooner, and particularly thofe which are not inclinable to turn in, or cabbage, as the gardeners call it. Another method practifed in winter on celery, endive, dandelion, &c. is by earthing them up to their tops, which not only b anches, but alfo protects them from the frofts.

BLAST, the fame with blight. *See* BLIGHT.

BLAZE, a white mark in a horfe's face.

BLEA, that part of a tree which lies immediately under the bark, or between that and the hard wood, and is the firft progrefs of the alteration of the bark into wood, by the natural growth, and ftrengthening of the fibres.

While the blea remains any thing foft, and retains fomewhat of the nature of bark, it may maintain a feeble vegetation; but when it is grown abfolutely hard and woody, it can no longer contribute to carry on that operation.

BLEEDING, an operation frequently neceffary among all kinds of cattle, particularly horfes; and confifts in opening a vein by means of an inftrument called a fleam.

Thofe horfes that ftand much in the ftable, and are full fed, require bleeding more than thofe that are in conftant exercife; but efpecially when their eyes look heavy and dull, red and inflamed; or when they look yellow or inflamed in their lips, and infides of their mouths; when they feem hotter than ufual, and mangle their hay. Thefe are all indications that require bleeding, and likewife to lower their diet till they have more exercife.

Young horfes fhould be bled when they are fhedding their teeth, which is a relief to them, and removes thofe feverifh heats, to which they are fubject at that time.

The fpring is always a proper feafon for bleeding, becaufe their blood is then more luxuriant than at other times; and in fummer it is often neceffary to prevent fevers, always choofing the cool of the morning, and keeping them cool the remaining part of the day.

Some bleed their horfes three or four times a year, or even oftener, by way of prevention. Thefe take a very fmall quantity at a time, not exceeding a pint, or a pint and a half, only to give a kind of brifker motion to the blood, and by that means to preferve or render it more thin and fluid, and to prevent its ftagnating in the fmaller veffels, which indeed is the firft beginning of almoft all difeafes; but how far this fucceeds, can only be known to thofe who have practifed it a fufficient time. There is, however, this inconvenience from frequent bleeding, that it grows into a habit, which, in fome cafes, cannot be eafily broken off without hazard; and fome horfes have been known to become weak from frequent bleeding, while others have had their necks fo full of fcars, that they are apt to inflame and fefter every time they are bled, which is always troublefome, and often ends with the lofs of the vein. And therefore to prevent fuch accidents, thofe who bleed horfes fhould not confine their operation to one place of the vein, as they generally do, but ufe themfelves to open it higher or lower as they fee occafion; and if they meet with any difficulty in bleeding in the neck veins, the plate veins, or any other large veins, that can be made to run a full ftream, will equally anfwer the fame end.

But the cafes that require bleeding moft, are colds, fevers of almoft all kinds, falls, and bruifes, which are fometimes dangerous to horfes, becaufe of their great weight. Hurts and wounds of the eyes, ftrains in hard riding, or drawing, and all other accidents where a ftagnation of the blood may be fuddenly expected, or where the fmall veffels may be broke, and the blood extravafated. Thofe horfes that refufe their food after riding, or any fort of work, require to be bled more frequently than others, to prevent fevers, and inward inflammations of the lungs, the liver, or any of the principal vifcera. Nor is it lefs neceffary to bleed horfes at grafs, when the purgation is over, and they begin to gather flefh, or at any other time, when they look heavy about their eyes, for that is a proper indication for bleeding; and fome rank paftures require more bleeding than others.

There are alfo other indications that require bleeding by way of prevention, viz. when any epidemic diftemper prevails among the horfes; at fuch times the found ones may be bled, to keep them, if poffible, from being infected; and if the contagion continues, it may not be amifs to repeat the bleeding once in two or three months, or oftener; but in fmall quantities, for the lofs of too much blood may be hurtful in fome times of contagion. It is likewife neceffary to keep found horfes from the unfound, or to remove them into places where the infection has never fpread itfelf. *Gibfon on the Difeafes of Horfes, vol.* I. *pag.* 218.

BLEYME, an inflammation in an horfe's foot, occafioned by blood putrified in the inner part of the coffin towards the heel, between the fole and the coffin-bone.

There are three forts of bleymes; the firft, bred in fpoiled, wrinkled feet with narrow heels, are ufually feated in the inward or weakeft quarter: the fecond, befides the ufual fymptoms of the firft, infects the griftle, and muft be extirpated, as in the cure of a quitter-bone. *See* QUITTER-BONE. The third is occafioned by fmall ftones, or gravel, between the fhoe and the fole. For the cure they pare the foot, let out the matter, if any, and drefs the fore like the prick of a nail.

BLIGHT, a general name for various diftempers incident both to corn and fruit-trees.

M. du Hamel treats that part of this fubject which relates to corn in a very mafterly and inftructive manner; dividing what we generally call blights into the following fpecies, viz. empty ears, parched and fhrivelled corn, glazed corn, abortive or rickety corn, barren corn, and fallen or lodged corn. The reader will find each under its proper articles, as EMPTY EARS, &c.

"There is nothing, fays Mr. Miller, fo deftructive to a fruit-garden as blights; nor is there any thing in the bufinefs of gardening which requires more of our ferious attention, than the endeavouring to prevent or guard againft this great enemy of gardens.

"In order, therefore, to remedy this evil, it will be neceffary firft to underftand the true caufes of blights: and, although many curious perfons have attempted to explain the caufes of them, yet very few of them have yet come near the truth, except the reverend and learned doctor Hales, who hath, in his curious book, intitled, Vegetable Statics, given us fome accurate experiments upon the growth and perfpiration of plants; together with the various effects the air has upon vegetables; fo that, by carefully attending thereto, together with diligent obfervations, we need feldom be at a lofs how to account for the caufes of blights, whenever they may happen.

"Blights are often caufed by a continued eafterly wind, for feveral days together, without the intervention

tion of showers, or any morning dew, by which the perspiration of the tender blossoms is stopped; so that, in a short time, their colour is changed, and they wither and decay: and if it so happens, that there is a long continuance of the same weather, it equally affects the tender leaves; for their perspiring matter is hereby thickened, and rendered glutinous, closely adhering to the surfaces of the leaves, and becomes a proper nutriment to those small insects, which are always found preying upon the leaves and tender branches of fruit-trees, whenever this blight happens.

"The best remedy for this distemper, that I have yet known to succeed is gently to wash and sprinkle over the trees, from time to time, with common water (that is, such as hath not had any thing steeped in it) and the sooner this is performed (whenever we apprehend danger) the better; and, if the young and tender shoots seem to be much infected, wash them with a woollen cloth, so as to clear them, if possible, from all this glutinous matter, that their respiration and perspiration may not be obstructed; and if we place some broad flat pans or tubs of water near the trees, that the vapours exhaled from it may be received by the trees, it will keep their tender parts in a ductile state, and greatly help them; but, whenever this operation of washing the trees is performed, it should be early in the day, that the moisture may be exhaled before the cold of the night comes on; especially if the nights are frosty: nor should it be done when the sun shines very hot upon the wall, which would be subject to scorch up the tender blossoms.

"Another cause of blights in the spring is, sharp hoary frosts, which are often succeeded by hot sunshine in the day-time; which is the most sudden and certain destroyer of fruits that is known: for the cold of the night starves the tender parts of the blossoms, and the sun rising sun hot upon the walls before the moisture is dried from the blossoms (which, being in small globules, collects the rays of the sun) a scalding heat is thereby acquired, which scorches the tender flowers, and other parts of plants.

"But there is another sort of blight, against which it is very difficult to guard our fruit-trees; this is sharp pinching frosty mornings, which often happen at the time when the trees are in flower, or while the fruit is very young, and occasion the blossoms or fruit to drop off; and, sometimes, the tender parts of the shoots and leaves are greatly injured thereby.

"The only method yet found out to prevent this mischief is by carefully covering the walls, either with mats, canvas, reeds, &c. which being fastened so as not to be disturbed with the wind, and suffered to remain on during the night, by taking them off every day, if the weather permits, is the best and surest method that hath yet been used in this case; which, although it has been slighted, and thought of little service by some, yet the reason of their being not so serviceable, as has been expected, was, because they have not been rightly used, by suffering the trees to remain too long covered; by which means, the younger branches and leaves have been rendered too weak to endure the open air, when they are exposed to it; which has often proved of worse consequence to trees, than if they had remained entirely uncovered.

"Whereas, when the covering before-mentioned has been performed, as it ought to be, it has proved very serviceable to fruits; and many times, when there has been almost a general destruction of fruits, in the neighbouring gardens, there has been a plenty of them in such places where they have been covered; and, though it may to some seem very great trouble, yet, if these coverings are fixed near the upper part of the wall, and are fastened to pullies, so as to be drawn up, or let down, it will be soon and easily done; and the success will sufficiently pay the trouble.

But there is another sort of blight, that sometimes comes later in the spring, viz. in April or May, which is often very destructive to orchards, and open plantations, and against which we know no remedy. This is what is called a fire-blast, which, in a few hours, hath not only destroyed the fruit and leaves, but many times parts of trees, and, sometimes, whole ones have been killed by it.

"This is supposed to effected by volumes of transparent flying vapours, which, among many forms they revolve into, may sometimes approach so near to a hemisphere, or hemi-cylinder, either in their upper or lower surfaces, as thereby to make the beams of the sun converge enough to scorch the plants or trees they fall upon, in proportion to the greater or less convergency of the sun's rays.

"The learned Boerhaave, in his Theory of Chemistry, observes, that those white clouds, which appear in summer time, are, as it were, so many mirrors, and occasion excessive heat; these mirrors are sometimes round, sometimes concave, polygonous, &c. and therefore when the face of the heavens is covered with such white clouds, the sun, shining among them, must of necessity produce a vehemen heat; since many of his rays, which would otherwise, perhaps, never touch our earth, are by that means reflected to us: thus, if the sun be on one side, and the clouds on the opposite, they will be perfectly burning glasses.

"I have sometimes, continues he, observed a kind of hollow clouds, full of hail and snow in this position; during the continuance of which, the heat was extreme; since by such condensation they were enabled to reflect more strongly: after this came a sharp cold, and then the clouds discharged their hail in great quantities; to which succeeded a moderate warmth. Frozen concave clouds therefore, by this great reflection, produce a vigorous heat; and the same, when resolved, excessive cold. Whence, as doctor Hales observes, we see, that blasts may be occasioned by the reflections of the clouds, as well as by the above-mentioned refraction of dense transparent vapours.

"Against this enemy to fruits, &c. as has been already observed, there is no guard to our plantations, nor any remedy to cure it: but as this more frequently happens in close plantations (where the stagnating vapours from the earth, and the plentiful perspiration from the trees, are pent in for want of a free air to dissipate and dispel them; which are often observed, in still weather, to ascend in so plentiful a manner, as to be seen by the naked eye; but especially with a reflecting telescope, so as to make a clear and distinct object become dim and tremulous) than in those which are planted at a greater distance, or are not surrounded with hills or woods; this directs us in the first planting of orchards, &c. that we should allow a greater distance between the trees; and make choice of clear healthy situations, that the air may freely pass between the trees, to dissipate those vapours before they are formed into such volumes, whereby the circumambient air will be clear, and less subject to injuries: as also the fruits, which are produced in this clearer air, will be much better tasted than those that are surrounded with a thick rancid air; for, as fruits are often in a respiring state, so they, consequently, by imbibing a part of these vapours, are rendered crude, and ill tasted; which is often the case with a great part of our fruits in England. *Miller's Gard. Dict.*

BLIND, deprived of the sense of sight.

Moon-BLIND, or *lunatic*, a disease to which horses are subject, the symptoms of which are no other than the forerunners of cataracts, and generally end in blindness.

Signior Ruini, says that experienced writer Mr. Gibson, and most other foreign writers, both French and Italia, in treating the diseases of horses, have all of them reckoned the moon-blind symptoms as a peculiar disease of the eyes, without having any relation to a cataract, which they have considered a-part, as another disease of the eyes, which shews they built more on books than experience. But from many years observation, I do not remember I have ever seen a cataract bred in the eyes of any other horses than those which were called lunatic, or moon-blind. The Arabians were the first that ascribed so much to the moon in the diseases of the human body; and after the decay of learning all over Europe, their superstitious notions were so firmly riveted, and so universally prevailed, that they could not be easily exploded, even by the ablest physicians, till the modern discoveries in natural knowledge

ledge made way for more solid improvements in the medicinal art; and therefore it is no wonder, that the first writers on the subject of farriery, notwithstanding some of them were men of learning, should fall in with all the common superstitions that had so long prevailed, and had so great an influence on the practice of physic.

These writers have described this distemper as appearing at certain times of the moon, coming sometimes at the new-moon; sometimes at the full; and sometimes in the wane of the moon; that it sometimes returns once in three months; sometimes once in two months, and in some not above once in six months: that the eyes look so clear when the distemper abates, that it is impossible to see any imperfection in them. But these observations are very liable to exception; for any one who has the least knowledge of the eyes, must needs see, that when the distemper is the most abated, and the eye the most clear, it still shews a remarkable weakness, and upon full trial, the sight will be found defective. Neither could I perceive that the eyes were affected by any of the moon's periods, so as not to vary, unless by mere accident. And therefore these observations are neither of any great use to the knowledge of the distemper, nor to lead us into a right method of curing it when it happens.

I have already taken notice, that the symptoms which appear in the moon-blind horses, are, for the most part, no other than the prognostics of breeding cataracts. These symptoms generally make their first appearance, when a horse is turned five, coming six, at which time one eye becomes clouded, the eye-lids swoln, and very often shut up; and, for the most part, a thin viscid water runs, from the diseased eye, down the cheek, which is generally more or less in proportion, as the eye and eye-lids happen to be more or less swelled and inflamed; and in some constitutions, the inflammation is so great, and the humour so sharp and corrosive, that it scalds and fetches off the hair wherever it comes. The veins of the temples and under the eye, along the side of the nose, are also turgid and full: others run but little; nor is the humour very sharp.

This disorder is apt to come and go, till the cataracts are perfect and ripe, and then all pain and anguish, and the soreness and running of the eyes, go off with blindness, when the horse is between seven and eight years old, this being about the time when most horses are spread and come to their full growth; so that from its first appearance to its completion, is generally about two years, or two years and a half, during which time, some horses have the returns of the disorder, not only more frequently than others, but the symptoms also are more strong and violent. In some the eye is not much disturbed above a week, when it clears up again, and returns to its former state. In some horses the eye continues bad a fortnight or three weeks. In others a month or longer, before the disorder goes off; and the time of the return, so far as I could observe in many horses, was always uncertain, and could not be fixed to any period of the moon, as many have imagined, being sometimes sooner, sometimes later, according to its predominancy, or according to the treatment a horse meets with from his farrier and keeper. Some have their returns once within the space of two or three months; some within the space of four; and, with the greatest care and pains, the disorder seldom keeps off above five months, without a relapse.

This is usually the case of those moon-blind horses, which have their eyes strongly infected with a hot sharp humour, that shuts them up with swelling and inflammation. But there is another kind of moon-blindness, which is also the fore-runners of cataracts, where no humour or weeping attends the eye. It is never shut up or closed, as in the case above described, but will now and then look thick and troubled, at which time the horse sees little, and, perhaps, nothing distinctly. Here the eyes always appear sunk and perishing, though the cataracts do not become so soon complete, as in those that are full, and where a humour is predominant; nor is it unusual in this case for one eye to escape, whereby a horse will retain sight to guide him, so as to render him fit for common drudgery.

The causes of this distemper are various, and when it proceeds from a natural defect in the eyes, it may no doubt be hereditary; but in a horse that has naturally good eyes, and yet turns moon-blind, it is usually owing to sickness, or some other malady that has terminated in the eyes; though we seldom see horses turn moon-blind and breed cataracts, but where the eyes are naturally in fault. These eyes are, for the most part, faulty, that are very large and prominent, or very flat, small, and sunk; both which defects in the eyes of horses are liable to blindness, though they differ in their manner; and therefore colts, that have large eyes, that run abroad, always feed with their heads downwards, and are continually exposed to the sun in hot weather, may easily contract an habitual weakness in their eyes, especially as the blood and juices of all young animals are naturally of a viscid and balsamic texture, and thence may be the more easily retarded in the vessels of the eye, which are exquisitely fine. These causes produce weakness and relaxation in the eyes, and this still increases till the blood is in that state, which we may reasonably suppose to continue till a horse has done spreading, and turned seven, for then the cataracts generally grow complete. On the other hand, when the eyes are flat, and lie deep within their orbits, the surface of the eye being also flattish, the rays of light falling directly upon the pupil, and these not being sufficiently refracted, as they are in those eyes that are more convex, or of a rounder make, must needs weaken the eye, affect the optic-nerve, and consequently weaken the tone of the muscles. And, perhaps, this may be the reason why the eyes perish and decay, while the cataracts are growing.

The signs of this distemper may, in some measure, be deduced from what has been already observed; viz. swelling and inflammation of the eyes alternately, sometimes one eye, and sometimes the other, with a running of a thin watery serum, which is often so hot and scalding, as to fret off the hair. In others the eyes run but little, and some not at all; but look deadish, sunk, and perishing. In all moon-blind horses, the eyes are sometimes tolerably clear, at other times thick and muddy, of a wheyish colour, or a dusky yellow; and when this happens, a moon-blind horse sees but little, and when he is brought out into the light, he takes little notice of any person or object that is near him, but always looks upwards, with his head raised, lifts his feet high, and sets them down with fear. Though in this distemper the humour shifts from one eye to the other by turns, and at some intervals seems to go off, yet when the eyes of such horses are at their best, they look weak, and with a deadness, and when any such horse has his head held up, the weakness of the muscles, and of the whole eye, is easily perceived.

When this distemper happen to horses that have large full eyes, resembling those of a calf, and when the humour continues by long periods, and the returns are frequent, there is great danger of blindness. If the eyes be of a moderate size, well formed, and the periods or returns of the distemper short; if the horse sees perfectly when the humour goes off, and the eyes in those intervals look clear, the horse may recover. When the humour attacks one eye without changing to the other, there is also hopes of a cure, at least, of saving one eye. But when the eyes look flat and depressed, and decay gradually, it is generally the fore-runner of blindness; for in this case the nerves and muscles of the eyes are affected, and the cataracts always grow in the progress of the distemper. Here, however, as in the preceding case, when the distemper seizes only one eye, the other may be sometimes saved, and when this happens, the remaining eye generally grows stronger when its fellow is gone. But when the distemper proceeds from a violent cold, as sometimes happens, whereby we often see the eyes swoln, and quite shut up, though the horse may be threatened with blindness by several returns, yet by good management it may sometimes be prevented, and the eyes recover. Nor does the distemper always prove incurable, when the eyes are darkened with a yellow cloud, provided the eye be not naturally bad, and the above symptom of long continuance. In all cases of moon-blindness, the most promising signs of a recovery are when the attacks come more seldom, and their continuance grows shorter: or when the inflammation and swelling in those eyes that are naturally full and large abates. Also, when the eyes, that looked sunk and perishing, grow more plump and full;

and

and when in either the cornea looks clear and tranfparent, without muddinefs, and the horfe looks more attentive to his way, and goes on without much fear or ftartling; all thefe are promifing figns, and with good and careful management he may recover.

The moft difficult part ftill remains to be treated of, namely, the method of curing this diforder, for few moon-blind horfes efcape; and when it is hereditary, or the eyes naturally defective, it is not advifable for any one to be at much expence and trouble to fave them, as there is great reafon to fear he will meet with a difappointment. We, however, fometimes fee moon-blind horfes, at leaft fuch as have many of the fame fymptoms, recover and do well, even beyond expectation.

If the eyes are large, full, fwoln, and inflamed, the horfe fhould be bled at proper intervals; fometimes in the neck, and fometimes backward, to make a revulfion. But where the eyes appear funk or perifhing, bleeding is often pernicious. After bleeding, for thofe that are full and run a thin fharp water, make a ftrong tincture of rofes in the following manner:

> Take two drams of red rofe-buds, either frefh or dried, infufe them in half a pint of boiling water in the manner of making tea; when it has ftood to be cold, pour off the infufion, which will be of a reddifh colour.

In four ounces of this tincture diffolve half a dram of fugar of lead, and wafh the horfe's eyes, and all over his eye-lids, with a piece of fponge, or a clean bit of rag, twice a day. If the matter digeft and thicken, which ufually happens before it abates, add to the whole quantity of this tincture about two drams of honey (which will diffolve in the fluid, by holding the phial near the fire, and fhaking it) and ufe it as before. At the fame time, if the parts near the eye be hot, and the veins over the face, and along the fide of the nofe be turged and full, bathe thofe parts frequently with the beft vinegar, verjuice, or vinegar of rofes, till the heat and running of the eye abates, the veins fink, and become lefs apparent, and the eye begins to look clear. In the mean time fome lenient mild purges may be adminiftered, fuch as the following:

> Take lenitive electuary and cream of tartar, of each four ounces; fyrup of the juice of buckthorn berries, two ounces; mix thefe with white wine and water, warmed, about a pint, and give it fafting. Or,

> Take lenitive electuary and cream of tartar, of each four ounces; Glauber's purging falts, three ounces; the folutive fyrup of rofes, two ounces; to be mixed with white wine and water, or warm water-gruel.

Either of thefe may be given to moon-blind horfes. The latter is rather the more mild and cooling, and exceeding proper if the horfe be fat and full of blood, and will work fo gently, that it may be repeated twice a week, till the eye becomes clear, and attains its ufual brightnefs.

The horfe fhould have feeds of fcalded bran while thefe lenitives are given him, and he may have moderate exercife, or may be made ufe of in any kind of eafy bufinefs; for thefe draughts, for the moft part, work off in about two hours. But as the blood in all thefe cafes is generally fizy, and as this difpofes young horfes to frequent returns of the diftemper, it is, therefore, neceffary to adminifter fuch things as may attenuate the juices and preferve them in a more fluid ftate. Thefe are called alteratives, becaufe their property is gradually to alter the ftate of the blood. The following has been often ufed, in this and many other cafes, with great fuccefs:

> Take the fineft fuccotrine aloes, half an ounce, or fix drams; cream of tartar, half an ounce; frefh jallap, in fine powder, and falt of tartar, of each one dram; make the whole into a ball, with a fufficient quantity of oil of amber, and roll it in liquorice powder.

One of thefe balls may be given every week, in the manner of a common purge, with fcalded bran, and his water milk warm. The firft day it will work plentifully by urine, and the day following both ways; but no more than juft to empty his guts, unlefs when there is a foulnefs, by reafon of a redundant flime and greafe; when it will often work very powerfully two or three days, without the leaft diminution of the horfe's ftrength, or lofs of flefh. Thefe alterative purges fhould be continued for a month or fix weeks, and after omitting another month to begin again; in all which time the horfe may be kept in any common bufinefs, except hunting, going journies, or any other laborious exercife.

In the intervals between the purges it will be proper to give him an ounce of crude antimony every day, made into a fine impalpable powder, in one of his feeds, which may be continued for three months or longer. But if the horfe be of value, inftead of crude antimony, he may have powders compounded of native cinnabar, or cinnabar of antimony, and gum guiacum, equal parts, giving him an ounce every day, till he has taken two or three pounds; and after an interval of about three months, to proceed in the fame method till the eyes look ftrong and clear, and the horfe fhews no figns of blindnefs, or any defect in his fight or weaknefs in his eyes. Several gentlemen have followed this method with good fuccefs, where the eyes have been full, and no way perifhed. A pound of guiacum wood boiled in three gallons of water till it is reduced to two, is a cheap remedy, and may be profitably adminiftered to horfes of fmall value. It promotes perfpiration, dries up fuperfluous humidity, ftrengthens the folids when relaxed, and fweetens the blood. It may be given a quart or two every day, in a horfe's water, and will have a good effect to prevent moon-blindnefs, where it is not hereditary, nor proceeds from a natural defect in the eye.

But when the eyes are funk and perifhing, and the eye-brows are pinched at their inner corners next the nofe; when there is little or no inflammation or running, except a more than ordinary moifture in the caruncle, or haw of the eye, or where there is no moifture at all, as we often find in many moon-blind horfes: wherever thefe fymptoms are, a method of cure is required quite different from the preceding. For as we fuppofe here the nerves of the eye to be affected, and the fupplies of the arterial blood by that means denied; therefore, wherever the fault may be, whether originally in the blood or in the nerves, it is neceffary, in either cafe, to adminifter fuch things as not only attenuate the blood, but may caufe a greater derivation thereof to the eye: fo that the moft likely way to fucceed is by the proper ufe of mercurials; and thefe fuch as are the moft efficacious, and at the fame time the moft fafe. But firft of all let the horfe have the laft mentioned purge given him by way of preparation, and when the operation is over, which will be mild and gentle, the following ball may fucceed:

> Take mercurius dulcis that has been often fublimed and dulcified, two drams; make it into a fmall ball, with a fufficient quantity of conferve of red rofes, and wheat flour.

Let this ball be given early in the morning fafting, and tie up the horfe from eating two or three hours after it; then let him have a feed of fcalded bran, with warm water, or warm gruel to drink; which regimen ought to be continued the whole time he is under this courfe of mercurial and purging phyfic; cold water and other cold drinkables, being fomewhat unfafe at fuch a time. The mercurial ball may be repeated every other day, in the morning, till the horfe has taken three or four. If his mouth grows tender, which may poffibly happen, if he be not of a pretty ftrong conftitution, he muft be fed with water gruel for two or three days, till that fymptom wears off. At the fame time the purge may be repeated once or twice, and the following eye-water applied outwardly to both his eyes, if both be weak and difordered:

> Take crude fal ammoniac, cleaned from the black fcurf that is ufual on the outfides of the cakes, two drams; diffolve it in a pint of warm water, or the above tincture of rofes; and add to it a

gill of spirit of wine, or the best brandy, shaking them together in a quart bottle.

The eyes may be bathed all over with this mixture, twice a day, or it may be used in the manner of a fomentation, by wringing cloths out of it, and applying them warm over the eyes. This will act as a stimulus, and may also help to thin and rarify the gummy juices, and bring new supplies of nourishment to the perishing eyes. At first it may cause a little smarting; but after using it a day or two that symptom goes off, and if the eyes grow more plump and full, there will be hopes of a recovery, at least of saving one eye; and therefore the best way upon this prospect is to proceed in the same method, after a month's interval, and so on, as you find encouragement. And in all the intervals, the powders mentioned above, should be given in all his feeds, or the decoction of guiacum in his water.

Some take up the eye-veins to prevent blindness, but without distinction, whether the eyes are full with redundant humours, or sunk and perishing. In the latter case the taking up the veins may possibly be of service, because by that means the eyes may be better supplied with its proper nutritive juices; but this too is uncertain, because the fault may be in the nerves, or the distemper may proceed from some original configuration of the eye, which may be defective, and then such operations are like to prove fruitless. But the taking up the veins where the eyes are full, must, for the most part, prove hurtful, by cutting the channels which should convey the blood juices from thence in the course of circulation, and consequently increase the distemper, instead of abating it. In this case the taking up the arteries might be of some service; but this is an operation that only persons well skilled in the anatomy of a horse, should presume to undertake, and in the end might perhaps be uncertain.

The cutting out the haw is another operation usually performed on moon-blind horses. The haw is a swelling and spunginess of the caruncle or fleshy substance in the inner corner of the eye next the nose, and when it is soaked with too much moisture and humidity it swells and turns spongy. The membrane to which it adheres also grows thick, and spreads itself so as to cover a considerable part of the eye, but seldom reaches so far as to cover any part of the pupil. The ligament which runs along the verge of this membrane becomes horny; and when it rises to this state, it compresses the eye-ball like a hoop, and by its continual pressure causes constant pain, and increases all those bad symptoms that are the fore-runners of blindness. Haws grow sometimes in eyes that are not naturally bad, after colds and surfeits; but moon-blind horses are seldom without them; and wherever this symptom appears, that the haws grow large and spongy, and derive a drain of humours upon the eye, the operation becomes necessary, and is performed by taking hold of the membrane with a small hook, and cutting off so much of the caruncle as looks moist and spongy, with part of the membrane and gristle that cause a pressure on the eye. When this operation is well performed, it does great service, and often recovers horses that are not subject to cataracts; and even in this case it makes the eyes look something better, and helps to protract the blindness, but will not prevent it when it is hereditary. This is an easy operation, and what almost every farrier pretends to; but they are apt to cut off too much of this substance, and by that means weaken the eye, and forward the blindness, instead of preventing it. The proper application after cutting out the haw, is honey of roses, or rather tincture of roses, with a little honey dissolved in it. But if the eye continue still to abound with moisture, after the haw is extirpated, and threatens a fresh fungus, the case may be deemed bad; and then it will be necessary to blow into it a small quantity of burnt alum and fine loaf sugar, equal parts, once or twice a day; or one part of white vitriol, and two parts of sugar; and in some cases it may be touched with the blue vitriol-stone, or the lunar caustic; but these violent symptoms seldom happen, and when they do, we may suppose the blood to have a very bad disposition; so that it will be hardly worth while to attempt a cure, considering both the length of time, and the uncertainty of success. *Gibson on the Diseases of Horses, vol.* I. *pag.* 326.

BLINDNESS, a want of sight. The sheep in some parts of Wiltshire are troubled with a blindness, and are cured by anointing their eyes with goose dung. *Lisle's Husbandry, vol.* II. *pag.* 212.

BLISTERING *ointment*, a name given by farriers for a sort of charge or plaster for raising a blister in horses. There are various prescriptions for making this ointment, but the following is equal to any yet known:

> Take nerve and marshmallow ointment, of each two ounces; quicksilver one ounce, thoroughly broke with an ounce of Venice turpentine; Spanish flies powdered, a dram and a half; sublimate one dram; oil of origanum, two drams.

BLITHE, gay, airy, frolicksome, chearful.

BLOOD, a red liquor circulating through the veins, arteries, and other vessels of animal bodies; and serving for the support of life, and nourishment of all their parts.

Blood is an excellent manure for almost any sort of soil. Mr. Evelyn tells us, "that after the battle of Bagnam fields, in Devonshire (where lord Hopton obtained a signal victory) the blood of the slain fertilized the land, which had been sown with corn a little while before, to such a degree, that most of the wheat stalks of the ensuing crop bore two, three, four, nay seven, and some even fourteen ears; a thing almost incredible. The owner of the land seeing how miserably it had been trodden down, thought of resowing it; but was dissuaded from that design (perhaps to make the experiment) and had the above-mentioned surprizing crop." The husbandman should, therefore, be careful to procure the offals of the shambles, where they are to be had, as they will prove an excellent manure.

Blood-*letting*. *See the article* Bleeding.

Blood-*spavin*, a swelling and dilatation of the vein that runs along the inside of the hock, forming a little soft swelling in the hollow part, and is often attended with a weakness and lameness of the hock.

The cure should be first attempted by bathing the part twice a day with vinegar or verjuice; or let it be fomented with a decoction of oak bark, pomegranate, and alum, boiled in verjuice, binding over it, with a roller, a woollen cloth soaked in the same, which will contribute greatly to strengthen all weaknesses of the joints, and, if early applied, will frequently remove the disorder: but if by these means the vein is not reduced to its usual dimensions, the skin should be opened, and the vein tied with a crooked needle and waxed thread passed underneath it, both above and below the swelling, and the turgid part suffered to digest away with the ligatures: for this purpose the wound may be daily dressed with turpentine, honey, and spirit of wine, incorporated together. *Bartlet's Farriery, pag.* 279.

BLOSSOM, a general name for the flower of plants, but more especially of fruit-trees.

Blossom, or *peach coloured horse*, is one that has white hairs intermixed all over with sorrel and bay hairs.

BLOWING *of a flower*, an artificial process, in order to bring a flower to display itself with greater perfection and beauty than it would arrive at in the natural way of blowing.

The usual method for carnations is this: about April, when the flower stems begin to put forth, or spindle, as the gardeners call it, they place by each flower a strait stick, about four feet long, and tie the spindles to it as they shoot. As soon as the flower-buds appear, they displace all, except the largest, leaving only one on each flower-stem to blossom. About ten days before the flowers open themselves, the round-podded kinds will begin to crack their husks on one side; when the careful gardener, with a fine needle, splits or opens the husk on the side opposite to the natural fraction; and about three or four days before the complete opening of the flower, cuts off, with a pair of sciffars, the points on the top of the flower-pod, and supplies the vacancies or openings on each side the husk, with two small pieces of vellum, or oil-cloth, slipped in between the flower-leaves on the infide of the hufk; by this means the bloffom will difplay its parts eqally on all fides, and be of a regular figure. Befides this caution, when the bloffom begins to fhew its colours, they take care to fhade it from the extreme heat of the fun with a fmall board, or other device, faftened to the ftick which fupports it; for flowers as well as fruits, grow larger in the fhade, and ripen and decay fooneft in the fun. *Bradley's new Improvement in Gardening*, &c.

BLOW-MILK, fkimmed, or floten milk; that from whence the cream is blown off.

BLOWN, fwelled or hoved. *See the article* HOVED.

BLUE-BALL, a name given to the cone-wheat in Somerfetfhire, from the dark colour on the edge of the hufks of the chaff, which cover each grain, and the falling off of the awms when ripe; fome of the ears having awms, and others none. *See the article* CONE-WHEAT.

BLUE-BOTTLE, *knapweed*, *matfellon*, or *centaury*, the name of a weed abounding in many corn lands, flowering in July, and ripening its feeds in autumn.

Mr. Miller fays the corn blue-bottle is an annual plant; but Mr. Ray and Mr. Lifle think its root is perennial; becaufe, as the latter obferves, it not only puts forth new buds every fummer at the root for the growth of the next year, but feems alfo not to feed early enough, before the corn is cut to propagate itfelf by its feed in corn lands, in which it moft abounds, efpecially in a gravelly foil.

BLYME, the fame with bleyme. *See* BLEYME.

BOAR, the male fwine. *See the article* HOG.

BODY *of a horfe*, the material part or fubftance of a horfe, ufually called his carcafe. *See the article* CARCASE.

BOG, properly fignifies a quagmire, covered indeed with grafs, but not folid enough to fupport the body; in which fenfe it differs from moors or fens only as a part from the whole. *See the articles* MOOR and FEN.

Mr. King, in his account of the bogs in Ireland, publifhed in the Philofophical Tranfactions, Numb. 170, imputes the true caufe of them to want of induftry.

" The fprings, fays he, with which Ireland abounds, are generally dry, or near dry in the fummer time, and grafs and weeds grow thick about the places where they burft out. In the winter, they fwell, run, and foften, and loofen all the earth about them. The fward or fcurf of the earth, which confifts of the roots of grafs, being lifted up and made fuzzy by the water in the winter, as I have feen it lifted up a foot or two at the head of fome fprings, is dried in the fpring, and does not fall together, but withers in a tuft, through which arifes new grafs; which is alfo lifted up the next winter. By this means the fpring is more and more ftopt, and the fcurf grows thicker and thicker, till at firft it make that which we call a quaking bog; and as it grows higher and drier, and the roots of the grafs, and other vegetables become more putrid, together with the mud and flime of the water, it acquires a blacknefs, and grows into that which we call a turf bog. I believe that when the vegetables rot, the faline particles are generally wafhed away with the water, as being apt to be diluted in it. The oily, or fulphureal, are thofe which chiefly remain, and fwim on the water; and this is that which gives turf its inflammability.

" I muft confefs, that there are quaking bogs caufed otherwife. When a ftream or fpring runs through a a flat, the paffage, if not tended, fills with weeds in fummer, trees fall acrofs it, and dam it up: then, in winter, the water ftagnates farther every year, till the whole flat is covered. Afterwards, a coarfer kind of grafs fhoots up, peculiar to thefe bogs. This grafs grows in turfs, its roots confolidate together, and its height increafes every year; infomuch, that I have feen it as tall as a man.

" This grafs rots in winter, and falls on the tufts, and with it the feed, which fprings up the next year, and fo ftill makes an addition. Sometimes the tops of flags and grafs are interwoven on the furface of the water, and this becomes by degrees thicker, till it lies like a cover on the water: then herbs take root in it, and by the matting of their roots it becomes very ftrong, fo as to bear a man. I have gone on bogs which would rife before and behind, and fink where I ftood, to a confiderable depth; under which was clear water.

As a farther proof that want of induftry is the principal caufe of bogs, Mr. King obferves, that the higheft mountains in Ireland being full of fprings, and uninhabited, are over-run with bogs, as well as the plains, becaufe no care is taken to clear the fprings.

" Ireland, continues he, abounds in mofs more than, I believe, any other kingdom. This mofs is of divers kinds, and that which grows in bogs is remarkable. The light fpongy turf is nothing but a congeries of the threads of this mofs, as I have frequently obferved, before it be fufficiently rotten. The turf then looks white, and is light. I have feen it in fuch quantities, and fo tough, that the turf-fpades could not cut it. In the north of Ireland, they call it old-wives tow, being not much unlike flax. The turf-holes, in time, grow up with it again; and all the little gutters in bogs are generally filled with it. To this I chiefly impute the red or turf bog; and from the fame caufe even the hardened turf, when broken, is ftringy; though there plainly appear in it parts of other vegetables: and I am almoft, from fome obfervations, tempted to believe, that the feed of this bog-mofs begets heath, when it falls on dry and parched ground. However, the mofs is fo fuzzy and quick growing a vegetable, that it greatly ftops the fprings, and contributes to thicken the fcurf, efpecially in red bogs, where I remember to have obferved this moft particularly."

A flat fpot of ground, lower than the level of an adjoining river or lake, may alfo give rife to a bog; for when that part is filled up by the flime and earth brought from the furrounding grounds, and the rotten plants and animals, which are buried in it, have choaked it up, it will become a bog; and then the water will continue to flow into it from the river or lake, efpecially when either of thefe is fwelled by a fall of rain, or the melting of fnow. Thefe waters may alfo fometimes have this effect, without a communication above ground, by foaking through a fandy or gravelly foil.

Another caufe of bogs have frequently arifen from the fall of a number of trees, which, being neglected, have neceffarily occafioned a ftagnation of the water brought down from higher grounds; fo that the earth and other foil conveyed with it, have of courfe remained among the fallen wood, and given birth to a moffy ground, which, it is plain from hence, is not an original foil. Coarfe grafs, and weeds which cattle will not eat, fpring up in thefe places, and die there, after fhedding their feeds, which, being prevented from rotting by the bituminous acid in the moffy water, produce new plants; fo that, this being repeated every year, an annual addition is made to the depth of the mofs.

Draining of BOGS. Among the many and great inconveniences which neceffarily arife from bogs, Mr. King mentions the following, as cogent reafons why every endeavour fhould be ufed to bring them, firft to a lefs hurtful ftate, and afterwards to a condition in which they may be of fervice to mankind.

" The fineft and fmootheft plains, which generally fhould be meadows, are often covered with ufelefs, too often with really pernicious bogs. Thefe bogs are a great deftruction to cattle, the chief commodity of Ireland. In the fpring time, when the cattle are weak and hungry, the edges of the bogs are commonly cloathed with grafs, and the beafts, in venturing to get it, fall into pits or floughs, where they are either drowned, or, if they are found, hurt, and often maimed, in the pulling out. The fogs and vapours which arife from thefe places are commonly putrid, ftinking, and very unwholfome: for the rain which falls on them, ftagnating upon their furface, and in their hollows, than which there is hardly any fubftance, equally foft, more impenetrable by water, corrupts there, and is exhaled by the fun; fo that, very little of it running off, it muft of neceffity affect the air. They corrupt other water, both in its colour and tafte: for the water which ftands in the pits, or lies on the furface of the bog, is tinctured by the reddifh-black colour of the turf; and when a ſhower comes, ſo as to make theſe pits overflow, the water which runs from them tinges all it meets, and gives its colour and ſtench even to many rivers. The only advantage derived from any bog, is turf for fuel. It makes a tolerable ſweet fire, in the common way of uſing it; and is, when charred, perhaps, the ſweeteſt and wholeſomeſt thing that can be burnt, fitter for a chamber, and for conſumptive people, than either wood or coal.

"All the inconveniencies of our bogs, continues Mr. King, may be remedied, and they may be made uſeful to us, by draining: for I never obſerved one bog without a fall ſufficient to drain it, nor do I believe there is any. The great objection againſt this improvement is the expence; in which I cannot but think the people are often terrified without ſufficient cauſe. One trench will drain many acres in quaking bogs, which, when dry, are generally meadow, or the beſt grazing ground. Every red bog has about it a deep, marſhy, ſloughy ground, which is called the bounds of the bog. A deep trench round ſuch a bog keeps out cattle, and turns the bounds into good meadow. I remember a red bog of ſixty acres, which a gentleman reduced to good grazing ground, worth three ſhillings an acre, for twenty-five pounds, which is leſs than three year's purchaſe. In all improvements of this kind, gentlemen ſhould conſider, that what they lay out goes by degrees, ſo that they ſcarcely feel it; that it goes among their tenants, whom it helps to enable to pay their rent; that they do a work of charity in employing the poor; and that they at the ſame time contribute to both the ornament and general profit of the kingdom.

"The deep trench before mentioned, round a red bog, not only drains and improves the bounds of the bog, as I ſaid before, but goes a great way towards drying the bog itſelf. It ſerves likewiſe as a common ſink, into which all the drains vent themſelves. Theſe drains ſhould be cut ſo as to croſs the little ſloughs that run in the bog. The firſt drains ſhould not be above two or three feet deep, or wide: for the bog is ſo ſoft, that deep trenches will not ſtand, but fill up again. When the ſurface of the bog is cut in little trenches, ſuppoſe at twenty, thirty, or forty perches diſtance, it will ſoon be ſo dried that cattle may graze on it all the ſummer. A year or two after this, by which time the bog will be ſomewhat dry towards the ſurface, the drains may be made ſix feet wide, and as deep as the ſoftneſs of the bog will permit. This will certainly make the bog uſeful for grazing: and at the end of another year or two, an attempt may be made to cut one or two of the trenches down to the bottom of the bog; for till that be done, I do not reckon the bog ſecured. A gentleman may oblige all his tenants to cut their turf in theſe trenches, and likewiſe have his own cut there." *Philoſophical Tranſactions, Numb.* 170.

Small bogs may be turned to very good account by planting them with oſiers, willows, and alders: but where the extent is conſiderable, this object becomes of too little conſequence. Draining will be however neceſſary before they can be improved any other way; as a previous ſtep towards which, it will be neceſſary to examine from whence their too great quantity of water ariſes, and what retains it. When the cauſes are known, their effects will be the more eaſily removed.

The ſources from whence the too great quantity of water proceeds, may either be without or within the bog. This is eaſily diſcovered by the greater quantity of water in one place than in another, and obſerving that the water ſpreads from thence, even under the ſurface, as through a ſponge.

If the water from without comes from neighbouring grounds, it is uſually kept off by a ſurrounding ditch, made large enough to contain the quantity that may at any time flow down, and by extending that ditch to the moſt convenient outlet, according to the declivity of the ground. If the bed of gravel or ſand through which the ſprings within the bay run, be cut quite through, the ſource of thoſe ſprings will certainly be deſtroyed; and if that bed be only opened in digging this ſurrounding ditch, the water will ſo readily diſcharge itſelf thereby, that the ſprings will probably be dried up.

Before any drain be made in the bog itſelf, an exact level of the ground ſhould be taken; and when the two great moiſture proceeds from a ſpring or ſprings within the bog, a large ditch ſhould be made, beginning at the loweſt part of the bog, where an outlet can be had, and continued from thence to the ſpring. If the bog be firm enough to bear it, this ditch ſhould be dug down to the very bottom of the bed on which the peat or moſs is formed, which, in caſe of ſprings, is always gravel or ſand: for otherwiſe the water would force itſelf a paſſage in another part, and ſo make it neceſſary to extend the ditch thither. If there be more ſprings than one, the main ditch muſt be extended to each of them. In all caſes, the ſureſt way is to dig the ditch, where it can be done, at leaſt a foot deeper than the ſpring lies. Between the principal ditches cut in the bog, there ſhould be ſmaller, emptying themſelves into thoſe larger, to carry off the remnant of ſtagnating water, and to preſerve the ſurface dry. Care ſhould be taken not to lay the earth dug out of any of theſe ditches too near their ſides, leſt its weight ſhould make them fall in.

Bogs are generally higher than the land about them, and higheſt in the middle; the chief ſprings that cauſe them being generally about the middle, from whence they extend by degrees, and puff up the earth in ſuch a manner, that perſons are often apt to think the ſprings lie deeper than they really do. A ſure way to know whether the ditch be deeper than the ſpring, is, to obſerve whether the water comes in at its bottom, or through the ſides. The width of the main ditch ſhould be proportioned to its depth; and both will, in a great meaſure, depend upon the quantity of water neceſſary to be drained. In general, it ſhould widen progreſſively from its head to its outlet, becauſe the quantity of water in it will be conſtantly encreaſed. The ſides of the ditch ſhould always be dug either more or leſs ſloping, according to the ſoil. If the ground be very looſe and light, and conſequently very liable to fall in, it will ſometimes be neceſſary to make a ſlope ſo great, that the top of the ditch will be four times as wide as its bottom. If the ſoil be ſtiffer, the ſlope may be leſs; but no ditch ſhould ever be dug quite perpendicular.

If a deep trench be cut through a bog, the original ſpring will be found, vaſt quantities of water will iſſue from it, and the bog will ſubſide. Mr. King ſays that he was informed that the bog at Caſtle Forbes, where this was done, ſubſided thirty feet, a fall which ſeemed indeed incredible: but he found by computation that it could not be leſs than fifteen.

Mr. Elliot's contrivance for draining a bog, or what he calls a ſhaking meadow, containing about forty acres, deſerves to be mentioned, for the ſingularity as well as the uſefulneſs of the invention. The ſurface of this ground, over-run with cran-berry vines and wild graſs, ſeemed to be only a ſward of their roots laid over a pappy mud, and was deemed ſo poor that nobody would rent it. At the ordinary outlet of this meadow, there was a ſufficient fall, but very rocky, ſo that it was neceſſary to dig four or five feet to take advantage of it. In March, when this gentleman went to make the outlet drain, the torrent of water was ſo great, that nothing could be done in the uſual way. He therefore ordered a tree to be felled a croſs the brook, and pieces of plank, the upper ends of which reſted againſt the tree, to be driven down aſlant into the mud. The chinks and crevices of theſe planks were then cloſely ſtopped with tow, by which means the water was ſhut into the meadow. The trench or main ditch was then worked at in the day, and the water let out at night, till the drain was completed. When the weather grew ſufficiently warm, and the meadow was a little ſettled, croſs ditches were cut, one on each ſide, and another in the middle, and, ſo far as they extended, the meadow ſoon became firm and dry. "Some, adds Mr. Elliot, are deterred from ſuch an undertaking as that of draining their land, by reaſon of the great charge. They terrify themſelves without reaſon. When I was about to cut my main drain, ſome thought it impoſſible; others, that it would coſt, at leaſt, an hundred pounds. The place was full of rocks, ſome of which we dug up, others were broken with ſteel wedges, and others were blown up with powder. The whole expence

pence did not exceed twenty pounds." *Essay I. on Field Husbandry*, p. 7.

When the ditches and trenches are finished, great care must be taken to keep them in good and lasting condition, lest all the labour bestowed upon them should be lost. There are different ways of doing this. If the ditches are left open, they must be well cleansed from weeds and mud, twice every year, once in the spring, and once in the autumn. It will also be right to drive in from space to space, along the inside of their banks, strong stakes of oak or alder, to strengthen them, and keep them from falling in. Willows, which delight in a watery soil, may be advantageously planted upon these banks, which their roots will help to keep up and bind.

If a bog be so entirely surrounded with high grounds, as not to have any declivity whatever, by the help of which its waters may be drained off, ditches must then be dug round it, to receive the water from the neighbouring hills, and a very large pond must be made in the middle or lowest part of the bog itself, for its waters to run into; to facilitate which, large trenches should be cut from the surrounding ditches to this pond, and channels communicating with these trenches a-cross different parts of the bog. The number and size of which will depend on the greater or less wetness of the ground. When the water is thus collected, engines must be used to raise it to a proper height for a channel to carry it off. The reader will find a description of several new and useful engines of this kind under the article, DRAINING MACHINES.

Improvement of drained BOGS. The most lasting and most perfect improvement of bogs, is effected by paring off their surface and burning it. *See the articles* MOOR and BURN-BAKING. In order to this the bogs should be levelled; and whatever earth remains unemployed in filling up hollows, should be burnt together with that taken out of the ditches, unless the latter has been already carried off for fuel. The greater quantity of ashes there is, the greater will be the improvement of the soil itself, and the more will the earth brought upon it be benefited. The fire on the surface of the moss, exhales a very considerable part of the bituminous acid of this soil, and the fixed alkaline salt, always found in some proportion in the ashes, corrects or neutralizes it, so that no inconvenience arises from it afterwards, if the ground be kept dry as it ought to be. The fire should not be fierce but rather smothered.

When the bog is pared, and the clods are collected to dry, the farmer must prepare earth to cover the surface. Marle, which is often found under bogs, presents the best covering that can be desired. If a clay lies under the bog, it must be prepared before it is spread in the manner directed under the article COMPOST, excepting only that the quantity of other substances mixed with it, such as dung, &c. need not be so great in this case, because the ashes, and the bog itself, will greatly assist in opening the body of the clay. If a loamy earth be near at hand, it will perhaps be less expensive to the farmer to bring such earth to cover the bog, than it will be to dig and prepare the clay. But of whatever kind the earth be, which is laid upon the bog, the quantity should always be sufficient to cover its whole surface four, five, or six inches deep, according to the stiffness of the soil so brought. Thus four inches of clay, when mixed with the ashes, and a due quantity of the earth of the bog itself, will give a depth of covering mould equal to what six inches of loam will do, when likewise mixed in proportion to its quality. If the bog be intended for arable land, the depth of the covering earth should be greater; because all kinds of grain, especially wheat, require at least a foot depth of good mould to extend their roots in, before they come to any cold or tenacious substance like peat or clay. The covering, therefore, of clay or marle should be in this case, six or seven inches thick, and that of loam eight or nine inches.

As soon as the surface is burnt, its ashes should be spread and mixed with the additional covering, which will then be fit for the farmer's purpose, whether for corn or grass. If the extent of the bog intended to be improved be considerable, it should be advisable, by means of a sluice, to fill the ditches contiguous to the spot which is to be covered, and to bring the earth in barges, or flat-bottomed boats, kept on purpose to transport the necessary manures, and the produce of the ground. By this means a saving will be made of the surface otherwise necessary for cart-ways. Besides, this soil, especially, when newly trained, does not well bear heavy carriages: a circumstance which renders it needless to observe, that broad wheels are always the most proper, when any must be used upon such land.

The bog being covered with a proportion of earth, the husbandman must next determine to what lasting purpose he can best apply it. The too great moisture of these soils, which always lie flat, renders them unfit for continued tillage; and their mould becomes so loose, by frequent ploughing, that it does not afford sufficient stability to the roots of corn. For this reason, barley, oats, and rye, do better here than wheat, which requires a firmer footing: but neither of them should ever be sowed thick; because the fruitfulness of the soil will always make up in the size of the plants, what some might think wanting in their number. The most beneficial method of employing this sort of land is, undoubtedly, by converting it into meadow; because, when thus prepared, and not injudiciously exhausted by crops of corn, it will yield great quantities of excellent grass. It is, however, usual to begin with sowing some kind of grain on this prepared surface, to indemnify the farmer by the plentiful crop which it generally yields; such, indeed, as sometimes defrays at once the whole expence of the improvement. Perhaps the most profitable method may be, to sow it in the autumn with rape, the leaves of which, shading the surface in hot weather, and rotting in the winter, contribute greatly to mellow the earth: the strong roots of this plant open the soil; its ashes enrich it, when burnt, and its seed brings a great return when sold for making oil. One or two ploughings will then prepare it for a crop of wheat. After this is taken off, and the stubble turned down or burnt, white clover and grass seed from upland pastures should be sowed, and the ground should then be laid down for a lasting meadow; or, if turnips are sowed, or cabbages planted, in the autumn, these, in the spring, may be succeeded by barley, with which the grass seeds may be sowed.

When, either through necessity, for want of other arable land, or out of choice, the farmer intends to continue ploughing his improved bog, the surface must be raised in ridges, and the farther management of it may be like that of most other ploughed grounds.

If a soil of this kind happens to be situated near a town, a greater profit will accrue from planting it with garden stuff, than from any sort of grain. Beans, pease, cabbages, potatoes, turnips, carrots, &c. thrive exceeding well in such earth as this, as the marquis of Turbilly experienced to his entire satisfaction.

" I received, says he, from Strasburg, in the year 1755, some seed of the large hard cabbage, which was immediately sowed in my garden, from whence it was afterwards transplanted into a bog, which I had drained and cleared. This spot contains about an acre of ground, and forms a kind of island in my river. It had been pared and burnt; but never received any other manure than the ashes produced by that burning; no sort of dung having ever been laid upon it. The whole of it was planted with this kind of cabbage, excepting only a corner, where a few carrots, parsnips, and beet-roots, all of which grew to a prodigious size, and proved exceeding good, were set out of curiosity. These cabbages throve wonderfully, several of them weighing forty pounds a piece, were well tasted, and very wholesome, though some of the country people seemed positive that they and the other pot-herbs would be hurtful, unhealthy food, as, said they, all plants are during the first year of their growth in new drained bogs.

" These people pretended to have experienced this in other places; but not finding it so here, I ascribed the effect they talked of to some pernicious quality in the soil; for I was very sure, that the violent operation of the fire which mine had undergone, had not left any bad property in the earth. During the rest of the summer, and the autumn, some of the neighbouring peasants, whom I hired for the purpose, carried this great quantity

tity of cabbages to the markets of three different towns, about ſix miles off: there they ſold them; and the accounts which they gave me of their produce amounted in all to eight hundred and fifty livres, that is thirty-ſeven pounds, three ſhillings, and nine pence. The wages of theſe men and the expence of carriage, amounted to about half this ſum; which being deducted, my acre of bog produced clear four hundred and twenty-five livres, that is, eighteen pounds eleven ſhillings, and ten-pence halfpenny, with which I was the better ſatisfied, as the cultivating of it had coſt me but little. The ſoil, being light, was eaſily turned up, though fat; and I had drained off the water without difficulty, by means of a ſlope which happened to be properly ſituated. I never had been offered above a crown a year for this marſhy land, which was quite a ſhaking bog, and often overflowed. When drained, its ſurface ſunk a foot lower than before. So great a produce, from ſo ſmall a ſpot of ground, of which no one knew the goodneſs, ſhews what vaſt riches are hid beneath the ſeveral bogs in this kingdom. They are not, however, all like this, which chanced to be a very fertile ſoil. I could wiſh to be maſter of ſeveral others like it. It has ſince been ſowed with hemp, peaſe, and ſeveral other plants, which have done very well, though none of its crops have produced ſo much money as this firſt; which ſhews the difficulty of ſetting a juſt value upon land. All the other bogs which I have drained and cleared in different ways, have anſwered, in general; but no one ever yielded, in proportion, any thing like this ſpot." *Memoire ſur les Defrichemens, pag.* 167.

BOG-*Spavin*, an encyſted tumour, or according to doctor Bracken, a collection of browniſh gelatinous matter, contained in a bag or cyſt, which he thinks to be the lubricating matter of the joint altered, the common membrane that incloſes it forming the cyſt: this caſe he has taken the pains to illuſtrate by an inſtance of a young colt of his own, where he obſerves, that when the ſpavin was preſſed hard on the inſide of the hough, there was a ſmall tumour on the outſide, which convinced him the tumour was within ſide the joint: he therefore cut into it, diſcharged a large quantity of this gelatinous matter, dreſſed the ſore with doſſils dipped in oil of turpentine, putting into it, once in three or four days, a powder compoſed of calcined vitriol, alum, and bole: by this method of dreſſing, the bag ſloughed off, and came away, and the cure was ſucceſsfully completed without any viſible ſcar.

This diſorder, according to the above account, will ſcarcely ſubmit to any other method, except firing, when the cyſt ſhould be penetrated to make it effectual; and in all obſtinate caſes that have reſiſted the above method, both the cure of this, and the ſwellings called wind-galls, ſhould be attempted in this manner. If, from the pain attending the operation or dreſſings, the joint ſhould ſwell and inflame, foment it twice a day, and apply a poultice over the dreſſings, till it is reduced. *Bartlet's Farriery, pag.* 279.

BOIL, a diſeaſe to which cattle, eſpecially ſheep, are very ſubject.

In order to cure theſe boils, it will be neceſſary to bring them to a head, by applying to them a plaſter compoſed of wheat flour, yolks of eggs, and tar: and when they feel ſoft under the finger, to open them with a lancet, and let out the matter. Then anoint the part with ointment of tobacco, and apply over it the following plaſter. Take of turpentine, burnt ſalt, honey, and galbanum, of each one ounce; of roſin an ounce and a quarter. Melt the whole into a ſalve over the fire. *Ellis on Sheep, pag.* 101.

BOLE, the body or trunk of a tree.

Bole alſo ſignifies the ſtalk or ſtem of corn.

Bole, a meaſure of corn, containing four buſhels.

Bole *of ſalt*, contains two buſhels.

BOLING *Trees*, pollard trees, or thoſe whoſe heads and branches are cut off, and only the boles or bodies left.

BONE, a hard, brittle, inſenſible part of an animal body, affording form and ſupport to the whole machine.

All marrow-bones, fiſh-bones, hoofs, horns, or ſhavings of horn, are very uſeful in manuring lands. Bones are moſt ſerviceable when raſped or broken into ſmall pieces; becauſe their ſalts, in which their principal virtue conſiſts, are more eaſily extracted by the rains and dews, and communicated to the ſoil.

Bone-*Spavin*, a boney excreſcence, or hard ſwelling growing on the inſide of the hock of a horſe's leg.

A ſpavin that begins on the lower part of the hock, is not ſo dangerous as that which puts out higher, between the two round proceſſes of the leg-bone; and a ſpavin near the edge is not ſo bad as that which is more inward towards the middle, as it does not ſo much affect the bending of the hock. A ſpavin that comes by a kick or blow, is at firſt no ſpavin, but a bruiſe on the bone, or membrane that covers it; therefore not of that conſequence, as when it proceeds from a natural cauſe: and thoſe that put out on colts, and young horſes, are not ſo bad as thoſe which happen to horſes in their full ſtrength and maturity; but in very old horſes they are generally incurable.

The uſual method of treating this diſorder, is by bliſtering and firing, without any regard to the ſituation or cauſe, from whence it proceeds. Thus if a fullneſs on the fore-part of the hock comes after hard riding, or any other violence which threatens a ſpavin, ſuch coolers and repellers are proper as are recommended in ſtrains and bruiſes. Thoſe happening to colts and young horſes are generally ſuperficial, and require only the milder applications; for it is better to wear them down by degrees, than to remove them at once by ſevere means.

There are various forms for making what is called the bliſtering ointment; but of the beſt of that kind, and what will infallibly anſwer the intention, has been already given under the article Blistering Ointment.

When a bliſter is thought neceſſary, the hair ſhould be cut as cloſe as poſſible, and then the ointment applied pretty thick over the part; this ſhould be done in the morning, and the horſe kept tied up all day without any litter till night; when he may be untied in order to lie down; and a plaſter of pitch, or any other ſticking ſubſtance, may be laid over it, and bound on with broad tape, or a bandage, to keep all cloſe.

After the bliſter has done running, and the ſcabs begin to dry and peel off, it may be applied a ſecond time in the ſame manner as before; the ſecond application generally taking greater effect than the firſt, and in colts and young horſes makes a perfect cure.

When the ſpavin has been of long ſtanding, it will require to be renewed perhaps five or ſix times; but after the ſecond application a greater diſtance of time muſt be allowed, otherwiſe it might leave a ſcar, or cauſe a baldneſs; to prevent which, once a fortnight, or three weeks, is often enough; and it may in this manner be repeated ſix or ſeven times, without the leaſt blemiſh, and will generally be attended with ſucceſs.

But the ſpavins that put out upon older, or full aged horſes, are apt to be more obſtinate, as being ſeated more inward; and when they run among the ſinoſities of the joint, they are for the moſt part incurable, as they then lie out of the reach of applications, and are arrived to a degree of impenetrable hardneſs.

The uſual method in theſe caſes is to fire directly, or to uſe the ſtrongeſt kind of cauſtic bliſters; and ſometimes to fire and lay the bliſters immediately over the part; but this way ſeldom ſucceeds farther than putting a ſtop to the growth of the ſpavin, and is apt to leave both a blemiſh and ſtiffneſs behind; beſides the great riſk run (by applications of theſe fiery and cauſtic medicines, to the nervous and tendinous parts about the joints) of exciting violent pain and anguiſh, and deſtroying the limb.

The beſt and ſafeſt way therefore is to make trial of the bliſtering ointment given under that article, and to continue it according to the directions above laid down, for ſome months, if found neceſſary; the horſe in the intervals working moderately: the hardneſs will thus be diſſolved by degrees, and wear away inſenſibly.

When the ſpavin lies deep, and runs ſo far in the hollow of the joint, that no application can reach it, neither firing nor medicines can avail, for the reaſons abovementioned: though bold ignorant pretenders have ſometimes ſucceeded in caſes of this ſort by the application of cauſtic ointments

ointments with ſublimate, which act very forcibly, enter deep, and make a large diſcharge; deſtroying by that means a great part of the ſubſtance, and diſſolve away the remainder. Though whoever is at all acquainted with the nature of ſuch medicines, muſt know how dangerous in general their operation is on theſe occaſions, and that a properly prepared cautery made like a fleam, under the direction of a ſkilful hand, may be applied with leſs danger of injuring either tendons or ligaments. After the ſubſtance of the ſwelling has been properly penetrated by the inſtrument, it muſt be kept running, by precipitate mixed with the medicine uſed in dreſſing the part, or with a mild bliſtering ointment.

Where the ſpavin lies not deep in the joint, and the bliſtering method will not ſucceed, the ſwelling may be ſafely fired with a thin iron forced pretty deep into the ſubſtance, and then the part ſhould be dreſſed as above directed. *Bartlet's Farriery, pag.* 257.

BOORCOLE. *See* BORECOLE.

BOOSE, a ſtall. Thus ox-booſe ſignifies an ox-ſtall, &c.

BOOT, profit, gain, advantage.

BORAGE, an annual plant, propagated in gardens, and if ſuffered to ſcatter its ſeeds, the plants will come up in plenty without care; or if the ſeeds are ſown either in ſpring or autumn, on a ſpot of open ground where the plants are deſigned to remain, the ground be hoed to deſtroy the weeds, and the plants cut up where they are too near each other, they will require no further care; unleſs the weeds ſhould come up again, when the ground ſhould be a ſecond time hoed over again to deſtroy them. This, if well performed in dry weather, will clear the ground from weeds, ſo that it will require no more cleaning till the borage is decayed. *Miller's Gard. Dict.*

BORECOLE, or BOORCOLE, a ſpecies of cabbage, of which there are three ſorts, namely, the common borecole, the green borecole, and the Siberian borecole, which is the curled colewort, by ſome called Scotch kale. All theſe are for winter uſe, but the laſt is moſt eſteemed. The two former are ſown about the middle of April, and are fit for tranſplanting in about two months after. When this is done, the plants of either of theſe ſorts ſhould be ſet a foot aſunder in rows two feet diſtant from each other. They ſhould not be eaten before the froſt has rendered them tender; for till then they are tough and bitter. The Siberian borecole, which is extremely hardy, never injured by froſt, and always ſweeter in ſevere winters than in mild ones, need not be ſown till the middle of July, and when the plants are ſtrong enough for removing, that is when they have ſix or eight leaves, they ſhould alſo be ſet in rows; the diſtance between which ſhould be about two feet, and that between the plants, ten inches. Theſe will be fit for uſe ſoon after Chriſtmas, and continue good till April. The ſoil for borecole ſhould be a good, freſh, deep-looſened earth.

Borecole has been lately found by Mr John-Wynn Baker, to be an excellent food for cattle; and the Society for the Encouragement of Arts has accordingly offered two premiums for cultivating it, one of twenty, and the other of fifteen pounds.

Mr. Baker made the experiment under the direction of the Dublin Society, who deſired him to print his account of the experiment, an abſtract of which we ſhall give the reader.

This experiment was made on a piece of ground that had been cropped the preceding year with potatoes. After he had reduced the ſoil to a pretty good tilth, and manured it with a compoſt compoſed of earth, lime, and dung, he planted three rows of borecole plants, in ridges two feet aſunder. On the 17th of Auguſt they were horſe-hoed for the firſt time, by taking off, at one furrow of the plough, only one ſide of each ridge cloſe to the plants; in which manner they remained till the twenty-fifth, when he ran the plough in the ſame furrow, by which, with the firſt furrow, he ploughed about twenty-one inches deep. This being finiſhed, the earth was immediately returned back to the plants, which afforded them freſh nouriſhment; and in order to give their roots time to penetrate this freſh earth, which, by the horſe-hoeing was become very fine mould, he let them remain in this ſtate till the 12th of September, when he horſe-hoed them again, by taking off the other ſide of every ridge; and on the twentieth deepened the furrow in the ſame manner as the former, and immediately returned the mould back to the plants; and on the eighteenth threw up a ſmall furrow to each ſide of every ridge, which finiſhed the culture, and reſtored the ridges to the form they were in when the borecole was planted.

"On the 18th of December, continues Mr. Baker, I cut two perches in length of one of the rows of borecole, which contained twenty-one plants; they weighed one hundred and eighteen pounds, which is very near five pounds ten ounces for each plant: but I am inclined to believe that theſe plants will ſucceed as well, if they are planted only eighteen inches aſunder in the rows. However, at the above proportion, there would be ſeventeen tons, and fourteen hundred upon an acre. But, if the produce would be the ſame, were the plants only eighteen inches aſunder, in that caſe, an acre would produce, by this culture, above twenty-three tons, and twelve hundred.

"This plant is well worthy the farmers or grazier's attention, for, as faſt as it is cut, it will again, in about a month or ſix weeks, afford another crop: I have been cutting theſe plants for my family uſe, ever ſince the middle of Auguſt laſt; I believe ſome of them have been cut three times, and they are excellent for the table. For feeding cattle and ſheep they are highly valuable, as no froſt will injure them; and although the firſt crop amounts not to as many pounds upon any given quantity of ground as thoſe of cabbage or the turnip-cabbage, yet the ſucceeding crops will, I believe, make their produce nearly, or quite, of equal weight with any other of the cabbage kind. But I muſt not omit to obſerve, that, as theſe plants afford only open leaves, and many of them very ſmall, there will be a little more trouble in collecting and carrying them to the ſheep and cattle, than there will be with the other kinds.

"It may not be improper to obſerve likewiſe, that, upon the approach of ſpring, when they begin to throw out their ſpring ſhoots for ſeeds, if the large leaves have not been taken off for winter uſe, they will decay and fall off.

"I have not yet tried it; but I believe the beſt way of uſing this plant, would be to allot one whole field to the culture of it, proportioned in ſize to the ſtock intended to conſume the produce; and in September or October, to turn the ewes into the field for a few hours, morning and evening, and then to lodge them on any piece of graſs or fallow, which may want improvement, to which they will greatly contribute by emptying themſelves upon it; and thus continue to turn them into the borecole field, till they have eat all the luxuriant leaves; then let the plants reſt a month, and there will be another crop. By having two ſmall fields under this crop, a flock of ſtore ſheep might be maintained a whole winter at a very ſmall expence; for while the produce of one field would be conſuming, the other would be coming on.

"This method accrued to me from an accident which attended my borecole this year. My cows got into the field, and preſently devoured ſome of the leaves of the plants; theſe plants have engaged my attention ever ſince, and I have the pleaſure of ſeeing them again in a very luxuriant ſtate.

"If any perſons ſhould be able to put this ſcheme in practice, before I can accompliſh it, I recommend it to them not to let the ſheep paſture ſo long on the crop, as to injure the ſtalks for want of leaves; as too great an injury to the ſtalks may check the ſucceeding growth; which injury, I am inclined to believe, will not happen to the plants, at leaſt not in ſo great a degree, whilſt they have a ſufficient quantity of leaves.

"It will doubtleſs be obſerved, that I confine this ſcheme to ewes or ſtore ſheep: my reaſon for that is, that fat ſheep ſhould always have as much food before them, as they chooſe to eat; add to this that ſheep when they are fat, are more ſubject to be lame than ſtore ſheep, to which ploughed ground will greatly contribute."

BORDER, a bank raifed about a garden, and planted with flowers, fruit-trees, &c.

Borders are of four forts: thofe are the moft common, that are continued about parterres without any interruption; and wrought with a gentle rifing in the middle, like an afs's back, and planted with low fhrubs and flowers.

The fecond fort of borders are fuch as are cut into compartments, at convenient diftances, by fmall paffages, and being alfo raifed in the middle, as before-mentioned, are likewife fet off with fhrubs.

The third fort are fuch as are laid even and flat, without flowers, having only a verge of grafs in the middle; being edged with two fmall paths, raked fmooth, and fanded. Thefe are fometimes garnifhed with flowering fhrubs, and flowers of large growth; or with vafes and flower-pots placed regularly along the middle of the verge of grafs.

The fourth fort are quite plain, and are only fanded, as in the parterres of an orangery; and are filled with cafes ranged in a regular order along thofe borders, which are edged with box on the fides next to the walks; and on the other, with verges and grafs-work next the parterre. Sometimes a yew is planted between each cafe, which makes the border appear richer, and the parterres handfomer, during the winter feafon.

Borders are either made ftraight, circular, or in cants, and are turned into knots, fcrolls, voluces, and other compartments.

Florifts alfo make borders either long walks, or detached; and in thefe they raife their fineft and choiceft flowers. Thefe are frequently encompaffed with border boards painted green, which makes them look exceeding neat.

But, in large parterres, this is not to be expected; fince, if they be ftocked with flowers fucceeding one another in their feveral feafons, it is fufficient, fo that nothing appears bare and naked.

It is ufual to difcontinue the borders at the ends next to the houfe, that the embroidery and rife of the parterre may not be hidden by the fhrubs and flowering plants, and that the defign may be better judged of.

And fometimes there are branched out of it foliage, palm-leaves, and fhells fporting among the fands.

Since the modern tafte of gardening has been introduced into England, all the French tafte of parterres, fcroll borders, and fret work in box, has been juftly banifhed our gardens: therefore I have only mentioned them here, to expofe the tafte of thofe architect-gardeners, who have no idea of the noble fimplicity of an open lawn of grafs, properly bounded by plantations; but, inftead of this, divide that part of the garden, near the houfe, into various forms of borders edged with box, and fand or gravel-walks leading about them; by which the ground is cut into many angles, fcrolls, &c. which is very hurtful to the eye of a judicious perfon: therefore, where flowers are defired, there may be borders continued round the extent of the lawn, immediately before the plantations of fhrubs; which, if properly planted with hardy flowers to fucceed each other, will afford a much more pleafing profpect than the ftiff borders made in fcrolls and compartments, after the French manner, can poffibly do.

Thefe borders may be made fix or eight feet wide, in proportion to the extent of the garden, and fize of the lawn: for a fmall lawn fhould not have very broad borders; nor ought a large lawn to be bounded by fmall borders; fo that a due proportion fhould be always obferved in the laying out of gardens. *Miller's Gard. Dict.*

Mr. Hitt, in his Treatife of Fruit-trees, has laid down the following directions for making borders for peaches, nectrines, pears, plums, cherries, &c.

" If the land, fays he, be a ftrong clay, take fea-fand, if it may eafily be had, if not, any other fand that is neareft, and about one fixth of the quantity of coal-afhes, that have been kept very dry; riddle them, but not too fine; for if fome of the larger parts be left, they will difunite the tough body of clay, and make it more open and tender, and the finer parts that are more burnt, will add more falts to it.

" But if afhes cannot be had, take about a twelfth part as much lime as fand. About a third part of the depth of the borders ought to be of thefe ingredients; and in trenching the borders, there muft be a layer of thefe, and a layer of the natural foil, from the bottom to their furface, in the above proportion; but they ought to be turned over twice at leaft before plantings, in order to mix them the better.

" If the foil of borders is mixed with large pebbles, they muft be picked out, and may be of ufe, though otherwife hurtful, to lay in the drains.

" And as this kind of land is generally of a loofe fandy nature, it muft be mixed with fomething more ftrong and binding, which is clay, the tougheft that can be got, and neareft. If it be taken from the fides of ditches, whofe foil is naturally a clay, or from ditches in which there is fometimes a current of water falling from tillage fields of that kind of foil, and there leaves its fettlement, it will be as good as any.

At the bottom of the borders lay this clay fix inches thick throughout, it will prevent the moifture from running off too faft in the fummer, as it is apt to do from open fandy ground, efpecially where there are any drains made; then to each cart load of clay add three pecks of pigeon dung, or lime, or five of foot, and mix them with a quantity of the natural foil equal to half of them: if coal or wood afhes are made ufe of inftead of foot, they muft be made very fine, otherwife they will open this fort of land too much; befides, the finer they are made, the more falts they add to it.

" But where fandy lands are dry, the draining part muft be omitted; and the other ingredients only are to be made ufe of. It may be faid, that trees will grow well upon fandy land, without any improvement: I grant they will: but they are not fo long-lived, being more fubject to blights, and the fruit is both fmaller, and of a worfe tafte, than thofe upon ftronger ground inclining to clay.

" If land defigned for a garden is either hard rock or creach, and lies within the depth which the borders ought to be, let it be picked up and fkreened to take out the ftones; which will be of fervice when laid under grafs or gravel walks; as they will be drier, and lefs fubject to worm fprouts. Then as you find the land, after fkreening, either light or ftrong, add to it one of the mixtures which you fee it wants, according to the former directions, to bring it to a proper depth, and a foil more inclining to clay than fand, with a covering of ftrong clay at the bottom fix inches thick.

" If the land be frefh and proper for fruit-trees, yet it ought to be trenched as deep as others; and if towards the top there be ufed a fmall quantity of the ingredients mentioned before for the enrichment of foils, it will be of good fervice; for it muft be noted, that in making the trenches, the worft part of the foil will be uppermoft.

" If borders are to be planted with trees where others have grown before, the depth and quality of the foil muft be examined, and if it be deep enough, and of a proper mixture of fand and clay, then it only requires trenching, with the former addition of lime or foot, &c. which will be a better border than if the cold earth had been taken out, and frefh laid in without lime, &c. and alfo much cheaper.

" In borders thus prepared to fix feet wide or more, though it is proper to make the borders as wide as the walls are high, I have known all kinds of fruit-trees profper well, and bear excellent fruit, except vines and figs; for which the natural foil may be mixed with rubbifh, as lime fcraps, fmall pieces of bricks, &c. for a foot deep in the bottom or more." *Hitt's Treatife on Fruit-trees, pag.* 6.

BORD-*Lands*, the demefnes which lords keep in their own hands, for the maintenance of their board or table.

BORD-*Service*, the tenure of bord-lands, by which the tenants were to provide provifions for their lord's tables. There is ftill fome remains of this tenure remaining; but the tenants pay only a fmall rent per acre, inftead of finding the provifions formerly required.

BORER, or *Screw-borer*, an inftrument invented by the marquis of Turbilly, for fearching or exploring the nature of any foil.

Thefe

This borer is compofed of two rods of iron, Plate I. Fig. 6 and 7. each fix feet long, and an inch in diameter. The end A, of Fig. 6, fcrews into the end B, of Fig. 7, after taking out the ftopper C, the ufe of which is to hinder either dirt or duft from getting into the fcrew. The fcrew is an inch and a half long, and three quarters of an inch in diameter. D, Fig. 6, is a fteel point fomewhat blunt to pierce the earth, or any fubftance it may meet with. It fhould be about three inches long, and made with either three, four, or more fides, as may be thought moft convenient. It is fcrewed into the rod A in the fame manner, and with a fcrew of the fame fize as A is fcrewed into the rod B. E is a groove fix inches long, a third of an inch wide, and three quarters of an inch deep, rounded in the bottom, and intended to bring up part of each different layer through which it paffes. When fprings are fought for, a bit of fponge is put into the groove. At the end F, of the rod, Fig. 7, is a fcrew to fix into another rod of the fame kind, if it be found neceffary to lengthen the inftrument; and this may be repeated by the addition of more rods, to any depth defired. G H, Fig. 6, is the handle of this inftrument, two feet and a half long. This handle is faftened to the rod by means of a clafp I, lined with fteel, fixed at one end by a hinge, and at the other by the fcrew L; fo that it may be placed at any height. Fig. 8, is the handle feparated from the rod, and marked with the fame letters as before. Fig. 9, marked with the fame letters as before, is another handle, or rather lever, like the handle already defcribed, except its having only one branch or lever marked G. This ferves to ftop the borer when we are bringing it up from a confiderable depth, and alfo to fcrew and unfcrew the feveral bars, or joints, as occafion requires: and to put on, or take off the fteel point at the bottom. The handle G A, Fig. 6, is that by which the rod is held, and worked into the earth, either by twifting it round, efpecially at firft, or after it has penetrated to the fame depth, by lifting it up, and letting it fall again, which it does with fuch force as to pierce even the hardeft rock; efpecially if it works at any confiderable depth, and has of courfe been lengthened accordingly; for every foot of this rod weighs three pounds. Two men will eafily found the depth of twelve feet in lefs than a quarter of an hour, if they do not meet with many ftones. When the rod becomes too heavy to be properly managed by hand, it may be raifed by a rope faftened at one end to the handle, and at the other to a roller, or kind of windlafs, erected at a proper height, perpendicularly over the hole, and turned with either one or both handles. This will coft but a trifle, and will eafily raife the other rod, which, when let go, will fall with fuch weight, as to ftrike each time very deep into the earth. The marquis tells us, that he has feen it worked in this manner to the depth of more than an hundred feet.

The tougheft iron is the beft for making this inftrument, which fhould be well hammered, till its furface be quite fmooth and even; for the leaft roughnefs and inequality would occafion a friction, which would greatly retard its working. For the fame reafon, and alfo to increafe the force of its fall, it is neceffary that it fhould be perfectly ftrait: nor fhould it ever be ftruck with a mallet, hammer, &c. to force it down; becaufe a blow might bend it, and it would eafily break afterwards. The female fcrew muft be turned like that in the breech of a gun barrel, in a feparate piece of iron, crofs-ways to the grain, and this piece muft be afterwards well foldered on to one of the ends of the rod. The reafon for this is, that if the female fcrew were bored only at the end of the rod, it would, by being hammered out in the fame direction with the grain, be ftringy and porous, and confequently fo weak as to give way, or burft, in the working of the rod; whereas when made of a feparate piece, taken crofs-ways of the grain, the threads of the fcrew will run with the grain of the iron, and be thence confiderably ftrengthened. A bit, like that of an augre, proportioned to the thicknefs of the rod, may at any time be fubftituted inftead of the fteel point, to draw up a fample of the fubftance from the very bottom of the founding.

If the only thing wanted be to know the nature of the under foil, and layers of earth, fo far as they may effect the vegetation of plants, it will be very fufficient to bore eight or ten feet deep. A greater depth is only requifite when water, marle, ore, &c. be fought for.

The common augre indeed will do very well for fhallow boring, as we have already obferved under that article. *See the article* AUGRE.

By either of thefe inftruments, there is a certainty of difcovering, without much charge, or any hazard, not only what earths are under the upper foil, but alfo whether any other fubftance of value lies concealed there, fuch as marle, chalk, fuller's-earth, foffile fhells, coals, quarries of flate or ftone, ores, &c. many of which are hid, and entirely unthought of in places, where their value, was it known, is ten times more than that of the eftate which covers them.

BORING, an operation fometimes practifed for the cure of horfes, whofe fhoulders are wrenched.

The operation is performed in the following manner: they cut a hole in the fkin in the middle of the fhoulder, and with the fhank of a tobacco-pipe, blow it as a butcher does a fhoulder of veal; then they run a cold flat iron, like a horfeman's fword-blade, eight or ten inches up between the fhoulder blade and the ribs, which they call boring; after that, they burn him round the fhoulder with a hot iron. *Burd. Gent. Far.*

This is a very abfurd and cruel treatment, and can be of no manner of fervice. *Bartlet's Farriery.*

BOSQUETS, fmall groves or compartments in gardens formed by the branches of trees, difpofed either regularly in rows, or wildly and irregularly, according to the fancy of the owner.

BOSTAL, a way up a hill.

BOTTS, a name given to a fpecies of worms infefting horfes and other cattle.

The botts which breed in the ftomachs of horfes, and which are fometimes the caufe of convulfions, appear to be very large maggots, compofed of circular rings, with little fharp prickly feet along the fides of their bellies (like the feet of hog-lice) which, by their fharpnefs, equal to that of the fineft needle, feem to be of ufe to faften them to the part where they breed, and from whence they draw their nourifhment, and alfo to prevent their being loofened from fuch adhefion, before they come to maturity. The eggs from whence thefe botts are produced, are difpofed in clufters round the lower orifice of the ftomach, and are laid under the inner coat, or thin membrane of the ftomach; fo that when the animals come to life, they burft through this inner coat, their breech and tail ftrait outwards, and their trunks fo fixed into the mufcular or flefhy coat of the ftomach, that it fometimes requires a good pull to difengage them: from the blood of this laft coat they draw their nourifhment, which they fuck like fo many leeches, every one ulcerating and purfing up the part where it fixes, like a honey-comb; and they often make fuch quick havock as to deftroy the horfe.

The botts which many horfes are troubled with in the beginning of fummer, are always feen fticking to the ftrait gut, and are often thruft out with the dung, together with a yellowifh coloured matter refembling melted fulphur; they are no ways dangerous there, but are apt to make a horfe reftlefs and uneafy, and rub his breech againft the pofts. The feafon of their coming is in the months of May and June, after which they are feldom to be feen, and rarely continue in any one horfe above a fortnight or three weeks. And the creature may be eafily cured when they are only in the ftrait gut, by giving him a fpoonful of favin cut very fmall, once or twice a day in his oats, or bran, moiftened: three or four cloves of garlic may alfo be added to advantage. The following purge fhould likewife be given:

> Take fine fuccotrine aloes ten drams; frefh jallap one dram; birthwort and myrrh powdered, of each two drams; oil of favin and amber, of each one dram; fyrup of buckthorn enough to form the whole into a ball.

But the botts, which take their lodgement in the ſtomach, are, as has been already obſerved, extremely dangerous, by cauſing convulſions, and are ſeldom diſcovered by any previous ſigns before they come to life, when they throw the horſe into violent agonies. The only cure for theſe is mercurial medicines; the following will anſwer the intention:

> Take quickſilver two drams; Venice turpentine half an ounce; rub the quickſilver till no gliſtening appears; then take an ounce of aloes, a dram of grated ginger, thirty drops of oil of ſavin, and ſyrup of buckthorn enough to make the whole into a ball.

One of theſe balls may be given every ſix days, with the uſual precautions with regard to mercurial phyſic: and the following powders immediately:

> Take powdered tin and Æthiops mineral, of each an ounce; and give it every night in a maſh, or in his corn.

Theſe medicines, or any of the various preparations of antimony and mercury, ſhould be continued ſeveral weeks together, in order to free the animal entirely from theſe vermin. *Bartlet's Farriery, pag.* 150.

BOUDS, a name in ſome countries for the inſects generally called weevils, breeding in malt.

BOW, a name in ſome counties for a yoke.

BOWER, a ſhady place under the covert of trees or branches interwoven. It is either round or ſquare at the bottom, and covered with a ſort of dome at the top.

BOWS *of a ſaddle*, are two pieces of wood laid archwiſe to receive the upper part of the horſe's back, to give the ſaddle its due form, and to keep it ſteady.

BOX, the name of a well known tree, of which botaniſts enumerate ſeven ſpecies; viz. 1. The box-tree. 2. The narrow leaved box-tree. 3. The ſtriped box. 4. The gold-edged box-tree. 5. The dwarf box. 6. The dwarf-ſtriped box. 7. The ſilver-edged box.

The firſt and ſecond ſorts grow in great plenty upon Box-hill near Darking in Surry, where were formerly large trees of theſe kinds: but of late they have been pretty much deſtroyed; yet there are great numbers of theſe trees remaining, which are of a conſiderable bigneſs. The wood of this tree is very uſeful for turners, engravers, and mathematical inſtrument makers; the wood being ſo hard, cloſe, and ponderous, as to ſink in water; which renders it very valuable for divers utenſils.

All the varieties of the trees, or large box, are proper to intermix in clumps of ever-greens, &c. where they add to the variety of ſuch plantations: theſe may be propagated by planting the cuttings in autumn in a ſhady border, obſerving to keep them watered until they have taken root; when they may be tranſplanted into nurſeries, till they are fit for the purpoſes intended. The beſt ſeaſon for removing theſe trees is in October; though, indeed, if care be uſed to take them up with a good ball of earth, they may be tranſplanted almoſt at any time, except in the ſummer: theſe trees are a very great ornament to cold and barren ſoils, where few other things will grow; they may alſo be propagated by laying down the branches, or from ſeeds: the laſt being the beſt method to have them grow to be large, the ſeeds muſt be ſown, ſoon after they are ripe, in a ſhady border, which muſt be duly watered in dry weather.

The dwarf kind of box is uſed for bordering of flower-beds, or borders; for which purpoſe it far exceeds any other plant, it being ſubject to no injuries from cold or heat, and is of a long duration; is very eaſily kept handſome, and, by the firmneſs of its rooting, keeps the mould in the borders from waſhing into the gravel-walks, more effectually than any plant whatever: this is increaſed by parting the roots, or planting the ſlips; but, as it makes ſo great an increaſe of itſelf, and ſo eaſily parts, it is hardly worth while to plant the ſlips that have no roots; but it is now become ſo common, that it may be purchaſed from the nurſeries at a cheap rate. *Miller's Gard. Dict.*

BOX *of a wheel*, the aperture wherein the axis turns.

BOX *of a plough*, the croſs-piece in the head of a plough which ſupports the two crow-ſtaves. *See* PLOUGH.

BRACE, a general name for a couple, or pair of any thing, as bucks, hounds, partridges, &c.

BRACE alſo ſignifies a piece of timber framed into the beams, &c. with bevel joints, to keep the building from ſwagging either way.

BRACKEN, the ſame with brakes, or fern. *See the article* FERN.

BRACKET, a kind of wooden ſtay, ſerving to ſupport ſhelves and the like.

BRAGGET, or BRAKET, a ſort of compound drink, made with honey, ſpices, &c.

BRAKE, the ſame with fern. *See the article* FERN. It is likewiſe applied to the place where fern grows.

BRAKE, is alſo a name given to an inſtrument often uſed by farriers, &c. generally called barnacles. *See* BARNACLES.

BRAKE *of a pump*, ſignifies the handle wherewith it is wrought.

BRAKE, is likewiſe the name of a wooden-toothed inſtrument, uſed to bruiſe and break the bun of hemp, and ſeparate it from the rind. *See the article* HEMP.

BRAN, the ſkin or huſks of corn, eſpecially wheat, ground and ſeparated from the flour by means of a ſearch or boulter.

Bran is a uſeful ingredient in a horſe's diet, if diſcreetly uſed, and when ſcalded is a kind of panada for ſick horſes. But nothing is worſe than a continual uſe of bran raw or ſcalded, as it is apt to weaken a horſe's bowels, and thereby expoſe them to many diſorders. *Gibſon on the Diſeaſes of Horſes, vol.* I. *pag.* 172.

Mr. Mills aſſures us, that a little wheat bran boiled in our ordinary beer, will make it mantle in the cup. *Huſbandry, vol.* I. *pag.* 407.

BRANCH, an arm of a tree, or a part which ſprouting out from the trunk, helps to form the head or crown.

As branches have their outward parts common with the chief ſtem, ſo in like manner do their inward conſiſt of a multitude of tubes, which are alſo provided with a number of ſmall glands, veins, and muſcles, interſperſed here and there, where the ſap coming from the firſt canal is rendered much more delicate.

Branches are diſtinguiſhed into various kinds: 1. Wood-branches, which are thoſe that form the ſhape of the tree, and are to be pruned from four to twelve inches, according to the vigour of the tree. 2. Fruit-branches, which are ſlenderer than the wood-branches, and have their eyes near to one another and large, by which the fruit-buds are formed. If they are too long, they are to be topped; but if they are of a juſt length, they are to be preſerved, only juſt cutting off the extremity. 3. Branch half-wood, that which, being too ſlender for a wood-branch, and too big for a fruit-branch, is cut off at the length of two or three inches, to make it produce a better ſhoot, whether wood or fruit. 4. Irregular branches, which are ſmall and confuſed: they muſt be cut off, becauſe they are neither fit for wood nor fruit. 5. Branches of falſe wood: theſe are ſuch as grow upon the true wood-branches, and have flat eyes at a diſtance one from another; for which reaſon they are uſeleſ, and therefore muſt be cut off. 6. Luxuriant branches, which are ſuch as ſhoot out from the large wood-branches: theſe are as taper and as big about as one's finger, the back being ſmooth and even, and having broad eyes at a diſtance from one another: theſe muſt all be cut off. 7. Spurious wood-branches, ſuch as come contrary to the order of nature, or otherwiſe than from the cuts of the preceding year; or which, coming on ſuch cuts, are big in the place where they ſhould be ſmall.

The diſtinguiſhing marks of good branches are, that the eyes, in the whole extent, be thick, well-fed, and very cloſe one to another. The good ſtrong branches are employed in producing yearly, on their extremities, other new branches, ſome ſtrong and others weak. The good weak branches are ſuch as are well placed, and being of a mean thickneſs and length, may be able to produce ſpeedily beautiful and good fruit.

The diſtinguiſhing marks of bad branches are, when in the lower part the eyes are flat, ill-fed, and hardly formed, and at a large diſtance one from another. See the article PRUNING.

BRANK,

BRANK, the ſame with buckwheat. See the article BUCKWHEAT.

BRANT, a ſteep, riſing with a conſiderable inclination.

BRAWN, the fleſh of a boar, boned, rolled up, or collared, boiled, and laſtly pickled.

Brawn is made only of the flitches, without the legs: the oldeſt boars are choſen for this uſe, it being a rule, that the older the boar the more horny the brawn.

The method of making it is as follows: the bones being taken out of the flitches, the fleſh is ſprinkled with ſalt, and laid in a tray, that the blood may drain off; after which it is ſalted a little, and rolled up as hard as poſſible. The length of the collar of brawn ſhould be as much as one ſide of the bone will bear; ſo that when rolled up it may be nine or ten inches in diameter.

The collar being thus rolled up, it is boiled in a copper or large kettle, till it is ſo tender that you may run a ſtraw through it; when it is ſet by till thoroughly cold, and then put into the following pickle. To every gallon of water add two handfuls of ſalt, and as much wheat-bran: boil them together, drain the liquor as clear as poſſible from the bran, and when the liquor is quite cold, put the brawn into it.

BREAD, a well-known food chiefly divided into white, wheaten, and houſhold; differing only in degrees of purity. In the firſt, all the bran is ſeparated; in the ſecond, only the coarſer; in the third, none at all: ſo that fine bread is made only of flour; wheaten bread of flour, with a mixture of fine bran; and houſhold, of the whole ſubſtance of the grain, without taking out either the coarſe bran, or fine flour.

We alſo meet with ſymnel bread, manchet or roll bread, and French bread: which are only ſo many denominations of the fineſt or whiteſt bread, made of the pureſt flour; except that in roll bread there is an addition of milk, and, in French bread, of eggs and butter alſo. To which may be added, ginger-bread, made of white bread, with almonds, liquorice, aniſeed, roſe-water, and ſugar; and maſlin bread, made of wheat and rye, or ſometimes of wheat and barley.

The proceſs of making houſhold bread amongſt us, is thus: to a peck of meal they add a handful of ſalt, a pint of yeaſt, and three quarts of water, cold in ſummer, hot in winter, and temperate between the two; the whole, being kneaded in a bowl or trough by the fire in winter, from it in ſummer, and a little yeaſt added, will riſe in about an hour; they then mould it into loaves, and put it into the oven to bake. *Hought. Collect.*

For leavened bread, part of the flour intended for it, being made into dough with warm water and a little ſalt, is laid in the reſt of the flour an hour or more, in which time it riſes to three times the bulk; then they mix and knead the whole with more water, till it be brought into a ſtiff dough; which, being formed into loaves, is baked in the oven: though the more uſual way is to take a piece of dough kneaded, and leave it in the tub till next time, when they break it ſmall, and mix it with the meal, adding ſome yeaſt. *Hought. Collect.*

For French bread, they take half a buſhel of fine flour, ten eggs, and a pound and a half of freſh butter, into which they put as much yeaſt, with manchet; and, tempering the whole maſs with new milk, pretty hot, let it lie half an hour to riſe; which done, they make it into loaves or rolls, and waſh it over with an egg beaten with milk: care is taken the oven be not too hot. *Ruſt. Dict.*

BREAK, land ploughed the firſt time after it has lain fallow in ſheep walks.

BREAST-PLOUGH, a ſmall plough contrived ſo that a man may ſhove it before him. It conſiſts of a cutting iron about eight or nine inches long, and having one of its ſides turned up to cut the turf. This iron is fixed to a pole bending upward about five or ſix feet long, and forked at the upper-end, having a crutch, or croſs handle, mortiſed into the forks. Againſt this crutch the ploughman places his breaſt, and ſhoves along the plough in order to turn up the turf, its only uſe being for cutting up the ſurface of the ground in the operation called burn-baking. See the article BURN-BAKING.

BRECK, *or* BRACK, a breach or gap made in a hedge

BREW-HOUSE, a houſe erected for the purpoſes of brewing.

The conveniency of water is one of the firſt things to be attended to in erecting a brew-houſe, becauſe the frequent carriage of that neceſſary fluid greatly enhances the coſt of the beer. The water ſhould be ſoft, and if ſupplied from an adjacent river, it ſhould be conveyed by a paſſage under-ground, in order to its being pumped up from thence into the copper, or into troughs properly placed for carrying it where it may be wanted. If there be a reſervoir for rain-water, it ſhould be made as near the brew-houſe as poſſible.

The brew-houſe ſhould be ſo ſituated as to face the north, for ſhade and coolneſs. It ſhould be as near as poſſible to the cellar, that the labour and expence attending the carriage of the liquor may be ſaved, and the danger of expoſing it to either too hot, or too cold an air prevented. The floor ſhould be paved with ſtone or hard bricks, and raiſed in the middle, to give an eaſy diſcharge to the water, ſo as to keep the brew-houſe always clean.

The copper ſhould be proportioned to the quantity brewed, and ſhould be raiſed ſo high that the water may run from it to the maſh-tub, and the wort to the coolers. For this purpoſe there ſhould be either a cock in the ſide at the bottom of the copper, or a braſs pump ſhould be fixed to its ſide, by means of which the water or wort may be conveyed through a trough to their proper receptacles.

The maſh-tub ſhould be round, not too deep, and perfectly ſmooth on the inſide. It ſhould have a falſe bottom, which may ſerve as a ſtrainer, when by turning a cock placed below, the wort may be drawn off into the receiver: or the wort may be let out by means of an upright plug ſurrounded with a baſket-ſtrainer.

The receiver ſhould be lined with milled lead, which is eaſily kept perfectly clean, and is not apt to contract any bad taſte or ſcent, as wood is known to do, notwithſtanding the greateſt care. The beſt method of conveying the wort from the receiver to the copper is by means of a hand-pump.

There ſhould be two coolers, or backs, as the brewers call them. Theſe ſhould alſo be lined with milled lead, or made of the heart of oak rendered perfectly ſmooth; and placed as near as convenient to the copper.

The working veſſel or tun ſhould be placed at ſome ſmall diſtance from the cooler. It ſhould be round, but not lined with lead; becauſe this would cool the liquor too much in cold weather, during the fermentation.

The cellar ſhould, as already obſerved, be near, if poſſible, and ſunk much lower than the working-tun, that the beer may be conveyed into the caſks by a cock and hoſe, or ſome other eaſy method.

There muſt be in the brew-houſe an oar to ſtir the malt in the maſh-tub, with bowls, pails, and other utenſils, neceſſary in different operations. Theſe, as well as every other implement employed in brewing, ſhould be boiled in the copper, or well ſcalded every time before they are uſed.

Too great care cannot be taken to keep every veſſel perfectly clean and ſweet: for if they are the leaſt tainted, the liquor will contract a diſagreeable ſcent. When any taint is ſuſpected, the veſſels ſhould be well waſhed with a ſtrong leye of clean wood-aſhes. This leye ſhould be put into them ſcalding hot, and every joint, crevice, and ſmalleſt hollow muſt be well ſcrubbed. If there are no aſhes to be had, lime may be ſlaked in water in the veſſels; and if this be done in caſks, they may be bunged up as ſoon as the ebullition is over, and not opened till three days after. The more effectually to prevent the lodging of any kind of filth, the ſides of every veſſel ſhould be as ſmooth as poſſible; and after every brewing they ſhould be waſhed with boiling water, and laid up dry.

BREWING, the operation of preparing beer, or ale, from malt and hops.

The uſual proceſs of brewing is as follows: the ingredients being ready, the water muſt be made to boil very ſpeedily, and while boiling with the greateſt violence, the fire muſt be immediately damped, or put out; when the height of the ſteam is over, the water is put into the maſhing-tub, to wet the malt; then ſo much being poured out, as to make it of a conſiſtence ſtiff enough to be rowed up, let it ſtand thus a quarter of an hour, after which another quantity of water is added, and rowed up as before; at laſt the full quantity of the water is poured upon it, and that in proportion as the liquor is intended to be ſtrong

or

or weak: this part of the operation is called mafhing. Afterwards the whole may be left to ftand two or three hours, more or lefs, according to the ftrength of the wort, or the difference of the weather; then let it run into the receiver, and mafh again for a fecond wort, in the fame manner as for the firft, only the water muft be cooler, and muft not ftand above half the time.

The two worts being mixed together, the quantity of hops that is defigned may be added thereto, and the liquor put into the copper, which being cofely covered up, let it boil gently for the fpace of an hour or two; then let the liquor into the receiver, and the hops ftrained from it into the coolers.

When cool, the barm is applied; which done, it is left to work, or ferment, till it be fit to tun up.

For fmall-beer there muft be a third mafhing; the water muft be near cold, and to ftand not above three quarters of an hour; to be hopped and boiled at difcretion.

Such is the procefs, as commonly delivered, for brewing; but it is in many particulars fo vague and uncertain, that proper explanations will be requifite.

The malt is ordered to be put into the mafh-tub, when the height of the fteam is over; but how is this to be known exactly? Some direct you to ftay till you can fee your face in the water, which is full as equivocal. Perhaps the method propofed by Dr. Shaw might anfwer the purpofe. He directs us to put a certain meafured quantity of cold water to the malt firft, and ftir that very well with it, fo as to from a kind of thin uniform pafte; after which the remaining quantity of the water may be added in a ftate of boiling, without the leaft danger. By this means, adds that able chemift, the proper or precife degree of heat, neceffary to extract the virtue of the malt with all advantages, may be very expeditioufly hit, or affigned, to a great exactnefs; as the heat of boiling water is a ftandard, which may at once be let down to any defired point of warmth, by a proper addition of cold water; due allowance being made for the feafon of the year, and the temperature of the air.

To employ only one copper in brewing is generally allowed to be bad management; becaufe the bufinefs muft, in that cafe, ftand ftill in fome part or the other, however well the procefs may be contrived. For this reafon, the beft and more ufual method is to brew with two coppers.

The great copper in which the water for the two firft extracts receive their temperature, is built very near the mafh-tub, fo that the water may be readily conveyed to the ground malt. At the bottom of the copper is fixed a cock, which being turned, lets the water run through a pipe to the real bottom of the mafh-tub. This is by far the beft way, becaufe it is the moft expeditious, and leaft liable to accidents.

When the water has been brought to a proper degree of heat in the mafh-tub, the malt is run very leifurely into it, whilft another perfon ftirs it all the time, fo as to mix the whole of it uniformly with the water, and prevent any of its parts from gathering into clods. In this operation rakes fhould be firft employed; becaufe by their horizontal motion, lefs violent than that of mafhing, the fineft parts of the malt are well wetted, without its flour being fcattered or loft in the air: but as a ftill more perfect penetration and mixture are neceffary, oars are afterwards ufed, by which a thorough inhibition of the water is effected. When the mafh has been fufficiently ftirred, it is covered with a fprinkling of malt, and the tub itfelf fhould alfo be covered with facks or other cloths to keep it warm.

After mafhing, the malt and water are left untouched for an hour and a half, or two hours; and during this interval, the large copper of water is brought to a proper heat for a fecond mafhing. The fecond extract is commonly mafhed three quarters of an hour, and is afterwards let ftand the fame fpace of time; and the third requires half an hour, both for mafhing and ftanding. As the firft drawn wort is immediately put into the large copper, the water for the third mafhing is boiled in the fmaller.

Small quantities of malt brewed in large veffels lofe their heat fooneft by lying thin and greatly expofed to the action of the air; and, on the contrary, a lefs allowance for the lofs of heat is required for large quantities brewed in proportionable veffels. This is the only difference between brewings carried on in large brew-houfes, and thofe which are made in private families. Care fhould be taken that the quantity of malt be not fo large as to exceed the bounds of one man's labour; nor fo fmall as to prevent the heat being uniformly maintained. It is alfo of great importance never to let the malt remain with lefs water than will cover it.

It is the general cuftom in private families to brew their fmall-beer after their ale: but they may be affured that if they have any regard to their fmall-beer, it is their intereft to brew it alone; for the beer thus made is incompably better, becaufe it then contains all the flavour of the malt, is undoubtedly more wholefome, and will keep much longer.

A correfpondent of the editors of the *Mufeum Rufticum*, vol. vi. p. 287, has given the following ufeful directions for making a kind of fmall-beer, which for cheapnefs, agreeablenefs, and perhaps wholefomenefs, is greatly preferable to that made from malt. It has alfo this further advantage, that it may be made ready for drinking in three or four days time.

The method is this: take of water fifteen gallons; and boil one half of it in any copper or pot that may be at hand. Put the part of the water thus boiled, while in its full heat, to the cold part contained in a barrel or cafk: and then add one gallon of melaffes, commonly called treacle, ftirring them well together. If the veffel be new, add a little yeaft; but if it has been ufed before for the fame purpofe, the yeaft will be unneceffary. Keep the bung-hole open for a day or two, till the fermentation appears to be abated, and then clofe it up. The beer will in a day or two afterwards be fit to drink.

But to return to the management of the wort. The beer-wort muft be boiled, in order to free it from particles which would render the liquor muddy and ill coloured, without adding to its ftrength; to extract the virtue of the hops; and to render the drink fitter for keeping.

Worts, like every other fweet vegetable juice, when once brought to ferment, are fo inclined to continue their fermentation, that it is difficult to retard their progrefs therein, to keep their prefervative qualities, and fo hinder them from turning acid. Among the many methods put in practice to retard this forwardnefs of the worts, none promifed fo much fuccafs as blending with them the juice of fuch vegetables as are not of themfelves eafily fermented. Hops are felected for this purpofe; and experience, which has proved their wholefomenefs, has alfo demonftrated their efficacy: for their refinous parts retard the aptnefs of malt liquors to ferment. By this means they keep malt-liquors found a longer time, and by repeated and flow frettings, give an opportunity to the particles of the liquor to be more feparated and comminuted, than they would otherwife be. Fermented liquors require hereby a greater pungency, fo that, even if they did not receive an additional ftrength from this ingredient, hops would be the means of improving their tafte.

The aromatic parts of hops are volatile, and a fmall heat difengages them from the plant. To preferve thefe parts in the procefs of brewing, the hops fhould be put into the copper as foon as poffible, and be thoroughly heated while the heat of the wort is at the leaft, and the fire under the copper has no effect there. Whoever will take the trouble of feeing this performed, will be convinced that the flavour of the hops is retained; inftead of being diffipated in the air, as it always is, when the wort is firft fuffered to boil.

In order to extract more gradually a fragrant tincture from the hops, they fhould be rubbed thoroughly between the hands, and then put into a bag or fine net, fo loofe that the wort may be eafily admitted among them, and in this ftate they fhould be placed in the receiver or under-back, fo that the wort may run upon them. After this gradual foaking, during which they will communicate much of their virtue to the wort, lefs boiling will ferve, and the beer will have their full flavour.

A correfpondent of the editors of the *Mufeum Rufticum*, vol. III. pag. 64, has made fome judicious remarks on the common practice of boiling the hops in the wort. He obferves that the rich, fat wort fheaths up the pores of the hop, and, as it were, embalms the leaves, fo that the beer or ale-wort can extract a very fmall part only of the neceffary quality of the hop: but

but when it is put into the ſmall beer, a fluid of a thinner nature, the pores are unſheathed; ſo that the latter becomes too bitter, while the former has hardly any taſte of the hop. To remove theſe inconveniencies, he propoſes to ſoak the hops previouſly in a pail or two of hot water, by which means the hop will impart its good qualities impartially, and both the ſtrong and ſmall beer obtain a grateful bitter. And with regard to the quantity of water uſed in ſoaking the hops, allowance may be made for it in the firſt quantity.

When the firſt wort is ſufficiently boiled, it is conveyed into the coolers; and if the hops are not contained in a net, it muſt be run through a ſieve or ſtrainer, to keep them back. If the coolers have not been perfectly cleaned from the ſediment of former worts, which is very apt to inſinuate itſelf into old or decayed wood, the wort intended to be cooled in them, will, before it is removed, contract from that ſediment a degree of fermentation. This accident generally happens in a little more than twelve hours after the putting in of the wort; and therefore may be eaſily prevented by not letting the wort continue ſo long in the coolers.

When the wort is of a proper degree of coolneſs, the yeaſt is generally put into a large bowl, and a little of the wort juſt warm is added to it. The yeaſt ſwims at firſt on the ſurface, but ſoon blends itſelf with the wort, and begins the fermentation. As ſoon as this happens, the whole is mixed with the wort in the working tun.

If the fermentation ſhould not riſe properly, a little of the fineſt wheat flour ſifted over the wort, ſo as to cover the whole ſurface of the liquor, will, by forming a kind of artificial head, confine the air, and ſoon produce the effect deſired. If a greater degree of warmth ſhould be wanted, a ſtone jug filled with boiling water, and put into the wort, will communicate a gentle heat to the whole, and as the liquor warms, the fermentation will come on in a gradual and proper manner.

In the courſe of the fermentation, it may ſometimes be neceſſary, in order to quicken it, to beat in the yeaſt, or rather to ſtir it with a whiſk, which ſhould be perfectly clean, ſcalded in boiling water, and then wiped dry. It will alſo by this means retain ſome degree of warmth, which will likewiſe help to promote the fermentation. Theſe meaſures, with an additional warmth given to the air, and warm coverings laid over the working tun, ſeldom fail to anſwer the end deſired.

If the fermentation proceeds too violently, owing to the warmth of the weather, or too great quantity of yeaſt, the beſt way of checking it is, to cool the air, by giving it a more free admiſſion, and to mix a little cold wort with the fermenting liquor. The practice of adding ſome unctuous ſubſtance is bad, and therefore ſhould be rejected.

Care ſhould be taken to have the caſks in good order againſt the time that the fermentation is completed in the tub; that is, they ſhould be tight and clean, and perfectly free from filth or ſmell; for if they have either of theſe defects, the whole labour will be loſt, becauſe the excellency and fine flavour of the liquor will be deſtroyed.

The perfection of malt liquors depends not only on the proportion of the oils to the ſalts, and on the proportion of hops uſed in brewing, but alſo on the fermentation's being carried on ſlowly and cooly. For this reaſon cool weather is beſt for brewing of beer intended for long keeping. If therefore the liquor be not drawn off before the fermentation has proceeded too far, ſome of the coarſer oils will return into the liquor, and give it a diſagreeable and greaſy taſte. On the contrary, if the fermentation has not been continued its due time, the impurities which would either have ſunk down in the lees, or have been thrown up with the head, will remain in the liquor, and prevent its becoming clear and well taſted.

When the fermentation is at its height, all the dirt or foul yeaſt, which riſes on the ſurface, muſt be carefully ſkimmed off.

When the fermentation begins to ſubſide after the liquor has been drawn off into the caſk, the caſk ſhould be filled up with a reſerve of the ſame liquor taken from another veſſel, but by no means with that which runs over.

When the fermentation has ceaſed, the caſk being filled up, ſhould be bunged cloſe down, leaving the vent-hole open, or but ſlightly covered, till all motion in the liquor is ſubſided; and after this is over, the vent-hole ſhould be ſtopped quite cloſe. The cuſtom of uſing bungs made of cork is wrong. A wooden bung ſhould be fitted to the bung-hole as exactly as poſſible, and covered with a clean cloth.

BRIDLE, a contrivance made of ſtraps or thongs of leather, and pieces of iron, in order to keep a horſe in ſubjection and obedience.

The ſeveral parts of a bridle are, the bit or ſnaffle, the head-ſtall, or leather from the top of the head to the rings of the bit; the fillet, over the forehead and under the foretop; the throat-band, which buckles from the head-band under the throat; the noſe-bands, going through the loops at the back of the head-ſtall, and buckled under the cheeks; the reins or long thongs of leather that come from the rings of the bit, and being caſt over the horſe's head, the rider holds in his hand.

Bridle-*hand*, is the horſeman's left-hand, the right being called the ſpear or ſword-hand.

BRIM, or Brimme, a word applied to a ſow when ſhe goes to the boar, which is called going to brim.

BRINE, pickle, or water replete with ſaline particles.

BRINING *of hay reeks*, a practice common in America, and conſiſts in mixing ſalt with the hay as they ſtack it.

A correſpondent of the editors of the *Muſeum Ruſticum* recommends this practice greatly, declaring that hay which has to all appearance been ſpoiled by the rain, will ſpend as well as that made and ricked in the fineſt weather.

"Juſt before I left America, ſays he, I had a crop of hay, which was in a manner ſpoiled by the rain, being almoſt rotted in the field; yet did this hay ſpend as well as if it had been got in ever ſo favourably.

"When my ſervants were making up the ſtack, I had it managed in the following manner; as ſoon as the bed of hay was laid about ſix inches thick, I had the whole ſprinkled over with ſalt; then another bed of hay was laid, which was again ſprinkled in the ſame manner; and this method was followed till all the hay was ſtacked.

"When the ſeaſon came for cutting this hay, and giving it to my cattle, I found that ſo far from refuſing it, they eat it with ſurprizing appetite; always preferring it to the ſweeteſt hay, that had not been in this manner ſprinkled with ſalt." *Muſeum Ruſt. vol.* II. *pag.* 210.

BRITE, a word applied to hops when they are over ripe or ſhatter, in which caſe they are ſaid to brite.

BROAD-WHEELED *waggon*. *See the article* Waggon.

BROCOLI, or Broccoli, a ſpecies of cabbage, of which there are ſeveral varieties. *See the article* Cabbage.

Brocoli requires a very good and pretty light ſoil, rather deep than otherwiſe. The proper time for ſowing it is from the latter end of April, till the beginning of June; and the manner the ſame as for cabbage. When the plants are about a fortnight or three weeks old, that is when they have got ſeven or eight leaves, they ſhould, like all others of the cabbage kind, be tranſplanted into beds of well prepared mould, and towards the end of July they will be fit to be tranſplanted into beds where they are to remain. This ſhould be a well ſheltered ſpot, but not under the drip of trees. The plants ſhould here be ſet in rows at leaſt two feet aſunder, but two feet and a half, or even three feet, will be ſtill better; and at the diſtance of a foot and a half, or rather two feet from each other in the rows. Towards the end of December, if the weather be not very ſevere, they will begin to ſhew their ſmall heads, which, eſpecially at their firſt appearance, are not unlike thoſe of cauliflowers. Theſe heads ſhould be cut off before they run up to ſeed, with about four or five inches of the ſtalks, and a great number of ſide ſhoots, produced from the ſtem, will ſucceed them, and continue fit for eating till the

the middle of March. They will not indeed be fo large as the former, but they will be equally well tafted. The fkin of the ftalks fhould be taken off before they are boiled.

There are three forts of brocoli cultivated in our kitchen gardens, viz. The Roman or purple brocoli; the Naples, or white brocoli; and the brown or black brocoli. The firft of thefe is the fineft flavoured, and continues longeft in feafon; and therefore is moft efteemed. The fecond, or white brocoli, has fo nearly the tafte of cauliflower, that it is not always eafy to diftinguifh them. The brown or black fort is the leaft delicate; but the hardieft, and grows to the largeft fize.

For a fecond crop to fupply the table after the firft is gone, Mr. Miller advifes the fowing of brocoli again in the beginning of July; but Mr. Switzer thinks it wrong to fow this plant even fo late as Midfummer, becaufe their ftems will not be ftrong enough before the winter to produce that number of fprouts they otherwife would do, if fown fooner. He therefore directs the plants to be divided into three parts, and to cut their heads off entirely within a foot and a half, or two feet of the ground; beginning to do this to one parcel about a fortnight before Michaelmas, to the next about a month after, and to the laft about a fortnight or three weeks before Chriftmas: by which means a continued fucceffion of fprouts will iffue from the fides of the remaining ftems. Either directions may be followed; but the largeft heads will be produced by Mr. Miller's method, and the greateft number by that of Mr. Switzer. *Miller's Gard. Dict. Switzer's Method of raifing Italian Brocoli*, &c. *pag.* 2.

BROKEN-WIND, a very fatal difeafe to which horfes are too often fubject.

This diforder hitherto feems to have been little underftood; but Mr. Gibfon is inclined to think, that the fource of it is frequently owing to injudicious, or hafty feeding young horfes for fale; by which means the growth of the lungs, and all the contents within the cheft, are fo increafed, and, in a few years, fo preternaturally enlarged, that the cavity of the cheft is not capacious enough for them to expand themfelves, and perform their functions.

A narrow contracted cheft with large lungs may fometimes naturally be the caufe of this diforder: and it has been obferved, that horfes rifing eight years old, are as liable to this diftemper, as at a certain period of life, men fall into afthmas, confumptions, and other chronic difeafes.

The reafon why this diforder becomes more apparent at this age may be, that a horfe comes to his full ftrength and maturity at this time: at fix he commonly finifhes his growth in height; after which he lets down his belly, and fpreads, and all his parts are grown to their full extent; fo that the preffure on the lungs and midriff is now more increafed.

But how little weight foever thefe reafons may have, repeated diffections have given ocular proofs of a preternatural largenefs, not only of the lungs of broken-winded horfes, but of their heart and its bag; and alfo of the membrane which divides the cheft; as well as of the remarkable thinnefs of the diaphragm or midriff.

This difproportion has been obferved to be fo great, that the heart and lungs have been almoft of twice their natural fize; perfectly found, and without any ulceration whatever, or any defect in the wind-pipe or its glands.

Hence it appears, that this enormous fize of the lungs, and the fpace they occupy, by hindering the free action of the midriff, is the chief caufe of this diforder; and as the fubftance of the lungs was found more flefhy than ufual, they muft of courfe have loft much of their fpring and tone.

This flefhinefs and fize of the lungs may, in a great meafure, be the caufe, why the infpirations in broken-winded horfes are difproportionately flow; for we may obferve that they draw their in breath flowly, their flanks filling up, and rifing with difficulty: but that their flanks fall fuddenly, and their breath burfts forth with violence, both from mouth and noftrils; infomuch, that a man in the dark, by holding his hands on the horfe's mouth and nofe, may eafily difcover if he is broken-winded.

Whoever confiders a broken-wind in this light, muft own that it may be reckoned among the incurable diftempers of horfes; and that all the boafted pretenfions to cure, are vain and frivolous, fince the utmoft fkill can amount to no more than now and then palliating the fymptoms, and mitigating their violence.

We fhall therefore lay down fuch methods as may probably prevent this diforder, when purfued in time; but if they fhould not fucceed, we fhall offer fome remedies and rules to mitigate its force, and to make a a horfe as ufeful as poffible under this malady.

It is ufual before a broken-wind appears, for a horfe to have a dry obftinate cough, without any vifible ficknefs or lofs of appetite; but, on the contrary, a difpofition to foul feeding, eating the litter, and drinking much water.

In order then to prevent, as much as poffible, this diforder, bleed him, and give him two drams of calomel, mixed up with an ounce of diapente, for two nights fucceffively, keeping him cloathed and well littered; and feeding him with fcalded bran and warm water.

The following balls are then to be taken for fome time, which have been found extremely efficacious in removing obftinate coughs:

> Take gum ammoniacum, galbanum, and affa fœtida, of each two ounces; fquills, four ounces; cinnabar of antimony, fix ounces; faffron, half an ounce: make the whole into a pafte with honey; and give a ball about the fize of a pullet's egg every morning.

Broken-winded horfes fhould eat fparingly of hay, which, as well as their corn, may be wetted with chamber-lye, or fair water; as this will make them lefs craving after water.

The volatile falts in the urine may render it preferable to water, and may be the reafon why garlic is found fo very efficacious in thefe cafes; two or three cloves given at a time in a feed, or three ounces of garlic bruifed, and boiled in a quart of milk and water, and given every other morning for a fortnight, having been found very ferviceable; for by warming and ftimulating the folids, and diffolving the tenacious juices, which choak up the veffels of the lungs, thefe complaints are greatly relieved.

Careful feeding and moderate exercife has greatly relieved broken-winded horfes; and though for the firft fummer they have not been able to endure much labour, yet many have been found lefs oppreffed the fecond, and fome fcarce perceptibly affected the third; and even able to bear great fatigue: and could a horfe be kept conftantly in the field, and taken up only when ufed, he might, by this management, do good fervice for many years.

But whoever expects to cure his horfe by fending him out to grafs, will find himfelf difappointed, efpecially if he remains abroad after the fpring grafs; for on his return to the ftable and dry meat, he will be more oppreffed and fhort breathed than before, for want of the open air, and the moift food he has been accuftomed to.

Horfes fent to grafs in order to be cured of an obftinate cough, have often returned completely broken-winded, where the pafture has been rich and fucculent, fo that they have had their bellies conftantly full. As the ill confequence therefore is obvious, where you have not the convenience of turning out your horfe for a conftancy, you may foil him for a month or two with young green barley, tares, or any other young herbage.

To purfive, thick winded horfes, Barbadoes and common tar have often been given with fuccefs, to the quantity of two fpoonfuls mixed with the yolk of an egg, diffolved in warm ale, and given fafting two or three times a week, efpecially on thofe days you hunt or travel.

But in order to make all thefe forts of horfes of any real fervice, the grand point is to have a particular regard to their diet, obferving a juft œconomy both in

that

that and their exercise; giving them but a moderate quantity of hay, corn, or water, at a time, and moistening the former to prevent their requiring too much of the latter, and never exercising them but with moderation, as has been before observed.

The following ball may be given once a fortnight or three weeks; and as it operates very gently, and requires no confinement, except the days it is given (when warm meat and water will be necessary) it may be continued for two or three months.

> Take succotrine aloes, six drams; myrrh, galbanum, and ammoniacum, of each two drams; bay berries, half an ounce; oil of amber, a spoonful: make the whole into a ball with a sufficient quantity of syrup of buckthorn. *Bartlet's Farriery, pag.* 68.

BROODING, the act of a hen, or other bird, sitting on a number of eggs, to keep them warm, till they hatch, or produce young ones.

BROOM, the name of a plant, of which two species are natives of this country, called the common and the small broom.

The common broom is the *genista trifolia* of Mr. Ray. It rises about three feet in height, with shrubby stalks, garnished with spear-like leaves, and terminated by loose spikes of yellow flowers, succeeded by short pods, which turn black when ripe, and contain four or five kidney-shaped seeds. It flowers in June or July, and the seeds ripen in autumn. The flowers of this plant are used by the dyers to give a yellow colour; whence it is called dyers broom, green-wood, wood-waxen, or dyers weed.

The small English broom, called also petty-whin, is the *genista spartium minus Anglicum*, of Tournefort. It rises like the former, with a shrubby stalk, but only to the height of about two feet, sending out many slender branches, which are armed with long single spikes, and garnished with very small spear-shaped leaves, placed alternately on every side of the branches. The flowers branch out without spines, short, and have five or six yellow flowers growing in a cluster at the end. They come out in April and May, and are succeeded by short turgid pods, containing four or five small kidney-shaped seeds, which ripen in July. This sort grows naturally upon open heaths, in many parts of England.

The twigs of broom are excellent for thatching barns, &c. being very tough, and of long duration. Ropes also, and those not bad ones, are made of the stringy fibres of this plant, of which the ancients used also to make a kind of flax.

According to Mr. Bradley's calculation, an acre of of broom is worth upwards of six pounds annually, for the feeding of bees only, besides the wythes and stumps, which will pay for the rent of the land. Certain it is, that no flowers are more pleasing, or more profitable to bees, than those of broom.

But considered as a weed, is one of the most pernicious plants that grows upon the land; for its roots penetrate deep, and, at the same time it sheds no leaves, so that it is continually sucking the moisture from the earth. The best method of destroying it, is by burning the land, then ploughing it deep, and manuring it very well with dung and ashes; or by spreading on the land chalk or marle, or manuring it with urine. If the ground be designed for pasture land, it is best to cut the broom close to the ground in May, when the sap is strong in it. By this artifice the roots are destroyed; whereas in the common way of pulling up the young plants, some strings of the roots will be left, and the least of these will grow. Foddering of cattle upon broomy land is one very good way of destroying the broom, their urine killing the roots, and their treading the land makes it less proper for the roots to extend themselves; for broom is seldom seen to grow near old paths. *Bradley's Husbandry, vol.* I. *pag.* 181. *Mortimer's Husbandry, vol.* I. *pag.* 308. *Mills's Husbandry, vol.* III. *pag.* 361.

BROWN, a dusky kind of colour, inclining somewhat towards redness.

A brown horse is not reckoned altogether so beautiful as the bay or chesnut. There are also degrees of this colour, some being light, and others very dark. They have almost always black manes and tails, and often their joints are black, though not so shining as the bays, but rusty. Almost all brown horses grow gradually lighter towards their bellies and flanks, and many are light about their muzzles. The most beautiful are those which happen to be finely dappled, for the plain brown are esteemed more ordinary. Many of them are coarse, but strong and serviceable, fit for draught, for burden, or for war. *Gibson on Horses, vol.* I. *pag.* 46.

BROWN-STOUT, a name given in some parts to strong brown beer, brewed from brown high-dried malt.

BROWSE, branches fit for the food of goats, &c.

BRUISE, a hurt caused by the force of something blunt and heavy.

Horses and other cattle are very subject to bruises from various accidents; but as the blood is no ways affected in these cases, one general method of cure is only necessary; and that is by coolers and repellers, such as white wine vinegar, old verjuice, or compositions made with alum, vitriol, and the like, which should be applied frequently to the swelling, till the heat and inflammation is abated.

BUCK-BEAN, or *Marsh-trefoil*, *trifolium palustre*, a plant with large oval leaves, pointed at each end like those of the garden bean, set three together on long pedicles, which embrace the stalk to some height, and there parting, leave it naked near the top, where issues a short spike of pretty large, reddish, monopetalous flowers, each of which is cut into five segments, hairy on the inside, and followed by an oval seed-vessel. It is perennial, grows wild in marshy places, and flowers in May.

Sheep, when sound and in health, always avoid eating buck-bean; but when the symptoms of the rot begin to attack them, they search for it by instinct, and devour it greedily. Where such sheep are pastured, no buck-bean is to be found, for in a week or two they devour it all. Might it not be prudent, therefore, in husbandmen, who graze large flocks, to cultivate an acre of this plant in some morassy ground, which otherwise would not yield them two shillings the acre? Some might be cut up green, for unsound sheep, and given them with lucern, as occasion requires; and some might be made into hay, and mixed with their fodder. I cannot remember that this advice has been given by any husbandry writer. *Essays in Husbandry, Essay* II. *pag.* 137.

BUCK-WHEAT, the name of a plant generally considered as a species of corn, though not such in fact; nor does it grow like any of the esculent grains. Its leaf, from being roundish at first, takes nearly the shape of that of ivy, but longer pointed, and much softer. Its stalk is round, hollow, and weak, sometimes reddish, but most commonly green, and growing to the height of about two feet and a half. Lateral branches, which shoot out almost at every joint, are terminated by purplish flowers, which are succeeded by small triangular seeds, black on the outside, and white within.

Buck-wheat will thrive in any soil, not excepting even barren sands, as they are commonly termed; but grows largest in dry ground which have been well ploughed. When raised for its grain, a bushel of seed is sufficient for an acre of land, which will frequently yield fifty or sixty bushels: but when it is intended for green fodder, which is the use most commonly made of it here, some people sow three or four bushels on an acre, in order to have a thick crop. The usual time of sowing it is about the beginning of May; but if it be sowed somewhat earlier, and a warm season ensues, it will bear cutting twice in the summer. It comes up soon, and ripens generally, according to M. du Hamel, in one hundred days after sowing, so that buck-wheat sown in June is reaped in September.

When mowed, it must be left in the field several days, that its stalk may dry before it is housed. There is little danger of the seeds falling out, nor is it much injured by wet. These seeds are excellent food for pigeons, poultry, hogs, rabbits, &c. and are found to make horses thrive when given among their oats: but for these they should be first cracked in a mill; being apt, otherwise, to pass through them whole. The flower of

buck-

buck-wheat is very white, and makes a good ſort of pancake, when mixed with a little wheat-flour. The poor in ſome countries make even bread of this mixture; but it is black, bitter, windy, and not nouriſhing. Its ſtraw, or haulm, is alſo given dry to cattle: but the beſt way is to feed it whilſt green, particularly juſt before it bloſſoms. Milch-cows fed with it will yield an extraordinary quantity of milk, remarkably good for making butter and cheeſe: and another advantage attending this paſture is, that it will continue green in the drieſt time of ſummer, when other graſſes are burnt up. It is an excellent dreſſing for land, where ploughed in without being mowed.

The ingenious author of the Eſſays in Huſbandry tells us, that in certain lands of Brabant, called Rempen, the huſbandman raiſes buck-wheat in ſmall fields near home, and places round them, under the hedges, a great number of bee-hives, from whence he draws conſiderable profit; for no plant affords theſe inſects a better ſupply of materials for making honey. *Eſſay* I. *pag.* 110. *Mortimer's Huſbandry*, *vol.* I. *pag.* 136. *Du Hamel's Elements of Agriculture*, *vol.* I. *pag.* 91. *Maiſon's Ruſtiques*, *tom.* I. *pag.* 624.

BUD, that part of the ſeed which firſt begins to ſprout, or rather the leaves which firſt appear.

Bud, alſo ſignifies the ſprout from whence the branch ariſes. Theſe buds in ſome meaſure reſemble ſeeds, as under a number of ſcaly coverings the rudiments of the young branch are ſeen: but neither the lobes nor the young root are met with; becauſe this tender ſtem is connected with a tree, which ſupplies it with the neceſſary food.

Bud is likewiſe uſed in ſome counties of England for a weaned calf of the firſt year; becauſe the horns are then in the bud.

BUDDING. *See the article* Inoculation.

BUGLE, *Middle Compound*, *Sicklewort*, or *Herb Carpenter*, the name of a low weed, with two kinds of ſtalks; round creeping ones, which ſtrike root at the joints; and upright ſquare ones, hairy on two of the oppoſite ſides, alternately, from joint to joint, bearing looſe ſpikes of blue labiated flowers, of which the upper lip is wanting: the leaves are ſomewhat oval, ſoft, ſlightly cut about the edges, and ſet in pairs at the joints. It is a perennial weed, infeſting moiſt meadows and paſture-grounds, and flowers in May.

BUGLOSS, or *Viper's Bugloſs*, the name of a plant whoſe ſtalks are rough, round, ſolid, erect, undivided, and marked with black ſpots: the leaves are very rough, long, narrowing to a point, and placed without any certain order. The flowers are large and ſpacious, of a beautiful blue colour, and grow in long bending ſpikes. They conſiſt of one petal, divided into five roundiſh ſegments, of different ſizes, and reſemble a horn in their figure, expanding by degrees, from a narrow beginning. The flower cup conſiſts of five narrow ſegments, and contains four rough ſeeds.

Bees are very fond of the viper's bugloſs, and there is reaſon to think that this plant, aſſiſted by the culture of a ſkilful gardener, may receive, perhaps, as many improvements as the auricula did. Its branches will riſe to the height of three feet, and no vegetable would better adorn flower-pots in large chimnies; for if the water be changed, it continues blowing near a fortnight after cutting. Its ultra-marine, blue-colour, is the fineſt that can be ſeen, and the ſtalks are garniſhed with flowers from top to bottom; dyers might, perhaps, extract an uſeful tincture from the roots. This plant grows wild in hard braſhy ſoils. *Eſſays in Huſbandry*. *Eſſay* I. *page* 110.

BUILDING. *See the article* Farm-houses.

BULB, or *Bulbous Root*, ſignifies a root of a roundiſh figure, and uſually furniſhed with fibres at its baſe.

Bulbous roots are ſaid to be ſolid, when compoſed of one uniform lump of matter; truncated, when compoſed of a multitude of coats ſurrounding each other; ſquamoſe, when compounded of, or covered with, leſſer flakes; duplicate, when there are only two to each plant; and congerate, when there is a congeries of ſuch roots to each plant.

BULL, the male of the ox kind. *See the article* Ox.

The bull, kept for propagating the ſpecies, ſhould have a quick countenance, his forehead broad and curled, his eyes black and large, his horns large, ſhort, and black, his neck fleſhy, his belly long and large, his hair ſmooth like velvet, his breaſt big, his back ſtrait and flat, his buttocks ſquare, his thighs round, his legs ſtrait, and his joints ſhort; this ſort of bull is the beſt for breed, and makes the beſt ox for draught. *Mortimer's Huſbandry*, *vol.* I. *page*. 226.

The bull chiefly ſerves for propagation; and though he may be ſubject to the yoke, yet there is no being certain of his working quietly, and the uſe he may make of his prodigious ſtrength, is conſtantly to be guarded againſt. This creature is naturally untractable, ſtubborn, and fierce; and in the bulling ſeaſon, abſolutely uncontroulable, and often furious; but, by caſtration, the ſource of theſe turbulent impulſes is deſtroyed, without the leaſt diminution of his ſtrength. He alſo grows larger, more heavy and unwieldly, and becomes more adapted to the labour for which he is deſigned. This operation alſo renders him more tractable, patient, docile, and leſs troubleſome to others. A herd of bulls could not be either tamed or managed by human ſkill. *Buffon's Hiſtoire Naturelle*, *tom.* IV.

BULLEN, hemp ſtalks ſtripped from the bark.

BULLIMONG, or *Bullimony*, a mixture of oats, peaſe, and vetches.

BULLS-FOOT, the ſame with colts-foot. *See* Colts-foot.

BULLWEED, *Great Knapweed*, or *Matfellon*, the name of a perennial weed common among corn: it riſes to about two feet high: the ſtalks are round, ſtreaked, and hoary: the bottom leaves are oblong and undivided, but thoſe which grow on the ſtalk are cut and divided. The flowers reſemble thoſe of the blue-bottle in ſhape, but are of a red colour. The ſeed is ſmall, oblong, reddiſh, and hairy in the upper part.

BUNS, the ſtalks of hemp after the bark is taken off.

BURN-BAKING, or *Burn-beating*, often called *Denſhiring*, or *Devonſhering*, from its being long practiſed in that country, a method of cutting up the turf, and after drying and burning it, the aſhes are ſpread over the ſurface by way of manure.

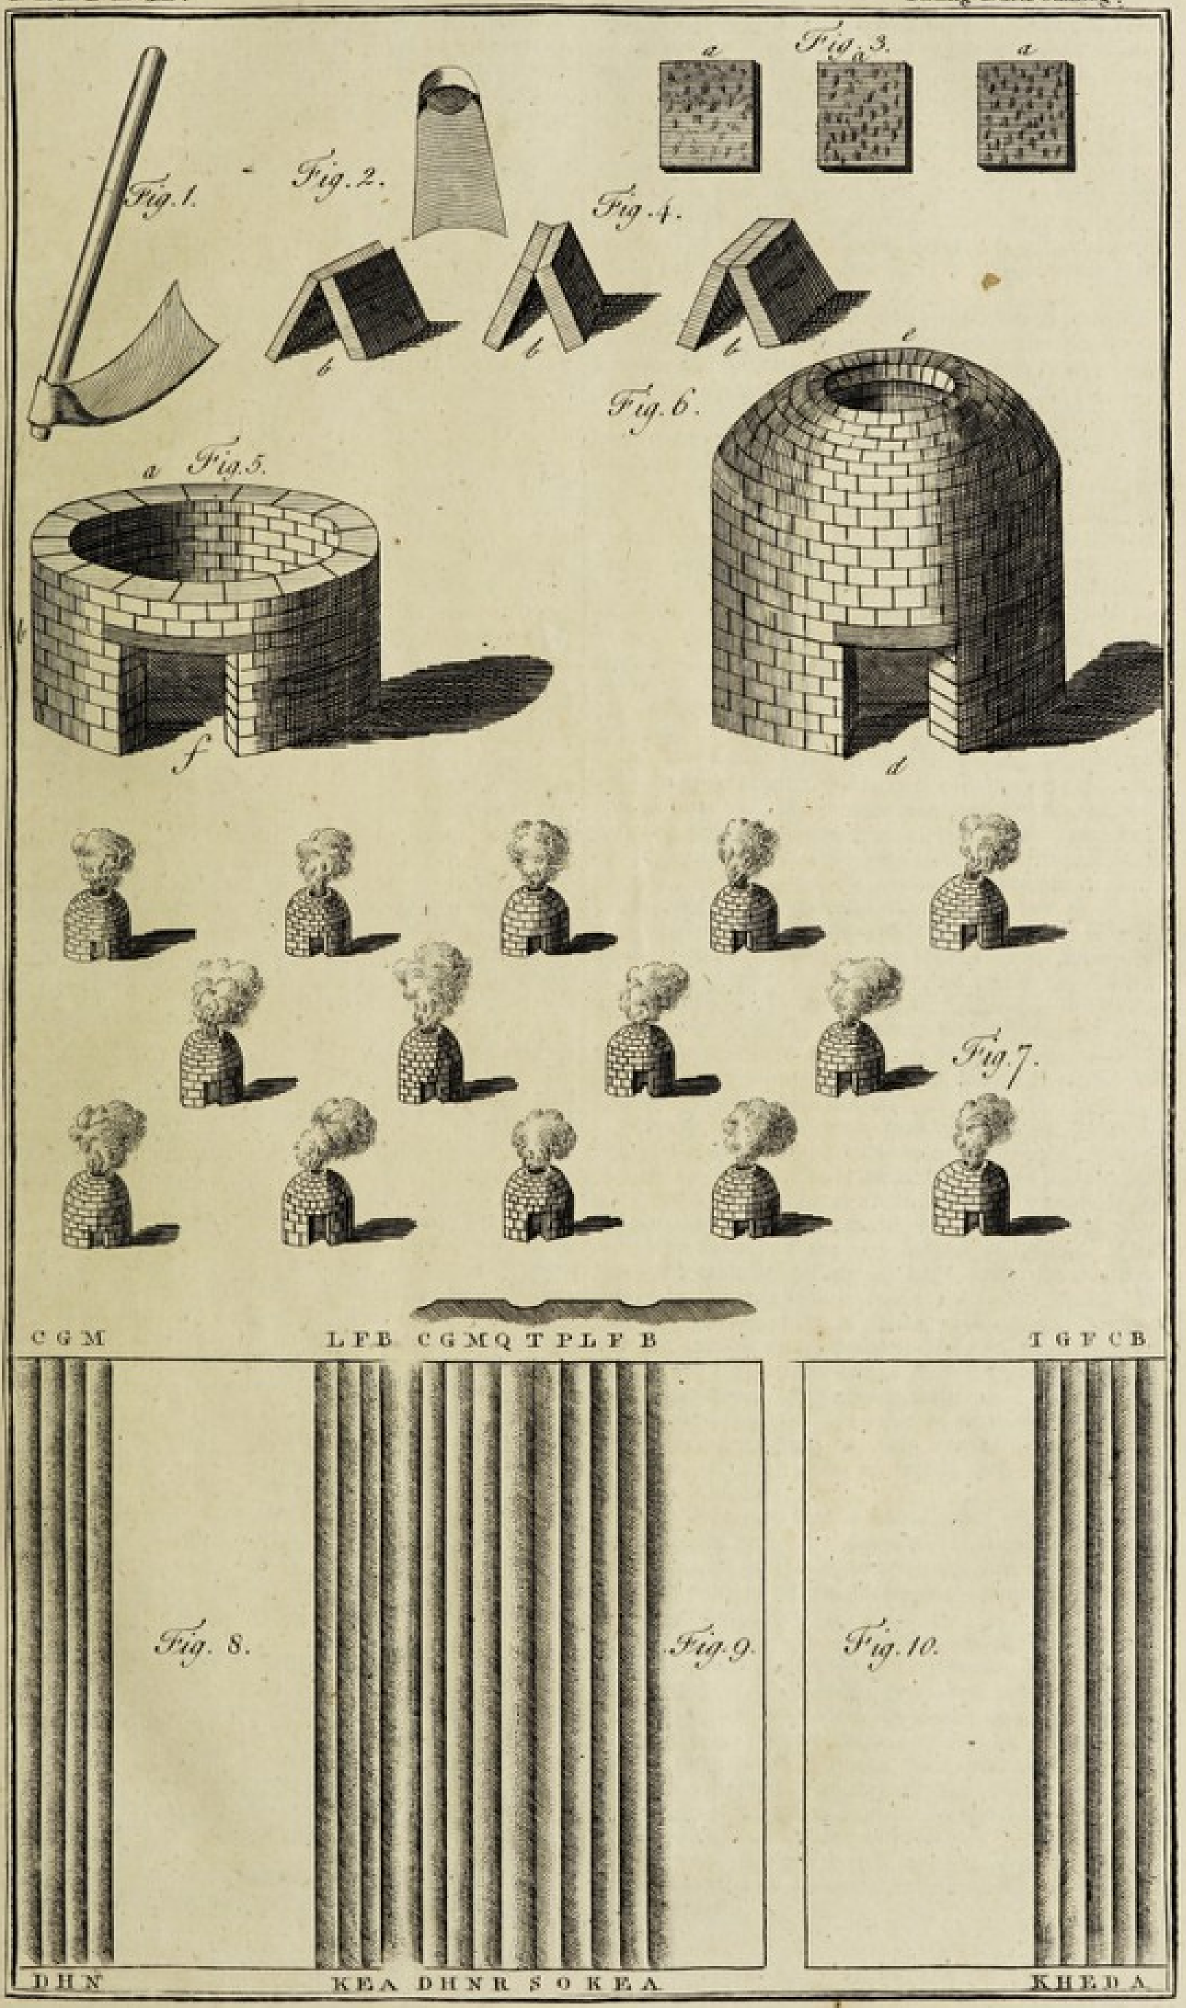
This method of improving land is very ancient, Virgil mentions it, and it has been practiſed time out of mind in Cornwal and Devonſhire. The marquis of Tourbilly has founded his famous treatiſe *Sur les Defrechemens*, publiſhed in 1761, principally on the art of burn-baking. We ſhall here give the ſubſtance of what the marquis has delivered on that intereſting ſubject.

When it is intended to break up any piece of waſte-ground, the nature of it ſhould be firſt conſidered, and may, in a great meaſure, be known from its natural produce, which is generally heath, ruſhes, fern, broom, furze, brambles, &c. intermixed with graſs: for, from the height, thickneſs, and vigour of this wild growth, a proper judgment may be formed with regard to the degree of the goodneſs of the ſoil, and what may reaſonably be expected from it.

When ſuch ground is to be broken up, it will be right to begin in the winter in order to get rid of the three principal obſtacles, namely, water, ſtones, and ſuch large roots as the paring mattock, or beating-axe, as it is called in the weſt of England, may not be ſtrong enough to cut. Afterwards, about the middle of March, the paring of this ground ſhould be begun, by a number of labourers proportioned to the extent of the land intended to be pared.

Every one of theſe labourers muſt be provided with a paring-mattock, or beating-axe, the form of which is repreſented on Plate II. Fig. 1. Towards the edge, where it is ſharpened like an addice, it ſhould be made of well tempered ſteel, and about nine inches wide. From thence the iron part, which ſhould be ſix inches in length, leſſens in breadth towards the handle, as in Fig. 2. where it is reduced to three inches. All the upper part muſt be made of the beſt iron, and ſhould be formed ſomewhat hollow, with a little bending inward. It ſhould be ſtrongeſt in the middle, and of a thickneſs

PLATE II. Facing Burn-baking.



thicknefs proportioned to its fize, as well as to the work, for which it is intended. The hole to receive the handle fhould be two inches in diameter, and the handle fhould be of wood, about three feet long, or a few inches more or lefs, according to the height of the man who ufes it. This inftrument, exclufive of the handle, fhould weigh from ten to twelve pounds, according to the ftrength of the labourer: a lefs weight would not be fufficient for the purpofe.

The ftouteft and moft intelligent labourer muft be then fingled out to lead the reft; for they cannot work in a row as when they dig. This leader ftanding in a proper pofture to manage his beating-axe, muft give two ftrokes with it, cutting into the foil, to the right, two more ftrokes to the left; and afterwards a fourth ftrait before him; by which means he will immediately raife a turf about a foot and a half long, a foot broad, and four inches thick of earth. This turf refting upon the axe as it was cut, is then, with one motion, to be placed on the labourer's right-hand, in its natural pofition, with the mould fide downwards. (See Plate II Fig. 3. where *a*, *a*, *a*, are three turfs as cut from the foil.) All the wild growth upon this land, will, if not very large, come off with the turfs thus cut; and the more there is of it, the better it will be. The turf muft abfolutely be cut with a depth of at leaft four inches of foil: for if the ground be pared to a lefs thicknefs, the work will be badly done; becaufe the beating-axe will not have gone under the netted roots of all the rubbifh growing on the furface, which it is indifpenfibly neceffary to deftroy: otherwife thefe roots will make frefh fhoots, injure the corn, and in time choak it entirely, as has happened to me in the beginning of my undertakings.

The workmen, efpecially if they undertake the work by the acre, would be glad to take this turf off as thin as poffible; becaufe that would fave them a great deal of time and labour. But I have experienced to my coft the imprudence of making fuch bargains. They muft therefore be well watched; for otherwife, befides the inconvenience of not effectually deftroying the wild growth, fuch thin turf would not yield a fufficient quantity of afhes for manuring the land. The bufinefs will indeed go on flower, but practice will foon render the workmen more expert.

Their leader having cut a turf, and placed it on his right-hand fide, muft then advance a fmall ftep, and take off another of the fame fize and thicknefs, which he muft alfo place on the fame fide, in a line with the former, on the further end of which the neareft end of this fhould reft, fo as to incline a little. He is then to proceed ftrait on, laying all the turfs in the fame manner. As foon as he has taken up the two firft turfs, the fecond labourer, ftanding on his left hand fide, is to take up his line of turfs in the fame manner, and place them on his right, in the void fpace cleared by the leader. As thefe advance, each of the other labourers, fucceffively one after the other, muft put himfelf on the left of the preceding, at the fame diftance, and do the fame work, following each other like reapers. Thus, if the firft began at B (Plate II. Fig. 10.) he lays his turfs along the line which terminates the plate; and when he has cut two turfs, the fecond begins at C, and lays his turfs in the fpace BA, cleared by the firft. The third follows the fecond in the fame manner, clearing the fpace FE, and laying his turfs in the fpace CD, cleared by the fecond. The fourth clears the fpace GH, and and the fifth JK, and fo on. The fame muft alfo be underftood of Fig. 8, and 9, which therefore require no further explanation.

When the labourers come to the end of the ground, which will likewife be in progreffive order, the leader muft return to the fide where he firft began, and refume his work clofe to the fpace already pared; the others are to follow in their regular turns, and repeat the fame operations as before; for this work muft always be performed in the fame direction, and not backward and forwards. Such fhould be the method till the whole ground is pared.

If, as it fometimes happens, there be reafon to apprehend that the fods will not dry faft enough when only laid a little flanting, with the end of one juft refting upon the extremity of another; they may in this cafe be piled, as faft as they are cut, in little heaps of three, four, or five together, according to their thicknefs, and the quantity of combuftible or vegetable matter contained in them. The air paffing between thefe fods, which are always laid with the heath or turfy fide uppermoft, penetrates and foon dries them, efpecially if the weather be fultry: but at the fame time it would be wrong to wait till they are quite dry, becaufe they would then burn too much, and too faft; in which cafe their afhes are neither fo good, nor in fo great quantity, as thofe of turf more flowly burnt. A juft medium, which practice will eafily teach, is to be obferved in this refpect.

Sometimes thefe turfs are fet upon their ends, two and two meeting at the top, and being further afunder at the bottom, like the roof of a houfe, with their heathy fides outwards, as reprefented at *b*, *b*, *b*, (Plate II. Fig. 4.) but this method, which lengthens the work, and therefore renders it more expenfive, is fitteft for the turfs of bogs or mafhes, when cut too wet.

With refpect to the roots, which I faid muft be got rid of before any land can be properly broken up, I meant only fuch large roots as the beating-axe cannot cut through, though fharpened with a whet-ftone from time to time, when its edge is either turned or blunted. For with regard to the roots of fmaller fize, fuch as thofe of the dwarf furze, the common heath and young fern, fmall holly, young plants of thorns and junipers, brambles, broom, and other wild productions, which have not attained too great ftrength, will, without much difficulty, be cut and pared off with the turf.

But the ftrong roots of fhrubs, bufhes, &c. which the beating-axe cannot fever, muft remain in the ground, though that will not hinder our taking off the turf between them to a proper thicknefs. The fods thus cut will indeed be often very irregular in length and breadth; but they are the better for burning, as they contain a greater proportion of vegetable matter.

It has been already obferved, that thefe turfs fhould be laid in little heaps as they are cut; thefe fhould be placed in the intermediate fpaces, where the ground has been pared between the roots yet remaining in the earth. Thefe roots fhould be grubbed up with a fpade, pickaxe, &c. without difordering the little piles of fods. It will be fufficient if this work be finifhed before the time of fowing. *See the article* GRUBBING.

Some grub up thefe roots before they burn the turf, and others after, as beft fuits their convenience: but in the latter cafe they fhould certainly be taken up in thofe places where the furnaces are to be made, becaufe it is of great importance not to ftir the heaps of afhes produced by them, till the very inftant of fowing. The holes alfo made by pulling up large roots, fhrubs, &c. fhould be filled up fo as to render the furface even. In countries where wood is fcarce, thefe roots, ftumps, &c. are carried away, and dried for fuel, efpecially for the kitchen; by which means they frequently repay at leaft the expence of grubbing them up. But in places where wood is of fo little value as to render thefe not worth the carrying off, the beft way is to burn them with the turf, the afhes of which they will both increafe and improve.

The thicker any land is covered with thefe wild productions, the better it will prove. If it cofts more than another parcel of ground to break up, and bring it into order, it will, in return, make ample amends, by producing greater crops.

When the feafon is not too wet, the turfs will generally dry fufficiently in about three weeks, even without being turned; but in rainy years they require a longer time, and muft be turned again and again, to prevent their ftriking out new roots and fhoots, which would hinder them from burning, as I have feen happen. Hence it appears, that this method of clearing and breaking up ground requires a longer time, and is attended with more labour and difficulty in rainy than in dry feafons. But as the turfs may be turned by women and children, the additional expence will not be very confiderable.

About Midſummer, or a few days before, when the turfs are ſufficiently dry, a number of women and children ſhould be employed, in fine clear weather, to gather them all up, ſome with iron forks, others with their hands, and pile them up from ſpace to ſpace, in round heaps about ten feet high, and of the ſame width at bottom, almoſt in the ſhape of charcoal furnaces. The heathy ſide of the turf muſt be placed downwards, and the earthy ſide upwards. A ſmall hollow ſhould be left in the inſide, in order to form a kind of chimney, the opening of which ſhould face the wind. *a b* (Plate II. Fig. 5.) repreſents a furnace of this kind partly built, where *f* is the door, or opening into the chimney of the furnace. Fig. 6. is a furnace completed, where *e* is the top of the chimney, and *d* the door. Fig. 7. repreſents a great number of theſe furnaces on fire.

It has been already obſerved, that this work muſt not be ſet about in rainy weather; becauſe if the heaps of turf ſhould unfortunately be ſo much wet as to imbibe the water, they would not burn, but muſt be pulled down and ſpread anew, to dry as before. They might alſo, in this caſe, require very frequent turnings, as has happened to me; which would retard the operation, and increaſe the expence: beſides which, it might not even be poſſible, by frequent turnings, to dry them ſufficiently before autumn, if the rains were frequent, which muſt occaſion a very conſiderable loſs.

However, this laſt accident, though poſſible, is very rare. It never befel me; and by enquiring of thoſe to whom it has happened, I found that it was, in a great meaſure, owing to their own negligence. The beſt method to avoid theſe inconveniencies is, to embrace the advantage of the firſt fine weather, and if it appears at all uncertain, to ſet more hands to work, without aiming at an ill-timed ſaving: for it is upon the due piling up and burning of the turfs, after being properly cut and dried, that the whole ſucceſs of this important branch of huſbandry chiefly depends. It cannot therefore be done too ſpeedily. When rain is apprehended, every other buſineſs ſhould be left for this, and all hands, men, women, and children, ſhould be inſtantly employed, to diſpatch it as ſoon as poſſible. Nothing requires greater diligence. The heaps ſhould be ſet on fire the moment they are finiſhed, or at leaſt, though the weather ſhould ſeem ſettled, before the huſbandman retires in the evening. Children may do this, by putting a little lighted ſtraw or heath, with an iron fork, into the chimnies of the furnaces. The dry heath, graſs, and roots, will catch inſtantly, and in a few moments the fire will become ſo violent, as ſcarcely to be approached. It may then be left, after taking proper precaution to prevent its extending further than it ought; eſpecially if it be near any wood, hedge, or heath, where it might otherwiſe do great miſchief.

The misfortunes occaſioned by fire have been ſo numerous and dreadful, that too much care cannot be taken to guard againſt them. If the ſituation of the land which is to be burned be ſuch as gives the leaſt room to fear any danger of this kind, the furnaces ſhould only be lighted in calm weather; leaſt the wind ſhould ſpread the flames to neighbouring grounds, where it might be impoſſible to ſtop them till they had done irreparable damage.

If it be ſurrounded on all ſides with woods, heath, or other vegetables eaſily ſet on fire, a row of furnaces ſhould, in this caſe, be made around the land to be burned, at the diſtance of twenty-five, or thirty feet from the neighbouring grounds, and at leaſt ten feet from the other furnaces, which are afterwards to be built farther within this incloſure. Care ſhould then be taken to obſerve from which ſide the wind comes, and fire ſhould be ſet to thoſe furnaces that are ſituated fartheſt from the wind, or neareſt to that ſide on which the wind blows. A number of men ſhould watch theſe furnaces while they burn, and ſhovel up earth upon them, if they are ſo full of heath or combuſtible matter as to occaſion too violent a flame.

The throwing on of this earth will deaden the flames, and concentrate the fire; by which means the furnaces will be conſumed by ſlow degrees, without hurting either the outward borders of the pared land, or its inner parts, where this fire might do miſchief two ways; firſt by ſpreading to, and burning the yet unpiled turfs, the aſhes of which would ſoon loſe their virtue, if ſcattered upon the ſoil in this looſe manner; and ſecondly, by catching the other furnaces, in caſe they ſhould be already made; by which means the fire would ſoon become ſo great, that it would be no longer poſſible to ſtop its progreſs, or prevent its extending to the neighbouring grounds.

When the firſt row of furnaces is thus conſumed, the next row may be burnt in the ſame manner, and ſo on till the whole is finiſhed.

The morning is doubtleſs the moſt proper time for lighting all theſe furnaces, becauſe the people employed in buſineſs have then the whole day before them, to watch the fire, and prevent accidents, which it might be very difficult to remedy in the night, particularly during the firſt violence of the flames. A number of proper perſons proportioned to the extent of the ground, ſhould remain upon the ſpot all night, as well to attend the burning of the turf, as to hinder wicked wretches from ſetting fire to other places, of which there have been too many inſtances.

By not neglecting any of theſe precautions, though all of them are not neceſſary where the fire cannot ſpread to adjacent grounds, every inconvenience may certainly be avoided.

If it ſhould be found neceſſary to light the furnaces in the evening, though as I have juſt obſerved, the morning is a much fitter time for it, they muſt be ſuffered to continue burning till the next day, when the violence of the fire will be abated. A few men, or even women and children, ſhould be then ſent in among the heaps, with iron forks, to give them a little ſtirring, and lay upon them the turf which may have fallen down. Theſe furnaces will ſtill continue burning for ſome days, during which the turfs will be ſlowly conſumed or calcined. If any of them ſhould be ſituated on wet ſpots, where they will not burn, theſe women and children muſt mend them, and add freſh fuel, ſuch as dry heath, ſtubble, or even a little dry wood, with ſome of the burning turfs from the adjacent furnaces. As ſoon as the fire is extinguiſhed in all the heaps, which will be then reduced to heaps of aſhes, finer or coarſer in proportion to the goodneſs of the ſoil, the women and children muſt ſhovel them up into little round heaps, leſt they ſhould loſe their fertilizing quality, if left in the manner they fell in the burning: for all our treaſure conſiſts in the ſalts contained in theſe little heaps, and the volatile parts of thoſe ſalts, which are much the beſt, would ſoon fly off, if expoſed to the air. The dews at night, and the firſt rain which falls upon thoſe heaps of aſhes, form on their ſurface a cruſt, which hinders their being blown away by the wind, renders them impenetrable to the action of the air, and keeps in all their virtue: the ſooner therefore rain falls after this operation, the better. Nor would it be any injury if it ſhould rain as ſoon as the furnaces are thoroughly lighted, unleſs it ſhould be very violent indeed, and of long continuance, which rarely happens at this ſeaſon.

When the aſhes are thus laid up in little heaps, nothing more remains to be done to this ground till the time of ſowing; care indeed muſt be taken, that neither men nor cattle approach them ſo as to break their cruſt. The land will from hence be freed from all ſeeds of weeds, and other wild productions, as well as from all worms, inſects, reptiles, and venomous creatures; the action of the fire of the furnaces being ſo ſtrong, that it heats not only the earth, beneath them, to the depth of ſeveral inches, but likewiſe all the intermediate ſoil.

A fortnight after the uſual ſeed-time of the country, for wheat and rye, will be early enough to ſow this burnt ground. When that is to be done, a number of women and children ſhould be ſent into the field, on a ſtill, calm day, with wooden ſhovels, to ſpread the aſhes equally over all the ground, excepting the ſpots where the furnaces were; for theſe are ſo thoroughly burnt, that they want no farther manure, and are always obſerved to produce the fineſt corn. Some of theſe women and children ſhould alſo carry iron forks, to break and ſpread ſuch turfs as may not have been thoroughly conſumed;

consumed; for these having been baked or calcined by the action of the fire, will be very beneficial to the land.

Immediately after the ashes are spread, the corn, whether wheat or rye, should be sown over those ashes by a skilful sower, in not more than about half the quantity generally used for a similar extent of other ground. The ploughman should follow the sower, with his team, either of horses or oxen, yoked to a strong plough, having two fins to the share. *See the article* PLOUGH. He should not, however, cut too deep this first year, but make only shallow furrows, going and returning, to cover the seed. Women and children, with hoes and iron forks, should then be employed to break carefully all the clods, together with every remaining bit of turf; and finally to close the tops of the ridges, which the plough cannot do with the necessary exactness in this ploughing. If several ploughs work at the same time, as is generally the case with many, the number of women and children must be increased in proportion, and there must be a sower before each plough.

It is very difficult to sow these lands with half the quantity of seed generally used in other places. The most dexterous are apt to mistake, and I have experienced the bad effects of employing only one sower for several ploughs. A man who goes before each of them will sow much more equally: nor need he even lose any of his time, because when he is not employed in sowing, he may help the women and children to break the clods. The ploughman should always proceed slowly and cautiously in this first tillage, especially if the ground seems never to have been ploughed before. If his plough should chance to be stopped by any stones or roots, which may have escaped the endeavours used to discover them by means of the borer (which should be always had recourse to as soon as the surface of the ground is cleared) the other men within call, or even the wo- and children, must immediately take them up with crows, and pick-axes, and carry them out of the field.

Care must also be taken not to spread the ashes out of the heaps over more ground than can be sown in the same day and the next morning, that they may not be unnecessarily exposed to the hazard of losing their efficacy: but if it should begin to rain, or the succeeding day be a Sunday, no more ashes should be spread than can be sowed and ploughed immediately. These two circumstances excepted, it would be right to spread over night what is to be ploughed in next morning; for I have experienced, that the little nipping frosts in this advanced season, will often be strong enough to freeze the ashes and bits of turf not thoroughly consumed, so as to render them unfit for spreading, till the sun has thawed them; by which means a morning's work might, without this precaution, be lost.

When the seed is sown and covered, drains should be cut with the same plough, either directly across the furrows, or in an oblique direction to them, according as the declivity of the ground may require, in such manner that they may empty themselves into the main surrounding ditches, to carry off the water, especially in the winter. Some of the men employed in breaking the clods will easily deepen these drains, to whatever degree you may think proper, with an instrument shaped like a hoe, with a strong flat iron spike, about fifteen or sixteen inches long, on each side of it. This instrument is very useful, and even necessary, upon several occasions; nor is there any better for stirring the ground. It will likewise serve to complete the breaking up of such parts of the spots where the furnaces stood, as may not have been sufficiently cut by the plough; and to finish the imperfect ends of the furrows, next the head-lands, where the plough could not reach, and where the grain would be otherwise exposed to the air and birds.

Though the spirit and warmth of the salts contained in the ashes, will soon render this corn more forward than any other; yet as there will not be among it either grass weeds, or wild productions of any kind, the seeds of all these having been destroyed by the action of the fire, it will appear thin during part of the winter: but on the approach of spring, it will shoot up, spread, and tiller, so as often to become too thick at last. It always ripens about a fortnight sooner than any other corn in the country; and the finest, as already observed, is constantly found on the spots where the furnaces were erected; the effect of the fire having been greater, and penetrated deeper in those than in any other places.

As all our riches, as before observed, consist in the ashes, the more there is of them, the more the ground thus broken up will be fertilized. But all kinds of soil do not afford an equal quantity of ashes when burnt; for though the burning be performed with ever so much care, repeated experience for some time past, has taught me, that only some of the earth and stones, according to their quality, are reduced into lime, or calcined, by the operation of the fire, and that other parts of them will run into glass. The soils that calcine most are undoubtedly best, and yield the largest produce of ashes; while those, on the contrary, which burn to a glassy substance, are the worst, and give the fewest ashes. Of this kind is sand; and indeed, we may judge with certainty of any soil intended to be improved by burn-baking, by previously making trials on different parts of it. If the owner cannot go thither himself, he may order some of the turfs, cut with a depth of four or five inches of earth, to be brought to him, in order to their being dried and burnt. He may also have, in the same manner, in bags of paper, properly numbered, samples of the soil, or of the stones underneath, at every six inches from the surface, to the depth of eight or ten feet. These samples may be easily procured by means of the borer, already described under that article.

If the person who makes these trials be not provided with a borer, holes may be dug. They will not cost much, and he will be thereby enabled to judge what grain, trees, or other productions, each soil is best adapted to. I have often practised this method with success, for improvements which lay at such a distance that I could not immediately inspect them myself: but as the judging of lands in this manner, without actually inspecting them, requires great attention and long practice, the surest method therefore is to examine them on the spot, and there make the necessary experiments. The furnaces which are the most burnt, or those which burn the fastest, are not the best; for the ashes are there too much calcined, and their quantity reduced.

I have often seen much finer corn grow in places where the uppermost turfs of the heaps, which had burnt slowly, were only calcined, and remained so nearly entire, that it was necessary to break them before the ground could be sowed, than in those place where the furnaces, after being entirely burnt, were totally converted into ashes. In general, those heaps which produce white ashes, after they are burnt, are the least valuable, and commonly yield the smallest quantity. This denotes a greater degree of vitrification than of calcination. In proportion as the ashes are yellowish, brown, or blackish, which last indicates the greatest perfection, they are better in quality, and generally more in quantity. According as these different colours appear, the calcination exceeds the vitrification. I have dwelt the longer upon these different operations of the fire in the burning of land, because they are of great importance to those who break up ground in this manner, and no writers have hitherto given a sufficiently distinct account of them, for want of having had the necessary experience.

I must farther observe, that no land ought to be pared again too soon after it has been burnt; because its turf being destitute of a proper covering, would not take fire well, as I have experienced. It will be necessary to wait till the heath or broom has shot up sufficiently, which seldom happens in less than about two years. The dangerous practice of some country people, who frequently set fire to their heaths in the spring, under pretence of bringing up grass for cattle, is so contrary to the right method of improving land, by burn-baking, that it always retards, and sometimes absolutely prevents the executing of this far more beneficial method; especially if those burnings have been too often repeated.

In countries where it is not the custom to plough in ridges, but either in broad lands, or quite flat, in order to sow afterwards with the harrow, I think it would, however,

however, be right, to sow the ground thus broken up, at least the first year, under furrow, with the two-finned plough already mentioned; after which the usual method of the country may be followed, if it be found the most proper. I advise this as the best practice, and am satisfied that none will have cause to repent the trial. It will save the greater part of the expence of ploughing; and the ashes being less exposed to the action of the air, will the more strongly retain their fertilizing power. But, if, notwithstanding these reasons, the common practice of the country should be still preferred, even in the first year, the husbandman, in this case, should begin to spread his ashes in the manner before directed, about Midsummer; as soon as the furnaces are cooled, without leaving any in the places where those furnaces stood. Immediately after, a slight ploughing, just sufficient to bury the ashes, should be given, with the precautions before-mentioned with regard to the furrows. No more ashes should be spread at any one time, than the plough can cover in the same day. A few days after this first slight ploughing, a second should be given, somewhat deeper, in the same direction; and these ploughings should be continued, each going a little deeper than the former, till the ground be loosened to a sufficient depth. Two good cross ploughings will then be of excellent service: after which a fifth ploughing a-cross them, will bring them up to the direction they were in at first. The ground should be harrowed several times between all these ploughings, with harrows heavy in proportion to the strength of the soil; and if any hard clods have resisted the force of the harrow, women and children should be employed to break them, it being necessary to pulverize the soil as much as possible. I say as much as possible, because that cannot be perfectly compleated this first year. Perhaps the spiky roller would be of excellent service here.

The same women and children will also clear away all the stones, if there be occasion. As each successive ploughing will turn the stones upon the surface; but such only as are bigger than a man's fist need be removed. If any of the stones should be too large for the women and children to remove, the carters must take them up as they pass by; and if there should chance to be any under ground so large that the men cannot move or load them, they must be broke with sledge-hammers, and other iron tools proper for this work: or, if they are great rocks, they must be blown up with gun-powder; for nothing should stop the progress of this undertaking.

The time to sow the land thus broken up for the first time, will always be a fortnight later than the common time of sowing other lands in the same country, with the same kind of grain. A few days before this is sowed, it should have another light ploughing; after which it should be sowed, in proper weather, with half the usual quantity of seed, whether wheat or rye, and this seed should be covered, in either with the plough, or with the harrow. Drains should also be cut in this land, in the manner directed under that article, as soon as possible, to carry off the water in the winter. If any very large clods are left on the ground, women and children should be employed to break them. This land being thus sowed, nothing more need be done to it till harvest.

The quality of the land must determine what sort of grain will be most proper for the first year's sowing in this husbandry. If the soil be rich, it will bear wheat; if of a middling quality, it will produce meslin, or a mixture of rye and wheat, consisting of a greater or lesser proportion of either, according to the nature of the ground; and if it inclines to poorness, it will produce rye. These particulars may be judged of immediately after the burning. In general, unless the soil be very excellent, I would always advise the sowing of rye the first year. There will be a certainty of success with that grain; and the husbandman will be enabled by its produce, and by the ploughings, to judge what his land will be capable of doing the next year, without running any hazard. This has been my method. I have also experienced, that rye does much better than wheat in all light sandy soils thus broken up. When they are afterwards enriched to a certain degree, they become fit to bear meslin, and then wheat: though if they should never produce any thing but rye, the difference would not be great in point of profit.

As soon as the ground is cleared, a light ploughing should be given it, to bury the stubble; and some days after it should have a second ploughing somewhat deeper, but in the same direction. When this is done, two good cross-ploughings should cut the soil to the proper depth for sowing; and a fifth ploughing, afterwards to be given, will leave the furrows in their first direction. Between these five ploughings, which are to be performed with the plough having only one fin to the share, the ground should be well harrowed several times, and the stones and roots picked out. All these ploughings and harrowings will pulverize the earth, and mix it equally with the ashes. If this land is to remain in ridges, the above will be sufficient till the sixth ploughing, which should be given it a few days before the sowing, and should be followed by the last, performed with the two-finned plough to bury the seed: but if it be to be sowed in broad lands, or quite flat, the former directions in that respect are to be observed here. In whatever manner any of these new grounds, broken up with the plough, are sown, they will not require near so many hands to break the clods this second year, as were necessary in the first. With regard to the quantity of seed, a little more may be sown now, that is, about a third part less than is commonly used in the country, of the same kind of grain, for an equal extent of land.

The lands thus brought into tillage by means of burning, become infinitely better than other grounds, and produce much greater crops. This process improves the soil for upwards of twenty years. No weeds will spring up among the corn for a considerable time; for there are scarcely any, even now, in the lands I first broke up. The vegetable food in the earth is not therefore wasted here upon useless plants, but serves intirely to nourish the corn, which accordingly shoots with redoubled vigour, produces well-filled ears, without the trouble and expence of weeding it; and, when threshed, is so clean, that it needs only to be winnowed. The bread made of it is excellent, and of a superior quality. When in process of time these burnt-lands shall produce as many weeds as other ploughed grounds, they will then be in the same degree of imperfection; but it will be a long while before that happens; even longer than I can say; for I have not yet seen an instance of it. The remedy, however, is always sure and ready, namely, to let them rest two or three years, by which time they will have acquired a new sward, thick enough to be pared off, and burnt as before. This will restore them to their former perfection, without being near so expensive as the first paring and burning: for there will be no roots to grub up here, nor any stones to carry off; nor will it be so difficult to break the now much fewer clods. I have managed in this manner with great success, where there has been a sufficient depth of mould, lands which had formerly been in tillage, and would no longer produce corn because they were exhausted, either by two many successive crops, or too great quantities of weeds. They are now as good as any other burned land.

Worn-out meadows, which I have restored by the same means, and formed a-new with grass-seeds, have yielded great quantities of excellent hay. I have collected plenty of this seed during some of the preceding years, from meadows which were not too wet. Several of my neighbours have practised the same method with equal success: and, in a word, it is the most powerful restorative for worn-out land.

From what has been said, it evidently follows, that the paring and burning of the surface of the earth, is, indisputably, the best and surest way, either to clear, or restore the soil. It is making a most advantageous acquisition to one's own estate, the value of which is at least doubled, and oftentimes quadrupled by this means. To enrich one's self, without doing it at the expence of any person whatever, and, at the same time, to enrich the state, is surely an action worthy of a true patriot, and of a respectable father of a family. This may be done by following the method here laid down; a method which has been long known, though very superficially. I will venture to say, that it never was carried to the degree of perfection to which my practice has brought it; doubtless because none applied themselves particularly to it. *Memoire sur les Defrichemens.*

A correspondent of the editors of the *Museum Rusticum* has given us the following method of performing this operation in the fens of Bedfordshire.

Rocque's Burnet.
Bent Grass.
J. Hulett sculp.

About the middle of May, says this gentleman, we plough the land for burning, which is sward-land, that has not been ploughed for four or five years, or perhaps a longer time: our ploughs are what are called Dutch ploughs, with a large share; the edge and point are very thin and sharp, and are kept so by filing: the furrows should not be more than seven or eight inches wide, and an inch and a half thick, having as few baulks as possible. When it has lain so long that the sods or furrows are dry (in which the farmer's own discretion must guide him, it being impossible to point that out by words) it must be made into heaps about the size of middling grass-cocks, each person carrying on before him as heaps about seven furrows: the work will then direct him how big the heaps should be; they should be made as narrow at top as conveniently they can, by way of prevention against wet weather. If every person keeps his work as to the number of furrows, the heaps will rise in regular rows; but it should be observed to keep these rows in quincunx order (as represented on Plate II. Fig. 7.) that when you come to spread the ashes, they may cover the ground regularly.

When it is fit for heaping, the customary way of this country is to let the burning out to people, to burn and spread the ashes, which must be spread so as to cover the ground all over: the usual price is from four to five shillings per acre; but that, in a great measure, depends upon the dryness or wetness of the season. It would, however, I think, be most adviseable, where hands are plenty, to do this work by the day, as you may then employ as many persons as you think fit; for it should be burnt off with all possible expedition, because if it be long in burning, it is attended with bad consequence, which in rainy weather is hard to prevent: it is therefore very requisite to pursue the work briskly, otherwise the grass-roots, which lie below the reach of the plough, when ploughed for burning, will shoot out, and become almost as full of grass, as though it had not been ploughed at all: then, when you plough it after the burning, instead of breaking so that the seed may fall into the cracks, it will burn up as strait as clay, and then no seed can grow any where but in the seams between each furrow.

When one side of the field is cleared, and the ashes spread, you must, as soon as there is room, get to ploughing and sowing the seed. Nor must the furrows now be wider than those already mentioned, and about two inches deep; for as fen-land in general ploughs tough, rather than breaks, you will have more seams than if the furrows were made wider: the custom with us is to sow the seed as soon as possible after the land is ploughed. *Museum Rusticum, vol. i. p.* 420.

BURNET, the English name of a plant, now greatly cultivated as a green food for cattle in the winter. We have given a figure of this plant taken from a specimen gathered in a field belonging to Mr. Rocque at Walham-green, on Plate III. Fig. 12.

It is very natural to think that we have in England many sorts of grasses, which are well adapted to the climate, are wholesome food for cattle, and, with the assistance of proper culture, would produce very advantageous crops both to the grazier and farmer. We have, for many years, been sensible of the great advantages that result from the culture of saintfoin: in some soils lucern has been sown with considerable profit, and the Dutch trefoil is known to be excellent, when properly managed: but these only serve for green fodder in summer: they may, indeed, be dried, and made into hay, and in that form be reserved for the cattle's food in winter; but this, independent of the inconvenience, trouble, and uncertainty, that attend the making and keeping it in proper order, is not sufficient; the farmer has also occasion for green fodder in the winter, and early in the spring, and that on many accounts, particularly for feeding such of his ewes as will yean early in the year, as well as keeping them from losing their flesh after they have dropped their lambs.

A plant therefore which will not only live through the winter, but will also, if possible, vegetate in that season, cannot fail of being highly advantageous, provided it be at the same time a pleasing and nourishing food for cattle. All these properties have been lately found in burnet; it not only preserves its verdure during the hardest frosts of our winters, but also increases in bulk, and grows, if the weather be at all open and mild; and is now known to be an excellent food for cattle. This discovery is owing to Mr. Rocque, of Walham-green, who, at the request of the late Mr. Wyche, spent some years in endeavouring to find a plant that would prove an useful and succulent food for cattle during the winter; and, at last, fortunately discovered that burnet would answer the intention.

Mr. Rocque has also found by experience, that it will grow in the driest land: for he has planted some of it even in the gravel walks in his garden, where every thing else is burnt up in the summer, but this never withers; one of the qualities of burnet being to continue in sap all the year. It is the opinion of many, who have seen the burnet of his raising, that if this plant is generally cultivated, there will never be a scarcity of hay in England, even in the greatest drought.

The land, on which it is sown, should be fine, because it is apt to shed, and it should afterwards be dried perfectly.

Burnet does not lose its leaves in drying; and though the hay made of it be sticky, it will, after threshing, be very agreeable to horses, which are so fond of it, that they never waste any. One acre will produce upwards of three loads of hay, and above forty bushels of seeds. Horses are fonder of this seed, than they are of oats: and Mr. Rocque is of opinion, that it is a more proper food for those who do not labour hard, because it is not of so hot a nature. Burnet bears seed twice a year, and will afterwards yield a good spring crop.

It is not only good for horses, but also for all manner of cattle; even for swine: and Mr. Rocque has experienced another virtue in it, which is, that, being stung by a wasp, the leaves of this plant rubbed pretty hard upon the part so injured, immediately took off the inflammation.

If the burnet does not grow equally every where, some plants must be drawn where they are too thick, and planted where they are thinnest: or the vacant spaces may be supplied from the nursery. If the land was not got in good order to sow the seeds at a proper season, the burnet may be transplanted at Michaelmas from this nursery, and set at nine or twelve inches distance every way, according to the richness of the soil.

The seed sown in May may be mowed at the latter end of July. That sown in June will yield a pretty good crop, and must be cut but once; and the same of that which is sown in July. The plants produced by seeds sown in August should be mowed, to destroy the weeds. These mowings may either be given green to horses, or made into hay. The first spring cutting will purge horses; and Mr. Rocque believes it will also cure the grease: but it is only the first crop that purges.

Burnet should be mowed but once the first year, in order to leave it rank in the winter; and in this case it will be ready to feed in February or March, or to mow again in April.

If natural grass grows among the burnet, it may be harrowed in the same manner as lucern; for having a tap-root, the harrow will not hurt it: but it must not be ploughed, lest the roots should be broken in the ground.

When the seeds of this plant are to be saved, it must neither be fed, nor mowed, in the spring. The seed will be ripe about the middle of June, when it must be reaped like wheat, and threshed on a cloth. It should be threshed before it is too dry, because it is apt to shed, and it should afterwards be perfectly dried.

As a great deal has been written on the subject of burnet, we shall endeavour to set the whole in a fair light, by adding two letters which have been sent from gentlemen of known character and reputation, to Dr. Templeman, secretary to the Society of Arts, Manufactures, and Commerce. The first is from Davies Lambe, Esq; and was sent in consequence of a letter sent that gentleman by a member of the society, requesting his opinion with regard to the usefulness of burnet.

"My burnet, says Mr. Lambe, though very green and beautiful all the winter, made no great progress till the middle of April following, when I thought it absolutely necessary to feed it. I did so, but I did it too late, and kept my cattle upon it too long, from the middle of April to the 20th of May. This was a very great mistake; the burnet plants were now headed for seed, and the stock chiefly fed upon the heads, which greatly lessened my quantity of seed, as well as retarded the growth of the plants. I turned into the field, ewes, lambs, and calves, and they all fed very greedily upon the burnet. From what I had heard of M. Rocque, I very much expected them to scour, but there was not the least appearance of it, and the cattle throve accordingly.

The 6th of July I began to mow, the weather being favourable; six men and four boys threshed and cleaned the seed in seven days. I had 200 bushels of very fine clean seed, as many sacks of chaff, and seven loads of hay, from a field of seven acres and a quarter.

Satisfied that 200 bushels of seed would be more than I should be able to dispose of, I was not anxious after another crop, being rather desirous of seeing what it would perform as a pasture. Accordingly, in about ten or twelve days after the field was cleared, I turned into it seven cows, two calves, and two horses; they all throve very remarkably, and the cows gave more, and we thought a richer milk than in any other pasture; I really expected, (as burnet is so strong an aromatic) that the milk would have had a particular taste; but far otherwise: the milk, cream, and butter, were as fine, if not finer tasted, than any from the best meadows. I am satisfied, that there is no better pasture for cows, whether milch or barren, than burnet. The weather was now extremely droughty, all our pastures were burnt up, yet the burnet flourished, and grew away, as if it had a shower every week. My stock of cows, horses, and calves before-mentioned, pastured in it almost continually, till Michaelmas; by the middle of November it was grown so considerably, that I have again turned in six head of cattle, and if the weather is not severe, I am of opinion, it will maintain them till Christmas.

The burnet-straw, or haum, is, after the seed is separated from it, a very useful fodder for horses, cows, calves, and sheep; the chaff is of good value, if mixed with any other, however ordinary, chaff. I have fed all the above-mentioned stock with it promiscuously together in one field; putting the haum into racks, and the chaff into troughs, and if the haum was chopped with an engine, it would still be of much more value.

Burnet, I am fully persuaded, will prove a very great acquisition to husbandry on many accounts, but more particularly for the following reasons:

Burnet is a good winter pasture, consequently it will be of great service to the farmer as a constant crop he may depend upon, and that without any expence for seed or tillage, after the first sowing; whereas turneps are precarious and expensive, and when they fail, as particularly this year, the farmer is very often put to great inconveniencies to keep his stock.

It affords both corn and hay too. Burnet-seed is said to be as good as oats for horses. I know they will eat it very well; judge then the value of an acre of land, which gives you at two mowings ten quarters of corn and three loads of hay.

The seed indeed is too valuable to be put to that use at present; though it multiplies so fast, that I doubt not but in a few years the horses will be fed with it.

It will bear pasturing with sheep.

It makes good butter.

It never blows or hoves cattle.

It will flourish upon poor light sandy, stoney, shaltery, or chaulky land.

Burnet, after the first year, will weed itself, and be kept clean at little or no expence.

The cultivation of burnet is neither hazardous nor expensive: if the land is prepared as is generally done for a crop of turneps, there is no danger of any miscarriage; and any person may be supplied with the best seed at sixpence per pound, by Mr. Charles Thorp, seedsman, in the White-Hart-Inn-yard, Borough.

I make no doubt but that burnet might be sown late in the spring, with oats or barley. A gentleman in my neighbourhood did so last summer, and it succeeded very well. I should think a buck-wheat season, which is sown the last of all corn, would suit it very well; but of this I have no experience, and could wish to have the experiment tried. A pea-field, drilled in rows, and kept clean, would make an excellent season for burnet, as the pea crop would come off soon enough to prepare the land with two ploughings by the middle of August, after which time I should not chuse to sow it.

It very frequently happens, that every farmer who sows many acres with turneps, has several worth little or nothing; the fly, the dolphin, the black caterpillar, the dry weather, or some unknown cause, often defeating the industry and expence of the most skilful farmer. When this happens, as it too often does, I would by all means advise him to sow it with burnet, and in March and April following, he will have a fine pasture for his sheep and lambs.

Burnet is a native of England, and will certainly perfect its seed twice in one summer; and a farmer, with a small plantation, may supply himself with seed of his own growth at very little or no expence: he may then be encouraged to make experiments on various seasons, without much loss or damage.

Thus, Sir, I have sent you a true account of the success of my burnet, and also my opinion of it. I wish what I have said may any ways contribute to dispel the prejudice, or inform the ignorance of my countrymen."

The other letter is from Christopher Baldwin, Esq; of Battersea, a gentleman well known, and justly respected for his candor and fidelity.

"In the years 1763 and 1764, says Mr. Baldwin, I made several experiments on burnet, with a view to make myself acquainted with its manner of vegetating, and the uses to which it might be applied: and having by this means acquired that knowledge I was desirous of attaining, I determined last year to lay down several acres with burnet; nor would I content myself with doing it in any one particular method: therefore in the beginning of July, 1764, I sowed about eight rod of ground with five pounds of Rocque's burnet seed. Rain falling soon after the seed was sown, the plants came up very finely, and throve in such a manner, that I was tempted to plough up about an acre of ground and plant it that autumn, in order to see what effect the winter would have on the young plants. Accordingly on the fourth of October I planted them in rows, about twenty inches apart, and about fifteen inches from each other in the rows. This distance, from experiments and observations which I have made, seems to me a very proper distance. These plants took very well, and through the winter throve with surprising vigour. Last spring I ploughed the remainder of the field, being three acres, and planted it in the same manner with my plants, the whole of which, notwithstanding the uncommon drought of last summer, grew well, and the verdure of the plants was really very beautiful. No water was used; indeed it would have been a vast work in a field of that size: however, I never saw any need of it. The plants were once hoed, and stood over for seed, of which the quantity collected was not very great; but this must be attributed to the uncommon drought, for I think we had not above one shower of rain from the planting to the gathering of the seed, the whole of which amounted to about 160 pounds.

The seed being got, I was impatient to see how the cattle would take to it, as it was roundly asserted by some gentlemen, that no cattle would eat it. Accordingly I ordered four cows and two horses to be turned into the field; the cows fed freely upon it, but the horses did not seem to like it so much at first, though in two or three days they fed well upon it. Burnet has strongly the taste of cucumbers, and I was fearful it might give a disagreeable taste to the milk; it therefore gave me great pleasure to find, in about four or five days, that the quantity of milk was not only much increased, but the flavour of the cream much superior to any I had ever had before, or ever tasted from cows fed upon the richest meadows. The cows and horses having fed down the field, it was hoed again, and then harrowed once over, which laid it very clean, nor could I find that the burnet was at all hurt by the harrow.

Here let me observe to you, that I fed my horses in the stables for about five weeks with the burnet straw, or rather haum, from which the seed had been threshed. These horses fed very freely, and throve much upon it, though

though they had only half their uſual allowance of oats. However, as I would by no means ſecrete any circumſtance that may appear unfavourable to burnet, ſo I muſt tell you that I obſerved, when any friend called upon me, and their horſes were put into the ſtable, that ſome horſes eat very greedily of it, and others would not touch it. I cannot ſay this gave me much concern. I ſatisfied myſelf with thinking, that ſome horſes did not know what was good for them; or to ſpeak more ſeriouſly, I thought the novelty of the food might as much diſpleaſe one horſe, as it pleaſed another; and doctor Templeman knows, that there are ſome things which we loath as children, that we are fond of as men; and that there are ſome things which we as much diſlike as men that are very wholeſome food: but to come nearer to the point. It is well known ſome ſheep and cows will not touch a turnep, yet is any one weak enough to infer from thence, that turneps are an unwholeſome or an improper food for cattle? And I was lately told by a particular friend, that he had often obſerved, when his horſes had fed for ſome time on the ſaintfoin hay, that it was ſome days before they would again take to meadow hay. I ſhould not have mentioned this circumſtance of the horſes, but to ſhew my impartiality; and I do it the more readily, as I find there are ſome gentlemen who are as fond of decrying, as others can be of promoting, uſeful experiments in agriculture.

Being well pleaſed with the ſucceſs that had attended my firſt experiments in the field, which I call four acres, I determined to proceed as I had intended in the ſpring of the year; accordingly as ſoon as the oats were got off a field of twelve acres, I ordered it to be ploughed and ſown with the 160 pounds of burnet ſeed before mentioned. This field was ſown on the twenty-ſixth of Auguſt laſt; and no rain falling till the eighteenth of September, the plants did not appear till the twenty-eighth of that month: however, there ſeems to be a good crop, and I intend as ſoon as they freſh up in the ſpring, to have the plants ſet out with ſmall hoes (ſuch as are uſed for carrots and onions) to about ſix inches apart. And in about a week after this is done, I ſhall harrow it with light harrows; for from experiments which I have made, this ſeems to me to be the beſt method of managing broad-caſt burnet. Having nothing farther to ſay in regard to theſe twelve acres, I muſt return to the four acre field tranſplanted, which having been hoed and harrowed as before-mentioned, was laid up for winter feed for my cows; but finding lately ſome gentlemen had again aſſerted, that ſheep in particular would ſooner feed on the quick-hedges than touch the burnet, I ſent to a neighbouring farmer for his flock of ſheep, and having a friend with me, we followed the ſheep into the field, who fell upon the burnet ſo greedily, that we found it very neceſſary to ſend them home again.

Being much vexed at theſe idle tales told about ſo much to the prejudice of this (as it appears to me) excellent plant, I determined to put it to as fair a trial as I poſſibly could. Accordingly, I ordered in four cows, which were in very good feed on natural graſs, and had beſides a large truſs of oat-ſtraw put in their cribs every night, notwithſtanding which they gave very little milk, and indeed were almoſt dry. Theſe cows, I declare, had not been in the burnet above ſix days, before they gave much more than double the quantity of milk; nay, was I to ſay three times the quantity, I know I ſhould not exceed the truth. The milk is exceeding fine, and free from all bad taſte; and further I muſt obſerve, that they ſoon began to leave half their ſtraw in their cribs; ſo that they are now ſerved with only half the quantity they had before. My land is a poor dry upland gravel; there are millions of acres in this kingdom of better land that do not fetch two ſhillings and ſixpence an acre. What a field therefore is here for improvement! Nay, I cannot but obſerve with amazement, the great numbers of country gentlemen who daily flock to this great city in purſuit of trifles, when they have ſuch inexhauſtible funds of knowledge within themſelves, if they would properly make uſe of them; confident I am, I could point out methods of improvement that would ſurpriſingly better their eſtates.

As the account I have now given you of burnet may appear a little extraordinary to ſome of the worthy members of your ſociety, ſo I ſhall be far from being diſpleaſed at their even doubting what I have now ſaid: on the contrary, it will give me pleaſure, provided any gentlemen, who have ſuch doubts, will do me the favour to call at my houſe, and convince himſelf by ocular demonſtration of what I have now ſaid."

BURNING *of heath*, a common practice of the country people for clearing heathy ground, in order to procure graſs and herbage for their cattle.

The fitteſt time for burning commons is towards the latter end of ſummer, when the plants are withered. But great care muſt be taken that the fire extends no farther than is intended.

This care conſiſts chiefly in clearing away all the graſs, &c. on the ſide you would preſerve from the flames, to a diſtance ſufficient to prevent all communication. The graſs, &c. cut down there ſhould be ſpread upon the part intended to be burnt, which will ſerve to kindle the fire after it is dry.

Beſides this precaution, a fair, calm day muſt be choſen; when by kindling the fire on the ſide the wind blows from, you prevent its ſpreading any further that way, and ſee it gradually remove up into the heath or common. The fire ſhould be carefully watched for fear of accidents. But, if notwithſtanding theſe precautions, it ſhould ſpread to places intended to be preſerved, and no water ſhould be at hand, the moſt effectual way of ſtopping the progreſs of the fire, is to dig a trench: for by throwing up the earth on the ſide where the fire is, you cover the graſs, and thereby hinder the flames from extending any further.

BURNING *of land*. *See the articles* BURN-BAKING.

BURNS, are accidents that often happen to animal bodies, whereby a ſolution of the continuity of the parts are produced.

In burns and ſcalds, when the ſkin remains entire, let the part be bathed well, and kept wrapped up in rags dipped in ſpirit of wine camphorated. Salt bound thick on the part has alſo been found very effectual for this purpoſe. Indeed all ſaline and ſpirituous applications excel all others, while the ſkin is yet unbroke; but when the ſkin is ſeparated, anoint the part, and keep it conſtantly ſupple with linſeed or ſallad oil, and a plaſter ſpread with bees-wax and oil. If the ſkin be ſo ſcorched, that ſloughs muſt be digeſted out, dreſs the wound with the wound-ointment and oil of turpentine, and finiſh the cure with any drying ointment.

The fire ſuppoſed to be left in the part after injuries of this kind, is nothing more than the inflammation, which is the natural effect of ſuch cauſes: ſo that the whimſical notions and conceits concerning fire remaining in the part, is extremely abſurd. *Bartlet's Farriery, pag.* 251.

BURNT-CLAY, a manure proper for cloſe compact ſoils, which it opens, warms, and invigorates, and thereby diſpoſes ſuch lands to part with their vegetative virtues.

A correſpondent of the editors of the *Muſeum Ruſticum*, tells us, that he has experienced the efficacy of this manure on wet, cold land; and given the following method for preparing it.

" I cauſed, ſays he, a labourer to dig as much clay as made a number of walls nine inches high, the ſame in thickneſs, and placed at the ſame diſtance from each other, in the ſame parallel direction, forming a ſquare of about three yards. Theſe vacancies, being like tunnels of brick-kilns, I filled with bruſh-wood, and on that threw ſome cinders or ſmall coal, of which I had ſufficient quantities, living then near ſome collieries; after which I covered the whole ſquare with clay about three inches thick, leaving the ends of the tunnels, open, which I then lighted on the windward ſide: as ſoon as the fire had got ſufficient head, I ſtopped the mouths of them; and when I perceived the covering was almoſt burnt through, I had a ſmall ſprinkling of cinders or ſmall coal, thrown on the heap, and then another covering of clay of the ſame thickneſs; and thus I went on till my fire was ſeven or eight feet high.

" When I found my fire was very well kindled, which was commonly about the time I put my ſecond coat on, I uſed to enlarge the baſe of the fire, by continuing

continuing the tunnels, and by adding new ones to the fides (which were filled and covered as the others, and then lighted) till I made my fire about feven yards fquare; for I foon found it never burnt well in the middle, if it was too large at firft.

" Care fhould be taken that the labourer does not put on too thick a coat at once, as it will be apt to fmother the fire: befides, by confining the heat in too much, the clay was apt to run and vitrify, which was then of little ufe.

" As foon as the heap was fufficiently cool (for the fooner it is laid on the land the better) I put about ten large cart loads on a ftatute acre, and found it an admirable manure for either meadow, pafture, or corn: for the latter it will not laft longer than three crops, though longer for the two former: and with this I have made prodigious improvements; but I do not believe it will anfwer for a fandy foil, as it will render it ftill lighter.

" This manure I burnt all times of the year, though flower in the winter than fummer, but always fafteft in windy weather.

" This I fancy may be burnt with brufh-wood, or furze only; which I apprehend will anfwer better between the coats than coal, as it will keep the clay more open." *Mufeum Ruft. vol.* I. *pag.* 407.

BURNT-*grain*, a diftemper common to corn, and too often confounded with fmut, though it is, in fact, very different, and much more dangerous.

The fmut, properly fo called, occafions the total lofs of the diftempered ears; but as the black duft is very fine, and the particles of it have no cohefion, the wind and rain carry it off, fo that fcarcely any thing is houfed in the barn, &c.

The burnt-grain is, on the contrary, often laid in the granary with that which is found, to which it communicates a contagious diftemper, and alfo darkens the flour, and gives it a bad fmell.

The characters of this diftemper are, 1. The plants that produce burnt ears are ftrong and vigorous.

2. The infected ears are not at firft diftinguifhable from thofe that are healthy; but when they are paft their bloom, they appear of a deep green colour, approaching to blue; they afterwards become whitifh, and are then eafily known. As this change of colour is effected by the fun, when a number of white ears have been fuddenly perceived in looking over a wheat-field, the fun's heat has been often thought to caufe this diftemper, or a fog preceding that heat.

3. Though all the ears produced from one grain are commonly infected, yet M. Tillet, Aimen, and myfelf, have met with found ears on plants that had produced others which were infected. We have even found fome ears, part of which only were vitiated, and finally fome grains enclofing partly a white flour, the remainder black duft.

4. In burnt ears, the chaff, or outward coat, was commonly found, with this fingle difference, that when the ears were near ripe, it appeared more withered and dry than in the healthy ears.

5. The bran, which immediately enclofed the grain, is not deftroyed, as it is in the fmut, properly fo called; but has confiftence enough for the grain to preferve nearly its natural form, with a whitifh look.

6. The burnt-grains are fhorter, rounder, and lighter than fuch as are uninfected: they are fometimes larger, fometimes fmaller. The furrow which runs the length of a grain of wheat is fometimes totally effaced, at others is vifible: the piftils at the extremity of the grains are dried up.

7. The bud of burnt-grains is not vifible.

8. Till the blooming feafon, there is very little difference betwixt the burnt-grain and that which is healthy: they are only a little more fwelled. But, in the blooming feafon, the infected ears affume a bluifh colour; the chaff is more or lefs fpecked with fmall white fpots: the grains are of a deeper green, and larger than in a ftate of nature; and, as long as they preferve that colour, they adhere ftrongly to the chaff. The diftemper has often attacked very young ears, while yet enclofed in the fheath. The ftamina on the fides of the grain are then dried up and fickly; the embrio in part takes the deep green colour above-mentioned; the infected ears have not the confiftence of thofe that are healthy; in the fame meafure the diftemper advances, the chaff becomes dry and whitifh.

9. The grains have fome degree of firmnefs. On opening them, which may eafily be done with the nail, there appears an unctuous, dark, brown, ftinking fubftance, not at all refembling the light duft of fmutty ears; the duft of burnt-grain has fome cohefion, and through a microfcope appears to confift of larger particles than that of the fmutty ears.

10. Some time before the blooming feafon, the grains appear to be filled with a whitifh fubftance, a little burnt towards the bottom, and this colour extends by degrees over the whole ear: the grain then appears divided, as it were, into equal quarters by furrows; which difappear as the grain increafes in fize.

11. By what has been faid, it is evident that fmut infects corn much fooner than the burnt-grain.

12. Grains that are much burnt are evidently incapable of fprouting. But I have had fome found grains taken from an ear greatly burnt, which, in a kitchen-garden, have produced very ftrong plants; and though the birds difturbed my experiment, it appeared to me that there were fome found ears amongft many more that were infected.

13. A part of the burnt-grain is bruifed by the flail, and their black duft is fcattered over the found grain; this unctuous duft chiefly fticks to the hairy extremity of the grain near the bud; it there forms a black fpot. Corn fo affected, is called *fpotted grain:* many of the grains which efcape the flail remain entire, on account of their lightnefs; a great deal is feparated by throwing, but the fpotted grain remains as well as many that are burnt; and this is enough to darken the flour, and give it a bad tafte.

14. To remedy this inconvenience, and make the beft bread, they pafs the corn through drum-fieves (*cribles à tambour)* made of pierced iron-plates, like the graters with which they rafp tobacco; the corn is then wafhed, and all the light grains that fwim fkimmed off, which are moftly burnt. The water takes off the fpots, which are but fuperficial; for if a fpotted grain is wiped, the fpot immediately difappears.

With refpect to the caufe of this diftemper, I confefs we are hitherto as much at a lofs as in the cafe of fmut. Some have attributed it to dung; others to fogs; many to the heat of the fun; fome to infects; others to the moifture of the land; and not a few to the feed not being ripe: but thefe opinions are confuted by good obfervations, and by experiments very carefully made. We refer to what has been faid of fmut.

It may feem improbable that a meer fuperficial duft, that only fticks to the bran, without penetrating the grain, fhould be fo contagious as to infect all the grain it touches, with a diftemper; what is more furprizing is, that it fhould injure the organs of fructification only. Yet, however improbable this may appear, the experiments made by Monf. Tillet put it paft a doubt; they fhew that the farmers are not without reafon cautious in avoiding to fow fpotted grain.

As it would take up too much room to mention, at large, all the experiments made by M. Tillet, which are to be found in the papers publifhed by him on that fubject, I fhall content myfelf with relating the refult of thefe experiments, and the inferences this able naturalift draws from them.

Several writers having mentioned dung as the immediate caufe of this diftemper, and others having afferted that it was hereditary, all M. Tillet's experiments were calculated to clear up thefe two points: he was at the fame time in hopes, by means of the fame experiments, of finding fome method of guarding againft this terrible diftemper.

1. The feveral kinds of dung had no vifible effect in producing burnt-grain. The infected feed produced as much burnt-grain in the ground that was not dunged as in that which was. He did not find that dung had any effect, either in favour of, or againft the diftemper.

2. Dung made of the ftraw of infected grain, did not feem to communicate the diftemper; but the infected ftraw unrotted feemed to communicate it. Yet the effect was moft vifible when the duft of burnt ears was mixed with the earth.

3. All grain naturally ſpotted, whether it grew on the land, or was brought from another place, bearded-wheat, ſummer-wheat, and wheat without awns, produced a great deal of burnt grain

4. Picked wheat taken from the fineſt ears, and carefully ſelected grain by grain, that none of it might be infected, being ſowed, ſome in dunged, and the reſt in undunged beds, without having received any preparation, yielded little or no burnt-grain.

5. Some of this ſame picked wheat being ſprinkled with the duſt of burnt-grain, produced as many diſtempered ears as that which was naturally ſpotted.

6. The picked wheat, being prepared with lime and a ſolution of the ſea-ſalt, yielded ſtill fewer infected ears than when unprepared.

7. There were ſtill fewer from what was prepared with lime and nitre.

8. Early or late ſowing ſeemed to be a matter of indifference.

9. It appears by M. Tillet's experiments, ſeveral times repeated, that the duſt of burnt ears is contagious, ſince ſound wheat ſprinkled with it, or ſowed in rills in which that duſt had been put, produced a great number of infected ears. He alſo found that this duſt, though expoſed to a ſtrong heat, as of ſixty degrees, is ſtill contagious, unleſs it is abſolutely burnt by the fire when it has not that effect. Though it is kept for years, its infectious quality continues as ſtrong as ever.

10. Some farmers waſh the ſacks in which they put their ſeed. And it appears by M. Tillet's experiments, that they are in the right; for if the ſacks had any of the duſt on them, it would certainly infect ſome of the ſeed corn.

11. M. Tillet thinks he has obſerved, that the infected plants are more ſuſceptible of injury from froſt than others.

If this is the caſe, hard froſts muſt be ſerviceable, ſince by deſtroying the infected plants, they would have the ſame effect, as if ſuch plants had all been pulled up. The land being cleared of theſe uſeleſs plants, would be better able to ſupply ſuch as are found with nouriſhment, and the crop would be exempt from infected ears, which are a great hurt to it.

12. The black duſt ſo contagious, is not ſo to rye or bere; but the duſt of darnel is pernicious to wheat.

13. Smyrna wheat is leſs ſubject to this diſtemper than other grain; but ſummer wheat is greatly injured by it.

It muſt be allowed that the knowledge which has been acquired of the cauſe of this diſtemper, has put the curious obſervers in a train of finding proper preſervatives. In fact, as the duſt of burnt-grain infects all the grain it touches, it is probable that every method ſhould be deemed efficacious, that is capable of taking away this duſt, provided the virus has not from its firſt contact affected the interior part of the ſeed intended to be ſowed. In this caſe the ſeveral ſieves which we have recommended to be uſed in the preſervation of corn, and the waſhings with fair water, which in many places is uſed on ſpotted grain, may be mentioned as efficacious preſervatives, as well as lime-water which our farmers uſe, the ſtrong brine uſed in ſome provinces of France, and the ſolution of arſenic, of which ſome perſons have made ſuch a ſecret: all theſe preparations ſhould be of ſervice; and, according to M. Tillet's experiments, they are ſo: yet they are often inſufficient. This point, therefore, merited to be cleared up by particular experiments, and with all neceſſary care. M. Tillet ſet about it with ſpirit, and the following are the inferences that may be drawn.

1. The effect of the black duſt on the ſeed is only ſuperficial till it is put into the earth, not at all affecting the interior parts.

2. Therefore every means that can tend to clear them of the duſt, muſt be of ſervice to keep them healthy, and free from the diſtemper.

3. Grain perfectly free from this, and from rottenneſs, will yield no diſtempered plants.

4. Grain blackened with this infectious duſt, may be made healthy by clearing it of ſuch duſt.

5. Sifting ſeed, and waſhing it in ſeveral waters, leſſen, it is true, the effects of the contagion; but this is not ſufficient, as many infected plants will be produced, though the ſeed was waſhed in ſeveral waters.

6. Lime, which is more efficacious than water, is not always enough ſo. I ſhall obſerve, on this occaſion, that ſeed was formerly limed in a manner different from what it is now. The ſeed was then put into baſkets, which were plunged into lime-water very hot. The ſeed was ſtirred in the baſkets, and all that ſwam on the water was taken out with a cullender; by this means they got rid of the infected grain; and the good ſeed was better cleaned, than by only throwing, as they do now, lime-water on a heap of ſeed, which is then ſtirred with a ſhovel, or by only mixing the ſeed with the ſlacked lime reduced to powder.

One of our farmers, a careful man, being obliged one year to ſow ſpotted ſeed, he limed it by immerſion, in the manner above deſcribed; and the year following had no burnt-grain.

Some experiments made in the country of Caux, by M. de Goufreville, have been publiſhed; they evince the good effects of lime uſed in the manner we have mentioned. And what is ſtill a farther confirmation of this is, that whenever our farmers ſow ſeed that has not been limed, their fields are amazingly infected.

7. It is a good precaution to waſh ſpotted grain in ſeveral waters; but it ſhould be ſoaked in brine, and this brine ſhould be abſorbed by lime, by immerſion, as we have deſcribed.

A ſtrong brine of ſea-ſalt is very good, and may be employed to great advantage in countries where ſalt is a merchandize.

9. One part of nitre to nine parts water is more efficacious than ſea-ſalt; this, therefore, ſhould be uſed where nitrous earths abound.

10. Strong alkaline lyes are ſtill better; ſalt wort, pot-aſh, aſhes of tartar, lyes of common aſhes much impregnated with ſalt and human urine, or cows urine, alkaliſed by putrefaction: of theſe various articles ſuch may be choſen as are moſt common. For inſtance, in Normandy aſhes of ſea-wrack, which are very cheap there, may be uſed. This, which is rejected for dying and lyes, as being more impregnated than alkaline with ſea-ſalt, may be advantageouſly uſed in the preparation of ſeed.

11. As it is evident that ſeed picked with care yields very few infected grains, it muſt, of courſe, where a farmer has ſpotted grain, be of great advantage to him to change his ſeed, in order to procure what is uninfected.

12. M. Tillet's proceſs may be comprehended in what follows: if the ſeed is ſpotted, it ſhould firſt be waſhed in ſeveral clear waters, till the black is quite got off; it ſhould then be put into the ſteep. If it is not ſpotted, ſoaking it in the following liquor will be enough. Make ſome lye, ſuch as is uſed for linen, in a bucking-tub, putting four pound of water to every pound of aſhes. If one hundred pounds of aſhes are uſed and four hundred pounds of water, there will be two hundred and forty pounds of lye, to which muſt be added fifteen pounds of lime, which will be enough to prepare ſixty French buſhels of wheat (between ſixteen and ſeventeen buſhels Engliſh meaſure). When this ſteep is to be uſed, it muſt be heated as hot as you can bear your hand in it; the ſeed, being put into baſkets, muſt be plunged into it, and ſtirred with a ſtick; the baſkets muſt then be raiſed and kept up by ſticks on the edge of the bucking-tub for the lye to drain; the ſeed being thus prepared muſt be laid on the floor of the granary till it is dry enough to ſow. If it is prepared long before it is wanted, it muſt be, from time to time, ſtirred with a ſhovel to prevent its heating; with this precaution it may be kept a month, or even a whole year.

We prepared ſome ſeed in this manner at M. Taponat's, near Rochefoucault in 1760; and in 1761 we ſaw with pleaſure that the corn ſo prepared was uninfected; whilſt in the neighbouring fields, a fourth, a third, and even half the crops, were ſpoiled by this diſtemper.

All the trials that have been made evince that acrid ſubſtances are proper remedies for this diſtemper: I alſo believe all the ſteeps to be good; but prefer M. Tillet's, as being more acrid, and leaſt coſtly. I imagine lye that had been uſed for linen might do, only ſtrengthening it with ſome ſea-wrack, and putting twice as much lime. I know this lye to be very acrid, but cannot anſwer for its efficacy in preſerving corn from being burnt, becauſe for ſeveral years paſt we have ſcarcely had any of our grain ſo infected.

13. Several farmers in different provinces have uſed a ſolution of arſenic to prepare their ſeeds. Great complaints have been made in all quarters of it. Among others, a phyſician publiſhed an eſſay to ſhew of how much importance it was to prohibit the uſe of this poiſonous ſteep. He there enumerates all the accidents that have happened to the ſowers, and to the men that made the preparation, of which himſelf was a witneſs. Since M. Tillet has given us a method ſimple and innocent in itſelf, but little coſtly, and of great efficacy to clean ſpotted grain, it is to be preſumed that no body will uſe this pernicious drug, from which ſuch melancholy conſequences may enſue, if by accident any of it ſhould be mixed with the meal, and if the light corn is given to the poultry or cattle; beſides, this poiſoned ſeed muſt kill all the partridges and pigeons that eat the uncovered grain.

As ſome people are fond of making objections, it may, perhaps, be urged, that if the black duſt was ſo infectious, this diſtemper would make from year to year ſuch progreſs, that in the end we ſhould have nothing but burnt-grain. But we need not be apprehenſive in this reſpect: and a year in which much corn is infected, ſucceeds one in which ſcarcely any burnt-grain was to be met with. Scarcely any was to be found in the crops of 1754, 1760, and 1761.

In reflecting on this objection, which has ſome weight, I think I have found an anſwer to it in M. Tillet's obſervations, which is, that hard winters, paſt all doubt killing the diſtempered plants, ſtop it progreſs.

It may alſo be ſaid, that if this diſtemper is only cauſed by the infectious duſt, how can it at firſt get footing in a province that was before unacquainted with it?

It is readily allowed that this diſtemper may be attributed to other cauſes beſides the black duſt: but M. Tillet's experiments inconteſtibly prove this duſt to be contagious; and his reſearches ſupply us with the means of leſſening conſiderably, if not entirely extirpating this diſtemper: thus we may have larger crops, better bread, and corn more proper for keeping. What a ſatisfaction muſt it be to a man to have made a diſcovery ſo uſeful to his fellow-creatures, whoſe chief food is the ſeveral ſorts of grain? We ſhall ſoon ſee whether habit, ſupineneſs, and ill-judged œconomy in the farmers, will not prevent them from reaping any benefit from M. Tillet's labours, who yet propoſes to them ſimple and cheap methods of attaining an end which to them ought to be of infinite conſequence. *Du Hamel's Elemens d'Agriculture, vol.* I. *pag.* 314.

BUR-TREE, a name given in ſome counties to the elder-tree.

BUSHEL, a meaſure of capacity for dry things, as grain, fruits, pulſe, &c. containing four pecks, or eight gallons, or ſixteen quarts.

A buſhel, according to a ſtatute made in the twelfth year of Henry VIII. is to contain 2,178 cubic inches, or eight gallons of wheat; the gallon of wheat to weigh eight pounds troy-weight. Mr. Ray tells us, that a buſhel in Warwickſhire is equal to two ſtrikes, or two buſhels, ſtatute, or Wincheſter meaſure.

The French buſhel conſiſts of four quarters, and the quarter of four litrons, each containing thirty-ſix cubic inches. Conſequently the buſhel contains 576 French cubic inches, which, according to Mr. Greaves's calculation, is nearly equal to 615 Engliſh inches. The French buſhel therefore is to the Engliſh buſhel, as 615 is to 2,178. That is, the French buſhel contains one peck, a quart, and two cubic inches nearly. It muſt however be obſerved, that the French buſhel for oats is double that of any other grain.

BUTCHERS-BROOM, or knee-holly, the name of a plant common in woods in divers parts of England.

BUTTER, a fat unctuous ſubſtance, prepared, or rather ſeparated, from the milk by churning it. *See the article* DAIRY.

BUTTER-BUR, or *peſtilent-wort*, the name of a weed reſembling colt's-foot in many reſpects; but the flowers are purple, and grow in a thirſe. The leaves come out after the flowers decay; and are like thoſe of colt's-foot in ſhape; but three or four times as big. It infeſts meadows and paſture grounds, where it proves a very troubleſome weed. *See the article* COLT'S FOOT.

BUTTER-FLY, the name of a numerous, and well known claſs of inſects.

M. Duhamel has frequently noticed, and made drawings of, a ſpecies of ſmall inſects, ſome of a bright red, and others black, which are found in great numbers in the ears of wheat. He ſuſpected that they fed on a ſweetiſh juice which is in the ear whilſt green: and M. Tillet, who was immediately of opinion that they might do conſiderable damage to the grain, followed them very aſſiduouſly in all their metamorphoſes, of which he has given a full account in a memoire that gained the prize of the Academy of Bourdeaux for the year 1755.

The inhabitants of a conſiderable part of the province of Angoumois have, for thirty years paſt, ſuſtained an hitherto irreparable loſs, by an inſect which begins to devour their corn even in the ear, before it is reaped. This ſcourge deprives them annually of their moſt promiſing crops. It appeared at firſt only in a few hamlets, but ſoon made a rapid progreſs, and has now ſpread to the lands of upwards of two hundred pariſhes. Famine and the moſt fatal epidemic diſeaſes have often taken riſe from leſs beginnings. Meſſieurs Duhamel and Tillet were deputed by the Academy of Sciences at Paris, of which they are members, to enquire into the nature of this inſect, and the means of preventing and curing the dreadful calamity occaſioned thereby. They have jointly publiſhed a ſmall treatiſe on this ſubject, from whence we ſhall extract the following remarks ſo much the more readily, as their means of prevention and cure in this particular caſe may be equally applicable to the injuries done to corn by inſects in general.

This inſect is moſt generally known as a butterfly, very much like the moth which preys on woollen cloths, or the falſe moth which is found in great quantities in the granaries of all countries, and which feeds on corn. M. de Reaumur, whoſe accurate inquiries into nature nothing could eſcape, has minutely deſcribed both theſe inſects.

The butterflies which proceed from the wheat caterpillar are often ſmaller than the falſe moth. Some of them are, however, larger, and longer ſhaped: but, that excepted, they are much like them: they are likewiſe of the claſs of four-winged phalenæ or night butterflies; their wings are long in proportion to their breadth, which is almoſt equal at the upper and the lower end. The colour of the upper wings varies; being ſometimes of a light, and ſometimes of a darkiſh grey brown, but always ſhining when expoſed to the ſun. The poſition of theſe wings, of which the edges are cloſe ſet with long hairs, is horizontal when the inſect firſt ſettles after having flown; but ſoon after thoſe edges incline downward. Its head (Plate V. Fig. 24, 25, 26.) is furniſhed with two antennæ (Fig. 27.) the joints of which, nicely fitted into each other, leſſen gradually up to the point. Its eyes are almoſt as large as thoſe of the falſe moth. Between the antennæ are two beards, (Fig. 28.) which proceed from the lower part of the head and riſe up above it; and likewiſe between the antennæ is a tuft of hairs, which turn up backward.

Theſe inſects do not take any food while they are in the ſtate of butterflies, as will be proved by ſeveral experiments; nor do, or indeed can they, prey upon and deſtroy corn during that time, as is the general, but miſtaken opinion in Angoumois; for they have not even organs capable of doing it the leaſt injury. Their only function then is to procreate their ſpecies.

The males of these butterflies seem, in general, to be larger than the females: but they cannot well be distinguished with certainty, unless they are seen coupled together, which, according to the very nice and careful observations of Mess. Duhamel and Tillet, never is but in the night time, or in a dark place. Their copulation then is like that of the silk-worm butterfly: the body of the male and that of the female then form one strait line; their heads are turned different ways; the ends of their wings rest upon each other; and their conjunction lasts several hours. The abovementioned gentlemen, with many other witnesses, saw great numbers of them in this situation, both upon heaps of corn in granaries, and upon ears of corn in the field. They catched two of them in the act of copulation, and put them into a glass covered over, where they then separated, but were found joined together again the next day, in the evening.

As soon as the female is impregnated, she lays her eggs in great numbers. Messieurs Duhamel and Tillet put a male and female, coupled, into a glass vessel, and, watching them carefully, saw the female, soon after her separation from the male, deposit her eggs, sometimes on one spot and then on another, in heaps of 60, 80, or 90 together. These eggs are squirted out, as it were, commonly by three, four, or half a dozen, and sometimes thirty, at once; and at each squirt of this kind the female changes her situation. Those which were inclosed in glasses cast some of their eggs upon a few grains of corn deposited at the bottom of those glasses, and, finding themselves cramped there, laid others on the sides of the vessel. These eggs are accompanied with a viscous matter which makes them stick to the places they are laid in; and this cohesion soon becomes very strong.

These eggs, as may easily be imagined from the size of the mother and the great number which she lays, are so extremely small that one of them would drop through a hole made in a bit of paper with the point of the finest needle. When examined with a microscope, they look, as in Fig. 4, not unlike the nymphs commonly called ants eggs. They are streaked length-wise, and appear rough or curdled. When first laid, they are white; and afterwards they become red, as if tinged with carmine; owing to the colour of the caterpillar within the egg, of which the shell is very thin and transparent, as is evident after the caterpillar has left it.

By means of the thinness and transparency of this covering, the caterpillar may be seen within the egg, as at *b*, Fig. 5. At first, it is bent, as in Fig. 6: some time after, it wriggles itself into the situation represented in Fig. 7; and then makes a hole through the end of the egg, and comes out there, as in Fig. 8. This opening remains at the end of the empty eggs, as at *c*, in Fig. 5.

It is with great difficulty that the caterpillar gets its two legs out of the egg; but after it has extricated four or six of its legs, it soon draws out the rest of its body. At its first issuing from the egg, this caterpillar looks like a bit of hair about a quarter or a fifth part of an inch long.

These caterpillars generally come out of their eggs on the sixth or seventh day after they have been laid. Some say they have seen them hatch at the end of four days. The temperature of the air will undoubtedly influence this variation. They are red, as was said before, whilst in the egg; but that colour goes off by degrees after they are hatched, and they soon become almost white.

The female butterflies which are upon the ears of corn in a field, endeavour to place themselves in such manner as to lay their eggs close to the place where the grain is fastened to the stalk. Fig. 1. represents some of them, at *a*, in the attitude of thus laying; in which case their eggs are deposited near the bottom of the grains, toward the stalk: but it often happens that, in their hurry to lay, they scatter their eggs in other places, as represented upon the husks in Fig. 2 and 3.

As soon as the caterpillars are hatched, they set about making their way into the grain, in order to feed upon its flour. If the eggs have been laid in the granary, after harvest, and upon the grains themselves, they generally creep into the furrow *a* of the wheat (Fig. 9. and 10), and there weave a slight web *bb*. They then tear a hole in the skin or rind, range around them the particles of the bran thus separated, and wriggle themselves into the mealy substance which is to be their food. The hole through which the caterpillar entered can then no longer be perceived, but by a little heap of bran which lies upon it, as in Fig. 11. This small quantity of pulverised bran, which is a sure sign that a young caterpillar has got into the grain, may easily escape the notice of those who have not observed it before; but when once known, it is easily distinguished.

When the eggs are hatched upon the ears, in the field, the young caterpillars soon find means to glide in between the chaff and the grain, and in that situation they pierce the latter, as was said before, generally in the furrow, but sometimes at the pointed end, which is a little hairy.

To set this in a yet clearer light, it is to be observed, that, in most kinds of wheat, three grains of corn adhere, or are fastened, at the same height, to the spike or stalk which traverses the ear, as at *bbb*, Fig. 1. in such manner as to form a sort of triangle, or flower-de-luce. Each grain is covered with three concave coats or husks, the smallest and thickest of which is represented by Fig. 2 and 3: their inner husk is covered by a broader, but thinner; and this grain is covered by a still larger, from which arises the beard, when there is one. Over all these there frequently is a fourth tegument, or very thin membrane, more or less wide. All these husks lap over each other like the scales of a fish, and envelop the grain. The end *e* (Fig. 9.) is uppermost, and the end *f* rests upon its supporter. The germ is at the end *f*, and the extremity *e* is covered with a hairy down.

The young caterpillar finds means to creep under all these scale-like coverings, and to get at the grain, which, after having wove a slight web of only a few fine threads, either to cover itself, or to hold by, it attacks, sometimes at the upper end *e* (Fig. 9), which is very soft in green corn; and sometimes, if it has crept in at the lower end, it lodges in the longitudinal furrow of the corn, and there begins to mine in the manner before related.

As the husks of barley are harder, and stick much closer to the grain, than those of wheat, it is almost always at the point *d* (Fig. 12.) that these caterpillars slip into that corn, by means of a small opening generally perceptible in that part.

To conceive how these small caterpillars, which are hardly able to pierce the rind or bran of wheat, can glide into barley by means of the opening before mentioned, it is necessary to consider the organisation of this grain. It is formed of two lobes *cc*, Fig. 12. which are partly separated by a furrow in its middle, and partly covered by a tegument *a a*, which fits exactly close and adheres strongly to the lobes *c c*, and terminates in a long awn or beard *b*, of which only part is represented in this drawing. The two lobes *c c* are again covered with their proper tegument, which ends in two small appendices at *d*. Here generally is a chasm or opening, through which the caterpillar penetrates to the mealy substance.

To trace this caterpillar in its further progress after it had crept in at this opening, and consequently disappeared, Messieurs Duhamel and Tillet tore off the appendices *d*, Fig. 13, and found, that after having wove a slender web, it had immediately begun to attack the lobes of the grain of barley, as was evident from the bran around it. After it had made its way entirely into the grain, and was buried there, they saw nothing but the little heap of bran it had thrown up, over the hole through which it entered.

Notwithstanding the industry of this insect, it seems highly probable that the young ones meet with great difficulties in their attempts to get into the grain; since very many of them die before they can effect a lodgment in the mealy substance. This number is so great, that it might induce one to wonder how such quantities of corn can be destroyed by these caterpillars, if one did not consider the vast fecundity of the female butterflies. But the sequel of this account will shew, that if prodigious numbers of them did not perish, it would hardly be possible to save a single grain of any kind of corn.

The people of Angoumois were strongly of opinion, that the mischief occasioned by this insect was peculiar to to the corn of their country, and that what was brought to them from other places always efcaped unhurt. To clear up this point, Meff. Duhamel and Tillet put into different glaffes wheat of the growth of other provinces, and with the grains, in each glafs, fome of thefe butterflies actually coupled. They foon faw the female lay her eggs upon thefe grains, and afterwards beheld the caterpillars hatch, and make their way into the grains. Their farther obfervations proved, that the principal caufe of the fpreading of this evil is, that the infect itfelf, which multiplies exceedingly, is conveyed to other parts with the corn in which it is inclofed.

The caterpillar inclofed in a grain of corn preys upon the mealy fubftance of that grain, till it has eaten it all; by which time the infect has attained its full growth. Whenever a grain was opened (Fig. 19.) in which the caterpillar was not full grown, a deal of flour yet remained: but when this infect was full grown, there remained only the fkin, or bran, fo deftitute of flour, as not even to difcolour clear water. Hogs, though very greedy creatures, and fond of bran, would not touch thefe hulls when given to them unmixed; but they eat them readily enough when mixed with other food.

M. de Réaumur fufpects that when thefe caterpillars have confumed all the flour, they eat the excrements which they had voided whilft young. At leaft it is certain that, upon opening feveral grains in which the infect was young, a number of fmall white pellets, like eggs, was found near the caterpillar; and a half-grown caterpillar being taken out of a grain, and laid upon a piece of glafs at the focus of a microfcope, it was feen to void a quantity of excrements, very white, fmooth, and oval; and when the caterpillars were ready to be metamorphofed in the fpring, there remained only a very fmall portion of dark brown excrements, quite different from the white that were obferved at firft.

The length of the corn-caterpillar, when full grown, is very little more than the twelfth part of an inch; and its thicknefs is, at moft, equal to half the circumference of the grain that contains it: its body is fmooth and entirely white: it is thickeft towards the head, in which one may perceive its mouth, two large eyes, and two kinds of horns: the head is a little browner than the reft of the body. This caterpillar has fixteen legs, of which the eight intermediate and membranous are only fmall prominencies, fo minute as not to be diftinguifhed even with the help of a microfcope, unlefs the infect be laid upon its fide.

Our authors make here the following digreffion, to fhew the difference between this infect (Fig. 23.) and the falfe moth (Fig. 31.); it being the more important to diftinguifh them, as they are very much alike in many refpects, and often blended together in the fame granaries.

The falfe moth proceeds from a fmall caterpillar, the body of which is fmooth and whitifh. It has fixteen legs, does not lodge in the grains of corn, but contrives to faften feveral of them together with a web which it fpins, and with which it makes itfelf a dwelling place like that of common caterpillars. This dwelling-place, or fheath, in which the caterpillar of the falfe moth ufually abides, is generally in the middle of the little heap of grains which it has collected for its food, as in Fig. 30: but, which diftinguifhes it from the caterpillar of the true moth, it can quit this fheath at any time, to eat the grains around it, one after another. It generally attacks feveral grains at once, and always without order, eating fometimes of one, and fometimes of another, fo that feveral are gnawn when not one is wholly confumed. When thefe infects are very numerous in a granary, all the grains upon the furface of the corn are linked together by a web, fo as to form a cruft which is fometimes three inches thick. This caterpillar turns into a chryfalis, or aurelia, in a grain which it has hollowed, or in the fheath of its web, and iffues from thence, in the month of June, in the form of a butterfly. When a heap of corn is ftirred in which there are many caterpillars of the fpecies of this falfe-moth, thofe infects crawl up the walls: but they foon return to the heap, and, by the very next day, cover it all over with a new web.

The infect which defolates many parts of Angoumois is more fparing of the mealy fubftance of the corn, than the caterpillar of the falfe-moth; for the former feldom confumes more than the contents of a fingle grain. Nothing is more uncommon than for it to pafs from one grain to another, even though it be immediately contiguous. It eats the flour in fuch manner that the fkin or rind of the grain, which is entirely emptied, looks whole and found: but the leaft preffure then eafily reduces it to powder; and it rifes up to the furface of water more or lefs quickly, according as the infect has left in it more or lefs flour.

As heat haftens the metamorphofis of the infect, it is not unufual to find, in very hot weather, fome of thefe caterpillars transformed into aureliæ, before they have confumed the grofs excrements before-mentioned, or even eaten all the mealy fubftance of the grain. In this cafe, the aureliæ are very fmall, and produce only fmall butterflies. The fame happens to other infects of this kind. Silk-worms eat but little when they are fickly, and, if that ficknefs continues, they are metamorphofed fooner than others which are healthy; but then their cocons always are fmall. If a field caterpillar be fhut up in a box before it has attained its full growth, it will, after having fafted fome days, be converted into a fmall aurelia, from will iffue a butterfly fmaller than others of the fame fpecies. In like manner, when one fees among the corn caterpillars fome larger than others, it may reafonably be prefumed that this difference proceeds from there having been a greater quantity of flour in the grains on which they fed, than in thofe which were the nourifhment of fmaller flies; or from their having been of a ftronger conftitution. It likewife appears that fome of thefe caterpillars are fo much more voracious than others, that the flour of one grain is not fufficient for them. M. Duhamel put feveral of them into a box of flour: they throve there, and feemed to grow larger than in their common way of feeding in the grain.

In general, they are matamorphofed much fooner in fummer and when the air is warm, than in winter, or in cold weather. It may likewife be obferved, that the mealy fubftance of a grain is more completely confumed when the metamorphofis is flow, then when the contrary happens.

The fagacity of M. de Réaumur was requifite to difcover a fingular circumftance relative to the working of this infect, and of which Meff. Duhamel and Tillet have been witneffes. The caterpillar, exactly inclofed in its grain, forefees, or acts as if it knew, that, in its future ftate of butterfly, it will be deprived of the organs neceffary to pierce through the rind of bran which forms its prifon. However, whether it has or has not that forefight, the fact is, that the caterpillar, before it is changed into an aurelia, makes in this covering of bran a fmall trap *a* (Fig. 21.) which remains fhut. Meffrs. Duhamel and Tillet could not eafily difcover it at firft; but after fome fearch, a little fpot whiter than the reft, about as big as the head of a fmall pin, and fomewhat prominent, fhewed them where it was. They then, upon lifting up this trap (Fig. 22.) with the point of a fine needle, could fee the chryfalis in the infide of the grain, and could alfo, fometimes, clofe the trap again fo exactly, as not to leave the leaft appearance of a hole.

When the caterpillar has attained its full growth, and formed its trap, or outlet, it weaves a cocon, and is afterwards metamorphofed, within the grain, into an aurelia (Fig. 20.) which feems at firft to be divided by ringlets (Fig. 14.): but when the butterfly is formed within the aurelia, its wings may be difcerned through the membranes which cover it, as in Fig. 15, 16, 17, 18. The above-mentioned accurate obfervers opened fome of thefe aurelia in an advanced ftate, and took out of each of them a butterfly greatly rumpled and benumbed. When one of thefe caterpillars firft iffues out of an egg, and when a full grown one is taken out of a grain of corn, the body of each, then feemingly more at eafe, dilates, fo that one can hardly conceive how it could be contained in fo fmall a fpace as that from whence it came. The cafe is different when one opens a grain in which there is an aurelia; for it is eafily feen that

this

this occupies little more than half of the inner capacity of the grain which incloses it, and that the caterpillar, in forming a cocon, has divided the grain into two spaces or cells, in the largest of which, being somewhat more than half, the aurelia is lodged, whilst one sees in the other nothing but its excrements. The aureliæ are therefore small in comparison to the caterpillars that were metamorphosed into them. Nor is it less surprising how a butterfly just come out of the aurelia could be contained within that covering.

The butterfly, being entirely formed in the aurelia, breaks the skin of it at the end, opens with its head the little trap which the caterpillar had made on the outside of the grain, and comes out at the little hole which was covered and shut by that trap. The mealy substance of the grain has, by that time, been so far consumed, and the outside husk or bran rendered thereby so light, that the butterfly, after having disintangled its wings, takes its flight, and sometimes carries away the empty hull. As soon as the butterflies are out of the grains which contained them, they couple, and the females lay their eggs in the manner before related. Such is the circle of their life.

This insect, like all others of the same species, remains, as was said before, a longer or shorter time in its different states, according as the temperature of the air is more or less favourable to its several changes. It is known that an aurelia of a caterpillar, which generally produces a butterfly in eight days, will continue three months in the state of an aurelia, if it be put into an ice-house, and that the butterfly does not, in that case, come out, till after it has been removed into a much warmer air. For this reason one cannot fix precisely the time within which the caterpillars are transformed into aureliæ, nor how long they remain in this state: it can only be said, that they come out of their eggs very soon when the air is warm, and that they sometimes continue long in the state of caterpillars, as well as in that of aureliæ, if the weather be cold: to which may be added, that both caterpillars and aureliæ, of different sizes, are seen in the field in warm weather; that butterflies are seen to issue out of corn from harvest till the end of September; and that caterpillars of various sizes may be found in the infected grains during the whole winter.

"In the middle of May 1761," continue Messieurs Duhamel and Tillet in their account of this insect, "when we arrived at la Rochefoucault, there were many caterpillars in the corn, very few aureliæ, and not many butterflies. The weather was then very dry, and the nights were cold. On the 21st, the wind changed to the west; and in a few days after it began to rain, and continued so to do till the end of the month. During this time the thermometer was at from 13 to 14 degrees of Reaumur, or from 56 to 58 of Farenheit.

"In the beginning of June, we found in the grains of corn many more aureliæ than caterpillars; and on the 5th of that month, the air being then become pretty warm, we saw numbers of butterflies. By the 15th, they were increased so prodigiously in the closets where we made our experiments, that they perfectly darkened the day, and flew into our mouths if we opened them. We could then find but very few caterpillars, except in the corn which had been laid in cool places. We believe that the duration of the life of the butterflies is, in general, a fortnight or three weeks; though some of them have lived a month in our glass vessels. The sequel will shew that the whole circle of the life of this insect may be completed in less than fifty days, when the air is warm.

"The coming out of the butterflies is generally denoted by a great heat in the heaps of corn, or in the sheaves, according as the grain is laid up in one or other. It was such as to make the liquor in M. de Réaumur's thermometer rise to 25 and 30 degrees (from 62 to 71 of Farenheit) when the outer air was at 15, (35 and a half of Farenheit). This heat certainly accelerates the hatching of the insects; for prodigious multitudes of butterflies issue out of the heated corn in a few days after the ferment has taken place.

"The coolness of autumn interrupts their propagation; and no more butterflies appear from that time, till the warmth of spring begins to be felt. But, may not the heat which favours the multiplication of these insects be produced by the creatures themselves when assembled in vast numbers? This is very possible: for it is well known that there is a considerable warmth in well stocked bee-hives; and that corn greatly infested with weevils or moths, is also very hot. We shall hereafter have occasion to observe that no sensible heat is perceived in heaps of grain in which there are but few caterpillars, and that the heat abates after most of the caterpillars have been changed into butterflies. It sometimes happens that, through some cause or other, the heat goes off soon, and at other times it lasts three weeks or even a month. Perhaps too this great heat of corn full of caterpillars may proceed from the moisture which those insects occasion, and from thence may arise a fermentation capable of hatching the eggs, of making the caterpillars grow, of hastening their transformations, and of bringing forth the butterflies, at the same time that it damages the corn, which thereby contracts a bad smell. It is certain, that when the harvest is wet, and warm rains fall at that time, the corn heats very soon, and then these insects make an extremely rapid progress. The heat which the corn contracts is doubtless very favourable to that progress, and the insects certainly may then attack the grains softened by the moisture, more easily than they can those which are hardened by drought. Accordingly, in 1760, a year in which the heat was great, and the air very dry, the corn in Anjou kept cool so long that many of the inhabitants of that province thought there would be but few insects, and that the great heat of the sun had killed most of the caterpillars. They flatter themselves with the same hopes whenever these insects do not appear in great numbers quite so soon as usual, and imagine that few or none of them will come afterwards: but in that very year, which they thought so fatal to insects, we saw butterflies come out of the ears of corn while they were in the reapers hands; we saw still more fly about the sheaves laid up in barns, and an inexpressible multitude upon the surface of corn deposited in granaries, though neither of these grew very perceptibly hot till about the middle of September. In 1761, the corn was so much heated on the 8th of September, that though the outward air was of the same temperature as that in the vaults of the observatory at Paris, Réaumur's thermometer placed in one of those heaps rose to 53 degrees, (131 of Farenheit's). The great heats of the summer had therefore only deferred the evil, and perhaps lessened it a little. But this dreadful scourge returns every year. These caterpillars, inclosed in their grain of corn, and sheltered in barns or granaries, are screened from the vicissitudes and rigour of the air which destroy other insects that are exposed to them.

"Let us now review our insect in all the seasons of the year, in order to try to find under what circumstances it may be attacked with most advantage.

"At harvest-time, we saw butterflies come out of some grains, which were already empty and entirely consumed, before they were reaped. Doubtless these first butterflies couple and lay their eggs upon the other unreaped ears, and probably part of those eggs are destroyed by the action of the flail, when the corn is threshed and cleansed soon after its being cut: but as the caterpillars are hatched very speedily in hot weather, and many of them can, as in fact we saw them, enter into the corn that is reaping, and shelter themselves there; they will do all their mischief, if speedy care be not taken to stifle them, as we shall hereafter observe.

"The reaped corn is laid up in sheaves, in barns, till the husbandman can find time to thresh it, which is sometimes sooner, and sometimes later. The corn thus piled up, heats; and the transformations of the insects inclosed in it are then the sooner effected. When any of these piles of sheaves were stirred in our presence, we saw butterflies come out of them, and the grains from which they issued were empty of flour, and absolutely spoiled. The moment these butterflies are out of their pfifon, they couple, and lay their eggs upon the ears which they find in the barn. Part of thefe eggs, and of the young caterpillars, might certainly be deftroyed by the flail and winnow, as we faid before, if they were ufed fpeedily.

"Many peafants in the country we are fpeaking of make all the hafte they can to threfh their little crops, which they generally do upon a very dirty floor made in a hurry in the open air. They winnow and cleanfe their corn as foon as it has been threfhed; and the empty grains are then partly feparated from thofe that are full, by the wind, which carries the lighteft away with the chaff.

"As the dirtinefs of the floor on which the fheaves are threfhed fouls the grains of corn, thefe people wafh them, and thereby take off fuch of the remaining light grains as fwim upon the water. They likewife feparate the grains of which the caterpillars have eaten fo much of the mealy fubftance as to render them fpecifically lighter than the water: but the grains of which the caterpillars have not eaten much of the flour, fink to the bottom with found ones; and the caterpillars devour thofe infected grains after they are foftened by the water, much fooner than thofe which are thoroughly dry.

"Moft of thefe peafants, knowing the ill fate that will attend their corn, fell it as foon as poffible to dealers, who carry it into the neighbouring provinces, and with it the contagion. This is the real caufe which fpreads the evil. Others have their corn ground immediately after harveft; and this is the beft method they can take, though not without its inconveniencies: for, in the firft place, there are not mills enough in the country to grind immediately the whole produce of the crop; fecondly, the meal of corn gathered in a wet harveft will not keep long; and laftly, though the friction of the mill-ftones undoubtedly deftroys almoft all the infects, it is not certain but that fome of them may efcape; and in that cafe they will thrive, and go through their feveral metamorphofes, firft into aureliæ and afterwards into butterflies, in the flour, as we have experienced in the manner before related.

"Several of the inhabitants of the country in queftion lay their corn up in granaries, in order therewith to pay their rent, which, in general, is not due till the beginning of October. From thefe heaps of referved corn iffue multitudes of butterflies, which, as we have obferved, couple and lay upon that corn an immenfe quantity of eggs, from whence proceed caterpillars which get into the grains, and devour their infide during the whole winter.

"It is highly probable that, in mild and moift autumns, fome of the firft hatched caterpillars may be changed into butterflies early enough to produce a fecond generation before winter; nor will this feem furprifing to thofe who know how rapidly warm weather makes thefe infects go through all their metamorphofes. But, independant of this, it is certain that butterflies are continually feen to come out of all the heaps of wheat, barley, and rye, in Anjou, during the whole fummer, and till the autumn begins to grow cold; that numbers of live caterpillars are found in the grains during the winter; that many aureliæ are found in them towards the end of May; and that prodigious multitudes of butterflies iffue from them as foon as the weather begins to be hot, that is to fay, towards the middle of June.

"Thus we fee that there are, in a manner, two flights of butterflies; one which appears from harveft time till the weather grows cold in September, and the other which appears in June, and lafts till harveft. The former, in our opinion, proceed partly from granaries in which corn of the preceding year has been laid up with young caterpillars in it, and partly from the eggs firft laid upon the ears, towards the end of May, or upon the new reaped corn; fo that the fecond flight begins juft as the firft flight ends.

"A circumftance well worth obferving, and which will be more particularly noticed hereafter, is that moft of the butterflies of the fummer flight remain in the granaries, faft clung to the threfhed corn, upon which we have feen them couple and lay their eggs. It looks as if thefe butterflies knew that there then no longer is in the fields any corn fit to feed their pofterity. On the contrary, thofe of the fpring flight endeavour to get out of the granaries, and do in fact get out in vaft numbers, through the windows, to fpread in the fields, and lay their eggs upon the yet green corn."

That this is really the cafe, and that thefe infects are of the fpecies called *phalenæ*, appeared evidently from feveral very accurate obfervations, made by Meffrs. Duhamel and Tillet, and of which it may be fufficient to mention here only the following.

In June 1761, they went, at different hours of the day, into granaries where there were heaps of corn infected with thefe infects. While the day lafted, they perceived a multitude of butterflies which ftirred a little upon thofe heaps, but did not quit them. When they returned into the fame granaries a little after fun-fet, they faw thofe butterflies rife from the corn, and fly to the walls, where they fettled for a while; after which they took their flight in vaft numbers, through the windows, and went off with fuch rapidity that they foon got out of fight. If Meffrs. Duhamel and Tillet went back into thefe granaries at ten or eleven o'clock at night, they no longer faw fo great a number of butterflies, and thofe that did remain feemed to be lefs agitated.

To be ftill more perfectly acquainted with fome circumftances of the life of this infect, they put different forts of corn into fmall clofets, in September 1760, after having pafted white paper all over the walls and ceiling. In the beginning of June 1761, thefe clofets fwarmed with butterflies, which feemed to be pretty quiet during the day, and were feen to be greatly agitated towards the fetting of the fun: but they could not get out of the clofets, becaufe the windows were clofely fhut. On the 9th of June, towards eight o'clock in the evening, one of the clofet doors being opened, a prodigious number of butterflies immediately iffued out, and, with furprifing fwiftnefs, traverfed an oppofite granary, without making the leaft ftop, though feveral heaps of wheat lay in it. They bent their courfe directly to an open widow of the granary, at fome diftance from the clofets, and inftantly haftened out. Several people, who were prefent, followed them with their eyes, till the ridge of a barn near forty feet off, and the decline of the day, prevented their feeing them any further. Our obfervers returned to the fame clofet at about ten o'clock at night, and then found the remaining butterflies very quiet, fcarce one of them attempting to fly out.

Thefe obfervations prove fufficiently that this fpecies of butterflies is nocturnal, and that thofe of the June flight have a different inftinct from thofe which do not appear till after harveft. Thefe laft remain upon the corn in the granary, and there couple and lay their eggs, from whence proceed caterpillars which penetrate into the grains as foon as they are hatched. The June caterpillars, on the contrary, act as if they knew that the bloffoming of the corn is paft, and that its ears are fitted to fupply their pofterity with the neceffary food. They feldom leave the granary before fun-fet, unlefs dark clouds chance to beguile them earlier, in which cafe numbers of them become the prey of fwallows and martins, which fly about the windows.

As thefe little infects fly very fwiftly, and rife to fuch a height that the eye cannot follow them long, efpecially when the dufk of the evening begins to come on, Meffrs. Duhamel and Tillet were obliged to try feveral methods before they could be certain what became of them. The caterpillars which they found in the grains of ftanding corn made them conclude that the butterflies, when out of the granary, flew directly to the green corn, and laid their eggs upon its yet tender ears: but none of the country people, of whom they inquired, had ever obferved them in the fields, or could give any fatisfactory account of them. Another well attefted circumftance, which ftrengthened their conjecture, was their being affured by perfons of undoubted credit, that the corn which grows neareft to villages, farm-houfes, barns, or buildings ufed for granaries, is always much more da-

 maged

maged by insects than that which grows at a distance from any habitation. Their own observations confirmed this fact; and their experiments, dictated by reason, soon proved that they had conjectured right.

Desirous to know what was become of the swarms of butterflies which they had seen go out of the granaries in June 1761, they searched all the neighbouring fields of every kind of corn, and beat even the surrounding hedges, at all hours of the day, to no sort of purpose: not a butterfly could they find, excepting a few dead and dried ones intangled in spiders webs along the outside of the corn. This very circumstance led them to the discovery they were in quest of: for, rightly reflecting that these insects, which neither they nor any other persons had been able to find in the fields in the day time, must certainly be of the *phalenæ* or nocturnal kind; they, without farther delay, set out with a candle and lanthorn, repaired to one of the corn fields which they had visited in the afternoon, and, in the night between the 5th and 6th of June, soon descried a great number of the very butterflies they were seeking for, upon the beards of the ears of wheat. They returned to the same spot early the next morning, and could not then find a single one.

From that time they saw and shewed to whoever chose to see them, a great number of these butterflies upon the standing wheat and barley. Some were upon the beards, and others had made their way to the point of the grain. Scarce an evening passed without their seeing some of them coupled. Though every circumstance concurred to prove, and indeed left no room to doubt, that these butterflies were the same as those which infested the corn in granaries; yet, to be thoroughly convinced, and to convince others, in this respect, they took some of them from off the ears of corn in the field, examined them with a microscope, and found them to be of the very same species. A farther demonstration of this resulted from the following incidents. M. de Taponnat, one of their friends in Angoumois, had, in a small granary, several heaps of wheat differently prepared, which he kept by way of experiment. Messrs. Duhamel and Tillet observing numbers of caterpillars in two of those heaps, advised him to put that corn into an oven properly heated, in order to prevent the dispersion of the butterflies, which they knew would otherwise infallibly proceed from thence: but this was neglected. On the 21st of June, about seven o'clock in the evening, they visited this little granary, and found upon the corn a multitude of butterflies in great agitation, and of which a considerable number soon flew out at the windows. They took leave of M. de Taponnat, assuring him that this flight of insects would soon light upon his standing corn. When they were gone, M. de Taponnat had the curiosity to step out, to see whether any great quantity of butterflies still continued to issue from his granary; which he could easily do, as the window was very low. He was amazed at the numbers he saw fly out at that one window; being, as nearly as he could compute, about fifty in a minute. He observed, that they directed their flight towards a field of wheat not far off, and thereupon went thither with five or six other persons, all of whom saw them arrive in swarms, proceeding chiefly from the granary. They saw many of them light upon the ears, and on their running a cane gently over the awns, beheld them rise by dozens at a time. M. de Taponnat was so struck with this sight, that he ordered the window of his granary to be shut the next day, and his corn to be put into an oven properly heated, as soon as possible.

A clergyman in the neighbourhood, who had a little barley infested with these insects, could not be persuaded to do the same, though his whole quantity was but a few bushels. The consequence was, that a multitude of butterflies were soon seen to proceed from the window of his granary, and spread so thick over an adjacent field of barley, that not an ear could be found without several of them upon it.

These facts confirm all the former remarks of our accurate inquirers, who, after observing that the fittest time to find these butterflies upon the ears of standing corn, is about half an hour after sun-set, continue thus.

"On the 10th of June, about eight o'clock in the evening, we visited the fields around la Rochefoucault, and then perceived only a few butterflies upon the ears of the corn: they were greatly agitated; and we soon after saw numbers of the same species arrive on all sides, but chiefly from certain mills on the banks of the river. Those that were upon the corn flew away as soon as we approached them with a light. This was probably the time of their arrival. Towards nine o'clock we renewed our search, and saw many of them clung to the ears, either actually coupled, or seeking to couple. The light did not affright them then, and we had time enough to examine them with a microscope. We found fewer of them towards midnight, and could not see any early the next morning. It is not to be supposed that the dispersion of these butterflies happens always regularly at the hours before-mentioned; for we have observed several variations, which depend on the warmth of the air; and they commonly settle upon the corn earlier when the sun is over-cast with clouds just before its setting.

"As we have not ever met with these butterflies in the day-time, it may be asked, where they then retire to? This question deserves an answer. We have searched for them in vain in hedges and among the blades of corn. Light certainly incommodes them: for when we exposed to the sun vessels in which some of them were inclosed, they hid themselves in the shade formed by creases of the paper at the bottom of those vessels, in such manner that we were sometimes puzzled to find them again. One day that the sun shone very bright, we took two crystal cups, into one of which we put a few grains of wheat with some butterflies, then covered it with paper, and placed it upon its bottom, in a garden exposed to the sun. We put some butterflies into the other, but not any corn, and placed it close to the former, with its bottom uppermost, that the butterflies might receive the full heat of the sun: and lastly, we set one of M. de Réaumur's thermometers upon the ground, just by these cups. When the liquor had risen to from 45 to 50 degrees, (from 112 to 124 of Farenheit's) we saw that all the butterflies in the cup where there was not any corn, were dead: in the other, only some were dead; because most of them had found a shady shelter, either by making their way into the grains, or by hiding themselves under the paper cover. We knew before, that these butterflies are greatly agitated, and flutter very much when they are exposed to the sun; but we could not tell whether that proceeded from pleasure or pain. The doubt is now removed; and we are of opinion that they retire to a cool or shady place during the day time, and that their smallness prevents our finding where they are hidden, which may perhaps be in woods or thickets, in crevices in the barks of trees, or in the earth."

That the caterpillars which produce first aureliæ, and then these butterflies, can, and frequently do, live under-ground, that they can pass the winter there inclosed in the grain with which they are sown, and even undergo their several metamorphoses in the earth, so as to arise from thence in the form of butterflies in the spring, has been demonstrated by the following experiments.

In May, 1761, Messieurs Duhamel and Tillet planted, in a garden-pot, corn in which they knew there were caterpillars. They buried it an inch deep, watched it carefully, and saw that, notwithstanding plentiful rains had fallen upon it, those caterpillars changed into aureliæ just as if they had been in a granary. These aureliæ produced butterflies, which, weak as they were when first hatched, soon made their way out of the ground.

To be the more certain of their power, with respect to this last article, the same gentlemen put some thoroughly dry, and well pulverised earth into a glass vessel, then laid upon that earth a layer of corn in which they knew there were aureliæ, and covered this with equally well dried and pulverised earth, at least half an inch deep; after which they tied a paper over the vessel, to keep in the butterflies, in case they should pierce through the upper mould. In effect, they did pierce through it, coupled, and laid such quantities of eggs as covered its whole surface.

To see whether these insects would rise as easily from underneath a stiffer earth, and what effect their being buried deeper would have, a wooden box was divided into three partitions, and filled with common mould taken out of a kitchen-garden. Corn known to be infested with these caterpillars was planted an inch deep in one of these partitions, two inches deep in another, and three inches in the third. All of them were then covered with a glass frame, and butterflies soon appeared in each of the divisions; but they were far most numerous in that where they had been buried but an inch deep. In another trial, a number of infected grains was covered with a still stiffer earth, wetted, and pressed down; and not any butterflies appeared there. At their first coming out of the ground, they are rumpled, as when taken out of a chrysalis: but after resting a moment, they shake their wings, set them right, and soon take their flight.

That some of these butterflies can, and do come out of the ploughed ground which has been sown with infected seeds, is certain: but Messieurs Duhamel and Tillet are thoroughly satisfied that their number is but small, that most of the caterpillars sown with the grain perish before they can reach the surface of the earth, and that the butterflies which proceed from granaries are the great source of the increase of this insect: for, say they, the grain which contains a young caterpillar will grow, if its germe has not been damaged; and as its mealy substance is consumed by the plant, the caterpillar must die for want of food. Besides, as is proved by the last-mentioned experiment, the butterflies cannot pierce through a close and hardened earth; which generally is the case of ploughed land that has been exposed to the winter rains.

After observing that the two sexes sometimes unite a second time after separation; that the female deposits her eggs almost immediately after they are fecundated, in small parcels of from 6 to 30, and that each female lays in all from 60 to 90; adding to this, that there are generally three flights in a year, one at the latter end of May or in the beginning of June, a second in August, and a third in some of the subsequent months, during which a fourth also, and even a fifth, have been known; we may, from the following calculation, form an idea of the astonishing multiplication of these insects, and consequently of the ravages which they must make where they have established themselves.

Every female produces from 60 to 90 eggs, of which 75 is the medium: but let us suppose the number to be no more than 70. Let us suppose also, that of those 70 eggs, one half only produces females, which makes the number 35. This multiplied by 70, the number of eggs laid by each, gives for the second brood, from a single insect, 2450: the half of this number, supposed to be females, is 1225, which multiplied by 70, gives 85,750 for the third brood. The half of this number, being 42,875, multiplied by 70, gives for the fourth brood, 3,001,250; and the half this, 1,500,625, multiplied by 70, gives 105,043,750 for the fifth brood: so that supposing five broods in a year, each female butterfly of this species that exists in May, produces, before the May following, no less than one hundred and five millions, forty three thousand, seven hundred and fifty individuals of the same kind.

It is not agreed whether these insects prefer wheat, barley, or rye. The observations and trials made by Mess. Duhamel and Tillet seem to prove, that they attack indifferently whichever lies most convenient for them; and that they do not spare maize, when it is stripped of its stalk and laid up in a granary, where they can come at the soft inside part of the grain; or even oats, though it be the common, but mistaken opinion of the people of Angoumois, that this last grain is a preservative of others, especially of barley, when sown with it, or intermixed in the same heap.

M. Tillet inclosed several ears of standing oats in a wide-mouthed glass bottle, and put into it some of these butterflies; after which he covered the mouth with a piece of fine linen. The butterflies coupled there, laid their eggs upon the ears, and several caterpillars which proceeded from those eggs, actually introduced themselves into the grains. A manifest proof that, though the pendent position of the grains of oats, whilst growing, may be inconvenient to the female butterflies, many of whose eggs may be washed or blown off, more easily than from other corn, before they are fixed by the viscous matter which fastens them to the husks; yet the corn-caterpillar can live upon oats. What is still more extraordinary is, that grains of wheat, barley, rye, and oats, were mixed together in a glass vessel, into which some of these butterflies were put: and the oats were damaged by caterpillars, as much as any of the other grain: though it is certain that these insects do but little mischief to oats in the granary; happily for the poor people who make bread of this corn.

In guarding against these insects, the farmer has three objects: 1, to preserve his grain for seed; 2, to keep it for food and market; and, 3, the total destruction of the insects.

To preserve the corn for seed, it should be threshed out as soon as possible, in order to prevent the transformation of the caterpillars brought from the field, which otherwise soon become butterflies, whose prodigious number of eggs would exceedingly increase the evil. For want of this precaution, two thirds of the store of seed-corn has frequently been destroyed.

The seed should either be dried in an oven, in which the heat should be strong enough to kill the caterpillars, without destroying the vegetative power of the grain; which will be properly effected by 124 degrees of heat on Farenheit's thermometer, or soaked in a strong lye of wood-ashes and quick-lime, heated to such a degree that the finger can just bear it. Let the corn contained in a basket be stirred in this lye, and the grains skimmed off that float on the surface. When the corn has been thus soaked for about two minutes, the basket which contains it should then be lifted up, and suspended by two poles, till the lye is drained off. The grain should then be spread very thin on the floor of a granary to dry, while a second basket-full is prepared in the same manner. The corn thus steeped, and well dried, will keep a year, and continue fit for sowing.

By following the above directions, corn may be preserved from the ravages of these or any other similar insects that prey upon it. *Histoire d'un Insecte qui devore les Grains de l'Angoumois.*

BUTTER-JAGS, flowers of the wild trefoil.

C.

CABBAGE, the name of a plant well known, and of which there are feveral fpecies cultivated in gardens, and alfo in fields as a food for cattle.

Cabbages of all fort delight in a deep, rich, light, and well-loofened ground, in an open fituation. They will indeed grow in any ordinary ground that has been dug; but the better the foil and its tilth are, the finer and better flavoured the plants will prove.

The early and the fugar-loaf cabbages, are the forts generally fown for fummer ufe. The moft proper feafon for fowing them is about the end of July, or beginning of Auguft. When the plants have feven or eight leaves, they fhould be removed into beds of well prepared mould, and there fet about three or four inches afunder every way, that they may grow ftrong, without running up in height: and towards the latter end of October they fhould be again tranfplanted in the place where they are to remain. They fhould be here fet in rows three feet afunder, and two feet and a half diftant from each other in the row. They muft be kept clear from weeds, and fhould either be earthed up from time to time, as is the common practice, or, which will be much more beneficial, the ground between them fhould be repeatedly dug pretty deep, or otherwife well ftirred and loofened, during their growth. About May they will turn in their leaves for cabbaging; and if this be then affifted by tying them up pretty clofe with a flender twig of ofier, their heads will be blanched in the middle, and fit for cutting, at leaft a fortnight fooner than they would be, if not tied up. But it muft be obferved of this early kind, that the cabbaging is foon completed after the leaves begin to turn, and that the heads almoft as quickly afterwards become hard and burft. The fugar-loaf cabbage is therefore more generally planted, becaufe it is not fo clofe leaved, grows and cabbages more flowly, and continues good for a longer time.

The mufk cabbage, which requires exactly the fame culture as the former, will be fit for ufe in October, and will laft till Chriftmas; but is more tender, and therefore more liable to be killed by hard weather.

The common white, red, flat, and long fided cabbages, are cultivated chiefly for winter ufe. The time for fowing them is in the beginning or middle of April. The young plants of thefe forts, like thofe of all other cabbages, fhould be pricked out into fhady borders, when they have got fix or eight leaves, that they may acquire ftrength, and not run up with high ftems; for the fhorteft fhanked cabbages are always found to fucceed beft. Towards the middle of June they fhould be tranfplanted from thefe borders into the places where they are to remain, at the diftance of two feet and a half from each other, in rows three feet and a half afunder; for this will be fufficient either for earthing up the ftems, as is commonly practifed, or for the more beneficial method of digging and ftirring the earth between them. If they are planted out in a dry feafon, they fhould be watered every other evening, till they have taken frefh root.

The kitchen gardeners near London generally plant rows of thefe cabbages between their artichokes, cauliflowers, &c. but they feem, upon the whole, to do beft when planted alone. They will begin to be fit for ufe foon after Michaelmas, and will continue good till the end of February, if the winter be not fo fevere as to deftroy them. This may, however, be prevented by pulling them up in November, trenching the ground up in ridges, laying the cabbages as clofe as poffible, on one fide againft thofe ridges, and then throwing in the earth fo as wholly to bury their ftems. In this manner they may be kept till after Chriftmas: for though their outer leaves may decay, as they often will in very wet or hard weather, their infide will remain found, provided they were large and hard when thus laid down.

That fpecies of cabbage called favoy, require exactly the fame treatment as the foregoing, except that, as they do not grow fo large, they need not be planted fo far afunder. Two feet and a half fquare will be a fufficient diftance between them. They always thrive beft in an open fituation, quite free from trees and hedges; for they are very apt to be greatly preyed upon by caterpillars and other vermin, in clofe places, efpecially if the autumn proves dry. If thefe vermin are not very numerous, they may be picked off by hand as faft as they are feen, and deftroyed by treading them under foot: but when their numbers are very great, the moft expeditious way of deftroying them is, to turn a parcel of hungry turkeys in among them. Savoys are moft efteemed after they have been pinched by the froft.

The management of the Ruffian cabbage, which is fo hardy as to bid defiance to the fevereft winter, requires the fame management, except the time of fowing, which like the favoy fhould not be till late in the fpring, and being very fmall, does not require fo much room when planted out. It fhould alfo have a clear open ground to grow on; but it will not laft long before it will burft, and run up to feed. Many think it a very fweet and well tafted plant, though it is not now cultivated near fo much as formerly. The trading gardeners around London feem to have excluded it entirely from their grounds; perhaps chiefly on account of its fmallnefs; but it ftill deferves a place in private kitchen gardens.

The fea-cabbage grows naturally upon the gravelly fea-fhores of many parts of England, and particularly in Suffex and Dorfetfhire, where many people dig it up from among the gravel, in the fpring, and prefer it to every other kind of cabbage. In that blanched ftate, before its fhoots have been expofed to the air, it is very fweet and tender, and may be eafily propagated in gardens, by fowing its feeds foon after they are ripe, in a fandy or gravelly foil. It will thrive there exceedingly, and increafe greatly by its creeping roots; but its heads will not be fit to cut before the fecond year. To have it in perfection, a layer of fand or gravel, four or five inches thick, fhould be fpread, at Michaelmas, upon the bed in which thefe plants grow, in order to allow a fufficient depth for cutting their fhoots, before they appear above ground; for till then they will be white, tender, and well tafted; but the air renders them green, tough, and bitter. This earthing up, or rather new fanding or gravelling the bed, fhould therefore be repeated every autumn, in the fame manner as is practifed for afparagus. It is the only culture that this fort of cabbage will require.

The beft methods of faving the feed of all forts of cabbages is this: about the end of November you fhould make choice of some of your best cabbages, which you should pull up and carry to some shed or other covered place, where you should hang them up for three or four days by their stalks, that the water may drain from between their leaves; then plant them in some border, under a hedge or pale, quite down to the middle of the cabbage, leaving only the upper part of the cabbage above ground, observing to raise the earth about it, so that it may stand a little above the level of the ground; especially if the ground be wet, when they will require to be raised considerably above the surface. If the winter should prove hard, you must lay a little straw, or pease-haulm, lightly upon them, to secure them from the frost; taking it off as often as the weather proves mild, lest by keeping them too close they should rot. In the spring of the year these cabbages will shoot out strongly, and divide into a great number of small branches: you must therefore support their stems, to prevent their being broken off by the wind; and, if the weather should be very hot and dry when they are in flower, you should refresh them with water once a week, all over the branches, which will greatly promote their seeding, and preserve them from mildew.

When your pods begin to change brown, you will do well to cut off the extreme part of every shoot with the pods, which will strengthen your seeds: for it is generally observed, that those seeds which grow near the top of the shoots are subject to run to seed before they cabbage; so that there will be no loss by this method, but a great advantage. When your seed begins to ripen, you must be very careful to secure it from being eaten by the birds, which are very fond of it: and when it is fully ripe, cut off the stalks, thoroughly dry the whole, thresh out the seed, and preserve it in bags for use.

Cabbages have lately been cultivated for the food of cattle, and by several experiments found to produce a very large increase when managed according to the principles of the new husbandry. M. de Chateauvieux has been very particular in relating the success of his experiments, which we shall therefore give the reader.

"I began, says this curious gentleman in a letter to M. du Hamel, by retrenching the dung; though the spot I chose for my first trial had not received any for several years. It had indeed been well prepared by ploughing the preceding year, when one half of it bore barley, and the other oats. I now made it into a bed, the middle of which was directly over the last year's furrow. I ploughed this bed on the twenty-fifth of September, 1751, in the same manner as if it had been intended for wheat. I planted on it a single row of white cabbages, which I watered to make them take root the better. The length of this bed was one hundred and sixty feet, and its breadth six feet seven inches.

"That I might be able to make a just comparison between the cabbages of this bed, and those of the kitchen garden, I planted a spot of ground in the latter, the same day, with the same sort of plants. This spot had been extremely well dug, and plentifully dunged by the gardener, who took all possible care of these plants during the summer, and weeded them as often as was necessary. Instead of cabbaging, most of them ran up in height: upon which I plucked them up, and planted others in their stead.

"I bestowed the same care and culture on my row of cabbages in the bed, as if they had been wheat.

"On the ninth of March 1752, the alleys were stirred with the plough. On the twenty-fifth of April, I gave them a second stirring with the cultivator. On the third of June they had a third stirring with the plough: and on the twentieth of July, I made my gardener hand-hoe them, for fear the plough should damage several stalks of wheat which grew on the next bed, and were bent, but not lodged.

"These cabbages were never watered, except once, which was at the time of planting them; and yet they were always crisp and firm, even in the hottest days. By this easy and expeditious culture, they attained all the perfection that could be desired; and surpassed those of the kitchen garden, as much in goodness, as they did in bulk. Most of them weighed between fifteen and eighteen pounds, and the smallest between eight and ten. The weight of all the plants which grew on this bed, was 840 pounds."

The intelligent and careful cultivator Mr. John-Wynn Baker, in a report he made to the Dublin Society, tells us, that he also cultivated cabbages after the manner of the new husbandry, on a piece of ground that had bore potatoes the preceding year. It was manured with a compost of lime, earth, and dung, perfectly incorporated. On the sixth and seventh of July 1764, he planted one row of cabbage plants on the middle of every ridge, of about an acre of ground, the plants in the rows being two feet from each other, and the rows five feet asunder. On the sixth of July a fine rain fell, and more on the eleventh and twelfth, which saved the expence of watering, and secured life to the plants.

On the seventh of August the cabbages were horse-hoed, by taking off, at one furrow of the plough, only one side of each ridge, close to the plants: in this manner they remained till the twenty-fifth, when the plough was ran along in the same furrow; by which, with the first furrow, the soil was ploughed about twenty-one inches deep. This being finished, the earth was immediately returned back to the plants, which afforded them fresh nourishment; and in order to give their roots time enough to penetrate this fresh earth, which, by the horse-hoeing, was become very fine mould, they were suffered to continue in this state till the twelfth of September; when they were again horse-hoed, by taking off the other side of every ridge; and on the twentieth the furrow was deepened in the same manner as the former, the mould immediately returned to the plants. On the eighteenth of October a small furrow was thrown up to each side of every ridge, which finished the culture, and restored the ridges to the form in which they were when the plants were put upon them.

The plants all grew luxuriantly; and in the hottest weather were infinitely more brittle in their leaves, than any in the neighbouring gardens; which is a certain indication of health in these kind of plants.

The horse-hoeing was so effectually destructive to the weeds, that the expence of weeding was a mere trifle.

On the eighth of December Mr. Baker cut one row of these cabbages, they then beginning to decay, which is indicated by their bursting. The number was two hundred and fifty-eight, and they weighed sixteen hundred weight, three quarters, and twenty-one pounds; which, at an average, is seven pounds and near six ounces for each cabbage.

The produce upon an acre, on weighing this row, which was five hundred and sixteen feet long, amounted to twenty-three tons, four hundred, two quarters, and fourteen pounds; which Mr. Baker observes is, at least, from ten to seventeen tons less than the product would have been upon an acre, could he have obtained the large, late, Dutch cabbage.

The ingenious Mr. Randall, in a treatise lately published, entitled Semi-Virgilian Husbandry, has given us the following method of cultivating cabbages, according to his newly-proposed system, which is nothing more than the New Husbandry executed by the ordinary implements.

The soil on which the cabbages are to grow, is supposed to be a loam in good heart; and as the Semi-Virgilian Husbandry requires only that the soil should be made exceeding fine, without the assistance of any dung, therefore the land destined for these cabbages must be thrown up to be fallowed, that it may enjoy all the advantages of a winter and summer fallow, so as to be exquisitely well prepared for the reception of the plants about Old Michaelmas.

As cabbages extract their nourishment from a considerable depth, as well as from the surface of the soil, it will be necessary that the land should be double-trenched during the time of fallowing.

The loam, immediately after harvest, is to be turned up, and the workman is to go as deep as he can with his plough, another plough is immediately to follow in the same furrow with a higher earth-board, which will cast the mould over, and bury the ſtubble, if it was not before, by ſome other method, deſtroyed: in this manner the field will, as it were, be turned upſide down, double ſpitted more than a foot deep, and the ſtubble will be ſooner rotted. The harrows muſt then make the ground as fine as the ſeaſon will at that time permit.

The next thing to be done, when the weather will admit of it, is to double trench the land, and lay it up till the ſpring in ſharp ridges.

Here Mr. Randall makes a very ſenſible and uſeful obſervation, namely, that the teams muſt not be ſuffered to go upon the ground till it is firſt tried with a ſpade, to ſee whether the ſoil is dry enough to the depth it was ploughed before; for treading the ground in any ſeaſon of the year, when it is not in order, or ſufficiently dry, is a very deſtructive practice. The ſtandard in this caſe recommended, very properly by Mr. Randall, is, when the mould crumbles or feels mellow between the finger and thumb, inſtead of adhering, ſo as to judge by the touch, whether the parts will give way to the tread, or whether the earth be in ſuch a ſtate of coheſion as to be padded under the horſes feet.

The following directions are given for performing the ridge-work, or laying up the ſoil for the winter.

The ploughman is to begin in any part of the ground he pleaſes, and go one bout, throwing the furrows in ſuch a manner, that they may form a little ridge. When this is done, the horſes muſt turn to the left, and the ſhare-point be put to the end of the trench; then go another bout in the manner already mentioned, the horſes again turning to the left, and continuing to go on in this manner, till the piece of ground is ploughed throughout. If the plough begins cloſe to a hedge, it may ſave ſome little trouble in going over more ground than is neceſſary; and where it can conveniently be done, the plough ſhould croſs the path the horſes went in the firſt operation, as this croſs-ploughing is often a means of ſtirring the baulks made by a former ploughing.

The firſt bout ſhould be drawn out as ſtrait as poſſible, as the reſt will depend upon it; and if the hedge is not ſtrait enough to allow this, the ploughman ſhould begin at ſome diſtance from it for the advantage of a ſtrait line, leaving the ſkirtings near the hedge to be laſt finiſhed. The land will now lie in gentle riſing ridges and regular valleys, ready for the third operation.

In this the ploughman is to go the very ſame ground over again, with the ſame plough, or one a little wider and higher in the earth-board, and throw the mould over the right and then over the left ſide of the firſt ridge, going four inches and a half, or five inches deep, and turning off, as before, continually to the left. This trench-work requires four good horſes to a plough; and the ſecond team, in the firſt operation, if the ground be hard, and has not been ſtirred for a long time, may require five horſes, but not more.

The ground will now lie in ſharp ridges, and deep trenches; and if the work be well executed, the bottom of the hollows, or little ridges, will be near twelve, or at the very leaſt nine, inches below the baſis of the ridges, or ſurface of the ground, and about eighteen inches wide; and the diſtance from the top of one ridge to another will be near three times and a half the width of the plough, as it runs in the ground after the horſes; the breadth of the ground, which each ridge ſtands upon, being about fourteen inches.

In this ſituation the land is to remain till the month of February, when the firſt opportunity that occurs in that month, the ridges and the whole ground being of a proper dryneſs, is to be ſeized for the next operation.

In the firſt place, a pair of ox-harrows, or the heavieſt of all, in many counties called drags, are to be yoked together, and the cattle are to go a-breaſt, not in a line; but two on one ſide, and two on the other, and to walk in the trenches, having a ridge between them; by which means the harrows will move on the crown of one ridge, at the center; and the outward parts, when well guided, will reach to the top of a ridge on each ſide that which divides the cattle. The harrows, which are to go only once in a place, will greatly reduce the ſoil, and pulling down the ridges, the ſoil will be in a manner level, yet not ſo even but that the ploughman may with eaſe diſcover where the ridges ſtood. The ploughman is now to proceed in the ſame manner as when he threw the ground into ridges, keeping the plough-ſhare along the crown of a ridge, which will be viſible enough after once harrowing. When he has gone one bout, which muſt be on the tops of two ridges, the furrows will be turned to the right, and lie pretty flat on that part which was a trench before: thus proceeding throughout the field, the whole will again lie in ſingle ridges, and ſingle trenches; but, if the weather permits, as ſoon as this operation is performed, the ſoil muſt be double trenched, in the ſame manner as the ſecond ploughing of the ſecond operation, when it is laid in ridges for the winter: thus the whole field will again lie under the double work of high ridges and deep trenches.

We are now to ſuppoſe the ridge-work brought forward to the latter end of the ſpring, or the beginning of the ſummer, when weeds begin to grow plentifully.

The ridges muſt, at this time, be pulled down as before, with heavy harrows; but inſtead of going once, the ſervant muſt go twice in a place, and then uſe the lighter harrows, and afterwards the fineſt of all, in order to prepare the ground in ſuch a manner, as to induce a large crop of weeds to grow: but if the weather will permit the horſes to tread on the ground without ſpoiling it, the weeds muſt not be ſuffered to grow more than a plough can bury by going the uſual depth; and when the weeds are turned down, another plough is to follow, and to cover the furrow of the firſt, after which the land is to be harrowed down again as level as poſſible, in order to prepare it for yielding another crop of weeds.

When the ſecond crop of weeds is got to a tolerable height, it may be proper to try, with a ſpade, whether the firſt weeds, which were turned town to the bottom of the ſecond ſtratum, are ſufficiently putrified: if they are, the land is to be ploughed as before; but if they are not, the weeds now growing muſt be turned down by one ploughing by ſuch a depth only as to bury them, and the land muſt be afterwards levelled with a loaded buſh-harrow.

We may ſuppoſe, that by the middle of Auguſt, the weeds firſt turned down will be rotted; therefore at that time the third crop of weeds may be turned down by the double ſpitting, already mentioned, and left in this condition till there is occaſion to make uſe of the land.

Juſt before the time of planting the cabbages, the land muſt be laid as level as poſſible, and by frequent harrowings it will not be inferior to a garden for fineneſs.

The ground being now ready to receive the plants, it will be neceſſary to point out how they are to be raiſed and tranſplanted, which cannot be better done than in Mr. Randall's own words.

" The ground on which the cabbage-ſeed is to be ſown, muſt be exceeding fine, in great heart, and abſolutely clear of weeds, otherwiſe it will be difficult to raiſe the plants in perfection; and, in order to this, the richeſt and cleaneſt piece of ground muſt be fixed on, immediately after the ſame harveſt, when the fallow for cabbages begins, and the nurſery for the plants muſt have all the advantages of fallowing equally with that which is to receive the plants; and about the middle of July the cabbage-ſeed is to be ſown: but as huſbandmen are unacquainted with the manner of ſowing this ſeed, it will be neceſſary to employ an honeſt gardener to perform this buſineſs as it ought; and the ſame perſon may be alſo employed to pick out the young plants upon another piece of ground, in great heart, and clear of weeds, leſt they ſhould draw one another before the ſeaſon arrives when they are to be tranſplanted out for good and all, on the ground whereon they are to ſtand for a crop: one perch will raiſe plants ſufficient for more than an acre of cabbages, from two ounces of ſeed, but it is better to have a great choice, as there will be ſome puny plants in the nurſery, let the gardener, or thoſe who prepared the ground, take what care they can; and the ſeed muſt be procured from Scotland, as the Scotch cabbage-ſeed is the propereſt for this vegetable, when deſigned for the uſe of cattle, as they will grow late, and to an enormous ſize, when they have all the advantages of ploughing among them, during the time of their growth.

" If the gardener is diligent, the expence of thus pricking out the tender plants, at ſix ſquare inches, on about ſix perches and a half, will be about four or five ſhillings; but if the owner can depend upon the nurſery's being clear of of weeds, though the weather be very growing, there is a much cheaper method of raising the plants: for if the gardener, with the above two ounces of seed, to be sown on six perches and a half, takes care to set out the plants with a small hand-hoe, before they begin to draw one another, he may hoe up the puny, and leave none but the stoutest plants, at a proper distance, suppose six inches, asunder, rather under than over. While he is doing this, he may assist the plants he suffers to stand, by giving them a little mould to their stems, and checking any weeds that appear; by this means, the plants will grow to perfection, and need not be removed till they are transplanted out for the crop: and if the gardener sows the seed, and leaves the plants on the same ground, about six inches asunder, one perch will transplant twenty-five, and, consequently, six perches and about a half will transplant an acre, from two ounces of seed on six perches and a half, and set out at six inches from each young plant.

" When the plants are thus raised on the nursery, by either method, pricking them out, or setting them out with the small hand-hoe, and the season is arrived for transplanting them on the ground they are to stand on to be cabbages, the next business is to consider the distance they are to stand from each other, when transplanted; and here we must first observe, that gardeners usually set them about two feet and a half from each other throughout the piece of ground allotted for that purpose; and, during their stay on the soil, they only hand-hoe and earth them up, when on the bed they are transplanted upon, without ever giving themselves any farther trouble about them, being no ways anxious to make them grow to the largest size which they are capable of.

" In an acre there are 4840 square yards, which is about sixty-nine yards and a half every way; but in order to proportion an acre in a piece of ground, if the length be measured, and the above number of square yards, in an acre, be divided by the length, the quotient is the breadth, and both dimensions multiplied together will give 4840 yards. Now, as gardeners plant their cabbage-plants at two feet and a half asunder, this is allowing six square feet and a quarter for each plant, and makes the number of about 6970 plants on an acre; and plants set in two rows, at two feet asunder, and the plants set two feet from each other in those rows, and then measuring out four feet and a quarter from one of those rows, and setting two rows more in the same manner, and so on throughout the ground; when the plants are set in this manner, the number of cabbages will be about 6970, which is the same as the gardeners raise on an acre, and the liberty of ploughing on one side of every row, or in the interval, and horse-hoeing between the narrowest rows, or the partitions.

" When the proper season arrives, about Old Michaelmas, or a little after, the plants are to be set, as above, first one row the length of the ground, at two feet distance from each other; and, when this is done, then another row in the same manner, at two feet distance from the last; and, when this is done, another row must be planted, in like manner, at the distance of four feet three inches from the last; then another row of plants, at two feet distance from the last: here, then, one system will consist of one partition of two feet, and an interval of four feet and a quarter, and of two plants to each system; for four feet and a quarter, added to two feet, and then multiplied by two feet, the distance of the plants in the rows, gives the parallelogram for two plants, or twelve feet and a half; and this, divided by two, gives six feet and a quarter; which is the gardeners distance, in their practice of cultivating these plants, or raising about 6970 cabbages on an acre, which is 2130 more than can be raised when they are planted in square yards throughout the acre.

" The ground being thus planted, we are now to conduct these vegetables through all the stages of their growth, and to help them to nutritive principles in the state of their greatest exigency; and, in order to this, at the beginning of winter the ground must be taken good care of, not only to keep it dry, but also to drain off the chilling wets from the bed of plants, which, as was said before, contains two feet. The first thing, then, to be done, at the approach of winter, but when the soil is dry, is to throw the intervals up into a sharp ridge, at two bouts, twice in a place, and as deep, each time, as the plough can go; this ridge-work, and double spitted, may be performed very well at two bouts, as it will allow nine inches in the middle of the interval, when the ploughman begins to turn the mould of the first bout upon; and then, at the second bout, he will reach within three inches of the plants, if he measures the ground as he ought with his plough, in leaving nine inches to turn the first furrow on, and keeps exactly nine inches, in the second bout, from the land side of the first: however, he must so manage his two bouts, as to come no nearer than three inches to the beds of plants, whilst he is going the second bout.

" This operation being over, the ground will then lie in the following form: there will be a high two-bout land in the interval, taking up five furrows in breadth, or three feet nine inches, reckoning nine inches for the breadth of the plough, as it runs in the ground; and there will be a drain, on the outside of each bed of plants, nine inches wide, and, it being double spitted, or twice in a place, near a foot deep, at least cut so with the plough, though some mould will unavoidably fall back again, notwithstanding the care the ploughman may take to prevent it: and from the edge of the land side of each drain, or the breadth of each bed of plants, there will be two feet and a half of ground, which, through the winter, will be kept very safe from too much wet, by means of those drains; which is of great consequence to the plants, as much cold moisture brings on such a condensation and contraction among the component parts of this vegetable, that all the expansive principles in the spring and summer cannot unbrace; by which a dwarf state of the plant necessarily ensues.

" About the latter end of March, or the beginning of April, if the ground be dry, the ploughman is to go once in a place in the drain, or open trench, in order to deepen it still more, and to stir the mould; and the ploughman need not be in any pain for the fibres of the roots, though he cuts or disturbs some of them in this operation: for as the fibres, which have stretched out into the bed, are undisturbed, he may cut off the outermost as near to the roots as he pleases, without doing any harm, unless he lets the plants down into the trench.

" When this operation is over, he must immediately throw down the ridge, by turning it back again, and leave an open trench in the middle of the interval, which may be done, very conveniently, at two bouts, without overthrowing the mould upon the plants; but he must remember to go twice in a place with his plough, to keep the ground double spitted, which is of great consequence to the plants, and therefore he must not think of omitting it: after this operation, the soil will have a double trench, in the middle of the intervals, the width of twice the breadth of the plough, and about twelve inches deep, if some of the earth did not fall back again; and there will be mould, the quantity of what is thrown out by the plough, in double spitting, lying between the plants and this open trench, and which will be thrown pretty near the roots of the plants; which mould is to continue there till the wants of this vegetable require us to make an alteration, when we have paid some attention to the partitions, and also to the plants themselves.

" About the middle or latter end of April, if the ground is dry, the horse-hoe must be used in the partitions, and the ploughman must go as deep with it as he possibly can, in order not only to disturb the young weeds, but also to stir the earth, in the most effectual manner, within the reach of the fibres; but, immediately before this operation, the hand-hoe is to be used in the rows, between plant and plant, to check the weeds, and refresh the mould about the roots, and the hoer must strike his instrument as deep as he can; and when the weeds, any time after this, appear above ground, in the partitions, or among the plants, the horse-hoe and hand-hoe must be used as before, but generally so timed, to be about a fortnight or three weeks after any alteration has been made in the intervals, that the fibres may have time, in either case, to heal again, instead of being disturbed all at once.

" About

" About the beginning of May the ploughman is to draw the heavy harrow, and then the finer, over the intervals, in order to pull the mould into the open trench, level, and make the whole interval fine, and to prepare it for a ploughing. These harrows, being the fame formerly mentioned, will do this bufinefs very well, without doing any harm to the plants; and if there be a good weight laid on them, they will do great execution, in pulling down the earth into the trench, and making the ground exceeding fine; which laft article is of importance, as the plough will, in future operations, turn down this fine furface to a depth where the lower horizontal fibres will meet with it, and find plenty of nourifhment therein.

" When the harrows have done their utmoft, the ploughman is to go one bout, and throw up a ridge in the middle of the interval, if the ground is dry, and to double trench, as before; and, in order to come near the plants, he may leave the breadth of about two furrows, on which to turn his bout, and then he will reach within fix or feven inches of the plants with his fhare: when this is performed throughout the ground, the harrows muft immediately be ufed as before, and then the ploughman is to turn all the mould towards the plants in two bouts, and double trenching, by which there will again be an open deep trench in the middle of the intervals: and about a month after this he is to ufe the harrows again, if the plants do not fpread too far into the intervals; if they do, he muft level the ground with his plough, or the horfe-hoe, and then go one bout, and turn the mould on the breadth of a furrow and a half, ftill going twice in a place; and then the ridge, and open furrow, on each fide, will contain about two and thirty inches, or the breadth of three furrows and a half, and he will have gone within nine inches of the ftems of the plants, which is near three inches farther off them than before.

" In this form the ground is to lie a month, unlefs the feafon be very growing, and the weeds make a bold appearance; in that cafe, it may be neceffary to difturb them fooner, by turning the ridge back again into the open trenches, and leaving the interval open in the middle, as formerly; and about Lammas, or a little before, the ploughman is to throw down the mould, into the middle open trench, and make the intervals level and fine, and this is the laft operation arifing from ploughing; the ground being now to remain, without difturbance, any farther than what enfues from the ufe of the horfe-hoe, in the intervals, after the ground is made level, as, before fummer is over, there may come up fome weeds, which muft not be fuffered to appear with impunity. It is prefumed, that due care has been taken throughout the feafon of the partitions, and between plant and plant in the rows, and likewife on the outfides near the plants, in the intervals, where the fhare and coulter could not reach without doing damage; and therefore, when the vegetables fhut out the horfe-hoe, in the partitions, or where the plough could not, or durft not, reach, the hand-hoe was to have done its office, to fupply thofe wants, in the beft manner it could.

" There is another method, which we have not mentioned, to tranfplant this vegetable on the ground it is to grow into a cabbage, which is cheaper; and it is this: thofe ploughmen, who can draw out a very ftrait furrow, fet off firft, and the perfons, who are ready with the plants, put them into the trench, fo made with the plough, at their proper diftance from each other; and when the ploughman has gone the firft bout, within the compafs of three feet and a half from the fhare point, he is to go another bout, to turn the mould into the firft open furrow, fo as not to bury the plants, in this operation; and he will have gone thefe two bouts, one to open the ground for the reception of the plants; and the other to give them mould, by the time the people have fupplied the furrows with plants, fo that they may be all ready to ftart together again when the team returns to the head land, from making his fecond bout.

The plants, on this occafion, muft be placed upright in the trench, ftanding againft the right-fide of it, which may be done if the plough cuts the ground true, and the mould be well fcooped out; and this will fhew care in the perfon that holds it, and that his inftrument is a good one. There muft be a perfon to carry a gage, divided into two feet, in each divifion, ten feet in length, which will contain fix points, the two ends, and four intermediate ones, numbered from one to fix; which divifion and points fignify, that a plant muft be placed in the open trench, directly againft one of thofe figures, as the gage lies upon the ground, when the man, who has the care of it, lays it down in a ftrait line, according to his office. In order to fhew how the plants are to be ranged, in a moft regular manner, exactly at two feet from each other, in the rows, we will fuppofe the ploughman to be juft fetting off to go his firft bout: in this cafe, the gager is to ftand with his inftrument, which may be a fquare piece of wood, of about three inches over, or twelve in the girt, and numbered 1, 2, 3, 4, 5, 6, facing the right fide of the plough when it fets off; he muft lay his right-hand juft beyond figure 4, and his left juft beyond figure 3, and, holding it in this manner, he will poife the gage very well, and lay it down, take it up, and remove it, without trouble to himfelf.

" Now, by ftanding about five feet, on the right fide, from the place where the plough enters, and two perfons with plants in their aprons, and a woman with a bafket full behind him, ftanding on the left fide, in this pofture of the people, the plough is then to move on, and when the ploughman has paffed by the end of the gage, the gager is then to lay it down, but in fuch a manner, that the end, number 1, may touch the place where the plough entered the ground, and the end, number 6, may lay in the right edge of the trench, on the mould turned out. The firft man muft fix his eye on figure 1, and, at the fame time, the fecond man on figure 4, and each of them, is to place a plant againft his own figure; and then the firft gardener puts down another at figure 2, and another at figure 3, and while he is doing this, the fecond gardener fupplies figures 5 and 6, in the very fame manner; and, when they are fupplying figures 3 and 6, the gager is to ftoop down to be inftantly ready to take up the gage, in the manner before directed, and the gardeners muft take care to keep time with each other, that there be no delay in moving after the plough, in its progreffive motion.

" The gager is inftantly to remove his inftrument, placing the left end clofe to the laft plant, and the other end as before; and the gardeners are to take care of the three figures belonging to their office, the firft man managing the three firft numbers, and the fecond the three laft. They may go on very faft in this manner, if they pleafe, and, if they are three honeft active men, no plough can out-travel them in making one bout: and in this operation it is expected of the ploughman, that he will make his horfes ftep on brifkly, which they may very well do with fuch light work; for, by the fwifter motion of the plough, there is not only lefs expence attending this culture, but the trench is better cleared of the mould, and left fquare; and the furrow is thrown fo far to the right as to be in lefs danger of falling back again, which it may otherwife do, from a creeping fluggifh motion of the plough.

" Though two active gardeners, or hufbandmen, when the latter are ufed to the nature of plants, and placing them in the ground, may get forwards as faft as the plough; yet, in order to have the plants properly put againft the figures, it may be better to have them take their time, and to proportion their work in fuch a manner, that they may finifh by the time the team is at their heels, in ending the fecond bout. The gager, and the two gardeners, need not be afraid of too much ftooping; for the gager, when he ftoops to put down his gage, has walked five feet, from the laft place where he took it up, and, in fact, is only diverfion and exercife for him; and the firft gardener, when he ftoops to put down his three plants, ftepping along at the fame time, in that pofture, has fix feet of ground to walk upright upon, which he may difpatch very nimbly, if occafion requires it; and the fecond gardener, in like manner; and as a perfon attends them at their backs with a bafket of plants, they may, without lofs of time, be fupplied, while they are walking, and take lefs or more into their aprons,

aprons, or hands, as they see convenient, and consistent with dispatch.

"When the gager gets up to the far end of the ground, he must remember to keep on the furrow side of the plough, that is, on that side towards which the mould is turned; and the ploughman is now to receive farther directions how to proceed, when he has gone the two bouts, mentioned before. He was desired to draw out a very strait furrow when he first went up the ground, by taking sight of a tree, bush, or any other mark, exactly in the middle of the ground, and directly opposite to the place where he is to set off from, and which he judges to be in the middle; or he may use any method agreeable to himself, provided a strait line be only drawn out by the plough, for on this depends the regularity of all the rest of his bouts, and the operations of horse-hoeing and ploughing during the growth of the cabbages. The first furrow being thus drawn out, the next business is, to turn the horses to the right, and then to measure three feet and a half, from the edge of the land side of the first furrow, or that edge cut with the coulter; and, making a mark at the end of three feet and a half, he must put the share point in there, and come strait back again, keeping exactly three feet and a half from the far edge of the other furrow; and then, as was said before, he must go a second bout, to turn the mould into the open furrow where the plants are placed, which he may very well do without doing them any harm: if he proportions the depth of the furrows, where the plants are put, to their size, as they will be greater or less, just as the season has been for their growth on the beds whereon they grew.

"When all this is performed, and the ploughman is ready to set off again, in order to make another bout, he is to turn to the right, to draw out another furrow, which is to receive the plants, which must stand four feet and a quarter from the row of plants now on his right-hand; to do which he is to consider, that the near edge of the open furrow next to him is the breadth of two furrows, or eighteen inches, from that row of plants; and taking eighteen inches from four feet and a quarter, the remainder is thirty-three inches; and because the plants must stand on the furrow side, therefore we must add the breadth of the plough, which is nine inches, to the above thirty-three, which then will make three feet and a half from the edge of the open furrow next to him; and now measuring three feet and a half from that furrow, he must make a mark, and go his bout, turning to the right, and making the same mark from the outermost furrow as before, and so proceeding strait back again.

"He is now to go another bout, to earth his plants, and when he has done this, he must still turn to the right, and make a halt on the head land, to consider what is next to be done: he knows the edge of the open furrow, now on his right-hand, and next to him is eighteen inches from the nearest row of plants, and that the furrow he is going to open is for the plants to stand just two feet from the last row; and therefore taking eighteen from twenty-four, the remainder is six: and because the breadth of the plough is nine, therefore he must measure fifteen inches from the edge of that open furrow next to him, and making a mark there, that is the place where he is to set off: and when he gets to the far end of the ground, he must turn to the right, and measure off fifteen inches from the edge of that open furrow next to him, as he comes down again: he is to go another bout to earth his plants, and then all things will be easy to him, as it will be only repeating what he did before; for as he is now going another bout, he is to measure three feet and a half, from the near edge of the open furrow next to him on his right-hand, and go strait up, and turning still to the right-hand, he must measure the same distance, as he comes down again from that open furrow, and when he has made another bout to earth those plants, he measures fifteen inches from the edge of that furrow; and when the plants are put into that he is now making and earthed, he then proceeds to measure off three feet and a half, which forms the interval, and so on earthing, and then measuring fifteen inches alternately with the other, for the partitions, till all is finished.

"By which operations the whole ground will be planted with two rows, at two feet the partitions, and four feet and a quarter the intervals. Thus, then, upon the whole of these directions, when he first sets off, and gets to the far end, and, turning to the right, he measures three feet and a half; when he has earthed plants, he measures three feet and a half for the next bout to receive the plants; and, earthing these, he measures fifteen inches for another row of plants; and, earthing these, he measures three feet and a half; and earthing these, he measures fifteen inches; and so on, alternately, three feet and a half, and earthing; then fifteen inches, and earthing; then three feet and a half again."

The farmer will, doubtless, be glad to know what crop he is to expect from his land after all his labour; he has already been informed, that the number of cabbages on an acre, if they have all stood to maturity, will be six thousand, nine hundred and seventy: these may be allowed to weigh, one with another upon a medium, three quarters of a stone each; and if an ox be allowed to eat nine stone a day, that is, twelve cabbages, then six oxen will live three months on one acre of them; so that supposing one acre of turnips, raised in the common method of husbandry, to be sufficient during the same space of time for two oxen, we may still expect, in proportion, three times more benefit from the cabbages than from the turnips.

Mr. Randall assures us, that the oxen will grow very fat upon such food; that he has given it to many cows for a long time together, without perceiving the least disagreeable taste, either in the milk or butter: on the contrary, the milk was rather richer and sweeter; and that both oxen and cows are exceedingly fond of this food. The same may be said of sheep, which improve in their flesh very fast, and grow surprizingly fat on cabbages; yet has the mutton no disagreeable taste; so that there is perhaps no vegetable which will raise lean sheep of the largest breed sooner than cabbages. *Randall's Semi-Virgilian Husbandry, p.* 315.

CADDOW, a name given to the jack-daw, in some of the northern counties of England.

CADMA, the least of the pigs which a sow has at one farrowing; for they have generally one which is remarkably less than the rest.

CALF, the young of a cow.

There are two ways of breeding those calves you design to rear; the one is to let them run with the dam all the year, which is the common way used in the cheap breeding countries, which they reckon makes the best cattle; and the other way is, to take them from the dams after they have sucked about a fortnight: then they teach them to drink flet or skimmed milk, which they make just warm for them, it being very dangerous to give it them too hot. The best time for weaning of calves is from January to May. Let your calves have milk for about twelve weeks; only a fortnight before you wean them from milk, let water be mixed with the milk; and after your calf hath drunk milk about a month, take some of the freshest, sweetest hay you have, and put little wisps of it into some cleft sticks, which place so as the calf may easily come at them to learn to eat; and after Lady-day, when the weather is fair, turn your calves to grass, taking them in a few nights at first, giving them milk and water, and sometimes giving the same to them in a pail in the field, till you find they are able to feed themselves, so as not to desire it: but by no means let your grass be too rank, but short and sweet, that they may get it with some labour. All wean their calves at grass; for if you wean them in the house with hay and water, it is apt to make them big-bellied, and to rot; and when you have resolved which of the males to keep for bulls, let the others be gelt for oxen, which the sooner you do the better: when they are about ten or twenty days old, is the best time, and least dangerous.

In Hertfordshire, Essex, and most places near London, they commonly fat all their calves for the butcher, because they have there a good market for them, and the lands are not so profitable to breed on as in cheaper countries; a good calf there often selling for as much as a good heifer, especially if they are very fat and white, which they take a great deal of care to make them. Their way of doing this is by keeping them clean, giving them fresh litter every day, which they lay upon their old litter; for they clear out their coops but two or three times in a year, and most commonly at a time when they have no calves in them; they constantly also let them have a large chalk-stone or two to lick, which they bore a hole through, and hang up by a string in a corner of the coop, which prevents their fouling it with dung and urine. They also observe to set their coops where they may have as little sun come to them as they can, that they be not made close and stifling, and that they stand a yard above the ground, that the urine may run from them: and to make them white, they often let them blood when they are about a month old, and a little before they kill them; and because they are often loose, they do not let them suck their fill; but instead of it they sometimes give them chalk scraped into milk, which they pour down with a horn; also salt and water, and sometimes they cold bathe them, and give them bole-armoniac and chalk, which they moisten with milk, and make it into balls, and give it them. If a cow will not let a strange calf suck her, rub both hers and the calf's nose with a little brandy. *Mortimer's Husbandry, vol. I. pag.* 228.

A young calf is left with its dam the first five or six days, that it may be kept always warm, and suck whenever it pleases: but if in those five or six days it grows and gathers strength, there is a necessity for making a separation, as he would exhaust the cow if left always with her. Sucking two or three times a day will now be sufficient. If you intend to fatten him speedily, and, at the sme time, render his flesh fine and delicate, let him have every day raw eggs, boiled milk, and the crumbs of bread: by this means the flesh, at the end of four or five weeks, will be excellent. Calves, therefore, intended for the butcher should not suck above thirty or forty days; but those designed for the dam for two months at least; as the more they suck, the stronger and larger they will prove. The best for bringing up are those calved in the months of April, May, and June. It is seldom that those which come later acquire sufficient vigour to support them during the inclemency of the following winter; the cold causing them to droop, and many of them to die. Thus calves designed for keeping should be weaned at two, three, or four months; but before taking them totally from the milk, a little good grass, or chopped hay, should be given them, that they may become accustomed to such aliment; for when they are to be entirely separated from their dam, they must never be suffered to come near her either in the stall or pasture, whither they should be sent every day, and remain there, during the summer, from morning to evening; but at the setting in of the cold weather in autumn, they must not be let out till late in the morning, and brought back early in the evening. And as the pinching cold of winter will be extremely detrimental to them, they should be kept very warm in a cow-house, and well supplied with water; saintfoin, lucern, &c. should be mixed with their common hay. They must be let out only in warm weather. A great deal of care is necessary to bring them through the first winter, which is the most dangerous period of their lives; for they will acquire so much strength during the following summer, that they will have nothing to fear from the cold of a second winter. *Buffon's Histoire Naturelle, tom.* IV.

The desire of profiting by the milk of the cow, is often the cause of the calf's being two early weaned. A month or two more, in short the time required by nature, would strengthen it in its youth; it would grow more successfully, and, in time, fetch a profit with good interest. But this is hardly done any where. No sooner is it believed that it can subsist without the mother's milk, than the farmer thinks he gains a great deal by weaning it: ill fed, and infirm, it grows at best to be a sorry bull, or feeble bullock, from which little profit, and much less service, can be expected.

Ignorance and want of reflection form the principal source of this abuse! People do not know, or do not reflect, that the vital flame, inclosed in the heart of a new-born animal, must be cherished and augmented; that it attracts and is nourished by that contained in the milk; that this vital flame, weak at first, would scarce have power to separate the auxiliary fire from the milky particles with which it is incorporated, if milk was a less delicate substance than nature hath formed it for this first service; but in proportion as the vital fire acquires force, the milk grows thick, because its grosser particles are destined for forming and consolidating the body of the animal. When the vital flame is arrived at such a degree, as to be superior to the succours which the milk can afford, nature excites the animal to seek a more solid nourishment, and then, but not before, is the time for weaning it. For, by anticipating that time, you run the risque of leaving the animal imperfect in its interior parts: the aliment which is administered being above its strength, it cannot perform a perfect digestion, and the nourishment it receives is so much the less; because, in all natural bodies, the strongest juices, and the most efficacious qualities are always mixed, and, as it were, blended with the hardest particles. Hence it happens, that a sickly animal does not derive from the same food so much nourishment as an animal in health. Indeed the vital flame, too much employed in resisting the attacks of the corrupted humours, hath not force enough to extract from the aliment the necessary auxiliary fire it contains. Besides, the food being only in part dissolved, passes away in the excrements, and forms only a thin inefficacious manure.

As therefore we may be assured, that by weaning a calf too early, it will continue infirm and of small value, so by leaving it with its mother, as long as its constitution requires, we may expect it will become strong and vigorous; and by following this method, we can hardly fail of raising a breed of cattle, that will redound both to the honour and profit of the farmer.

Young calves are apt to be attacked by insects, which disturb and torment them, and, at the same time, prevent their fattening. In order to preserve them from these insects, and even cure them when they are attacked, it will be proper to prepare an ointment of melted hogs-lard and quicksilver, well rubbed together in a marble or iron mortar. Spread this ointment upon a linen cloth, which wrap up in three folds, and stitch it for a collar to the calves. It will not only cure them, but also disperse the insects.

There is no better nourishment for young calves, than vetches soaked in water till they swell; but observe to steep no more than will serve them for once; because when they continue moist for any considerable time, they are apt to grow sour, and would then do them more harm than good. *Journal Oeconomique.*

CALKINS, a name given in some parts to a sort of horses shoes, made for frosty weather.

These shoes, by forcing the horse to tread wholly on the toes of his hind feet, are apt to occasion bleymes, and ruin the back sinews. The farrier, therefore, should be ordered to pare the horn a little low at the heel, and turn down the sponge upon the corner of the anvil, so as to make the calkin resemble the point of a hare's ear, which will remove the consequences often attending the common square calkin.

CALTHA, the marsh marygold, the name of a perennial plant, growing naturally in the low meadows, in many parts of England.

M. du Hamel recommends this plant to the notice of farmers, as very useful to be cultivated as a winter pasture for cattle; and experience has justified his recommendation. Perhaps it might prove as useful in this country as in France, especially as cattle are known to be extremely fond of it, and the plant might be easily cultivated.

CAMMOCK, the name of a troublesome plant infesting arable lands; but more generally known by the name of rest-harrow. *See the article* REST-HARROW.

CANARY-*seed*, the name of a small seed produced by a gramineous plant, cultivated in some parts of England.

A correspondent of the editors of the Museum Rusticum, has given us the method practised by the farmers of the island of Thanet, in the culture of canary-seed. He observes, that they generally chuse to sow it in fresh land; that is, fuch as has only borne grafs. After ploughing up the lay, and bringing the land into tolerable rough tilth, they fow it with peas; thefe are kept clean hoed as ufual, and yield a good crop. The next year the land is well ploughed, and planted with horfe-beans, which thrive well in that ifland. Thefe two crops effectually kill the greenfward, or grafs; take off the ranknefs of the foil; and the frequent hoeings, which are neceffary to keep the weeds under, bring the land into fine tilth. After the beans are off, a thorough ploughing is given to the land, and in that condition it remains till the fpring: about the beginning of March, if the weather be fine, and the feafon dry, the land is ploughed for the laft time; immediately after which the canary-feed is fown.

The farmers in that ifland ufed formerly to fow canary-feed with a broad caft, fpreading it all over the land; but when this was the practice, they found it very difficult to hoe and keep the plants clean from weeds: at prefent they fow it in furrows, made a-crofs the land, conftantly taking care to make the ridges between the furrows as fharp as poffible: by this means the feed, which is fown by hand, flips from the fides and tops of the ridges into the furrows, and the plants come up in regular rows. The plants muft be kept very clear of weeds by means of the hoe, weeding-hook, &c. and if it be a wet fummer, the intervals muft be hoed feveral times; but of this the intelligent farmer is the beft judge.

Three pecks of feed are, in general, enough to fow an acre, fometimes more, and often lefs. The canary-feed feldom comes on till the wheat harveft is entirely over, and the corn houfed: but it muft be obferved, that the wheat harveft is generally very early in that ifland. It is reaped with a hook, and as faft as it is cut, the reapers lay it on the land in wads, as they call them, or parcels about the quantity of half a fheaf of wheat unbound: in this manner, if the weather be favourable, it is left near a fortnight, at the end of which time, the wads muft be turned, that the other fide may be dried. If the weather be very wet, they muft be turned oftener, to prevent the feed from fprouting.

The price of reaping canary in that ifland is from fix to eleven fhillings per acre; and the price of threfhing and dreffing it is five or fix fhillings a quarter. According to the goodnefs of the land, and the tillage that has been beftowed upon it, the farmers there expect their return to be from twenty-five to fifty bufhels per acre; but the common crop is from thirty to thirty-four. It muft, however, be obferved that the farmers never pay fo much as ten or eleven fhillings per acre for reaping this crop, unlefs the canary be very much lodged and tangled, which it often is, owing to the land in which it grows being frefh, rich, and rank, and to the high winds to which that ifland is fubject.

They fow fucceffive crops on the fame land for eight or ten years; and fowing canary would be a very great improvement to lands which lie convenient for water carriage to London markets, was it not a crop the farmer ought by no means to depend upon, not only becaufe the return, or quantity it yields, varies greatly, but alfo on account of the fluctuation in the price of this feed in the London markets, where the greateft and indeed almoft the whole demand is. *Mufeum Ruft. vol.* I. *p.* 22.

CANKER, a fmall fpeck made by a fharp humour, which gnaws the flefh almoft like a cauftic.

This diftemper often attacks the foot of a horfe, and generally proceeds from thrufhes, when they prove rotten and putrid, though many other caufes may produce this diforder. The method ufed by farriers for the cure is generally with hot oils, fuch as vitriol, aqua fortis, and butter of antimony, which are very proper to keep down the rifing flefh, and fhould be ufed daily till the fungus is fuppreffed, when once in two days will be fufficient, ftrewing red precipitate powder over the new grown flefh, till the fole begins to grow.

There is one great error committed often in this cure, which is, in not having fufficient regard to the hoof; for it fhould not only be cut off, wherever it preffes upon the tender parts, but fhould be kept foft with linfeed oil; and as often as it is dreffed, bathe the hoof, all round the coronet, with chamberlye. Purging is very proper to complete the cure. *Bartlet's Farriery, p.* 314.

CANKER, in trees, implies a wound or blemifh in the trunk, which does not heal up naturally, but will increafe and damage, if not endanger, the whole tree.

The canker in fruit trees is moft commonly occafioned by wet, which gets in at the cleft where the tree was grafted, or at fome other wound which has been neglected: but it alfo proceeds fometimes from the foils not agreeing with the nature of the tree.

If this diftemper be only fuperficial, arifing from a bruife, for example, which the bark may have received, it may be cured by cutting the injured part out with a fharp knife, and then binding over it a mixture of cow-dung and earth, tied on with a wifp of hay, likewife daubed with cow-dung. This muft be done before the fap begins to rife; for otherwife the bark will peel, loofen, and wither much farther than the bruife, to the great hazard of the whole tree, efpecially if the ftem be the part affected; for as to a bruifed branch, the beft way is to lop it off at once, if there be the leaft fufpicion of danger. But when the canker has been bred in the tree, or when it has extended from the trunk to the branches, or from the branches to the trunk, fo that after cutting away to the very quick, there ftill remains an eye, or fpeck, like that which is fometimes feen to run through a whole plant of diftempered corn, the fhorteft way is, to commit the tree to the fire, and to plant another in its ftead. Mr. Nourfe is indeed inclined to think that, if the canker has not penetrated too far the tree or ftock, fuppofing it to be of the apple kind, it may poffibly be faved, by regrafting it with a winter quinnin, a boderan crab, a boon apple, or a golden pippen; neither of which he had obferved ever to canker: but how accurate his obfervations may have been in that refpect, we fhall not pretend to determine. Certainly it may be worth while to try a change of fruit in all fuch cafes, if they are not abfolutely defperate. He afferts, upon his own experience, that the apple which we call a woodcock, is no way apt to canker, or to be blafted.

This, if it be fact, renders it by fo much the more worthy of cultivation, as it is a great and conftant bearer, and yields an excellent juice. The misfortune is here, as well as in the attempts which have been made to fuit the foil and the fruit, that each of thefe is diftinguifhed, either by fuch general appellations and defcriptions as ferve only to puzzle the hufbandman when he comes to real practice, or by names which are not known out of the places where they are ufed. Doctor Cullen will render a great fervice to mankind, if he fhould happily fucceed in that important point, which, if we are rightly informed, is the object of his prefent ftudies; viz. to afcertain by an exact analyfis, which no one can be better qualified to do with the utmoft precifion, what are the component particles of each different fpecies of foil, and what proportion they bear to each other. This, divefted of that parade of fcience, and of fcientific terms, which the learned are too apt to difplay, and which ferves only to embarrafs common underftandings, will, fhould fuch a work appear, as it is hoped that it will foon, anfwer a very effential purpofe in agriculture, as well as lay a fine foundation for ufeful entertainment to gentlemen whofe leifure permits them to profecute fuch ftudies. But the tafk, confidered in all its various branches, is arduous indeed! worthy of that able phyfician, we ufe the word here in its moft extenfive and moft proper meaning, and fkilful chemift, whofe love for the welfare of mankind has prompted him to undertake it.

Mr. Worlidge affures us, that he himfelf cured a tree defperately difeafed with the canker, by cutting off as many as he could of the cankered boughs, laying its roots bare during all the winter, and applying to them in the fpring a great quantity of fwines dung, not too new, mixed with the earth, which was then returned into its former hole. If this does not do, he condemns the tree to be grubbed up, as being paft recovery. *Nourfe's Difcourfe on the Benefits and Improvements of Hufbandry, pag.* 138. *Worlidge's Syftema Agriculturæ, cap.* viii. *fect.* ii.

CAPELLETS, in horſes, are particular ſwellings which thoſe animals are ſubject to, of a wenny nature, which grow on the heel of the hock, and on the point of the elbow: they ariſe from bruiſes and other accidents, and when this is the caſe, ſhould be treated with vinegar and other repellers; but when they grow gradually on both heels or elbows, we may then ſuſpect the blood and juices to be in fault; that ſome of the veſſels are broke, and the juices extravaſated. In this caſe the ſuppuration ſhould be promoted, by rubbing the part with marſhmallow ointment; and when matter is formed the ſkin ſhould be opened with a lancet, in ſome dependent part towards one ſide, to avoid a ſcar: the dreſſings may be turpentine, honey, and tincture of myrrh. The relaxed ſkin may be bathed with equal parts of ſpirit of wine and vinegar; to which an eighth part of oil of vitriol may be added. The contents of theſe tumours are various, ſometimes watery, at others ſuety, or like thick paſte; which if care be not taken to digeſt out properly with the bag, will frequently collect again: was it not for the disfigurement, the ſhorteſt method would be to extirpate them with a knife, which, if artfully executed, and the ſkin properly preſerved, would leave very little deformity.

When thoſe tumours proceed from an indiſpoſition of the blood, they are beſt let alone, eſpecially thoſe of the watry kind, which will often wear off inſenſibly, without any applications: but when they are like to prove tedious, you ſhould endeavour to diſperſe them by bathing the parts with repellers, and have recourſe to rowels, purges, and diuretic medicines, to carry off the ſuperfluous juices and correct the blood. *Bartlet's Farriery, p.* 277.

CAPO, a word uſed in Cheſhire, to ſignify a working horſe.

CAPON, a cock chicken gelded as ſoon as left by the hen, or at leaſt as ſoon as he begins to crow.

Capons are very uſeful to lead chickens, ducklings, young turkeys, pheaſants, and partridges, which they will do better than the hen, and at the ſame time make a ſtouter defence againſt kites and buzzards. The largeneſs of their body is alſo of great advantage, as they will cover between thirty and forty of them.

CARAWAY-SEED, the ſeed of a plant growing wild in ſome rich meadows in Lincolnſhire and Yorkſhire; and is ſometimes found growing in the paſtures near London. It is alſo cultivated for uſe in Eſſex, and ſome other counties.

It is a biennial plant, which riſes from ſeeds one year, flowers the next, and periſhes ſoon after the ſeeds are ripe. It has a taper root like a parſnep, but much ſmaller, which runs deep into the ground, and hath a ſtrong aromatic taſte, ſending out many ſmall fibres; from the root ariſes one or two ſmooth, ſolid, channelled ſtalks, about two feet high, garniſhed with winged leaves, having long, naked foot-ſtalks. The ſtalks divide upward into ſeveral ſmaller branches, each of which is terminated by an umbel, compoſed of ſix or eight ſmall ſeparate umbels, ſuſtaining ſingle white flowers, with heart-ſhaped petals; the flowers of thoſe ſmall umbels are cloſely joined together. After the flowers are decayed, the germen becomes an oblong channelled fruit, compoſed of two oblong channelled ſeeds.

The beſt ſeaſon for ſowing the ſeeds of this plant is in autumn, ſoon after they are ripe, when they will more certainly grow, than thoſe ſown in the ſpring; and the plants which riſe in the autumn generally flower the following ſpring, ſo that a ſummer's growth is hereby ſaved. *Millar's Gard. Dict.*

Caraway-ſeeds delight in a dry mould, ſomething inclining to clay, or rich garden mould. Eight pounds will ſow an acre. *Mortimer's Huſb. vol.* I. *p.* 201.

CARBERRY, a name given in ſome parts of England to the gooſeberry.

CARCASE, a name generally given to the body of a horſe.

The carcaſe of a horſe ought not to be too ſmall and ſlender; for a ſmall carcaſed horſe is generally weak. On the other hand, a very large carcaſed horſe proves often heavy and unactive, and when he happens to be underlimbed, it is reckoned a great fault, though this remark often fails, and horſes, that have been reckoned very much underlimbed, have proved as ſtrong, and fully as ſerviceable as any other.

A low back is another fault that almoſt every body complains of, and indicates weakneſs, though a moderate ſinking below the withers is not at all amiſs, if the back be otherwiſe ſtrait. When this ſinking is not great, the forehand generally riſes well. But when a horſe has a low back, and is higher behind than before, it is not only ugly, but ſuch horſes are generally weak, are apt to be pinched in their ſhoulders, and have an aukward way of going, owing to the heavineſs of their hind parts, which hinders them from getting on.

Some are fond of horſes which are home ribed, which is indeed a property that denotes both beauty and ſtrength, as thoſe that are open ribed are looked upon to be weak and looſe; but in ſome horſes the ſhort ribs approach ſo near the haunches, that they have ſcarce liberty to breathe, and ſuch horſes are the moſt out of wind of any other when put upon hard exerciſe, and eaſily go broken winded. But a horſe that is open and looſe in his flanks, like a grey-hound, is liable to many diſadvantages, which it would be tedious here to relate; ſuch are always narrow over the chine, have little or no belly but what is forced by art and feeding; and though we find ſome of this kind more vigorous than others, and even exceed all expectation, yet the generality of ſuch horſes are ſeldom fit to carry a great weight, or to hold out in hard riding. Some are great admirers of ſhort backed horſes, which is a right way of judging, ſo far as this ſtands in oppoſition to a very long back. But ſome horſes are ſo very ſhort, notwithſtanding they are otherwiſe of a good ſize, that they ſeem to be loſt under common furniture. But when a tall horſe happens to have a ſhort carcaſe, and very long legs, like a ſpider, ſuch a horſe is ſeldom good for much. If a horſe's back be ſhort, his whole body and limbs ought to be ſhort, and then it denotes ſtrength and firmneſs; but moſt of theſe make but a ſlow progreſs on a journey, though they will endure and hold out as long as any other, unleſs they are urged on with horſes of greater ſpeed.

It always denotes ſtrength in a horſe, when his carcaſe is of a moderate ſize, his ribs large, his flanks not hollow but ſmooth and full, with a ſtrait back, or but a very little ſinking, his hinder parts, or uppermoſt haunches not riſing higher than his ſhoulders. *Gibſon on horſes, vol.* I. *p.* 31.

CARDOON, a kind of wild artichoke, propagated only by its ſeed, which is if an oval form, about as big as a grain of wheat, of a very dark green, or blackiſh colour, and marked with black ſtreaks from one end to the other. There are two ſeaſons for ſowing it: the firſt is from the middle to the end of April; and the other about a month later. The ſoil ſhould be rich, deep, and fine. In a bed of ſuch mould, four or five feet wide, two trenches ſhould be opened, a foot wide, ſix inches deep, and at leaſt three feet aſunder: or, to anſwer the ſame intention, the rows of holes of the ſame depth ſhould be dug ſtrait by a line ſtretched along the bed. Theſe holes ſhould be three feet aſunder, and in quincunx order; or, if a trench is uſed, the quincunx form ſhould be obſerved in ſowing the ſeeds, which is performed in the following manner. Five or ſix of the ſeeds are dropped nearly together, at the diſtances before mentioned, and then covered over: not with a deſign to let ſo many plants grow cloſe together in a thick cluſter; but, as the growth of theſe ſeeds is ſomewhat precarious, to be the more certain of having two or three plants at each ſtated diſtance: for if all of them come up, they are immediately thinned to that number; and if they miſcarry entirely in any one ſpot, the chaſm is filled up with plants taken from another place, generally a hot-bed, on which ſome of theſe ſeeds are moſt commonly ſown when its heat is expiring, for a recruit in a caſe of need. The firſt ſowing will generally come up in three weeks, and the latter in about fifteen days. Great care muſt be taken to keep thoſe plants clear from weeds, and to water them frequently, in order to make them increaſe in bulk, and not run to ſeed. But this intention will doubtleſs be much better anſwered in every reſpect by a judicious application of the principles of the new husbandry; we mean, by deep and frequent ſtirring of the ground on each ſide of the bed, letting the ſhare or ſpade approach to within a very few inches of the plants.

Towards the latter end of October, the cardoons thus cultivated will be fit for tying up, in order to be blanched. In order to this a dry day ſhould be choſen, when all the leaves of each cluſter being collected cloſe together, wiſps of ſtraw, or long litter, ſhould be twiſted round them ſo as to prevent the acceſs of the air to any part of them, except their very top, which ſhould be left open. In a fortnight or three weeks the plants thus covered will become white and fit to eat.

This tying up, and blanching of cardoons, may be continued till the winter approaches, and then thoſe who are ſo fond of them as to think it worth their while to be at the trouble, may take them up, with ſome earth about their roots, and remove them into a green-houſe, if they have one, or into a cellar, and by that means keep them for uſe all the winter. Some of theſe may be replanted in the ſpring, in an open border, as before, to feed in June or July; or they may be cut down to the ground, when hus planted anew, and their ſecond year's ſhoots may be ied up and whitened as before.

Beſides the uſe which the Italians, French, and Spaniards, make of this cardoon, in eating it raw with pepper, ſalt, oil, and vinegar, many think it preferable to celery, when ſtewed, becauſe it is mellower, and much more tender.

CARLICK, the ſame with charlock. *See the article* Charlock.

CARPET-WAY, a green-way, or path left in an arable field, without being ploughed.

CANE, a hollow place where water ſtands. It alſo implies a wood of alder, or other aquatic trees in a moiſt boggy place.

CARRIAGE, a general name for carts, waggons, and other vehicles, employed in carrying timber, corn, perſons, &c. from one place to another.

Carriage, alſo ſignifies a furrow, or trench, for conveying of water to overflow and improve meadow-land. It is diſtinguiſhed into two ſorts; the main carriage, which ſhould be made with a convenient deſcent; and the leſſer carriages, which ſhould be ſhallow, and as many in number as poſſible.

CARROT, the name of a root, too well known to need any deſcription here.

Carrots are propagated at two or three different ſeaſons, or ſometimes oftner, where people are fond of young carrots through all the ſummer months. The firſt ſeaſon for ſowing the ſeeds is ſoon after Chriſtmas, if the weather is open, which ſhould be in warm borders, under walls, pales, or hedges: but they ſhould not be ſown immediately cloſe thereto; but a border of lettuce, or other young ſallad-herbs, of about a foot wide, ſhould be next the wall, for otherwiſe they would run up to feed, without making any tolerable roots.

They delight in a warm, light, ſandy ſoil, which ſhould be dug pretty deep, that the roots may the better run down; for if they meet with any obſtruction, they are very apt to grow forked, and ſhoot out lateral roots, eſpecially when the ground is too much dunged the ſame year that the feeds are ſown, before it be conſumed, and mixed with the earth.

Theſe feeds have a great quantity of ſmall forked hairs, by which they cloſely adhere, ſo that they are difficult to ſow even, ſo as not to come up in patches; you ſhould therefore rub it well through both hands, whereby the feed will be ſeparated before it is ſown: then you ſhould chuſe a calm day to ſow it; for if the wind blows, it will be impoſſible to ſow it equal; for the ſeeds, being very light, will be blown into heaps. When the feed is ſown, you ſhould tread the ground pretty cloſe with your feet, that it may be buried, and then rake the ground level.

When the plants are come up, you ſhould hoe the ground with a ſmall hoe about three inches wide, cutting down all young weeds, and ſeparating the plants to four inches diſtance each way, that they may get ſtrength; and in about three weeks after, when the weeds begin to grow again, you ſhould hoe the ground over again a ſecond time, in which you ſhould be careful not to leave two carrots cloſe to each other, as alſo to ſeparate them to a greater diſtance, cutting down all weeds, and ſlightly ſtirring the ſurface of the ground in every place, the better to prevent young weeds from ſpringing, as alſo to facilitate the growth of the young carrots.

In about three weeks or a month after, you moſt hoe them a third time, when you muſt clear the weeds as before; and now you ſhould cut out the carrots to the diſtance they are to remain, which muſt be proportioned to the ſize you intend to have them grow: if they are to be drawn while young, five or ſix inches aſunder will be ſufficient; but if they are to grow large before they are pulled up, they ſhould be left eight or ten inches diſtant every way: you muſt alſo keep them clear from weeds, which, if ſuffered to grow amongſt the carrots, will greatly prejudice them.

The ſecond ſeaſon for ſowing the ſeeds is in February, on warm banks ſituated near the ſhelter of a wall, pale, or hedge; but thoſe which are intended for the open large quarters, ſhould not be ſown before the beginning of March, nor ſhould you ſow later then the end of the ſame month; for thoſe which are ſown in April or May will run up to feed before their roots have any bulk, eſpecially if the weather ſhould prove hot and dry.

In July you may ſow again for an autumnal crop; and in the end of Auguſt you may ſow ſome to ſtand the winter; by which method you will have early carrots in March, before the ſpring ſowing will be fit to draw; but theſe are ſeldom ſo well taſted, and are often very tough and ſticky. Many people mix ſeveral other ſorts of feeds, as leek, onion, parſnip, radiſh, &c. amongſt their carrots; and others plant beans, &c. but, in my opinion, neither of theſe methods are good; for if there is a full crop of any of theſe plants, there can be no room for any thing elſe amongſt them; ſo that what is got by one is loſt by the other; and, beſides, it is not only more ſightly, but better, for the plants of each kind to be ſown ſeparate; and alſo by this means your ground will be clear when the crop is gone, to ſow or plant any thing elſe; but when three or four kinds are mixed together, the ground is ſeldom at liberty before the ſucceeding ſpring: beſides, where beans, or any other tall growing plants, are planted amongſt the carrots, it is apt to make them grow more in top than root; ſo that they will not be half ſo large as if ſown ſingly without any other plants amongſt them.

But in order to preſerve your carrots for uſe all the winter and ſpring, you ſhould, about the beginning of November, when the green leaves are decayed, dig them up, and lay them in ſand in a dry place, where the froſt cannot come to them, taking them out from time to time, as you have occaſion for them, reſerving ſome of the longeſt and ſtraighteſt roots for feed, if you intend to ſave any; which roots ſhould be planted in the middle of February, in a light ſoil, about a foot aſunder each way, obſerving to keep the ground clear from weeds; and about the middle of Auguſt, when you find the feeds are ripe, you muſt cut it of, and carry it to a dry place, where it ſhould be expoſed to the ſun and air for ſeveral days to dry: then you may beat out the feeds, and put it up in bags, keeping it in a dry place till you uſe it. This feed is ſeldom eſteemed very good after the firſt or ſecond year at moſt; but new feed is always preferred; nor will it grow when it is more than two years old.

The Flemings have long known the advantage of feeding their cattle with carrots; though it is but of late years that this root has been cultivated for that purpoſe in the fields in England; nor does this uſeful and profitable practice extend even now to more than a few parts of this country; though there is ſcarce any root yet known, which is more heartening food for moſt ſorts of animals, or which better merits the huſbandman's attention; as one acre of carrots, well planted, will fatten a greater number of ſheep, or bullocks, than three acres of turnips, and at the ſame time their fleſh will be firmer, and better taſted. Horſes are extremely fond of this food, and there is not any better for hogs. Theſe roots have alſo been of ſuch excellent ſervice to deer, in parks, that when numbers of theſe valuable creatures have periſhed elſewhere,

where, through want in very hard winters, when there has been an extreme ſcarcity of their uſual food; thoſe that have been fed with carrots have kept their fleſh all the winter, and, upon the growth of the graſs in the ſpring, have been fat early in the ſeaſon. This is not an inconſiderable advantage, in places where the graſs is generally backward in its growth.

This plant has alſo a very great ſuperiority over turnips; namely, that the crop is not ſo liable to fail: for as the carrots are ſown in the ſpring, the plants generally come up well; and unleſs the months of June and July prove very bad, there is no danger of their ſucceeding: whereas turnips are frequently deſtroyed by the fly at their firſt coming up; and in dry autumns they are attacked by the caterpillars, which lay waſte whole fields in a ſhort time. But carrots are not preyed upon by either of theſe vermin. Every farmer who has a ſtock of cattle or ſheep, ſhould therefore always have good ſtore of theſe roots, if he has land proper for the purpoſe, which muſt be light, and of a proper depth, to admit the roots running down.

In preparing of the land for carrots in the open field, if it has not been in the tillage before, it ſhould be ploughed early in autumn, and then ploughed acroſs again before winter, laying it up in ridges to mellow by the froſt; and if the ground is poor, ſome rotten dung ſhould be ſpread over it in winter, which ſhould be ploughed in before the end of January; then in March, the ground ſhould be ploughed again to receive the ſeeds; in the doing of which ſome farmers have two ploughs, one following the other in the ſame furrow, ſo that the ground is looſened a foot and a half deep, or more; others have men with ſpades following the plough in the furrows, turning up a ſpit of earth from the bottom, which they lay upon the top, levelling it ſmooth, and breaking the clods; the latter method is attended with a little more expence, but is much preferable to the firſt; becauſe in this way the clods are more broken, and the ſurface of the ground is laid much evener.

If the land has been in tillage before, it will require but three ploughings: the firſt juſt before winter, when it ſhould be laid in high ridges for the reaſons above given; the ſecond croſs ploughing ſhould be in January, after which, if it be well harrowed to break the clods, it will be of great ſervice: the laſt time muſt be in March to receive the ſeeds; this ſhould be performed in the manner already mentioned: after this third ploughing, if there remain great clods of earth unbroken, it will be proper to harrow it well before the ſeeds are ſown. One pound and a half of ſeed will be ſufficient for an acre of land; but as they are apt to adhere togegether, they are more difficult to ſow than moſt other ſeeds; ſome therefore mix a quantity of dry ſand with their ſeeds, rubbing them well together, ſo as to ſeparate the carrots from one another, which is a good method. After the ſeeds are ſown they muſt be gently harrowed in to bury them; and when the plants come up they ſhould be hoed in the manner above directed, with this caution, to leave the plants at a greater diſtance. *Miller's Gard Dict.*

The ingenious M. Chateauvieux tells us, that having cultivated ſome carrots in the open field, according to the principles of the new huſbandry, found, when they were taken up, which was done on the 8th of November, that they were from eighteen to twenty, and ſome twenty-five inches long, and from two and a half to three and a half, and ſome four inches in diameter, and weighed from twenty-five, to thirty-three ounces each.

The Society for the Encouragement of Arts, &c. being perſuaded that the cultivation of carrots for the food of cattle could not fail of being advantageous to the farmer, publiſhed a premium of twenty pounds to the perſon who ſhould ſow the greateſt number of acres with carrots, for the feeding of cattle only; adding, that it was expected the perſon who received the premium ſhould give an account of the ſoil, culture, time of taking up, and their effects on the cattle fed with them.

This premium was accordingly given in the year 1766 to Mr. Robert Billing, a very intelligent farmer at Weaſenham in Norfolk; he having ſowed thirty acres and two rods of land with carrots, for feeding cattle only. At the ſame time he ſent an account of the methods he uſed in the culture of his carrots, which was ſo well approved of by the Society, that it was publiſhed at their requeſt: an abſtract therefore of this pamphlet muſt, we preſume, be very acceptable to the reader.

Mr. Billing obſerves, that the uſe of carrots for the winter feed of cattle has been long known and practiſed in the eaſtern parts of Suffolk, where it is common to make carrots ſerve the ſame purpoſe turnips have many years done in moſt parts of the county of Norfolk; beſides, that many are ſent from thence to the London market: but carrots never have been ſown in the latter county, for the maintenance of cattle, till he tried a ſmall parcel in the year 1761, and another in the year 1762.

He thought it prudent, he ſays, to make thoſe trials before he became a candidate for the premium offered by the Society; the hopes of deſerving which encouraged him to venture a pretty large and unuſual expence, as well as the loſs of a great part of his winter crop, and which has thus become the means of making known, in his part of the country, a ſpecies of huſbandry with which they had before no acquaintance but by hearſay, being above fifty miles from the country where it had before prevailed.

In the year 1763, he ſowed thirty acres and an half by menſuration.

This quantity of land lying in three parcels, one, of thirteen acres, bore wheat in the year 1762; one, of half an acre only, had borne clover; and the laſt, of ſeventeen acres, turnips that year. The piece of thirteen acres is a cold loamy ſoil, ſhallow, and upon a ſort of loamy gravel. The half acre is a ſoil much mixed, upon a moiſt clay. The ſeventeen acres may be divided into two parts, the one of fourteen acres, and the other of three. Both are a light and dry ſoil, newly improved with a marle; the former, an exceeding good tempered ſoil, upon a marle; the other, a ſhallow black ſand, upon a kind of imperfect grit-ſtone, called, in Norfolk, a carr-ſtone.

Previous to giving an account of the ſucceſs of his crop of carrots, and of the uſe he made of them in feeding cattle, he deſcribes the manner in which he cultivated theſe ſeveral pieces of land, founded as well upon the beſt information he was able to procure, as upon the obſervation afforded him by his own experience of the former year.

The wheat and clover ſtubble he ſplit down with the plough early in the preceding November, and is ſatisfied, from all the obſervations he has made ſince he firſt begun the cultivation, that whether the wheat ſtubble be, as it is called in Norfolk, flat work, or in ridges, or the carrots are to be ſown after clover or rye-graſs, the land cannot be ploughed too early; ſo that the froſt and ſnow may have their full effect in mellowing the ground for the reception of ſo ſmall a ſeed; and this is the more neceſſary to be attended to, the ſtiffer and tougher the ſoil ſhall chance to be.

The land that had been turnips he let alone till the end of January, or beginning of February, thinking this time enough, becauſe the earth was thoroughly cleaned by the cultivation and ſummer hoeing neceſſary for the crop of turnips.

Of the thirteen acres of wheat ſtubble, ſix were dunged for wheat, but not for carrots; four and a half not dunged at all; and two and a half for the carrot crop only. The clover land was dunged for the carrots: and of the ſeventeen acres that had been turnips in 1762, part had been tathed for the turnips, that is, where ſheep have been folded; and the whole crop of turnips was fed off by ſheep and neat cattle.

Four pounds of ſeed on an acre is ſufficient: but as the ſeed is very ſmall, light, and hard to ſeparate and diſperſe equally on the ground, he was at firſt a good deal puzzled how to overcome this difficulty; and though he was adviſed to make uſe of a mixture of ſand, he did not find it anſwer, becauſe the weight of the ſand carried it all to the bottom of the ſeed-cot: he ſows it therefore now unmixed, as they do turnips, after having forced it through a fine chaff-ſieve by rubbing.

It

It will be three weeks, after sowing, and sometimes longer, before the carrots appear: this is the principal advantage, besides the difference of expence, that turnips have over them, for the latter are not sown till about Midsummer, and coming quicker to the hoe, get the better of the weeds more easily; for weeds do not grow near so fast about Midsummer, as in the spring.

The carrots lying a longer time before they come up, and continuing afterwards a long time very weak, they are seven or eight weeks before they are fit for the hoe, and in the mean time afford the weeds an opportunity to get strength, in a season too, when unluckily they grow the fastest: Mr. Billing is therefore of opinion, that though it is necessary to sow carrots before turnips, it is better to sow them as late as you can with safety to the crop; for of his, those sown in April on the clover stubble came much the soonest to the hoe, though later sown.

The wheat and clover stubble were ploughed three times; the piece after turnips but twice; the first time shallow, the second as deep as the staple of the ground would permit; and on this ploughing the carrots were sown.

As it would remove some of the objections to a carrot crop, and lighten much the expence of weeding, could they be sown later; and as this might be done could the seed be made to come up sooner, this sensible farmer imagines the seed might be steeped in somewhat that would forward its vegetation, and afterwards sown, when dry enough to separate.

Yet however expensive the strength of the weeds in a crop of carrots makes the hoeing of them, the crop itself is not apt to suffer, for though the young carrots are quite covered in a thicket of weeds before hoeing, and should be buried in earth after the hoeing; yet they seem no way hurt if they get clear again, as they generally do in a fortnight after, if not cut off, or buried too deep, for want of skill in the labourer.

The Norfolk hoe is six inches wide. If the carrots chance to be tolerably clean, they may be hoed the first time for eight shillings per acre; but if the ground be full of weeds, occasioned either by much rain, the foulness of the ground before sowing, or the length of the time between the sowing and hoeing, the first hoeing will amount to ten or twelve shillings per acre.

About ten days or a fortnight after hoeing, they should be harrowed: this will displace the weeds, and prevent their growing again, which many of them will otherwise probably do, especially if it be showery weather: the harrowing does not hurt the carrot plants, but, on the contrary, does them much service, by bringing fresh earth to them, as well as killing the weeds.

About three weeks after the harrowing, in case it has not perfectly cleared the ground of weeds, or in case new weeds come up, Mr. Billing hoes the carrots a second time, which costs about four or five shillings per acre, as the ground is more or less foul; and after this, if there still remain any weeds, which will be the case if much rain falls during the time of the second hoeing, a second harrowing is bestowed.

Where the weather has been favourable, and those employed in hoeing have done their duty, the carrots once hoed and harrowed have been as clean as those on which two hoeings, and as many harrowings have been bestowed.

Mr. Billing next proceeds to inform us of the success he had in the year 1763, on the several parcels of ground already described. His carrots proved best on the piece of two acres and a half that had been wheat, not dunged for the crop of wheat, but dunged for the crop of carrots, and on the half acre clover stubble dunged for the carrots.

Many of the carrots out of both pieces measured two feet in length, those on the former from twelve to fourteen inches in circumference at the upper end, and those of the latter from twelve to sixteen; a difference of bulk owing, perhaps, both to the difference of soil, and the effect of former crops.

On the two acres and a half Mr. Billing computes he had from twenty-two to twenty-four loads per acre, and about fifty-five, or fifty-six cart loads on the whole: the half acre on clover stubble produced about twelve loads; the six acres and a half dunged for wheat, but not for carrots, produced from eighteen to twenty cart-loads per acre, and in the whole about one hundred and four loads; the four acres not dunged for either wheat or carrots, produced from twelve to fourteen loads per acre, and in the whole fifty-two loads.

He had but an indifferent crop of turnips the succeeding year, on the seventeen acre piece, but had from sixteen to eighteen cart-loads per acre of carrots on fourteen acres of it, but a very poor crop on the three remaining acres; so that he computes he might have on the seventeen acres after turnips not quite two hundred and seventy loads, which make, with the former, about five hundred and ten loads of carrots, equal in use and effect to near one thousand loads of turnips, or three hundred loads of hay, as experience has convinced him from the various methods in which he had tried them.

Mr. Billing thinks it is not improbable that he might besides lose five or six loads, which the poor people took, instead of a single load they might have stole, had the land been cropped with turnips; but this loss will be evidently much lightened, should the growth of carrots become general in the country.

The best method of drawing the carrots is with a four tined fork, with which a man breaks the ground six or eight inches deep, very carefully without injuring the carrots; and is followed by a little boy, who gathers the carrots, and throws them in heaps.

Our farmer began to draw his carrots for use about three weeks after Michaelmas; but as the cattle he intended to feed on them had never been used to so hard food, he thought it best to give them, at the same time, both cabbages and carrots, lest they should suffer by a distaste at the beginning.

He had about forty load of cabbages growing on one half acre, equal in use, as appeared on trial, to about seventeen or eighteen loads of carrots. He observed, that cattle of every sort naturally eat the cabbages as readily as they would have done turnips; and soon after having gradually learnt to eat carrots, began to prefer them. Both the cabbages and carrots, and afterwards the latter with turnips, were brought from a place where they grew, to a pasture close; and, without any other preparation than shaking off the dirt, they were dispersed on the ground for the cattle to feed on promiscuously.

From the experience Mr. Billing has had in fattening cattle on turnips in houses or stalls, he is persuaded that by this means the carrots might have been made to go a great deal further; but besides the great trouble attending this method, especially if the number of beasts be great, and the hazard of beasts foundering in the way to London, an accident that often happens to stall fed cattle, and that the benefit of their stale is lost to the ground, he is convinced the beef is not so good, though perhaps more sightly.

The first stock he began to feed in this manner consisted of twelve neat beasts, and forty-nine shearing weathers, or those not quite two years old: ten of the former were Norfolk bred steers, and began to feed on the first carrots he drew: at the same time he put on a cow, and a heifer three years old. At old Martinmas Mr. Billing bought seventeen Scotch bullocks, which, with a cow from his dairy, made up the number thirty; and soon after he increased this number to thirty-three, by adding three more from his dairy.

It is, however, to be observed, that when the cabbages were spent, he allowed a load of turnips each day for some time for this flock of cattle, which, with three loads of carrots, was a sufficient provision for them. This enabled him to determine, that one load of carrots is nearly equal to two of turnips; for if the cattle had been fed on turnips only, it would have cost him little less than seven loads, computing on the experience of many years fattening cattle with turnips; yet he declares he never knew cattle thrive faster.

Nine of the steers were sold fat in Smithfield on the seventeenth of February, and weighed about forty Norfolk

folk ſtone, that is, ſeventy London ſtone, each. Another ſteer and cow were killed in the country, the latter at Weaſenham town, and which died very fat, about the ſame time: the Scotch were ſold at St. Ives about the beginning of May: the ſteers ſold in Smithfield for about ſeven pounds fifteen ſhillings each.

Our farmer being told the market was then low there, ſold all the Scotch, except one, at St. Ives, where they fetched him about ſeven guineas each.

The former coſt about four pounds ten ſhillings each; the latter, three pounds fifteen. The other Scotch he ſent to London, where, though it weighed but a little above ſixty ſtone, it ſold for eight pounds, and was ſaid to be ſome of the fatteſt beef killed in London that winter, as Mr. Billing was informed by Mr. Brownſworth the ſaleſman: the others were not inferior.

The forty-eight weathers were ſold fat at St. Ives in the month of May, at about fifteen ſhillings each.

Theſe thirty-three beaſts, and forty-eight ſheep, brought Mr. Billing, according to his computation, about one hundred and twenty pounds profit; out of which deducting one tenth for the ſhare the cabbages and turnips had in fattening them, which is rather too much, eſpecially as the cattle ſoon began to leave the turnips, there remains one hundred and eight pounds to be carried to the account of the carrots.

The large quantity of carrots our induſtrious farmer had growing gave him alſo an opportunity of trying their uſe in feeding dairy cows, ſheep, horſes, and hogs.

In the month of April he found he ſhould have nine or ten acres to ſpare, beyond what was neceſſary to complete the fattening his bullocks. This happened too at a time when his turnips, as well as thoſe of his neighbours, began to decay, and enabled him to ſupply that defect, to which the Norfolk farmers are very ſubject in the ſpring of the year, and which no method of managing their turnips ever exempted them from, when the weather is wet and froſty by turns; and from this decay the carrots ſeem protected by their hardineſs. From this time he fed his whole dairy of thirty-five cows, and his flock of twenty-one ſcore of ſheep, on carrots.

At the ſame time he thought of a method of getting the carrots out of the ground with more eaſe and expedition than he had done before, which was of great uſe when he had other occaſions for his ſervants; beſides which it alſo prepared the land better for the enſuing crop.

They were ploughed up with a narrow-ſhared wheel plough; going ſlow, the ſhare opened the earth, and cut very few of the carrots; thoſe few being only ſuch as chanced to meet the very point of the ſhare.

The plat, or earth-board, turned moſt of the carrots out of the ground, and, by harrowing afterwards, were moſt of them quite cleared from the earth. Though the roots extended a good way into the ground, and below the pan, he did not think it neceſſary to plough ſo deep, and conſequently the land ſuffered no damage, which otherwiſe it might have done, as ſome few of the carrots inſtead of being turned out, were buried: it is alſo neceſſary to plough the land and harrow it a ſecond time; but though this ſhould be at an interval of a month, the buried roots will take no harm.

Mr. Billing turned his dairy cows and flock of ſheep on this land after the ploughing, without any further trouble or preparation, and had all the reaſon in the world to be pleaſed with the event: both took readily to eating the carrots, though he thinks the cows more ſo than the ſheep.

The former not only gave more milk than is uſual at that time of the year, but many continued to give milk, which would with ſuch turnips as he had then to give them, have been nearly dry. The butter made was likewiſe much better than that from turnips; and both ſheep and lambs did much better than he ever remembers them to have done at this ſeaſon of the year: beſides this, the land was evidently very much improved from the ſtale of the cattle, of which he plainly perceived the benefit in the enſuing crop.

It is proper to obſerve, that in this method, ſome few of the carrots continue buried, even after a ſecond ploughing; but theſe were turned out upon a third ploughing, when barley was ſown, and were clean eaten up by a flock of ſheep, without any injury to the new ſown barley.

In this manner the cows and ſheep were fed for three weeks, which Mr. Billing values at about twenty pounds; and, conſidering how he might have ſuffered, had he wanted turnips, and not been able to ſupply that want with carrots, he thinks, he might value his feed at a great deal more.

In November 1763, he began to feed ſixteen horſes, which did all his farming work, with carrots: they had neither hay nor corn, except his team that carried his corn to Brancaſter, a ſea-port, at fifteen miles diſtance: to this team he allowed a buſhel of oats a day to the whole team: the reſt had nothing beſides carrots, except peaſe-ſtraw and chaff, until the ſowing barley. In April he increaſed their work ſo much, that he thought it neceſſary to give them a few oats; but they continued to ſubſiſt chiefly on carrots, until they were turned to graſs, the latter end of May.

Mr. Billing declares he never knew his horſes in better order, or do their work better; and they were ſo fond of carrots, that he frequently found, that when the team mentioned before were ſo fatigued, that they refuſed to eat their corn, they would eat it when mixed with the carrots chopped.

It may be proper to obſerve, that he always chopped off the heads and tails of the carrots he gave his horſes, and ſometimes gave them another cut. Though he could not find it was neceſſary, he maſhed them alſo for his horſes, none of which trouble he found at all requiſite or even uſeful for other beaſts: the gathering and removing the carrots, and diſperſing them about the paſture-land where he fed his cattle, were ſufficient.

Mr. Billing gave the ſixteen horſes two loads of carrots every week; and theſe two loads, he computes, ſaved him more than a load of hay; which, at twenty-five ſhillings a load, amounted to thirty-five pounds.

To this might be added, the benefit received by the ſwine, to which he threw all the tops and tails of the carrots uſed for the horſes; and they throve exceedingly, and were ſo fond of them, that he could never find that any dirt which might ſtick to them, prevented their eating them: but as the principal part of the food of the ſwine was milk at firſt, and afterwards peaſe, our farmer has not ſet any value on this part of his profit; the total of what he has eſtimated it on the other articles, amounting to one hundred and ſixty-three pounds.

Of the thirty acres and a half, four were ſown in the year 1764, with oats, all the reſt with barley: the four acres were part of the land where he ploughed up the carrots; the reſt of this piece was ſown with barley: both produced a prodigious crop, not leſs than three loads of corn in the ſtraw, per acre: on the reſt of the land his crop was leſs bulky, and ſhorter, yet very good, perhaps not leſs in the quantity of grain than the other. And here it may not be improper to mention, that when in a former year, he had ſown the two ends of a large cloſe with carrots, without dung, and the middle with turnips, for which the land was well dunged, yet, when the whole encloſure was, the next year, ſown with barley, that after the carrots was the beſt.

Another recommendation of carrots is, that our intelligent farmer finds them a more certain crop, both for growth and duration, than turnips: the latter are exceedingly apt to fail, as well as rot, towards the ſpring, when moſt wanted. Perhaps the former is, in ſome meaſure, owing to the lands in Norfolk being, as the farmers expreſs it, ſurfeited with turnips, to which they have been ſo long accuſtomed. But however this be, there are many reaſons for chuſing both, that if one fail, we may rely, for ſo neceſſary a winter proviſion, on the other.

This candid farmer thinks he ought not, however, to conceal, that at the firſt beginning of a new ſort of huſbandry, many difficulties ſtand in the way: the expence is very heavy, much beyond the expence of turnips, and is, perhaps, increaſed by the aukwardneſs of labouring men and ſervants, who are both ignorant and perverſe about moſt new employments: beſides this, the cleaning of carrots from weeds is much more neceſſary than of turnips, and yet goes on much ſlower, ſo as ſometimes hardly to be completed: and, moreover, if a long continued froſt ſhould happen, it will be very difficult to get carrots out of the ground (indeed the turnips in this caſe are apt to ſpoil); but this inconvenience may, in ſome meaſure, be prevented, by drawing the carrots before the froſt; though this will be attended with difficulty when the quantity amounts to fifty or a hundred loads.

Such is the account given by Mr. Billing, with regard to the culture and uſe of carrots, for the feeding of cattle. And as theſe experiments were made ſo much at large, the farmer may, without heſitation, adopt this method; and if his ſoil is adapted to the growth of carrots, he need not doubt of greatly increaſing his annual profit. That they are wholeſome feed for cattle has been long known; but that ſuch advantages reſulted from their uſe as Mr. Billing relates, few farmers could have imagined.

Wild CARROT, *Bird's-neſt*, or *Bees-neſt*, the name of a biennial weed common in paſture grounds. It greatly reſembles the cultivated carrot, of which indeed it is only a ſpecies. The wild ſort however differs from the cultivated in its roots, which are ſmall and ſticky. In both ſorts, after they have done flowering, the umbels contract themſelves into the ſhape of a bird's neſt.

CAR SICK, a term uſed in ſome of the northern counties to ſignify the cart-rut, or gutter made by the wheel of a cart or waggon.

CART, a vehicle mounted upon two wheels, and drawn by one or more horſes.

The chief difficulty in the conſtruction of wheel carriages, conſiſts in properly adapting the wheels and axle, which ought to be done in ſuch a manner, that the carriage may move with the leaſt force poſſible. *See the article* WAGGON.

CART-LODGE, a ſmall out-houſe for ſheltering carts, waggons, &c. from the weather.

Farmers ſhould be very careful to place their waggons, carts, &c. under proper ſhelter, when out of uſe, as they will laſt twice as long by this means, as they would if expoſed in the yard to all weathers; for as they are thus ſometimes wet, and ſometimes dry, they ſoon rot, and become unfit for uſe.

CART-LADDER, a kind of rack, placed occaſionally at the tail of a cart or waggon, to make it hold the larger quantity of hay, ſtraw, &c.

CART-RAKE, the cart track, or furrow made by the wheels of a cart or waggon.

CART-RUT, the ſame with cart-rake. *See the preceding article.*

CARTWRIGHT, a perſon whoſe buſineſs it is to make carts, waggons, &c. generally called a wheelwright.

CARUE, or KERUE, ſour. Thus to carue, ſignifies to grow ſour, and is generally applied to cream.

CARUNCLE *of the eye*, the fleſhy ſubſtance in the inner corner of a horſe's eye, next the noſe.

CASINGS, or COW-BLAKES, dried cows dung, uſed in ſeveral parts for fewel.

CAST, a flight of birds, inſects, &c. Thus a caſt of bees, ſignifies a ſwarm or flight of bees.

CATCH-FLY, the Engliſh name of a ſpecies of lychnis, now greatly cultivated in gardens.

The double flowering ſort of catch-fly was accidentally obtained from the ſeeds of the ſingle; and has not been known above forty years in the Engliſh gardens. As this ſort never produces ſeeds, ſo it can only be propagated by parting and ſlipping the roots; the beſt time for this is in autumn, at which time every ſlip will grow. If this be performed in September, the ſlips will have taken good roots before the froſt, and will flower well the following ſummer; but if they are expected to flower ſtrong, the roots muſt not be divided into ſmall ſlips, though for multiplying the plant, it is no matter how ſmall the ſlips are. Theſe ſhould be planted on a border expoſed to the morning ſun, and ſhaded when the ſun is warm, till they have taken root. If the ſlips are planted in the beginning of September, they will be rooted ſtrong enough to plant in the borders of the flower-garden, by the middle or latter end of October. The roots of this ſort multiply ſo faſt as to make it neceſſary to tranſplant and part them every year; for when they are ſuffered to remain any longer, they are very apt to rot. It delights in a light moiſt ſoil.

It has the name of catch-fly, from a glutinous liquor, almoſt as clammy as bird-lime, ſweating out of the ſtalks under each pair of leaves; ſo that the flies, which happen to light on theſe places, are faſtened to the ſtalk, where they die.

CATCH-LAND, a name given to ſuch land as is not certainly known to which pariſh it belongs; and therefore the miniſter, who firſt gets the tithes of it, enjoys it for that year.

CATERPILLAR, a general name for all inſects of the butterfly kind, while they continue in their reptile or worm ſtate.

It is well known, that all winged inſects paſs through a reptile ſtate, before they arrive at perfection. This great change from a worm to a fly, or butterfly, was formerly eſteemed a real metamorphoſis, or change of one animal into another; but later diſcoveries have put it beyond all doubt, that the embrio butterfly, with all the lineaments of his parent, is contained within the external caſes, or coverings of the caterpillar. When the included animal has acquired a ſufficient degree of ſtrength, theſe coverings are thrown off, and it appears in its genuine form of a fly, or butterfly. It muſt, however, be obſerved, that before the creature can free itſelf from theſe coverings, it muſt paſs through a ſtate of reſt, called by naturaliſts nymph, or chryſalis ſtate.

Mr. Hitt obſerves, that there are two ſorts of caterpillars, at leaſt thoſe of two colours, which feed upon fruit-trees, the one black, and the other green. The black generally make their appearance in March, if the ſeaſon be dry, upon the pear, apple, and ſeveral other trees.

Sometimes great numbers of them are contained in a ſort of kel, or web, and, if they are to be come at, ſhould be taken off; for otherwiſe they will diſperſe themſelves to all parts of the tree, and there feed upon the bloſſoms, leaves, or their buds, before they are unfolded. After they have lived ſome time in this active ſtate, they generally conceal themſelves in a bunch of leaves, or in a cavity of the rind of a tree, where many of their eggs are hatched the ſame ſummer, and become very deſtructive. There is alſo reaſon to think, that ſome of their eggs are preſerved in thoſe places during the winter, as many of them, and ſome kindled or animated, have been found in old nail holes, and under pieces of dead bark, during the month of February.

The walls ſhould therefore be well waſhed, and the dwarfs and ſtandard trees well dreſſed and cleanſed at that ſeaſon.

The green caterpillars, which may, perhaps, be the ſame with the former at their firſt appearance, till their colour is gradually changed by living wholly on green food, are never ſeen ſo early in the ſpring as the former; but are very prejudicial to both the young branches and fruit of the apricot, cherry, plum, apple, pear, currant, gooſeberry, &c.

They are never ſeen in great numbers together incloſed in a kel or web; but are generally found ſingle, wrapt up in the extremity of a new made branch of the abovementioned trees, or in a bunch of bloſſoms of an apple, pear, or cherry-tree, and ſometimes on an apricot, with a leaf to cover them. Part of their bad effects may be prevented in wall-trees, or dwarfs, whoſe branches are within reach. If they be at the extremity of a branch, it will appear in a round knob, and they generally eat off the part they had wrapt together, which ſpoils the branch the next year. When they have incloſed themſelves in a bunch of bloſſoms, or young fruit, then they prove very deſtructive, by generally eating into all they had joined together, which cauſes much fruit to drop off ſoon after, and others when they are more grown.

Some of thoſe which are but ſlightly eat, will continue upon the tree till the time of gathering; but they never make good fruit, being generally ill taſted, and many times have a white grub within them.

When

When the caterpillars are firſt perceived upon the wall or dwarf trees, whether before or after they are wrapt up, a brine ſhould be prepared, and the trees ſwept all over with a bruſh or beſom dipt in it. This will deſtroy many of the inſects, by beating ſome off, and killing others. This work ſhould be often repeated, if there be a neceſſity for it, as there generally is in dry ſeaſons. Perhaps a ſmall engine would be the propereſt and moſt effectual inſtrument for this work.

But gentlemen, who have leiſure ſufficient, may eaſily preſerve their fruit-trees from the ravages of caterpillars, by carefully inſpecting them every day in the ſpring; for it will eaſily be ſeen when a bunch of bloſſom-leaves, or young fruit, are joined together by a caterpillar; and, on the firſt diſcovery, the leaves are to be ſeparated by the hand, and the caterpillars killed; this will ſave a young branch or bunch of fruit, which would otherwiſe have been certainly deſtroyed. Whoever perſeveres in this work will never have much of their fruit deſtroyed by ſuch inſects, which experience has ſufficiently demonſtrated to be more deſtructive to the fruit, than any other cauſes that happens in the ſpring, though many will attribute the ſcarcity of fruit to blaſts or lightnings, or to the branches being ſun-burnt, which are the common conſtructions put upon the effects of theſe inſects.

When ſtandard trees are properly ordered with cutting and dreſſing, they will not be much ſubject to be infected with caterpillars; for by taking off the old rind, and cleaning the cankered parts of thoſe trees, many of the inſects are deſtroyed, together with their eggs concealed in thoſe places; and by keeping the branches thin and open, they are more eaſily ſhaken off by the winds. *Hitt on Fruit-Trees, page* 265.

Caterpillars not only deſtroy the leaves and bloſſoms of fruit-trees, but they alſo deſtroy cabbages, and other productions of the garden; and are generally the effect of great drought.

To prevent their numerous increaſe on trees, gather them off in winter, taking away the prickets which cleave to the branches, and burn them; but if they get on cauliflowers or cabbages, take ſome ſalt water, or ſtrong brine, and water the plants with it, and it will kill the inſects: the ſame effect will be produced by taking ſome of the caterpillars themſelves, bruiſing them with garlic, and infuſing the mixture in water; or you may ſmoke them with wiſps of dry ſtraw in March, juſt as the bud begins to open.

In the ſummer while they are yet young, when, either through the coldneſs of the night, or ſome humidity, they are aſſembled together on heaps, you may take and deſtroy them; or you may waſh your trees with water, in which wormwood, tobacco-ſtalks, and coloquintida have been diſſolved; or take lime duſt, and when the wind is high, and the trees wet, ſprinkle the duſt, ſo that the wind may blow it on the trees. *Mortimer's Huſbandry, vol. I p.* 325.

CATKINS, a name given to ſuch flowers as have an aggregate of ſummits hanging down, in the ſhape of a rope, or cat's tail.

CAT's-FOOT, a name given in ſome countries to ground ivy.

CAT's-TAIL, a round ſubſtance growing upon nut-trees.

CATTLE, a general name for beaſts of paſture, that are neither wild nor domeſtic; but generally confined to thoſe of the ox kind.

Cattle are known to be very advantageous to the breeders of them; and therefore thoſe in middling fortune would do well to apply ſome part of their time and farms to this uſeful work: but people in theſe circumſtances, finding it impracticable to make large profits, too often reject, with diſdain, the ſmall advantages continually in their power. In vain the wiſe man informs them, that whoever neglects ſmall profits will daily decay; in vain reaſon dictates, that from a ſmall ſtock, they muſt be contented with ſmall gain; but that a great number of ſmall profits, which it is eaſy to multiply by labour, becomes in a ſhort time an object of conſideration.

It muſt not however be imagined, that in order to derive a conſiderable advantage from cattle, it will be ſufficient to have a great number, and to give them the neceſſary fodder: there are many other circumſtances to be attended to, without which it would be in vain to flatter ourſelves with the expectation of riches. They are often kept in too narrow a cow-houſe, from whence many inconveniencies ariſe. Sometimes they fight, and wound one another. The moſt voracious ſtarve their neighbours, from whom they carry off all the fodder within their reach; and the injured cows decay inſenſibly, become languid, or give little milk. In ſummer the heat incommodes them, a circumſtance which makes them grow lean, and diminiſhes the quantity of their milk. Care muſt therefore be taken that they have ſufficient room in their ſtalls; that they be cool in ſummer, and warm in winter. At all ſeaſons let them be dry, for that is a material point. Even in ſummer, humidity is diſagreeable to them, and in winter it chills them. To prevent this double inconvenience, it will be proper to pave the cow-houſes on a gentle deſcent, and to dig a pit to collect all water and ſtale. By this means the cattle will lye always dry, and the ſtale be collected for good purpoſes. Horned cattle ſometimes contract a habit of licking one another; and that injures ſo much, that a butcher who perceives it, will give leſs money for them than for others. They are cured of this habit, by rubbing the places they have licked with cow dung, the bitterneſs of which prevents them from purſuing it.

We ſhall inſiſt on the advantages attending the breeding of young cattle, whatever trouble it may coſt; becauſe there is no prudent countryman who is not fully perſuaded they are real. To buy what he may have of his own growth is to a farmer no acquiſition, but a diſſipation; becauſe the land produces no money, which is only to be obtained by the ſale of commodities, and very often the purchaſe of ſome goods deſtroys all the profit reſulting from the ſale of others. It ought, therefore, to be an inviolable maxim, eſpecially with thoſe in narrow circumſtances, to ſpare no pains in improving their ſtock, not making ſmall eſtimation of what has coſt them no money, but frugal as if they had bought it. By this means, if we accept unforeſeen accidents, which can never be prevented, they will find wealth flow in upon them annually, though ſlowly, and lay the foundation of a ſolid fortune. *Journal Oeconomique.*

Fattening and feeding CATTLE. Cattle are bought in to fat at ſpring, and about Michaelmas. Thoſe you buy in at ſpring will be fat in July, Auguſt, or September, according as they are forward, and you have keeping for them; and thoſe which you buy in Auguſt, September, or October, muſt be either to ſell in winter or in ſpring, and muſt be forward in fleſh to be improved the beginning of winter, and only kept up in fleſh during the hard time of winter, either with burnet hay, turnips, carrots, &c. to be fit for a good market whenever it offers; or they muſt be young, lean, cattle, that may by their growth pay for their wintering, and to be fit to fat the next ſummer. Some upon ordinary land buy in young Welch heifers, which, if they prove with calf, they ſell in ſpring, with a calf by their ſide for the dairy; and thoſe that are not with calf they fatten: all which ways turn to good account, according as prices fall out; but moſt commonly all meat, either at Chriſtmas or in the ſpring, is one third part dearer than in ſummer: becauſe all have not the conveniency either of hay, turnips, &c. to fatten cattle with in winter; and it is but in a few places, eſpecially near London, which is the chief market for fat cattle, that hay can be afforded to fatten them with; for they reckon an ox, that coſts about ſix pounds, will require about two loads of hay to keep him up all the winter.

For the wintering of cattle, you muſt about September turn out them you deſign to keep up for a winter or a ſpring market, and your cows, that give milk into your rowens, till either ſnow or a hard froſt comes on, as by that means they will need no fodder; but when either ſnow or froſt comes, you muſt give hay to ſuch cows as are near calving, or thoſe that have lately calved, or that give a great deal of milk, and alſo to your fattening cattle. This muſt be done every morning and evening, in proportion to the quantity of rowen you have upon the ground; for the more rowen you have, the leſs quantity of hay will do, and even the ſour graſs which your cattle would not eat before, will, when the froſt hath taken it,

become,

become good, fweet food for them, and what they will eat with pleafure, if it be not covered fo deep with fnow, that they cannot come at it. But for your lean cattle, and thofe that give but little milk, ftraw will do well enough to fodder them with; only you muft obferve to give barley-ftraw firft, and the oat-ftraw laft, except you value your milk: if you do, give fuch cows your oat-ftraw, provided the quantity of milk they give doth not deferve hay, or hay be fcarce with you; for barley-ftraw will quite dry up the little milk they have, though it is good food for dry cattle. But if your hay and carrots fail you, pour fcalding hot water upon your malt-duft, and, when near cold, give it the cows you defign to continue the milk of, and it will caufe them to give a great deal, though they eat ftraw with it. A bufhel, which cofts about three-pence, will be fufficient for a cow a week. But about London, where they have grains in plenty, they give them to their cows in winter, which makes them give a great deal of milk; but is apt to rot them, if given in too great quantities, and for too long a time.

When your rowen is quite eaten up, which will commonly be about February, you muft houfe your milch-cows, which you give hay to all night in your cow-houfe, and your other cattle in your yard: for which ufe you fhould have two yards; one for your cattle which eat ftraw, with racks and other conveniencies to fodder them in; obferving to feed them often, and not to give them too much at a time; becaufe when they have blown upon it, they will not eat it; both your yards ought to be well fheltered, and made as dry as poffible, and a good deal of ftraw given them to lye dry and warm in, which is a very great advantage to them, and will greatly increafe the quantity of your dung.

As to the buying of fat cattle, milch-cows, or lean cattle, experience, and the advice of fuch perfons as underftand them are the beft inftructors.

For the feeding of land, you may do it with beafts and horfes together, or with beafts firft, and horfes afterwards; and after both put in fheep. But let not your grafs be too rank before you feed it; for if you do it will be four, and your cattle will eat the tops only, fo that the other part will lie untouched, and rot upon the ground, as hardly any beaft will eat four grafs, till the froft hath taken it, except Welch heifers. Obferve alfo, where you have inclofures, to be often changing of your cattle from one pafture to another; for by that means you will give your land an opportunity of getting a frefh head, frefh grafs being a great help to the feeding of cattle. *Mortimer's Hufbandry, vol. I. p.* 231.

Cattle are frequently well fed in the winter with rye-ftraw, mixed with a little hay; with the ftraw or halm of buck wheat; with the leaves of white beet; with turnips, the turnip-cabbage, carrots, cabbages, burnet, and the bruifed tops of furze; as may be feen under each article. They are alfo well fed and fatted with the cakes of lin-feed and rape-feed, or cole-feed. *See the articles* COLE-SEED *and* LIN-SEED.

It is really furprizing that though plants have been conftantly obvious to the eyes of every man, nothing has been delivered down to us in any book, concerning the kinds of plants proper for the different kinds of cattle; the confequence of which inattention frequently is, that the farmer, by not diftinguifhing and felecting the feeds of proper graffes, fills his paftures with weeds, or, which is here equivalent to them, with bad graffes, unfit for the nourifhment of the animal he intends to rear.

The illuftrious Linnæus in his journey through Dalecarlia in the year 1734, made the firft attempt to lay down rules for the farmer's direction in this interefting fubject. In this journey he obferved, that the horfes eafily diftinguifhed wholefome from noxious food; for, being very hungry, they devoured all forts of plants, except the meadow-fweet, valerian, lilly of the valley, angelica, loofe-ftrife, marfh-cinquefoil, crane's-bill, hellebore, monkfhood, and feveral fhrubs. This gave him a hint to recommend to the curious to apply themfelves to examine what plants fuch animals as live on vegetables will not touch.

The ingenious author of the Swedifh Pan, in order to encourage inquiries of this kind, very properly obferves, that we admire the wifdom of the Creator, which has made fome vegetables abfolutely difagreeable to fome animals, while they are agreeable to others; and plants, which are poifonous to fome, are wholefome to others. This did not happen by chance; it was ordained for wife purpofes: for if the Author of nature had made all plants equally grateful to all kinds of quadrupeds, it muft neceffarily have happened, that one fpecies of them having remarkably increafed, another fpecies muft have perifhed by hunger, before it could have got into better pafture. In like manner we find it contrived in relation to the plants themfelves, which do not all grow in the fame country and climate; but every plant has its place, in which it grows more abundantly than elfewhere. From hence we may obferve, that thofe animals which live chiefly upon particular plants, abound moft in certain places. Thus one animal leaves that which is poifonous to itfelf, for another animal, which feeds upon it delicioufly. Long-leaved water hemlock will kill a cow, whereas the goat browfes on it greedily. Monkfhood kills a goat, but will not hurt a horfe. Parfly is deadly to fmall birds, while fheep, hares, rabbits, and fwine eat it fafely; and pepper is mortal to fwine, and wholefome to poultry. Hunger will often drive animals to feed upon plants which nature never intended for them: but after this has happened once, they become more cautious for the future.

Perhaps many of the terrible difeafes to which cattle are fubject, and which has fwept away innumerable multitudes, may, in part at leaft, be owing to the mixture of noxious plants among their food. The great Linnæus was of this opinion; and the following paffage in the writings of that admired naturalift is too interefting to be omitted in a work of this kind:

" When I arrived, fays he, at Tornea, the inhabitants complained of a terrible difeafe then raging among the horned cattle, which died by hundreds, foon after their being let into the paftures in the fpring. They defired I would confider this affair, and give them my advice what was to be done, in order to put a ftop to this evil. After a proper examination, I thought the following circumftances worth obferving:

" 1. That the cattle died as foon as they left off winter fodder, and returned to grazing.

" 2. That the difeafe diminifhed as the fummer came on; at which time, as well as in the autumn, few died.

" 3. That this diftemper was propagated irregularly, and not by contagion.

" 4. That in the fpring, the cows were driven into a meadow near the city, and that they chiefly died there.

" 5. That the fymptoms varied much, yet agreed in this; that the cattle, in grazing indifcriminately on all forts of herbs, had their bellies fwelled, were feized with convulfions, and in a few days expired with dreadful bellowings.

" 6. That no man dared to flea the recent carcaffes; as they found by experience, that not only the hands of fuch as attempted it, but their faces too, had been inflamed and mortified, and that death had enfued.

" 7. The people enquired of me, whether there were any kind of poifonous fpiders in that meadow; or whether the water, which had a yellowifh tint, was not noxious.

" 8. That it was not a murrain was clear, becaufe the diftemper was not contagious, and becaufe that diftemper is not peculiar to the fpring. I faw no fpiders but what are common all over Sweden; and as to the water, the fediment at the bottom, which caufed the yellownefs, was nothing but what came from iron.

" 9. I was hardly got out of the boat which carried me over the river into the meadow, before I gueffed the real caufe of the difeafe; for I there beheld the long-leaved water hemlock. My reafons for gueffing this were the following:

" 10. Becaufe in that meadow where the cattle firft fell ill, this poifonous plant grows in great plenty, chiefly near the banks of the river. In other places it was fcarce.

" 11. The leaft attention will convince us, that brutes fhun whatever is hurtful to them, and diftinguifh poifonous plants from thofe which are falutary, by natural

tural inſtinct; ſo that this plant is not eaten by them in the ſummer and autumn, which is the reaſon that few cattle died in theſe ſeaſons; thoſe only which eat of it by accident, or were driven to it by extreme hunger.

" 12. But when they are let into the paſtures in the ſpring, partly from their greedineſs after freſh herbs, and partly from the hunger they had undergone during the winter, they devour every green thing that comes in their way. It alſo happens that herbs, at this ſeaſon, are ſmall, and ſcarcely ſupply food in ſufficient quantity. They are beſides more juicy, are covered with water, and ſmell leſs ſtrong; ſo that what is noxious is not eaſily diſcerned from what is wholeſome. I obſerved likewiſe, that the radical leaves were always bitter, and the others not, which confirms what I have juſt ſaid.

" 13. I ſaw this plant in an adjoining meadow mowed along with graſs for winter fodder; and therefore it is no wonder, that ſome cattle, though but a few, ſhould die of it in the winter.

" 14. After I left Tornea, I ſaw no more of this plant, till I came to the vaſt meadows near Limmingen, where it appeared along the ſides of the road; and when I got into the town I heard the ſame complaints as at Tornea, of the annual loſs of cattle, with the ſame circumſtances.

" 15. It would therefore be worth while to eradicate carefully theſe plants, which might eaſily be done, as they grow on marſhy grounds, and generally by the ſides of pools and rivers. But if this cannot be performed, the cattle ſhould not be ſuffered to go into ſuch places, at leaſt during the ſpring: for I am perſuaded that later in the year they can diſtinguiſh this plant by the ſmell alone." *Lin. Flora Lapponica.*

Were experiments carefully and judiciouſly made on the above beneficial plan, we ſhould ſoon know with certainty what ſpecies of animals any paſture affords the beſt nouriſhment for. We ſee, for example, heifers fall away in encloſures, where the meadow-ſweet grows in abundance, and covers the ground ſo that they can hardly make their way through it: while the country people, imagining that the paſture is too rich for them, are quite amazed, and never dream that the meadow-ſweet affords them no nouriſhment: whereas the goat, which ſtands bleating on the other ſide of the hedge, is not ſuffered to go in, though he longs to be browzing upon this plant, which is to him a moſt delicate and nouriſhing food. Long experience has taught us, that ſheep take up poiſon in marſhy grounds, though no one till lately knew what the particular poiſon was: yet the ſpiderwort, the mouſe-ear ſcorpion graſs, the mercury, the ſun-dew, the hairywood-graſs, the leſſer ſpearwort, and the butterwort, have evidently ſuſpicious marks.

Hence we ſee, that what makes low grounds ſo noxious to ſheep is not wholly the moiſture, but the plants which grow there; for it is remarked by ſhepherds, that the great danger to ſheep is immediately after a freſh ſpring of graſs, when it is natural to think they lick up the young and tender ſhoots of poiſonous plants along with their proper food, not being then able to diſtinguiſh the one from the other.

From obſervations of this kind the huſbandman may form a right judgment of his meadows, and turn into each the animals beſt adapted to the nature of the paſture.

" The induſtrious farmer, ſays the author of the Swediſh Pan, may judge from hence, when he ſows his meadows with hay-ſeeds for paſture, that it is not indifferent what kind of ſeeds he chooſes, as the vulgar inadvertently think: for ſome are fit for horſes, other for cows, &c. Horſes are nicer in chooſing than any of our cattle. Plants, whoſe ſeeds grow in pods, are particularly reliſhed by them. Goats feed upon a greater variety of plants than any other cattle; but then they chiefly hunt after the extremities and flowers. Sheep, on the contrary, paſs by the flowers, and eat the leaves. And again, different animals have different diſpoſitions as to grazing more or leſs near to the ground. The huſbandman, who underſtands theſe things, and who, in conſequence thereof, knows how to lay out his lands, ſo as to aſſign to each ſort of cattle its proper food, will neceſſarily have his flocks and herds healthier and fatter, than he who is unacquainted with theſe principles. The good manager will alſo obſerve the ſame precautions in the making of his hay: for although many herbs are eaten when dry, which would be refuſed while green, it does not from thence follow, that they yield good nouriſhment. Much might be added concerning the propenſity of cattle to this or that plant: for example, that ſheep delight above all things in the feſcue graſs, and grow fatter upon it, than on any other kind of graſs; that goats prefer certain plants, but, being led by an inſtinct peculiar to themſelves, they ſearch more after variety, and do not willingly ſtick long to any one kind of food; that geeſe are particularly fond of the ſeeds of feſcue graſs; that ſwine hunt greedily after the roots of bullruſh, while they are freſh, but will not touch them when they are dry." *N. Haſſelgren. Amœnit. Academ. Suec. tom. II.*

If a farmer, ſays the intelligent Mr. Liſle, intends to graze cattle in a hill country farm, theſe three things are eſpecially to be regarded; firſt, to raiſe a good quantity of French graſs for hay and aftermaths. Secondly, to turn a good quantity of hill country meadow into rich paſture, by feeding it, dunging it, and laying on it other manure, to make it fit for raiſing the bullock or heifer in the ſpring, when he comes firſt from hay into graſs-leaſe, and to receive him with a vigorous aftermath, when other graſſes, as clovers, and French graſs aftermath, goes off. Thirdly, to have hovels in your bartons, incloſed with cloſe court-walls, to ſhelter your cattle in the winter from wind and rain. All theſe three things are neceſſary and uniform, correſponding with one another; without them, grazing muſt be carried on very defectively, and to little profit, by the hill country farmer.

By the methods here preſcribed, in order to the fattening of cattle, plenty of French graſs hay will enable the grazier to purchaſe barren beaſts before the ſpring graſs comes, when it is moſt likely they will be cheap, and may be bought to the beſt advantage, allowing the value of the hay they may eat in conſideration with the purchaſe; and if by winter-hayning ſome meadow ground (after it has been kept high in heart, by feeding and ſoiling it) you can early in the ſpring, by April, or ſooner, have a bite to take off ſuch grazing beaſts from hay to graſs, it will be very advantageous before clovers can be ready, which are ſeldom ſo, in the hill country, till a week or fortnight in May; and by hayning up ſuch meads for an aftermath, which towards the end of ſummer are in very good heart, you will ſupport your bullock, and carry him on when the ſpirit of other graſſes fail. Then ſuch cattle as are unfiniſhed being brought to French graſs hay, and tied up under hovels or coverings, and within court-walls, will proceed in thriving by being ſecured from the wind and rain, and the tedious hill country rimes, that often continue whole winter days, all which makes cattle brought from graſs to pitch, and maſhes them out. Beſides, if you have not plenty of French graſs hay, you cannot make the beſt of a milch-cow that warps, or of a cow that towards the latter end of winter you may perceive proves barren, or of a fat cow that caſts her calf before you kill her. The neceſſity of French graſs hay only, and not of clover hay, is mentioned here, becauſe it is ſuppoſed that the hill country farmer, who provides ſtore of French graſs hay, will be wiſe enough not to mow his clover, to feed them, in order to improve his lands; for the hill country farmers have generally ſo much land for their money, that all they can do is little enough to keep their arable land in ſuch heart as it ought to be in for their profit.

If the foregoing cautions are not obſerved, the ill conſequences that will follow muſt be ſuch as theſe: if the firſt of the three foregoing cautions be diſregarded, your cattle cannot at any time of the year be made fat, as they ought to be, and then you muſt be under the neceſſity of ſelling them half fat, of which neceſſity the buyer never fails to take the advantage; and ſell them you muſt, notwithſtanding there be ever ſo fair a proſpect of prices riſing in a month or two; and you will commonly find, that you have nothing for the meat they have eat whilſt they have been fattening. In the ſecond place, we will ſuppoſe that very few will be ſo unwiſe, as to to begin to fat a beaft in October with hay, and fo to keep him upon hay during the winter: but we may reafonably fuppofe, that warping beafts, barren heifers, &c. may, and commonly are begun to be fatted with hay from Chriftmas, in which cafe, though hay be plenty, yet if an early fpring grafs be wanting, fuch cattle muft be kept on it, at leaft, till the middle of May; for till then, in the hill country, it will not give a beaft a bite, and then commonly, where the mafter is at a lofs and difappointed, the cattle evidently fuffer before he can make the moft of them, and, in this cafe, he will find a beaft plainly pitch before he can find a purchafer for him. Again, if early fpring grafs be wanting, you cannot begin fummer fattening of cattle, nor buy a barren heifer till towards the middle of May, and then they are commonly very dear; and, in the hill country, from fo late a beginning, the fummer grafs will hardly fat a beaft, the ground falling early off its ftrength, being generally poor. And then, if you have not a quick growing aftermath treafured up, by keeping fuch ground as was formerly meadow in good heart for that purpofe, it is plain you muft again run into the firft evil; and, if you have fuch an aftermath, you may again often want hay in November and December, to finifh fummer fatted beafts: fo that plenty of hay is always neceffary, &c. And, laftly, though you have both hay and grafs, if you want winter fhelter, the cattle muft fuffer.

All fattening cattle, whether lambs, fheep, barren cows, or oxen, require a proportionable progreffion from coarfer to better food, as they grow more and more into good flefh; otherwife when half fat they will go back, and you will not without great difficulty raife them again, which will be a great lofs; nor will fuch beef fpend kindly.

A gentleman, who would make a good hill country grazier, ought, againft the time he buys in his heifers, to take care to be provided with an overplus ftock of middling good hay, or of winter vetches, or of barley ftraw, and autumn grafs, mixed together, layer and layer of each. Be it what it will, it ought to be at leaft better than barley ftraw; for he is to fuppofe he has bought barren heifers, which have been kept all the winter upon ftraw: if they have been kept better, for inftance, on ftraw and rowet, there is ftill the greater reafon for him to mend their keeping; and he is, from the time of buying, to confider, that he ought to begin to raife them in flefh; for the better cafe they are in when turned to fpring grafs, they will take to fattening the kinder, and bear their firft fcouring the better. If he could turn them into the field, for an hour or two in the day, where there is a little rowet, it would do well, and to have change of the above dry meats would keep them the better to their ftomachs.

Oxen are turned off to fattening at two feafons of the year, which, in feveral refpects, are very convenient. The firft is about May-day, when the labour of the ox is pretty well over for the fpring feafon, the fpring corn being then generally all fown. The fecond is the beginning of winter, namely, from the firft of October, to the middle of November, when the wheat and winter vetches are generally all fown, and the ploughman's hurry relaxes.

Oxen turned out at May-day will hardly get fat before Chriftmas, and if not turned out till June, will not be fat till March, April, or May; which again falls out very fortunately, becaufe from Chriftmas till the latter end of May cow-beef is very fcarce, and is generally fupplied with ox-beef; but then it is obvious, when an ox gets half, or three quarters fat by or before winter, he muft be fupported and carried on by a great quantity of hay, and that very good, for the beaft will then grow nice.

Thofe that are turned from the plough in October and November, ordinary food will ferve for fome time; for fhould you lay the beft hay before fuch an ox, then hungry and poor, he will devour more than the profit. The moft you can propofe by this method is to get him fat by July, inftead of September or October; during all which interval of time, heifer-beef will be plenty, and fink the price of ox-beef; fo chargeable a method therefore will not quit cofts.

What the grazier ought to do in this cafe is to bring his ox eafily and gently into good flefh by a rowet; for which purpofe he ought to have hayned up his grounds, and of which rowet he fhould give him the worft firft, except it be of fo four a kind as to want the correction of the winter frofts before he will eat it, of which kind ftubble rowet commonly is, and in fuch cafe that food muft be referved till then, or rather for young beafts and milch-cows. He ought to give him variety of dry meat along with his rowet, in which he fhould confult his tooth, by flinging before him, alternately, every fort of good ftraw, giving now and then a lock of winter vetches, or coarfe hay, but of every thing good in its kind, *i. e.* fweet and well made; and thus the ox ought to be carried on throughout the winter. About the beginning of March he ought to have better hay; not only becaufe the rowet may be fuppofed to be all gone, but alfo becaufe the ox, mending in flefh, grows nicer, and will be weary of dry meat, through the tedioufnefs of being foddered fo much with it during the winter; therefore his hay muft be mended, for not proceeding is going back. Againft April, if poffible, a fhort head of grafs fhould be got for him in your pafture grounds for cow-cattle, by hayning the pafture in February, that he may have grafs along with his hay, as was before obferved in the fattening of barren heifers; and againft May a head of hop clover muft be in readinefs, in the hill country, to receive him into his firft full grazing; for it is not to be fuppofed that the meadows of the hill country, which according to this fcheme are to be converted into pafture, can be fit before the firft of June to entertain a grazing ox; and it is alfo to be noted, that in the hill country, in the month of May, hop-clover will not afford a good bite for an ox or cow, unlefs the autumnal bud be hayned, and preferved by being fed by fheep: in the month of May, if it fhould prove a dry fpring, the fattening oxen and cows muft alfo have good hay given them, with their hop-clover, if it be fhort.

Fattening in the hill country, efpecially if you give your cattle hay in the winter, is more chargeable than in the vale; not only becaufe hay is dearer there, but alfo becaufe the winter feafon begins a month fooner, and continues a month later in the former than in the latter. The farmer in the hill country muft likewife, by forcing nature as it were, provide rowet and feveral forts of graffes in their due order, exactly accommodated to the feafon of the year, befides winter meat, &c. Whereas all may be procured by the latter in the natural courfe, with very little care and trouble.

It will be neceffary to obferve, that every hill country grazier goes to work without his tools, who does not lay down from fifty to an hundred acres of land proper for it, with French graffes, not only on account of making up the deficiency of the meadows not laid down to pafture, being converted to other ufes, but alfo to anfwer many other demands. *Lifle's Obfervations in Hufbandry, vol.* II. *pag.* 18.

A ftalled ox in the winter, if he be kept to hay only, will eat at leaft a load every two months. *Ibid. p.* 5.

Fourteen pounds weight of hay is the conftant allowance on the road to every fat beaft that is drove to London; they that entertain cattle fling fourteen pounds of hay for each beaft into the rack in the evening when they come into the inn, which is to ferve alfo next morning for their breakfaft; fo that half a tod, or feven pounds of hay, is fuppofed fufficient for a fat ox's bait at night, and the fame in the morning. *Ibid. pag.* 9.

For the manner of feeding and fattening cattle with cabbages, carrots, turnips, turnip-cabbages, &c. *See the articles* CABBAGE, CARROTS, *&c.*

CAULIFLOWER, or COLLIFLOWER, a fpecies of cabbage, lately fo far improved in England, as to exceed in goodnefs and magnitude thofe produced in moft parts of Europe.

Having procured a parcel of good feed, you muft fow it about the twenty-firft of Auguft, upon an old cucumber or melon-bed, fifting a little earth over the feeds, about a quarter of an inch thick; and if the weather fhould prove extreme hot and dry, you fhould fhade the bed with mats to prevent the earth from drying too faft, and

and give it gentle waterings, as you may fee occafion. In about a month's time after fowing, your plants will be fit to prick out; you fhould therefore put fome frefh earth upon your cucumber or melon-beds, or, where thefe are not to be had, fome beds fhould be made with a little new dung, which fhould be trodden down clofe, to prevent the worms from getting through it; but it fhould not be hot dung, which would be hurtful to the plants at this feafon, efpecially if it proves hot; into this bed you fhould prick your young plants, at about two inches fquare, obferving to fhade and water them at firft planting; but do not water them too much after they are growing, nor fuffer them to receive too much rain, if the feafon fhould prove wet, which would be apt to make them black fhanked, as the gardeners term it, which is no lefs than a rottennefs in their ftems, and is the deftruction of the plants fo affected.

In this bed they fhould continue till about the thirtieth of October, when they muft be removed into the place where they are to remain during the winter feafon, which, for the firft fowing, is commonly under bell or hand-glaffes, to have early cauliflowers, and thefe fhould be of an early kind; but in order to have a fucceffion during the feafon, you fhould be provided with another more late kind, which fhould be fown four or five days after the other, and managed as was directed for them.

In order to have very early cauliflowers, you fhould make choice of a good rich fpot of ground, that is well defended from the north, eaft, and weft winds, with hedges, pales, or walls; but the firft is to be preferred, if made with reeds, becaufe the winds will fall dead in thefe, and not reverberate as by pales, or walls. This ground fhould be well trenched, burying therein a good quantity of rotten dung; then level your ground; and if it be naturally a wet foil, you fhould raife it up in beds about two feet and a half, or three feet broad, and four inches above the level of the ground: but if your ground is moderately dry, you need not raife it at all: then plant your plants, allowing about two feet fix inches diftance from glafs to glafs, in the rows, always putting two good plants under each glafs, which may be at about four inches from each other; and if you defign them for a full crop, they may be three feet and a half, row from row: but if you intend to make ridges for cucumbers between the rows of cauliflower plants, as is generally practifed by the gardeners near London, you muft then make your rows eight feet afunder.

When you have planted your plants, if the ground is very dry, you fhould give them a little water, and then fet your glaffes over them, which may remain clofe down over them, until they have taken root, which will be in about a week or ten day's time, unlefs there fhould be a kindly fhower of rain; in which cafe you may fet off the glaffes, that the plants may receive the benefit of it; and in about ten days after planting, you fhould be provided with a parcel of forked fticks or bricks, with which you fhould raife your glaffes about three or four inches on the fide towards the fouth, that your plants may have free air: in this manner your glaffes fhould remain over the plants, night and day, unlefs in frofty weather, when you fhould fet them down as clofe as poffible: or if the weather fhould prove very warm, which many times happens in November, and fometimes in December; in this cafe, you fhould keep your glaffes off in the day time, and put them on only in the night, left, by keeping the glaffes over them too much, you fhould draw them into flower at that feafon; which is many times the cafe in mild winters, efpecially if unfkilfully managed.

Towards the latter end of February, if the weather proves mild, you fhould prepare another good fpot of ground, to remove fome of the plants into, from under the glaffes, which fhould be well dunged and trenched, as before; then fet off your glaffes, and, after making choice of one of the moft promifing plants under each glafs, which fhould remain for good, take away the other plant, by raifing it up with a trowel, &c. fo as to preferve as much earth to the root as poffible; but have a great regard to the plant that is to remain, not to difturb or prejudice its roots: then plant the plants which you have taken out, at the diftance before directed, viz. if for a full crop, three feet and an half, row from row; but if for ridges of cucumbers between them, eight feet, and two feet four inches diftance in the rows: then, with a fmall hoe, draw the earth up to the ftems of the plants which were left under the glaffes, taking great care not to let the earth fall into their hearts; and fet your glaffes over them again, raifing your props an inch or two higher than before, to give them more air, obferving to take them off whenever there may be fome gentle fhowers, which will greatly refrefh the plants.

In a little time after, if you find your plants grow fo faft as to fill the glaffes with their leaves, you fhould then flightly dig about the plants, and raife the ground about them in a bed broad enough for the glaffes to ftand, about four inches high, which will give your plants a great deal of room by raifing the glaffes fo much higher, when they are fet over them; and by this means they may be kept covered until April, which otherwife they could not, without prejudice to the leaves of the plants: and this is a great advantage to them; for many times we have returns of fevere frofts at the latter end of March, which prove very hurtful to thefe plants, if expofed thereto, efpecially after having been nurfed up under glaffes.

After you have finifhed your beds, you may fet your glaffes over your plants again, obferving to raife your props pretty high, efpecially if the weather be mild, that they may have free air to ftrengthen them, and in mild foft weather fet off your glaffes, as alfo in gentle fhowers of rain: and now you muft begin to harden them by degrees to endure the open air; however, it is advifable to let your glaffes remain over them as long as poffible, if the nights fhould be frofty, which will greatly forward your plants: but be fure do not let your glaffes remain in very hot fun-fhine, efpecially if their leaves prefs againft the fides of the glaffes; for I have often obferved, in fuch cafes, that the moifture which hath rifen from the ground, together with the perfpiration of the plants, which, by the glaffes remaining over them, hath been detained upon the leaves of the plants, and when the fun hath fhone hot upon the fides of the glaffes, hath acquired fuch a powerful heat from the beams thereof, as to fcald all their larger leaves, to the no fmall prejudice of the plants: nay, fometimes I have feen large quantities of plants fo affected therewith, as never to be worth any thing after.

If your plants have fucceeded well, towards the end of April fome of them will begin to fruit; you muft therefore look over them carefully every other day, and when you fee the flower plainly appear, you muft break down fome of the inner leaves over it to guard it from the fun, which would make the flower yellow and unfightly, if expofed thereto; and when you find your flower at its full bignefs, which you may know by its outfide parting, as if it would run, you muft then draw it out of the ground, and not cut them off, leaving the ftalk in the ground, as is by fome practifed; and if they are defigned for prefent ufe, you may cut them out of their leaves; but if defigned to keep, you fhould preferve their leaves about them, and put them into a cool place: the beft time for pulling them is in a morning, before the fun hath exhaled the moifture; for cauliflowers, pulled in the heat of the day, lofe that firmnefs which they naturally have, and become tough.

But to return to our fecond crop, the plants being raifed and managed as was directed for the early crop, until the end of October, you muft then prepare fome beds, either to be covered with glafs frames, or arched over with hoops, to be covered with mats, &c. Thefe beds fhould have fome dung laid at the bottom, about fix inches or a foot thick, according to the fize of your plants; for if they are fmall, the bed fhould be thicker of dung, to bring them forward; and *fo vice verfa*. This dung fhould be beat down clofe with a fork, in order to prevent the worms from finding their way through it; then lay fome good frefh earth about four or five inches thick thereon, in which you fhould plant your plants about two inches and a half fquare, obferving to fhade and water them until they have taken new

new root; but be ſure do not keep your coverings cloſe, for the warmth of the dung will occaſion a large damp in the bed, which, if pent in, will greatly injure the plants.

When your plants have taken root, you muſt give them as much free open air as poſſible, by keeping the glaſſes off in the day time, as much as the weather will permit; and in the night, or at ſuch times as the glaſſes require to be kept on, raiſe them up with props to let in freſh air, unleſs in froſty weather; at which time the glaſſes ſhould be covered with mats, ſtraw, or peaſe haulm, &c. but this is not to be done but in very hard froſts. You muſt alſo obſerve to guard them againſt great rain, which in winter time is very hurtful to them; but in mild weather, if the glaſſes are kept on, they ſhould be propped to admit freſh air; and if the under leaves grow yellow, and decay, be ſure to pick them off; for if the weather ſhould prove very bad in winter, ſo that you ſhould be obliged to keep them alſo covered for two or three days together, as it ſometimes happens, theſe decayed leaves will render the incloſed air very noxious; and the plants, perſpiring pretty much at that time, are often deſtroyed in vaſt quantities.

In the beginning of February, if the weather be mild, you muſt begin to harden your plants by degrees, that they may be prepared for tranſplantation. The ground where you intend to plant your cauliflowers out for good, which ſhould be quite open from trees, &c. and rather moiſt than dry, having been well dunged and dug, ſhould be ſown with radiſhes a week or a fortnight before you intend to plant your cauliflowers. The reaſon why I mention the ſowing of radiſhes particularly, is this, viz. that if there are not ſome radiſhes amongſt them, and the month of May ſhould prove hot and dry, as it ſometimes happens, the fly will ſeize your cauliflowers, and eat their leaves full of holes, to their prejudice, and ſometimes their deſtruction; whereas, if there are radiſhes upon the ſpot, the flies will take to them, and never meddle with the cauliflowers ſo long as they laſt. Indeed, the gardeners near London mix ſpinage with their radiſh-ſeed, and ſo have a double crop; which is an advantage where ground is dear, or where perſons are ſtraitened for room: otherwiſe it is very well to have only one crop amongſt the cauliflowers, that the ground may be cleared in time.

Your ground being ready, and the ſeaſon good, about the middle of February you may begin to plant your cauliflowers. The diſtance which is generally allowed by the gardeners near London (who plant other crops between their cauliflowers to ſucceed them, as cucumbers, for pickling, and winter cabbages) is every other row, four feet and a half a part, and the intermediate rows two feet and a half, and two feet ten inches diſtance in the rows; ſo that in the latter end of May, or the beginning of June, when the radiſhes and ſpinage are cleared off, they put in ſeeds of cucumbers for pickling, in the middle of the wide rows, at three feet and a half apart; and in the narrow rows, plant cabbages for winter uſe, at two feet two inches diſtance; ſo that theſe ſtand each of them exactly in the middle of the ſquare between four cauliflower plants, and theſe, after the cauliflowers are gone off, will have full room to grow, the crop, by that means, continuing in a ſucceſſion thro' the whole ſeaſon.

There are many people who are very fond of watering cauliflower plants in ſummer; but the gardeners near London have almoſt wholly laid aſide this practice, as finding a deal of trouble and charge to little purpoſe; for if the ground be ſo very dry, as not to produce tolerably good cauliflowers without water, it ſeldom happens, that watering of them renders them much better; and when once they have been watered, if it be not conſtantly continued, it had been much better for them if they had never had any; as alſo, if it be given them in the middle of the day, it rather helps to ſcald them; ſo that upon the whole, if care be taken to keep the earth looſe and drawn up to their ſtems, and every thing be cleared away that grows near them, that they may have a free open air, you will find that they will ſucceed better without than with water, where any of theſe cautions are not ſtrictly obſerved.

But in order to have a third crop of cauliflowers, you ſhould make a ſlender hot-bed in February, in which you ſhould ſow the ſeeds, covering them a quarter of an inch with light mould, and covering the bed with glaſs frames. When the plants are come up, and have gotten four or five leaves, you ſhould prepare another hot-bed to prick them into, at about two inches aſunder every way; and in the beginning of April harden them by degrees, to fit them for tranſplantation, which ſhould be done the middle of that month, at the diſtance directed for the ſecond crop, and muſt be managed accordingly. Theſe, if the ſoil be moiſt where they are planted, or the ſeaſon be cold and moiſt, will produce good cauliflowers about a month after the ſecond crop is gone, whereby their ſeaſon will be greatly prolonged.

There is alſo a fourth crop of cauliflowers, which is raiſed by ſowing the ſeed about the twenty-third of May; and being tranſplanted, as before directed, will produce good cauliflowers in a kindly ſeaſon and good ſoil, after Michaelmas, and continue through October and November, and, if the ſeaſon permit, often a great part of December. *Miller's Gard. Dict.*

CAUTERY, a name given to a red hot iron, uſed by farriers, to deſtroy fungous fleſh, &c.

CAUTING-IRON, an iron with which farriers ſear thoſe parts of a horſe that require burning.

CELERIAC, a ſpecies of celery which ſhould be ſown at two or three different times, in order to have, during the whole ſeaſon, a ſucceſſion of plants which do not run up to ſeed. The firſt ſowing may be in the beginning of March, in which caſe it ſhould be upon a gentle hot-bed, on account of the rawneſs of the weather at that ſeaſon. The ſecond may be at the end of the ſame month, in an open ſpot of fine rich moiſt and light earth, fully expoſed to the warmth of the ſun: and the third ſhould be by the latter end of April, or the beginning of May, likewiſe on a rich and moiſt ſoil, diſtant from the drip of trees. If this ground be expoſed to the morning ſun only, it will be ſo much the better. Theſe ſeeds muſt be watered frequently, if the weather be dry, for otherwiſe they will not grow; but with this care they will put forth plants in about three weeks or a month, and theſe will be fit to tranſplant in five or ſix weeks after their coming up.

When this is done, they ſhould be pricked out at the diſtance of three inches ſquare from one another, in well prepared, and warmly ſituated beds of moiſt rich earth; and if the ſeaſon ſhould prove cold, theſe beds muſt be covered with mats, to defend the young plants from the morning froſts, which would greatly check their growth, or, perhaps, even kill many of them. In drawing them out of the ſeed-bed, care ſhould be taken to thin them, where they grow too thick, and to leave the ſmalleſt to get more ſtrength before they are removed. By this means the ſame ſeed-bed will afford three different plantings, which will ſucceed each other for uſe.

By the middle of May, ſome of the firſt tranſplanted plants will be fit to remove again for blanching; and in this particular only the culture of celeriac differs from that of celery, the latter being tranſplanted into trenches, and there earthed up, whereas celeriac, which ſeldom grows above eight or ten inches high, and therefore requires but little earthing up, ſhould be planted in level ground, or in very ſhallow drills, its great excellency conſiſting in the ſize of its root, which often grows as big as an ordinary turnip, even in the common way of ſetting theſe plants only ſix or eight inches aſunder in rows, fixteen inches apart, and earthing them up but once. It is therefore highly reaſonable to think, that if the ſuperior method of culture uſed in the new huſbandry was applied to this plant, both the taſte and ſize of the roots would be greatly improved.

CELERY, or Celeri, the name of a well known plant, much uſed in ſoups, and other culinary uſes.

It requires exactly the ſame treatment as celeriac, laid down in the preceding article, till it is tranſplanted for the ſecond time, in order to be blanched. The uſual way of performing this, is to dig a trench by a line, about ten inches wide, and eight or nine inches deep, in a moiſt, rich, and light ſoil; and to looſen and lay level the earth at the bottom of this trench, and to throw up on each ſide a ridge of the mould taken out, that it may be in readineſs there for earthing the celery. Theſe trenches are generally three feet aſunder, which is a ſufficient ſpace for digging between them after they are filled up. When the young plants have been trimmed, and the tops of their longeſt

longeſt leaves cut off, they are ſet in one ſtrait row in the middle of the bottom of the trench, at about four or five inches diſtance from one another; their roots are then covered with mould trodden down cloſe to them; and care is taken to water them plentifully, till they have ſtruck out new roots. As theſe plants advance in height, freſh earth is drawn in cloſe to them on each ſide, but with great caution not to bury their hearts, or even to do this in wet weather, leſt it ſhould make them rot.

When the plants are grown conſiderably above the trenches, and all the ridges have been employed in earthing them up, a ſpade is uſed to dig up more earth from between their rows, and this is continued, at proper intervals of time, till they are fit for uſe.

The celery firſt planted out will be fit for uſe about the end of July. This will be ſucceeded by the after plantations; and the later ſowings, if rightly managed, will yield a conſtant ſupply of it till April. The laſt crop ſhould be planted in a drier ſoil than any of the preceding; and to prevent its being rotted by much wet in winter, it will be right to cover the ridges, eſpecially if there be any danger of hard froſt, with peas-haulm, or ſome other light covering, which will not ſmother the plants: for covering them too cloſe would alſo make them rot. However, this will be ſufficient to keep the froſt out of the ground, ſo that the celery may be taken up whenever it is wanted; which cannot be done when the earth around it is hard frozen. But this covering muſt be taken off as early in the ſpring as the weather will permit, leſt it ſhould make the plants run to ſeed.

Celery will not continue good above three weeks or a month after it is fully blanched, but will then grow hollow, or rot. A ſucceſſion of ſix or ſeven different plantings is therefore neceſſary for thoſe who would have a conſtant and regular ſupply.

CELLS, the ſmall diviſions in honey-combs, which, geometers have obſerved, to be always regular hexagons.

Cells, alſo denote the hollow places between the partitions in the pods, huſks, and other ſeed-veſſels of plants.

CENTAURY, the name of a weed abounding in arable lands, and generally called blue-bottle. *See* Blue-Bottle.

CERES, a pagan deity, the inventor, or goddeſs of corn.

CERT-MONEY, a fine paid yearly by the reſidents of ſeveral manors to the lord thereof, and ſometimes to the hundred, for the certain keeping of the leet.

CHAFF, the huſks of corn that are ſeparated by thraſhing and winnowing. *See the articles* Thrashing *and* Winnowing.

Chaff alſo ſignifies the rind of corn: thus, barley that has a thick rind is ſaid to be thick chaffed.

Chaff, likewiſe implies ſtraw, &c. cut ſmall, and given to horſes and other cattle, mixed with corn. *See the article* Cutting-Box.

CHALK, the Engliſh name of the white dry marl, with a duſky ſurface, found in hard maſſes.

Chalk is a laſting manure for ſuch lands as it agrees with, which are particularly thoſe of a cold ſour nature, and ſtiff untractable clays. Pliny tells us, it was the cuſtom of the ancient Britons to chalk their lands, by which they received a great and laſting improvement.

Farmers are apt not to diſtinguiſh ſufficiently between the different kinds of chalk. The hard, dry, and firm, is much the fitteſt for burning into lime; but the fat unctuous chalk is by far the beſt to be uſed crude. This oily, viſcous ſort of chalk, is uſed in many places inſtead of marl, to which it is nearly allied, though of an inferior quality. It is even called marl in the Iſle of Wight, where their chalk is of a remarkably fat ſoapy nature; and they ſometimes lay twenty-five waggon-loads of it upon an acre of ground. *Liſle's Huſbandry, vol.* I. *p.* 66.

A correſpondent of the editors of the Muſeum Ruſticum ſtrongly recommends chalk as a manure for clay lands; but adds, it ſhould be laid on rough, in large clods, whereby the land will gradually receive the greater benefit by it. The ſalts in the air will penetrate, and crumble the clods; and the land, on which the chalk is laid, will ſoon be brought into a ſtate of fermentation, reduced and pulverized in a ſpecial manner, inſomuch, that afterwards, one ploughing will go as far towards bringing it into tilth as two before.

The quantity of chalk ſhould be proportioned to the ſtubbornneſs of the ſoil; from fifteen to thirty tumbril-loads on an acre.

The virtues of this manure are not exhauſted under, at leaſt, twenty years; nor are they much perceived till the third year; but for twelve or fourteen years the farmer will have reaſon to thank thoſe who adviſed him to the ſtep of chalking his clay lands: and happy is he who can afford to do it, provided he has a long leaſe; for lands not worth five ſhillings an acre have, by this means been, in a year or two, worth twenty. *Muſeum Ruſticum, vol.* II. *p.* 305.

An old experienced farmer in the hundreds of Eſſex has, in the ſame work, given an excellent account of the benefits reſulting from chalk laid on clay lands, where, he juſtly obſerves, it inſinuates itſelf into the ſmall pores, and, raiſing a fermentation, expoſes the clay more to the operations of the froſts, rain, ſun, and air, by which means its too coherent particles are looſened, and it is reduced to a ſtate of pulverization.

" We all know, adds this intelligent huſbandman, that clay, when reduced, either by fermentation or attrition, into ſmall and minute particles, is an excellent ſoil for affording plenty of nouriſhment to almoſt every kind of vegetable: it is therefore natural to us, when poſſeſſed of a ſtiff clay, to go in ſearch of means for producing theſe deſirable effects.

" Chalk has been long allowed the palm in this reſpect: our anceſtors, the ancient Britons, uſed it with great ſucceſs; and the practice, as warranted by conſtant experience, has been handed down to the preſent age: is it not then a pity but a cuſtom ſo profitable ſhould not be made known to every part of his majeſty's dominions?

" The chalk we uſe in Eſſex is moſtly brought from Kent: it agrees well with our clays, and many fine fortunes have been made in this country by chalking farms: yet what may appear very ſtrange, but is not leſs true, this ſame chalk, when laid on the clayey lands in Kent near the pits, does by no means anſwer the farmer's expectation.

" It has been a common ſaying among farmers, that chalk laſts only for a certain number of years, after which it leaves the land in a worſe ſtate than that in which it found it: but this is probably a miſtake, owing to prejudice, negligence, or ignorance.

" When land has been chalked, under a notion it cannot be hurt by cropping, they generally keep it in almoſt conſtant tillage, and it pays well for the ploughings; but then the ſoil being, by ſuch conſtant working, reduced to a pulverized ſtate, the chalk eſcapes through the now-enlarged pores of the clay, and forms a cruſt under the looſe ſtratum on the ſurface of the hard clay beneath, being waſhed down by the rains.

" The particles of clay, being now deprived of their coatings of chalk, adhere one to the other, enlarge their ſurfaces, and become at length a coherent maſs of ſtiff ſoil, like what it was before the land was chalked at all, not worſe in quality, but nearly in the ſame ſtate. Probably the chief reaſon which induces farmers to think the land impoveriſhed by chalk is, becauſe they have, whilſt the manure acted with its full vigour, been for many years uſed to great crops, forgetting, or perhaps never knowing, what crops the land yielded before any chalk was laid on it.

" A great deal of care is requiſite in land after it is freſh chalked: if the large lumps are buried before they are ſtrongly impregnated with the influences of the atmoſphere, they will lie under ground undiſſolved, in a hard maſs, for a great number of years, without benefiting the land in the leaſt. For this reaſon, the farmer muſt not be in a hurry to bury his chalk: in fact, the longer it lies above ground the better, as it will then gradually be reduced into an impalpable powder, which, being mixed and incorporated with the clay, leſſens the coheſion of its parts, enlarges its pores, and diſpoſes it to yield that nouriſhment to vegetables, which, in its natural ſtate, it is too retentive of.

"Clay is, by nature, poffeffed of a large ftock of the food, whatever it be, which plants moft delight in; but it is a ftubborn foil, and will not, till compelled to it by fome extraneous caufe, give forth any of its riches. If it is pulverized by the inftruments of hufbandry which act by attrition, it becomes a proper bed for the reception of the roots of vegetables; but this pulverization is not to be effected without great expence of time and trouble: and it was the difficulty of this operation that induced our anceftors to fearch for fome eafier and fhorter method for reducing the folid particles of clay; they effected it by means of fermentation, and this fermentation was raifed, for the moft part, by rotten horfe-dung.

"When this manure became fcarce, and difficult to be procured, it was neceffary to have recourfe to fome other remedy to correct ftiff foils. Chalk was found well adapted to the purpofe: the ufe of it was after many years almoft univerfally adopted, and experience has now, for many ages, juftified the practice.

"It has been already obferved, that chalk improves clay, not by adding to it any vegetative quality, but by mixing intimately with its fubftance, and leffening the cohefion of its parts.

"Let us by way of illuftration, fuppofe any given quantity of clay mixed and incorporated with a proper proportion of chalk, it will be found that the clay will poffefs a degree of lightnefs, which nature has denied it. Let this mixed earth be fpread on a floor expofed to the weather in winter time; let it be frequently fprinkled with water, and be ftirred about feveral times a day for fome months: on an examination, it will then be found, that the chalk has fubfided, and the clay become more compact than it was, but not fo compact as it was before any chalk was mixed with it.

"The fubfided chalk will form a complete ftratum under the bed of clay.

"I have been the more particular in this account, becaufe on the principle of fubfidence I have founded a practice, which I have experienced to be profitable to myfelf, and therefore I think it not totally improper to be recommended to the notice of others.

"I had heard it long complained of, that the benefit refulting from chalk ceafed after a courfe of years. I always thought, and indeed found, that the chalk fubfided: this made me form an opinion that the chalk, even after it had fubfided, might, in part at leaft, be retrieved; for the earth, which had been loofened to a certain depth, was, at the bottom of the loofe mould, a hard compact body, which the chalk could not penetrate: here therefore it muft, of courfe, reft in its fubfidence, forming a thin coat on this hard body.

"About forty years ago I chalked the greater part of my farm in the manner prefcribed by the cuftom of this country. For about fourteen years I enjoyed very good crops; but at the end of that time they began to fail a little. As neceffity is the mother of invention, I came to a refolution of trying an experiment on a field of twenty acres: accordingly, when the time came in which it was to receive a whole year's fallow for a crop of wheat, I caufed the whole of it, foon after harveft, to be ploughed twice in a place, one plough following another in the fame furrow.

"By thefe means I turned up an entire new earth, on which I immediately laid in the proportion of about three loads of chalk an acre, fuffering it to lie rough all the winter.

"In the fpring I gave it a fecond ploughing, and beftowed on it three more ploughings before Chriftmas, when I again left it rough for the winter.

"I muft not, however, fail obferving, that in all the ploughings after the firft, the fhare went only the ordinary depth.

"In the fecond fpring I raifed as fine a mould as I could, by various operations, and fowed the field with barley, of which I had, at harveft, a crop to my entire fatisfaction: my next crop was wheat, on which I fprinkled fome clover-feed, which brought the land into the ufual courfe of hufbandry.

"The reafon why my land begins to fail, in about fourteen years after chalking is, becaufe I allow more ploughings to each crop than any of my neighbours, and thefe frequent ftirrings caufe the calk, as I imagine, to fubfide fooner.

"My method anfwered fo well, that I managed all my chalked land in the fame manner with good fuccefs; and had, in confequence, a fucceffion of good crops for ten years more.

"When the ten years were expired, I gave my land another trench-ploughing, which never failing to recover the chalk, I renew it at regular intervals, but lay no frefh chalk on it after the firft trench-ploughing, being in all the reft content with what is already in the land.

"This method has ftood the teft of many years experience, and I have not the leaft reafon to afcribe it to any thing peculiar in the quality of my foil: why, therefore, fhould it not fucceed as well with others as it has done with me?

"Let me perfuade fuch of your readers, as it may any ways fuit, to make the experiment; it cannot be any great expence, and the refult may turn out very greatly to their advantage.

"This doctrine of the fubfidence of chalk is certainly founded on reafon: the predominant natural foil will always precipitate that which is only adventitious, and in fmaller quantity; for the fame obfervation holds good when clay is laid on chalk.

"This fubfidence may alfo be obferved when clay is laid on fand, or fand on clay, as a manure; and might, perhaps, be extended to many other articles, fo as to be deemed a general principle.

"Few know the benefits refulting, on fome occafions, from deep ploughing: but in this, as well as in every other matter, difcretion is to be the grand guide; and I would, by all means, advife the farmer to examine into the depth of his foil, by remarking what is thrown out of his ditches, or by the help of a borer. Let him judge by this, and he cannot well go aftray.

"I muft alfo give another caution to my honeft brethren the farmers, which is, not to be in too great a hurry to crop a field after it has had a trench-ploughing; for the foil turned up from any confiderable depth will be fomewhat crude in its nature, till it is meliorated by the influences of the fun and air.

"I have generally found that one whole year's fallow is fufficient to effect this; but two winters and a fummer I never knew to fail: it is chiefly froft which contributes to pulverize the chalk, and fweeten the foil; not but that it receives great benefit from the rain and funfhine, and particularly from fnow, which is ftrongly impregnated with nitrous particles; all I mean to infinuate is, that one day's froft, contributes more to fweeten a ftiff, rough, foil, than two day's funfhine, rain, or fnow.

"Let me in this place hazard a conjecture, which may, however, prove a fact: the reafon why froft fo much contributes to difunite the particles of clay may be owing to its fwelling the clods, and increafing their furface: the cavities occafioned by this fwelling are filled with ice: when a thaw comes on, wherever the ice was, is a vacuum, and the particles of which the clay is compofed, being feparated one from the other, crumble and fall in pieces: when they are in this ftate, and the land has been chalked, a fingle ploughing, well-timed, will cover their furfaces with the chalk-powder, and prevent them from fpeedily adhering one to the other.

"Your readers, who have been in countries where there are quarries of ftone, muft have obferved, that, whilft in the quarry, it works better than after it has been expofed to the fun; for it hardens confiderably after it has been out of the quarry fome time. It is the fame with chalk, which is apt to be hardened by lying a fummer in the fun: for this reafon, it is advifable, that the chalk intended for manure fhould be dug as foon as the winter fets in, and laid prefently on the land. This method and time of chalking may occafion fome increafe in the expence; but the farmer will be well paid for it in the end, and he will, by this management, fooner reap the benefit of his labours.

"Let it not be imagined from any thing I have faid here, that I truft folely to chalk for bringing me good crops; no, I always beftow, once in a courfe of three or four years, a reasonable coat of compost dung. I do not lay on the chalk with any intention that it should enrich the clay: my desire is, that it should bring it to the nature of a loam, as the dung will then take effect, and ensure the farmer a large crop, provided he guards himself against the depredations of weeds, which are too apt to have their seeds mixed with the dung made of long straw, and often grow faster than the corn, with which the land should be cropped. Dung, when prudently applied, is, like many other things, of great use; but it is dangerous in the hands of an ignorant land-holder. The expence of procuring it in quantity will ruin him, and his crops will go near to be choaked by the encroaching weeds." *Museum Rusticum, vol.* III. *page* 198.

"If chalk, says Mr. Lisle, be laid on clay, it will in time be lost, and the ground again return to its clay; and if the clay be laid on chalk, in time the clay will be lost, and the ground return again to its chalky substance. Many people think the land, on which the other is laid for a manure, being predominant, converts the manure into its own soil; but I conceive, in both cases, the chalk and clay is filtrated through the land, on which it is laid, by time, and, being soluble by rains into small corpuscles, is washed through the land on which it is laid; for neither of these manures is able to unite, in its finest corpuscles with the corpuscles of the land on which it is laid, so as to form so strict an union and texture with it as the land doth with itself, and is therefore liable to be borne downwards with rains, till no sign of it be left.

"It is said to be a common practice with many tenants in Hampshire, three or four years before they leave their farms, to chalk their meadows; by which means they will for three or four years fling out a great crop of grass, but that they will be much the worse for it ever after. This seems to carry some reason with it; for the chalk so mellows and opens the pores of the meadow, that it enables the land to exhaust its strength in all parts: for chalk does not carry so much fatness as dung does to the land it is laid on; but it disposes the land to bear such crops by its sweetness, and well disposing of, and correcting an ill quality the land had before: but still I do not see that this is any objection to the chalking of meadows, provided, whilst, by virtue of the chalk, they are bearing such burthens, you take care to refresh them with dung.

"Though chalk laid on meadows enables them to give a great crop for three or four years, and will then impoverish them, yet I take it to hold quite contrary in pasture; for the grass being thereby so much sweetened and increased, keeps constantly so much the more stock, by which it is maintained always in the same vigour.

"It is probable, that chalk spread on sandy, or woodseary ground, laid up for pasture, may wash and sink in, and fill up the interstices, and thereby consolidate and mend the texture of such ground, and sweeten it, as it is a great alkali; and though in time most of the chalk may be washed downwards, so that the ground may lose its virtue, yet I do suppose the strength of the ground may still continue much better, by reason that such manure having made the sward of the grass come thicker and sweeter, the good pasturage on both accounts enlarges the quantity, and betters the quality of the dung the cattle leave on it, which, in return, maintains a better coat and surface to the ground: and as chalk fills up the vacuities of sandy, or wood-seary ground, so, on the contrary, it insinuates its particles into obstinate clayey and strong land, and divides it, by making in a manner, a scissure, thereby hollowing and mellowing it; so that the two contrary extremes are cured by chalk.

Chalk laid on hop-clover and rye-grass is a mighty sweetener and improver of these grasses, being laid upon it after harvest, at the beginning of winter, or whensoever one can best tend it; the benefit will be soon conspicuous, especially if the ground be a sour clay, and apt to run to coarse grass. *Lisle's Husbandry, vol.* I. *p.* 66.

CHALKEY *Lands*, are those which are impregnated with chalk, and from their white colour, are in some counties, called white lands.

The best produce of corn in chalky lands, is barley and wheat; oats will do well on them. Their natural produce for weeds is poppies, May-weed, &c. For grass-feed, saintfoin, trefoil, and, if rich, clover. The best manure for these lands is rags, dung, folding of sheep, &c. These land, if rain happens to fall on them just after sowing, before the corn gets up, will cause the earth to bind so hard, that the corn cannot get through it; but may be much helped by a light harrowing.

In Hertfordshire they manage these lands for corn in the same manner as they do their clay lands. In Oxfordshire they commonly manure these lands with half rotten dung, which, they say, prevents the binding of it, and some mix it with sand, which causes it to work short, especially if any thing dry; they commonly sow them there with wheat, missen, and barley; only after wheat they sow pease or vetches: in the sowing of which they are obliged particularly to take care to have fine weather, because of the land's binding; but if they have only two nights dry weather, they will do well enough. *Mortimer's Husbandry, vol.* I. *pag.* 68.

CHAMOMILE, a very common plant, growing wild upon commons and other waste lands in many parts of England, particularly in moist and shady places, which it most delights in.

It is a trailing perennial plant, which puts forth roots from the joints of its branches as they lie on the ground, and by that means spreads and multiplies exceedingly; so that whoever would cultivate it, need only procure a few slips of it in the spring, and plant them about a foot asunder, that they may have room to spread; they will soon cover the ground.

Chamomile walks were formerly a sort of fashion in gardens; and indeed they looked pretty enough for some time after they were mowed and rolled: but they are now entirely out of use, because this plant is very apt to decay in large patches, which then become disagreeable to the eye.

The chamomile flowers for medicinal uses should be of the single kind; but the market people generally sell the double, because they are the largest.

The double flowered sort of chamomile is as hardy as the single, and may be propagated in the same manner.

CHANFRIN, the fore-part of a horse's head from one hand to the other.

CHANGE *of crops*, a very judicious part of husbandry, consisting in a change of different species of grain on the same soil.

Experience soon taught men, that even the most fruitful soil cannot constantly yield the same grain; and this of course laid them under a necessity of seeking for means to remedy the defect. They found the plough the most ready, and perhaps the most effectual: and hence all the ancient writers so highly commend a thorough ploughing. At the same time the apparent loss of the produce of the ground during the year of fallow, put them upon enquiring how this inconvenience might be prevented, consistently with keeping the land in good heart. Repeated observations convinced the Romans, the most attentive of all nations to every thing relative to husbandry, that, besides the alternate resting of the land, wheat may, as Pliny observes, be sown after lupines, vetches, beans, or any other plant which has the quality of fertilizing and enriching the soil. This, says Mr. Lisle, deserves to be well noticed, because our farmers imagine they cannot make their rent, if they pay twelve shillings an acre, without sowing their land every year; nor will they be persuaded to lay it down to grass.

The most rational change of crops hitherto pointed out by any writer, is the following, planned by Camillo Tarello, and which he presented to the senate of Venice in the year 1566.

"Let the ploughings hitherto given to corn land divided into two portions (each of which being rested every alternate year, receives four ploughings that year) be transferred to the half of one of those portions, so that it be ploughed eight times, including the seed ploughing; I mean, that every farm in tillage be divided into four equal parts, and that only one of these parts, taking them alternately, be fowed with corn in any one year, after it has been ploughed eight times. Two of the other parts fhould be laid down to grafs; and the fourth fhould be fallowed a year, during which it fhould receive the above-mentioned number of ploughings.

" He, therefore, who has now, for example, ten acres under corn, fhould for the future fow only five, and fo in proportion for a larger or leffer extent; and all the manure and labour formerly beftowed upon his ten acres fhould be appropriated to the five only; that is, he fhould plough them eight times, unlefs the foil be extremely light.

" The hufbandman fhould begin to plough in October or November, about ten months before he fows, or fooner if he can; but always in dry weather. He fhould lay on his dung before the laft ploughing; and fhould not fow more than two thirds of the quantity of feed hitherto commonly ufed, and that feed fhould be of the growth of the country.

" Whoever follows this method may always depend upon reaping the following advantages:

" 1. This way of cultivating land leffens the expence and labour; it being eafier to plough one acre eight times, than to plough two acres four times each: becaufe, after the third time, an acre and a half, at leaft, may be ploughed as foon as an acre could have been before; and if he begins his work in October or November, while the land is in good condition for ploughing, he may continue it the following year, at fuch times as he will have little more urgent bufinefs, fo as to have four ploughings done about the end of May. By this means the four fummer ploughings will not require fuch ftrong ploughs as fome people now ufe, to the great hurt of their cattle, and fatigue of the ploughman, becaufe the ground will be already well loofened.

" 2. Thefe repeated ploughings will deftroy the feeds and roots of weeds, which rob the corn of its food, choak it, and hinder it from growing.

" 3. A field refted, and then prepared in this manner, will yield more than double the produce of two equal fpaces of land cultivated in the common manner, as I have often experienced. This is more than doubling one's income.

" 4. Over and above this great advantage, we likewife fave two thirds of the quantity of feed hitherto commonly ufed: for, by fowing only a quarter inftead of half of the land in tillage, there is an immediate faving of half the feed formerly required; and by fowing only two thirds of the ufual quantity upon that quarter, we again fave two twelfths, that is one fixth of all the former feed: now half and one fixth makes two thirds, to be deducted from the former ufual quantity.

" 5. We fhall have a fufficiency of ftraw of every kind for all our ufes, efpecially for litter and dung, fo indifpenfably ufeful.

" 6. We fhall have hay and fodder enough to keep many cattle; becaufe we may, and fhould fow one half of our ground with graffes, which will thrive extremely well, while the land is thus refted for two years, in order to be afterwards broken up, ploughed, and fowed with corn in its turn: for I again advife fowing only a quarter part of the whole farm with corn, and breaking up another quarter immediately after feed-time, before winter: and, on the contrary, neither of the other quarters fhould be ploughed during two years. But as the earth is deftined continually to yield productions of one kind or another, even while it refts, we fhall do well in following the path pointed out by nature, by helping it to produce clover, and other plants fit for fodder, which are of fingular fervice to us, not only on account of the hay we reap from them, but alfo becaufe their roots greatly improve the foil. In the country about Brefcia, plentiful crops of the fineft flax are reaped from fields where a quantity of clover has been lately mowed; and lands are let there for a great price, not only becaufe the foil is rich, and can be watered, but alfo becaufe it has juft been under clover. If fuch value is fet upon land intended only for flax or millet, how much more would good wheat land juftly deferve?

" 7. A feventh advantage will be, that land refted regularly for two years (I fay, with Virgil, that it refts when it is not ploughed) being well conditioned, afterwards well prepared, ploughed, enriched by the roots of the graffes, and kept clear of weeds, will yield crops more than twice as great as any we now reap; a truth which I have practically experienced, which the moft fenfible and moft judicious hufbandmen that ever lived have long told us, and of which a trial will foon convince the moft incredulous.

" 8. One of the moft confiderable advantages attending this method, is the eafe with which a great number of cattle may be reared, by means of the increafed quantity of hay and green fodder. We fhall confequently have more horfes, more oxen, more cows, more fheep, and more poultry. Every one knows of what infinite fervice all thefe are, to feed us, to cloath us, and to help us in our work. He, therefore, who has hitherto been obliged to have two yoke of oxen will, in this method, want only one, and may, inftead of the other, feed two or three cows: for as the labour is hereby leffened, and the quantity of good fodder increafed, two oxen will be fufficient to plough the land, efpecially as the foil will, by thefe means, be brought daily into better and better tilth.

" 9. From hence naturally arifes a ninth advantage, which is, the quantity of manure produced by the increafe of cattle and of fodder; an advantage which no good hufbandman will neglect to purchafe, if the means of doing it are but pointed out to him.

" The 10th and laft of the advantages which I fhall here enumerate, as refulting from this new method of culture, is, that poor and barren lands are hereby rendered, by degrees, good and fertile: for fuch is the conftitution of the earth, that ploughing and manuring alter its very nature, and improve it more and more, as experience repeatedly demonftrates. Valerius Maximus inftances the ftriking example of Mafiniffa, king of Numidia, who made agriculture flourifh fo much, that he left his country, which he found barren and defolate, ftored with riches and every good thing. It is in our power to do the fame. On the contrary, it is not lefs true, that even though the earth be rich and good, it will yield but little fruit, if it be not well cultivated; refembling therein the capacity of the human mind, which, according to Cicero's fine comparifon, is enlarged only by ftudy and exercife. Induftrious labour will not only procure us the neceffaries, nay, the fuperfluities of life, but will even change a barren country into a kind of garden. *Ricordo d'Agricultura di Tarello.*

M. Duhamel, after obferving that the French farmers, in general, change their crops, not on any principle dictated by reafon, but merely becaufe it was the cuftom of their forefathers, or they themfelves perhaps have occafion for fome particular growth, draws a parallel between the practice of dividing arable land into three parts, or into two, in order to their being alternately fown, and refted. " I have, fays he, fome acquaintance with the methods of practice in Guienne, and in part of Normandy; and am obliged to M. le Baron de Sournia, governor of Querebus, for enabling me to give an account of the methods ufed in the neighbourhood of Perpignan, where his eftate lies.

" In this hot climate they fow their lands in September, and begin to cut wheat about the twelfth of June; fo that their harveft is generally finifhed by Midfummer.

" They divide their lands into two portions only; fo that in one year they fow wheat, and the other the land fhould be fuffered to reft. But, on fuch part of their lands as are moft valued, they have feveral crops during the year of reft: this impoverifhes their lands, and they are obliged to fow their wheat too late, which leffens the crop. We fhall mention an inftance given by M. Sournia.

" In land they can water, they fow clover immediately after wheat-harveft, fcattering the clover-feed among the ftubble. The land is then immediately watered, and is afterwards feveral times repeated during the fummer: in the winter they feed it with fheep and lambs. Such as have no flocks fell their pafture to the upland farmers, who have flocks, but no winter fodder, their land being covered with fnow: this pafture therefore fetches a very high price.

" In

"In fpring, when the green fodder has been eaten down by cattle, they water the land, and by that means the clover fprouts apace; when it is in bloffom they mow it, make it into hay, and lay it up with the reft.

"Immediately after this crop, they dung the land; and fuch as are not afraid of exhaufting it, plough it, and fow either kidney-beans, or fmall millet: but as they cannot plough for wheat till thefe crops are off the ground, there is not time fufficient for giving the land proper tillage; the fowing is retarded, and the rich particles of the dung are partly confumed by thefe crops, while the manure might be more ufefully employed on lands they cannot water. M. de Sournia is, by repeated experience, convinced, that, to have good crops of wheat, they muft be contented with the crop of clover, and only fow kidney-beans, millet, &c. in fmall quantities for the ufe of the family.

"In Guienne, as well as in Anjoumois, they raife a crop of maize, which is a great impoverifher of the ground, during the year of fallow.

"The good hufbandmen alfo think, that in the rich lands, which they cannot water, it is beft, in a farm of three hundred acres, to be content with having one hundred and fifty acres of wheat, and to be careful to give proper tillage to the one hundred and fifty acres that fhould be in fallow, to make them proper for the reception of wheat. This is alfo the practice of fome diftricts of Normandy, where the climate being colder, and the foil more backward, they have fcarcely an opportunity of having any crop but wheat. However, when the land has been well dunged and tilled for maize, as they beftow three ploughings on that plant, there is commonly the next year a very good crop of wheat.

"It is evident, that by dividing a farm, that has three hundred acres in tillage, into two equal portions, which are fown alternately every other year, the tenant, during a nine years leafe, will reap one thoufand three hundred and fifty acres of wheat: whereas, if the land be divided into three portions, it will amount to nine hundred acres only. But, in the latter cafe, the former has nine hundred acres of fpring corn, which being eftimated at half the value of the wheat, make it juft equal to one thoufand three hundred and fifty acres of wheat. It follows therefore, that in grazing countries, where they plough with oxen, and ufe but few oats, it is moft advantageous to divide the land into two portions; but that this is not to be done in farms that are tilled with horfes, becaufe the neceffary purchafe of oats would amount to the value of the four hundred and fifty acres of wheat extraordinary.

"The farmers about Bayeux, in Lower Normandy, have two methods of changing their crops.

"According to one of thofe methods, 1. They fow buck-wheat towards the end of June; 2. When the roots and ftems of this plant are dead and withered, which is about All-faints day, they plough, and immediately fow wheat: the wheat is therefore fown on one fingle furrow. Thefe lands have indeed been ploughed for buck-wheat, and even thoroughly dunged; and plenty of manure can fupply the place of good tillage, and the latter can fupply the place of the former. 3. After reaping the wheat, they plough in the ftubble as foon as poffible; and, after giving the land a fecond ploughing in February or March, they fow it with oats; or a third ploughing is beftowed upon it, in order to crop it with barley: 4. They plough in the barley ftubble in winter, and after giving the land one fpring ploughing, fow either peas or tares: 5. Immediately after this crop is off, they turn down the land, that it may receive two ploughings before October, when it is fowed with wheat. 6. The following year they fow oats mixed with a little clover-feed; after which it is laid down in pafture for three or four years. It would be needlefs to mention that the farmer varies the order of his fucceffive crops, according to the nature of the foil, and his own occafions; but by this method, fix crops are reaped in fix years; two of wheat, two of oats, one of buck-wheat, and one of peas or turnips; and the field is then left in clover to be fed for four years.

"According to the other method, they fow no buck-wheat on the land they break up; it is left in fallow from February or March, when it is turned up, till October; and during this interval they manure it, and give it feveral ploughings to prepare it for wheat. In this cafe the crop is generally more plentiful, than when buck-wheat has been fown. In other refpects, the change of crops is the fame as was mentioned before." *Culture des Terres, tom.* VI. *p.* 34.

The changing of crops, upon rational principles, though of infinite confequence in agriculture, feems to have been neglected, and even forgotten, after the time of the ancient Romans, till Camillo Tarello pointed out its great importance, as we have already obferved in this article: nor do we, fince him, find much attention paid to this effential part of hufbandry, till very lately, when the culture of turnips probably gave the ufeful hint; the farmer obferving, that his land, inftead of being impoverifhed by that root, was enriched, and prepared to yield a better crop of barley in the fpring. This might naturally fuggeft to him, that other fucculent plants, which cover the earth with their leaves, might have the fame effect. The fuccefs has anfwered his utmoft expectation: for it is now found that a fallow does not become neceffary in feveral years; the ground being kept in heart by a variety of crops when rightly timed, and properly managed. The Society for the Improvement of Agriculture in Scotland, from whom we fhall borrow the following judicious inftructions, have the honour of fetting this difcovery in its proper light.

They obferve, "That fome crops, as peas, beans, clover, and all plants of the pulfe kind, are enrichers and cleaners of the earth; while wheat, oats, barley, and the whole tribe of vegetables, whofe roots are fibrous, and fpread far, impoverifh and rob the ground. The latter are alfo foulers of it, by giving way to weeds and grafs, which, being the natural product of every foil, are more readily nourifhed by it, than any plant which it does not fpontaneoufly produce; and if the earth be fed with any fort of manure, it will, while the weeds and grafs remain undeftroyed, like a tender mother, cherifh and nourifh them in proportion to the food fhe receives.

"Wheat and oats are great robbers of foils. Wheat remains a long time in the ground, during which the land untils itfelf, coalefces, and becomes of the nature of uncultivated earth; while the weeds, meeting with no oppofition, ripen, and fhed their feeds. Oats do not continue fo long: but they bind the foil by their ftrong roots, and give many weeds time to ripen. Barley, as it ftands only a few months, and feveral ploughings are given for it, binds the earth lefs than either wheat or oats. Peas, beans, tares, &c. are fuppofed to draw much of their nourifhment from the atmofphere, and that in proportion to the fucculency of their ftems and leaves, whereby it is probable their roots difcharge a moifture under ground; and their leaves, covering the furface of the earth, return the moifture and dews defcending through them, which mellow and rot them into a kind of manure." *Maxwell's Collection, p.* 219.

From the above obfervations, the farmer will be able to vary his crops in fuch a manner as always to keep his ground in heart, and free from weeds; particulars which cannot fail of producing very great advantages.

CHANNEL, of a horfe, is the hollow between the two bars of the under jaw bone, in which the tongue is lodged.

CHARCOAL, a fort of fuel, confifting of wood charred, or half burnt.

The duft of charcoal has been found, by repeated experience, to be of great benefit to land, efpecially to fuch as is ftiff and four. It is to be ufed in the fame manner as foot and wood-afhes. *See the articles* ASHES *and* SOOT.

CHARDS *of artichokes*, the leaves of artichoke plants, tied and wrapped up in ftraw, except the top, during the autumn

autumn and winter; by which means they will be blanched, and lose great part of their bitterness.

CHARDS *of beets*, are white beets covered over with dry dung, during the winter-season, when they will produce large tops, with a downy cotton shoot, which is the true chard, used in broths, &c.

CHARLOCK, called also *Chadlock*, *Catlock*, *Carlock*, and *White-Rape*, is a weed too generally known to need a particular description, the figure we have given of it on Plate V. Fig. 32. will be abundantly sufficient. Almost the whole plant is covered with bent pellucid hairs.

There are two sorts of charlock, one bearing white, and the other yellow flowers, but they seem to be only varieties of the same plant. The young plants of charlock so nearly resemble those of turnips, that they are not easily distinguished but by the taste; the charlock being hot and bitter, and the turnip mild. Farmers should therefore be very careful in weeding their turnips, lest they mistake them for charlock.

Mr. Lisle observes, that cold wet lands are always more subject to charlock than white or chalky lands; because the charlock-seed being very oily, resists putrefaction, and is not easily opened or penetrated by moisture, whereas white and light earth is soon dry after rain, and the water does not continue long enough on it to make such seed germinate so effectually as in the other. By an experiment which he made in sowing charlock-seed and turnip-seed at the same time, he found that the turnips will appear in three days, but the charlock in not less than ten. A hint that may prove very useful to the husbandman. *Lisle's Husbandry, vol.* II. *pag.* 297.

Mr. Mortimer, after remarking that both the white and yellow charlock are very prejudicial to corn, and that some lands are very subject to it, especially if manured with cow-dung alone, which he thinks increases it more than any other manure, unless it be mixed with horse-dung, or some other hot manure, mentions his being told that a person who had vast quantities of this weed in a field of barley, mowed the whole when the charlock was in flower, and ready to seed, which is commonly about the middle of May, as low as he could, without taking off more than just the tops of the blades of the barley; and that this gave the corn an opportunity to get above it, in such a manner, that he had four quarters of barley on an acre. He adds, that where a fallow is full of charlock, it will be right to turn in sheep, which will eat it very readily. *Mortimer's Husbandry, vol.* I. *p.* 311.

CHASE, a word used in some counties to signify a row or rank. Thus in the planting of quicksets, a single chase implies a single row; a double chase, means another row planted below the first, not immediately underneath the upper plants, but under the middle of the intermediate spaces. *Lisle's Husbandry, vol.* II. *pag.* 405.

CHATS, the keys of trees, such as the ash, sycomore, &c.

CHEDDER-CHEESE, a name given to a very large kind of cheese made at Chedder, a village near Mendip-hills in Somersetshire, famous for its pastures. It is common in this place for three or four dairies to join their milk, to make one great cheese, which generally weighs from one hundred and fifty to two hundred weight; and which they often sell at six-pence per pound on the spot.

CHEESE, a well-known species of food, prepared from curdled milk, pressed from the whey, and afterwards dried for use. *See the article* DAIRY.

CHEESE-LIP, a bag in which the dairy-women prepare and keep their runnet for making cheese. *See* RUNNET.

CHEESE-PRESS, a press used in dairies for squeezing the whey out of the cheese, We have given a drawing of the common cheese-press, on Plate VI. Fig. 1. where AB is the press, C E, and F G, are levers moveable about the points D, E, F, G, by applying the hand at C; S is the stone or weight; and H the cheese to be pressed.

CHEESE-RENNET. *See* YELLOW LADIES BED-STRAW.

CHERRY-TREE, the name of a well-known genus of fruit-trees, and of which there are several species, cultivated in gardens and orchards.

The cherry-tree, it is said, is a native of Pontus, a province of Asia Minor, from whence it was brought into Italy by Lucullus, the Roman, Anno Rom. 680; and about one hundred years after was introduced into England, where there are various sorts cultivated at present, such as the Flemish-cherry, Kentish-cherry, May-duke, arch-duke, red-heart, white-heart, black-heart, amber-heart, ox-heart, bleeding-heart, carnation, morello, and some others.

The several sorts of cherries are propagated by budding or grafting the different kinds into stocks of the black or wild red cherries, they being supposed to be of longer duration than the garden sorts.

Cherry-trees are raised in great quantities in the nursery gardens, both standards and dwarfs: the standards for planting orchards, particularly in Kent, where there are large plantations. The usual distance allowed for their standing is about forty feet each way. These standard trees should be planted in a situation defended as much as possible from the east and western winds; the one being likely to destroy their blossoms in the spring, and the other by its violence is very apt to break their tender branches: this occasions their gumming, and is very prejudicial to them. The sorts best approved of for an orchard are the Kentish, Flemish, duke, and common red cherry.

Cherry-trees may also be planted against walls in any exposure: the May-duke being generally planted against a south aspected wall, though it is not amiss to have some against a north wall, which will continue their season the longer; and the same may be done with the other sorts. The morello-cherry is generally planted against walls fronting the north. This fruit is commonly used in preserving: yet where they are planted to a better aspect, and suffered to hang on the trees till they are thoroughly ripe, they are not a bad fruit for the table; for by long hanging, it loses most of its acidity or sourness.

The less cherries are pruned, the better they like it; but, however, where weak or luxuriant branches happen, they must be governed by the knife. When cherry-trees take to bearing very early, and grow but little, it is best to pull off most of the bloom, and shorten the branches, which will cause the tree to shoot with fresh vigour.

The black cherry is supposed to be a native of England, it being frequently found in the woods; it grows large, and the timber is used by turners and other artificers in wood. From this sort the black-coroon-cherry is supposed to have been produced.

Cherry-trees thrive best in a dry hazely loam. In a gravelly soil they are very subject to blights, and seldom stand long good.

The wood of the cherry-tree is of great use to cabinet-makers, chair-makers, &c. as it is very durable, not liable to split, and looks nearly as well as the ordinary sort of mahogany.

CHERRY-TREE *with double flowers*, is a species of the former, and propagated for the beauty of its flowers, which are extremely fine. These are produced in large bunches, which renders the tree one of the most beautiful ornaments of a garden in the spring.

CHERRY-WINE, a very cooling and pleasant drink, made from the juice of cherries, properly fermented. The chief care necessary in making it, is to let the cherries hang upon the trees till they are thoroughly ripe, by which means their juice, which they yield in great abundance, will be the better perfected and enriched by the sun; to gather them in dry weather; press out their juice, and add a quantity of sugar proportioned to the strength you desire in the wine; for the more sugar there is added to the natural juice of the cherries, the stronger and richer the wine will prove, when of a proper age. When this is done the whole must be regularly fermented, according to the method

method laid down under the article fermentation. *See* FERMENTATION.

CHERVIL, the name of an annual plant raifed only from its feeds, which are black, very fmall, longifh, and ftreaked lengthwife.

It will thrive in any foil or fituation, and may be fown either in drills or broad-caft; but the former method is the beft, becaufe it greatly facilitates the weeding and cutting of the plants, whofe culture is, in all refpects, the fame with the common parfley. *See* PARSLEY.

The beft time to fow chervil is in the autumn, foon after its feeds are ripe; for they grow beft then, and the plants, which rife in that feafon, continue green all the winter; whereas thofe which are fown in the fpring feldom come up at all; or, if they do, their plants generally wither and decay, as foon as the warm weather fets in. The plants fown in autumn flower in April, perfect their feeds foon after, and then die away. To fave thefe feeds properly, their ftalks fhould be cut down when they begin to grow yellow.

Thofe who are fond of this plant, as many are in foups during the winter and fpring feafons, may have a fucceffion of it very young, by fowing it monthly during the feafon: but whoever ufes it fhould be careful to diftinguifh it from a poifonous plant that nearly refembles it, and called wild myrrh and cow-parfley. *See* COW-PARSLEY.

CHEST, the breaft, or that part of an animal's body which contains the heart, lungs, &c.

CHEST-FOUNDER, a diftemper incident to horfes, and occafioned by an improper treatment of an inflammation between the ribs. For if the inflammation be not difperfed in time, and the vifcid blood and juices fo attenuated by internal medicines, that a free circulation is obtained, fuch a ftiffnefs and inactivity will remain on thofe parts as will not eafily be removed; and this ftiffnefs is generally called cheft-founder.

The figns of this inflammation, are a ftiffnefs of the body, fhoulders, and fore-legs; attended fometimes with a fhort dry cough, &c. a fhrinking when handled in thofe parts.

Bleeding, foft pectorals, attenuants, and gentle purges, are the internal remedies; and externally the parts affected may be bathed with equal parts of fpirit of fal ammoniac, and ointment of marfhmallows, or oil of chamomile.

Thefe outward inflammations frequently fall into the infide of the fore-leg, and fometimes near the fhoulder; forming abfceffes there, which terminate the diforder. *Bartlet's Farriery, pag.* 57.

CHESNUT-TREE, the name of a tree, which well deferves the planter's care, affording excellent timber, and a very agreeable fhade. It will grow to a very great fize, and fpread its branches finely on every fide where it has room.

The leaves are large, and of a lucid green, and continue late in the autumn; nor are they fo liable to be eaten by infects, as thofe of the oak; nor is there any better food for deer, and many other animals, than the fruit of this tree.

Chefnut-trees are propagated by planting the nuts in February, in beds of frefh undunged earth. The beft nuts for fowing, are fuch as are brought from Portugal and Spain, provided they are not kiln dried, which is generally the cafe of thofe brought from abroad, to prevent their fprouting during their paffage; if they cannot, therefore, be procured frefh from the tree, it will be much better to ufe thofe of the growth of England, which are full as good to fow for timber or beauty, as any of the foreign nuts, though their fruit is much fmaller. The nuts fhould be preferved in fand, until the feafon for fowing, otherwife the mice and other vermin will foon deftroy them. Before you fet the nuts it will be proper to put them into water, to try their goodnefs, which is known by their weight; fuch of them as fwim upon the furface of the water fhould be rejected as good for nothing; but fuch as fink to the bottom, you may be fure are good.

In fetting thefe nuts, the beft way is to make a drill with a hoe, about four inches deep, in which you fhould place the nuts at about four inches diftance, with their eye uppermoft; then draw the earth over them with a rake, and make a fecond drill at about a foot diftance from the former, proceeding as before, allowing three or four rows in a bed, with an alley between, three feet broad, in order to clear the beds, &c. When you have finifhed your plantation, you muft be careful that it is not deftroyed by mice, or other vermin; which is very often the cafe, if they are not prevented by traps, or other means.

In April thefe nuts will appear above ground; you muft, therefore, obferve to keep them clear from weeds, efpecially while young: in thefe beds they may remain for two years, when you fhould remove them into a nurfery at a wider diftance. The beft feafon for tranfplanting thefe trees, is either in October, or the latter end of February; but October fhould be preferred. The diftance thefe trees fhould have in the nurfery, is three feet row from row, and one foot in the rows. If thefe trees have a downright tap-root, it fhould be cut off, efpecially if they are intended to be removed again; this will occafion their putting out lateral roots, and render them lefs fubject to mifcarry when they are removed for good.

The time generally allowed them in the nurfery is three or four years, according to their growth; but the younger they are tranfplanted, the better they will fucceed. Young trees of this fort are very apt to have crooked ftems; but when they are tranfplanted out, and have room to grow, they will, as they increafe in bulk, grow more upright, and their ftems will become ftrait.

After they have remained three or four years in the nurfery, they will be fit for tranfplanting where they are to remain; for the younger they are planted out the better they will fucceed. But if they are propagated for timber, it is by much the better method to fow them in furrows, and let them remain unmoved; for thefe trees are apt to have a downright tap-root, which, being hurt by tranfplanting, often checks their upright growth, and caufes them to fhoot out into lateral branches.

If you defign a large plantation of thefe trees for timber, after having two or three times ploughed the ground, the better to deftroy the roots of weeds, you fhould make your furrows about fix feet diftance from one another; in which you fhould lay the nuts about ten inches apart, covering them with earth about two inches deep; and when they come up, you muft carefully clear them from weeds. The diftance allowed between each row is for the ufe of the horfe-hoeing plough, which will difpatch a great deal of this work in a fhort time; but it fhould be performed with great care, fo as not to injure the young plants; therefore the middle of the fpaces only fhould be cleaned with this inftrument, and a hand-hoe ufed to clean between the plants in the rows, and alfo on each fide, where it will be unfafe for the plough to be drawn; and in hand-hoeing great care muft be taken not to cut the tender rind of the plant. But for the two firft years after fowing, it will be advifable to dig the ground each winter; becaufe the plants will be too fmall to admit the hoeing plough, and in fummer to hand-hoe the ground.

When thefe have remained three or four years, you will, if the nuts have fucceeded well, have many of thefe trees to remove; which fhould be done at the feafons before directed, leaving the trees at about three feet diftance in the rows; at which diftance they may remain for three or four years more, when you fhould remove every other tree, to make room for the remaining, which will reduce the whole plantation to fix feet fquare; which will be fufficient for them, till they are large enough for poles, when you may fell every other tree, within a foot of the ground, in order to make ftools for poles, which, in eight or ten year's time will be ftrong enough for making hoops, hop-poles, &c. for which purpofes they are preferable to moft other trees; fo that every tenth year here will be a frefh crop, which will pay the rent of the land, and all other incidental charges, and, at the fame time, a full crop of growing timber left upon the ground.

Chefnut-trees were formerly much cultivated in England, and doubtlefs produced good profit to the owners;

for the wood of this tree is equal in value to the beſt oak, and, for many purpoſes, far better; particularly for making veſſels to hold all kinds of liquor, it having the property, when once thoroughly ſeaſoned, of maintaining its bulk conſtantly; and is not, like other timber, apt to ſhrink or ſwell; and hence all the large caſks, tuns, &c. for wines in Italy, are made of this timber, as being preferred by the inhabitants to any other timber whatſoever. It is alſo very valuable for pipes to convey water under ground, as enduring longer than the elm, or any other wood. In Italy it is planted for coppice wood, and is much cultivated in ſtools, to make ſtakes for ſupporting their vines, as it will endure ſeven years, which is near double the time any other ſtakes will do. *Millar's Gard. Dict.*

CHEWING-BALLS, the name of a medicine adapted to reſtore a loſt appetite, an infirmity which horſes are often ſubject to, proceeding from a ſalt humour, and a bitter phlegm, which obſtructs the paſſage of the throat, and makes them loath their food.

Theſe balls are made in the following manner: Take a pound of aſſa fœtida, as much liver of antimony; half a pound of the wood of a bay-tree; an equal quantity of juniper-wood; and two ounces of pellitory of Spain: pound all theſe ingredients apart into a groſs powder, in order to which the woods muſt be previouſly well dried. Then put them all together into a mortar, and incorporate them with a ſufficient quantity of good verjuice, well clarified, pouring it in by degrees, till the whole is reduced to an uniform maſs. Make the whole into balls of an ounce and a half each, and dry them in the ſun. Wrap one of theſe balls in a linen cloth, and faſtening a thread thereto, make the horſe chew it for two hours in the morning, and he will eat as ſoon as you take off the bridle; do the ſame at night, and continue this method till the horſe recovers his appetite. When one ball is conſumed, put in another.

Theſe balls may be uſed on the road, as you travel, being faſtened to the bit of the bridle.

CHICKLING-*vetch*, called by gardeners, the common everlaſting pea, and by C. Bauhine, *lathyrus latifoliis*, a perennial plant, growing naturally in many parts of England.

A correſpondent of the editors of the Muſeum Ruſticum recommends this plant as well deſerving cultivation for the food of cattle, as the root, which will grow in almoſt any ſoil, yields every year a great burden of excellent provender.

"I ſowed, ſays this gentleman, three years ago, a rood of land, light, and but poor in quality, with this ſeed: the work was done early in the ſpring, the land being prepared as for barley.

"I ſowed it not in the broad-caſt way, as I ſhould have found it much more difficult to keep down the weeds; but I cauſed a ſlight furrow to be drawn the length of the land, with a light plough; and when the ſeed was thinly ſprained, or rather dropped into this, another was drawn at a foot diſtance, in which the ſeed was dropped in the ſame manner.

"An interval, or fallow ſpace, was then left at leaſt two feet wide; and then two more rows of the vetches, till the whole land was ſown. I muſt obſerve, that I covered the ſeed by means of a light harrow with wooden tines, drawn backward and forward acroſs the land.

"When the plants came up, I had them well hoed to clear the ground of weeds; and when they grew a little ſtrong, they were ſet out with the hoe to about a foot diſtance in the rows, that they might have room to ſpread and branch.

"The firſt year they yielded no great quantity of fodder, but they have ſince made me ample amends.

"The ſecond ſpring they came up very ſtrong and vigorous, branching out much; and when I turned a couple of horſes in to feed, they were very fond of it, eating it very greedily, though they were taken out of a good natural upland-paſture.

"The laſt ſummer the land was almoſt entirely covered, and it yielded a great deal of ſeed indeed: for experiment ſake, I cauſed a few roods to be mowed juſt before it flowered, and it made good hay, ſweet, and without being ſticky.

"I therefore think, from my little experience in the matter, I have ſome foundation for recommending this plant to the notice of the public. I could wiſh, indeed, I had been more accurate in my experiment; but what is paſt cannot be recalled: and ſome other perſon may, perhaps, hereafter, give the public more uſeful information on this head."

CHICKWEED, called by botaniſts *cucubalus*, flowers early in the ſpring, and, if it be ſuffered to grow, ſeveral times in the courſe of the year. The way to deſtroy it is therefore to pluck it up from time to time, before it can ſhed its ſeed.

The berry-bearing ſort, which grows with ſmooth, erect ſtalks, globular empalements, and ſtamina longer than the petals, is the wild lychnis, or white behen of the ſhops. This is a very rambling weed, natural to moſt parts of England, and is frequently called ſpatling poppy. Its roots are perennial, and ſtrike ſo deep into the earth, that they are not eaſily deſtroyed by the plough; for which reaſon, bunches of this plant are too common among corn, in land which has not been perfectly well tilled. Summer fallows, and carefully harrowing out every part of the roots, which ſhould then be burnt, will here prove the beſt and moſt effectual remedy,

CHICKWEED is alſo the name of an annual weed, called by botaniſts *alſine*. This weed, though it periſhes every year, will ſoon become very troubleſome, if ſuffered to ſtand till it ſheds its ſeeds, which Mr. Liſle thinks it will do ſeveral times in the year; for he obſerved on the 23d of October, a great deal of this weed, the branches of which carried many buds of bloſſoms, many flowers full blown, and many pods with white ſeeds almoſt ripe; ſo that its increaſe may be the leſs guarded againſt by any ſort of huſbandry in the common way. The repeated horſe-hoeings in the new huſbandry muſt here be of ſingular advantage; and, at all events, particular care ſhould be taken, to prevent the feeding of this plant upon dung-hills, where it is too often ſuffered to grow unnoticed and undiſturbed: for its ſeeds ſcattered there, and intermixed with the dung, will ſoon give birth to a multitude of weeds in the land upon which it is ſpread; unleſs it be kept, as indeed all dung uſed for manure ought to be, till it is thoroughly rotted, and the ſeeds have loſt their vegetative power.

To CHISSUM, to put forth roots, to grow.

To CHITT, to ſprout out, to grow.

CHITTED, ſprouted, ſhot out, grown.

CHIZZLE, bran, the huſky parts of ground wheat.

CHOCKY, the ſame with chalky, reſembling chalk, mixed with chalk, or of the nature of chalk.

CHOLIC. *See* GRIPES.

CHURN, the name of the veſſel in which the cream is coagulated by agitation.

There are two ſorts of churns, one called the common, or Dutch churn, and the other the barrel churn.

The common churn is repreſented on Plate VI. Fig. 2, 3. where Fig. 2. is the arbor or ſtaff; and Fig. 3. the body of the churn. The lower end of the ſtaff is placed in the body of the churn, and being raiſed with a pretty quick motion by the hand on the upper part of the ſtaff, the cream in the body is agitated, and by that means coagulated into butter.

Fig. 4, 5, 6, 7. repreſents the ſeveral parts of the barrel-churn.

Fig. 4. is the arbor of the barrel-churn. Fig. 5. its bung, or cover. Fig. 6. the body of the churn. And Fig. 7. the ſtand on which it is placed. The arbor cannot be taken out of the body of the barrel-churn, without the help of the cooper; but is here repreſented by itſelf, to ſhew the manner in which it is made. In Fig. 6. the churn is repreſented with the arbor on it, but not placed on its ſtand, in order to ſhew the latter. When the utenſil is to be uſed, the churn is placed upon its ſtand; the cream poured into it through the bung-hole, and the hole cloſed with its bung. The arbor is then turned round pretty faſt, by which the four leaves of the arbor agitate the cream, and coagulate it into butter. *See the article* DAIRY.

CIBOULES, a ſort of ſmall onions propagated only by ſeeds, which, if ſown in March, will be ripe in Auguſt;

August; and these are reckoned the best for keeping; but they may be sown in almost every season. They differ from the onions, of which they are probably a degeneracy, in that they do not form bulbs at their roots, but shoot out several upright blades, and those which produce the greatest number of these, are reckoned the best.

Their culture is the same with that of onions, like which they must be thinned, and well weeded. They will increase greatly, even in very dry summers, if they have been transplanted into beds of good earth, and those beds are kept well watered. The reddest, hardest, and mildest are the most esteemed.

CIDER, or CYDER. *See the article* CYDER.

CIONS, the shoots, or grafts which are fixed into the stock, in order to improve its fruit. *See the article* GRAFTING.

CIVES, a well known species of pot-herb, cultivated in kitchen gardens. They thrive best in a light rich ground, and are propagated by parting their roots, which never become bulbs; the best time for which is in March, though they may be transplanted in autumn, for they are very hardy; and in this case, they will produce blades fit for use early in the spring. It is for these blades only, which seldom grow above six inches high, and are very small and slender, that they are cultivated. They were formerly in great request for mixing with sallads in the spring, because they are milder than the ciboule, or Welsh onion. In good ground they will last three or four years, without removing, or any other trouble besides loosening the earth about them now and then, keeping them clear from weeds, and perhaps watering them a little in great droughts.

CLARY, the name of an herb cultivated in many kitchen gardens. The seeds should be sown during the spring, in good garden mould. When the plants are fit to remove, they should be transplanted into beds, and there set at least one foot asunder. If they are planted in more rows than one, it should be on an open spot of ground, at the same distance from one another, and with a space of at least two feet between the rows. After they have taken root, no farther care is necessary, except keeping them clear from weeds, and stirring the ground about them. In the winter and spring following, their leaves, which are the only part used, will be fit for gathering; and in the ensuing summer they will flower, seed, and decay; so that a succession of young plants should be raised every year.

CLASPERS, the threads or tendrils of creeping plants.

CLAVER, a word used in some counties of England for clover. *See* CLOVER.

CLAW, the foot of a beast or bird, armed with sharp nails.

CLAY, an unctuous and tenacious earth, justly accounted the stiffest of all soils.

Clays are of different sorts, and of as different colours. One kind of them is so obstinate, that scarce any thing will subdue it; and another so hungry, as not to be satiated without uncommon pains, because it absorbs whatever is applied, and turns it to as bad a clay as itself. Some clays are fatter than others, some more slippery; all of them tenacious of water on the surface, where it stagnates, and chills the plants, without penetrating the soil; and in dry seasons they harden with the sun and wind, are very barren, and extremely untractable. The closeness of clay hinders plants from extending their roots to search for their necessary food, and prevents the entrance of water, which would help to convey it to them.

The more unctuous and fat clay frequently lies upon the other, and has often a bed of chalk beneath it: but neither is this worth any thing till loosened, and fitted to admit the influence of the sun, air, frost, &c. The blue, white, and red clay, if strong, are all unkind: the stony and looser sort is sometimes tolerable; and the light brick-earth does very well with most fruit-trees.

Clay, in general, of whatever kind it be, is, of all earths, the very worst for vegetation: yet even this, as well as any other untoward soil, may, with industry, and proper correctives, be made to produce roots and plants which require the lightest and hollowest mould.

Among all the manures for clay, sea-sand claims the preference, founded upon experience, as best suited to break its too great cohesion. Dr. Cox has given us a very accurate account of the sea-sand used by the farmers of Cornwall, by which their lands are greatly benefited, and their crops largely increased. Doubtless the husbandmen of other parts of the kingdom, whose lands lie within a moderate distance of the sea, might find the same advantage from using the same manure, which many of them are too apt to overlook.

"The sea-sand made use of in the agriculture of Cornwall, says that ingenious gentleman, lies commonly at or near the shore. To distinguish it from what is useless, it is proper to observe, that this sand is formed by the grating of stones, shells, &c. rolled, and tumbled over by the wash of the sea. If the matter be shelfy, as it is called, that is, the particles formed by the rubbing of stones only, it is of small value: but if it be notably shelly, it is the thing desired. Of this shelly sand there are three colours. About Plymouth, and the southern coast, it is bluish, or grey, like ashes; which I conceive to be from the breaking of muscles chiefly, and oister-shells mixed with it. Westward, near the land's-end, the sand is very white; and in Scilly, glittering. This I think comes from the mouldering of moor-stones, or a kind of free-stone, mingled with the white shells of the scallop-fish. On the north-sea, about Padstow, and eastward of Lundy, the sand is rich, of a reddish-brown colour tinged with yellow, and consists cheifly of the broken shells of cockles; which I guess to be of that colour there, from the wash of the Severn, which falls very dirty into the Severn-sea.

"Besides these differences in the colour of the sand, there is also another in the bigness of the grain. The small is reckoned best for the tenant, who takes to tillage only for four years; because it works soonest, and yields the most speedy return. The larger grain is thought to be more profitable for the landlord, because it abides longer in the ground, and make the pasture afterwards the richer.

"In Falmouth-haven, near St. Mawe's Castle, there is a sort of sand, or rather coralline, that lies about a foot under the ooze; which ooze being removed, and the bed opened, this sand is taken up by a dredge, and is used about Truroe, Probus, &c.

"West of the mount, in Portcuthnoe-cove, is a large shelly sand. In White-sand-bay, and about St. Ives, it is very white and small.

"About Minver, Perinsand, and Lelant, the sands are frequently blown up by the wind, and cover abundance of good land. Some houses and even churches have been buried in it; nor has any method hitherto discovered been able to prevent its devastation.

"Of all these sands, the best are accounted, as to colour, first the reddish, next the blue, then the white. As to kinds, the most shelly, and the coralline are the best, especially if it be taken up from under the salt-water, either by dredges, or being left almost dry by the ebbing of the tide. The blown sand is accounted of no use: and, in general, if sand be only well drained of salt water, so that it can be conveniently carried, it is better than that which has lain long drying in the sun and wind, which takes off much of its virtue.

"These useful sands are carried by lighters as far up into the country as the tides will serve for that purpose, and there they are cast on shore. From thence they are fetched, in some places, by wheel-carriages; but in most, by reason of the hilliness, narrowness, and badness of the ways, on horse-back; one horse carrying about thirteen or fourteen gallons. One man drives seven or eight of these horses, tailed together, to the distance of nine or ten miles from the sand-place; and each horse-load comes to about eight-pence or nine-pence, in some places; though not so much in others: for where it is dredged out of the sea, it costs but twelve or thirteen shillings the lighter, containing sixscore horse-loads, at the landing-quay, or sand-place; and where it is loaded from the dry-beach, after the ebb, it is not above four shillings the lighter, exclusive of the land-carriage, which is computed at about thirty-two thousand pounds a year, in the whole of that country.

"When this sand is brought home, it is spread on the ground intended for wheat; or usually in the first crop of four, whatever be the grain. For after four crops, the Cornish farmers generally leave their land to pasture for six or seven years, before they till it again: and indeed the grass is so good, immediately after tillage, that they commonly mow it the first year, and which they call mowing of gratten.

"The Cornish acre contains eight-score yards, of eighteen feet to the yard. On one of these acres, if near the sand-place, good husbandmen bestow three hundred sacks, or horse-loads: if within the reach of three turns a day, two hundred; if within two turns, one hundred and fifty; where only one turn can be made, eighty or an hundred; and so in proportion at greater distances, even to twenty or thirty sacks on an acre rather than none.

"The effect generally is, that where much sand is used, the seed is as much as the straw little. Land thus manured has produced barley, of which the ear has been as long has the stalk it grew on. But where less sand is used, there is but little, and that little hungry grain." *Philosoph. Transact. Numb.* 113.

Where this excellent manure is found, it is taken up by a large bag of the strongest canvas, to the mouth of which is fixed an iron hoop, or frame, to keep it open, and sink it to the bottom of the sea, that it may take up the sand and coral, as it is dragged along by the bargemen. The Rev. Mr. Borlace says, that a barge-load, which is usually delivered for ten shillings, or less if near the place of dredging, will dress an acre, provided the land be tolerably good.

Large quantities of this shelly sand lie neglected on most of the coasts of England. The benefits arising from it, particularly when laid on clayey grounds, are indeed somewhat slow, but they are very lasting. The improvement is not the first or second year; because this manure consists of hard bodies, such as the sand itself, shells, fragments of coral, and other calcarious substances, which require time to dissolve them, and which afterwards enrich the land for many years. The best is that which is mixed with coral, and other hard substances of that kind. It gives the heat of lime, and the fatness of oil, to the land it is laid upon. Being more solid than shells, it contains a greater quantity of fermenting particles in an equal bulk; nor does it dissolve in the ground so soon as shells, but decaying more gradually, continues longer to impart its warmth to the juices of the earth.

Similar to this is the practice in Ireland, in that part of the bay of Londonderry, called Loughfoil, towards the eastern side of which lie several banks, about the level of low-water. They are formed of the shells of several sorts of sea fish, particularly periwinckles, cockles, limpets, &c. The country people go thither with boats, and take loads of these shells, which they leave in heaps on the shore, till they are well drained, and thereby rendered lighter for farther carriage. They then carry them in boats as far as the river will allow, and afterwards in sacks on horses, six, seven, or more miles up in the country. They allow sometimes forty, but more commonly eighty barrels to an acre. These shells agree with boggy, heathy, clayey, wet, or stiff land, but not with sandy. They seem to give the land a sort of ferment, as yeast does to bread, opening and loosening the clods, and by that means making way for the roots to penetrate, and the moisture to enter into the fibres of the roots. This manure continues so long, that the archbishop of Dublin, from whom this was communicated to the Royal Society, could not find any person able to determine the time of its duration.

The reason of its long continuance seems to be, that the shells melt every year a little, till they are all spent, which requires a considerable time; whereas lime, &c. operates, in a manner, at once. But it is to be observed, that, in six or seven years, the ground becomes so mellow, that the corn which grows on it cannot support itself, and the land must be suffered to lie a year or two, that the ferment may be a little quieted, and the clods harden; after which it will bear as long again, and continue so to do, with the like intermission, for twenty or thirty years.

The good and lasting effects of shelly-sand, for the improvement of clay, afford a strong presumption that there is an acid in the clay, which the shells absorb or correct: for when that acid is removed, the clay becomes more easily soluble, or miscible with water, or, as the farmers term it, is rendered mellow. This is contrary to the opinion of a very ingenious gentleman, Dr. Home, who, because he could not separate an acid from clay, concluded that there was none in it. That the first object in the improvement of clay is the destroying of this acid, is pretty evident from the qualities of all the substances useful for this purpose; every one of them being of the calcarious kind. The tenacity of clay does not seem to be owing to the smallness and unctuous smoothness of its particles; for in this some marles exceed it, and yet are perfectly and easily soluble in water, probably because they are of a calcarious nature: and if clay be rendered in some degree calcarious, by the addition of alcaline or calcarious substances, so long as it continues in that state, it is said to be mellow; that is, it is soluble like marle, and continues fit for the production of plants, till the acid in the air either neutralizes the alcali, or so far impregnates the calcarious substances, that they can no longer attract the acid. If this be fact, as it seems to be, common sand can be of little use; because the clay will cling as close to a stone, or grain of sand, as it would to part of itself, if the stone, or sand, does not so far change the body of the clay, as to take off its tenacity; and therefore Dr. Cox seems to be very right in saying, that the sand which is formed by the grating of stones only, is of little use as a manure. However, as some eminent writers on this subject strongly recommend sand in general, though they all agree in giving the preference to sea-sand, it may not be amiss to hear what they have said on the subject.

Columella, speaking in general terms, says, that his uncle used to carry sand on clay, and on the contrary, bring clay on sandy grounds, with good success.

Mr. Worlidge says, that the best sand for fertility is that which is washed from hills or other sandy places by the violence of rain; and that sands which are dry have little fertility in them. *Systema Agriculturæ, page* 67.

Mr. Bradley, after dividing sand into two general sorts, as Dr. Lister does, viz. the soft, round-grained sand, such as is found in bogs and hills; and the sharp or rag-sand, as it is commonly called, taken from the bottom of rivers, the sides of highways, or the sea; advises laying even the former on heavy soils, especially if it happens to be mixed, as it sometimes is, with rotted vegetable or animal substances: to which he adds, that its efficacy will be increased by the addition of sand of a sharper nature, about a load of which last, if used alone, should be spread upon every rod of very stiff land: for a sufficient quantity of it must be allowed, or else the clay will soon overcome it. *Complete Body of Husbandry, page* 84.

"The use of sand, says Mr. Miller, is to make the clayey earth fertile, and fit to feed vegetables, &c. for earth alone is apt to coalesce, and gather into a hard coherent mass, as is apparent in clay; and earth thus glued, as it were, together, is no way disposed to nourish vegetables: but if sand, &c. that is, hard crystals, which are not dissolvable in water, and still retain their figure, be intermixed with such earth, they will keep its pores open, and the soil loose and incompact, by which means the juices will circulate, and plants are nourished thereby. By means of sand, the earth is rendered, in a manner, organical; pores and interstices being thereby maintained, somewhat analogous to vessels, by which the juices may be conveyed, prepared, digested, circulated, and at length excerned, and thrown off into the roots of plants." *Miller's Gard. Dict.*

Small gritty gravel operates in nearly the same manner, as an opener of the earth, and is strongly recommended

mended by Mr. Evelyn, Mr. Worlidge, Mr. Bradley, and Mr. King. Good crops have been produced by very ftiff and four land, after it has been manured with gravel, which, to fit it for this purpofe, fhould be fkreecened, or fifted, fo as to leave among it as few ftones as poffible.

Shell-marle, or any marle, which makes a ftrong effervefcence when an acid is dropped upon it, is a particularly good manure for clay; becaufe diffolving eafily in water, it gives a fufficiently free paffage to this fluid, by which means the clay is kept dry even in winter: and if the foil be of a cold four nature, the abforbent quality of the marle deftroys that mineral acid, and keeps the ground warm.

The foffile-fhells which have been found in fome countries at a great diftance from the fea, are a good manure, if they ftill retain their quality of fhells: but befides their being generally petrified, they never are fo ferviceable as thofe which are taken from the fea-fhore.

All animal and vegetable fubftances are likewife proper manures for clay. *See the article* MANURE.

The alcaline quality of the afhes of all vegetables, and the calcarious quality of coal-afhes, render them fingularly beneficial to ftiff and four land, for which purpofe they are fuccefsfully ufed in the neighbourhood of fome great cities where coal is burnt for fuel. They open clayey grounds, and correct their bad qualities. The gardeners and farmers about London know their value, and make a very profitable ufe of them, particularly to bring into order thofe grounds which have been dug for brick earth. After fpreading thefe afhes upon the clay bottom, they either fow horfe-beans, or fet the early Spanifh, or, fometimes, the Windfor-bean, in thofe fpots; or elfe they lay fuch lands down with rye-grafs, which generally fucceeds very well. Mr. Bradley, blaming the people of Staffordfhire, and the countries adjoining, where there are coal-pits, for not improving their many heavy grounds around thofe pits, by manuring them with coal-afhes, which might eafily be burned out of the wafte coal, fays, "That wherever there are plenty of coal-pits, there can be no want of good profitable land." On the fame principle, we may account for the effects of the calcination of earth, commonly called, burn-baking, or Devonfhiring. *See the article* BURN-BAKING.

Lime, as it is generally ufed, is not found to be of fo great fervice in the improvement of clay, as a long eftablifhed practice might give room to think, or its qualities reafon to expect; becaufe its particles are fo extremely fmall, that when feparated, or mixed with the clay, they foon become part of its body, and, being fo much divided, are fpeedily faturated by the acid, either in the clay, or in the air: the beft method, therefore, of ufing lime as a manure for clay is, to fpread the lime-ftone unburnt; in which original ftate acids effervefce ftrongly with it, and therefore it will be likely moft effectually to mellow the clay. It is likewife, in this its natural ftate, attended with the farther advantage of faving the expence of burning, and becomes a very lafting manure; nay, probably a perpetual one, if the ftones are broke into fmall pieces, which is the proper method of ufing it; as is practifed at Horneton in Oxfordfhire, where they manure their land with a fort of ftone, common in thofe parts; and about Devonfhire, where a kind of red rock, very tender, and eafily broken into fand, is found to be of extraordinary fervice to clay, or other ftiff foils: for any foft ftone, broken fmall, will be of advantage to cold lands, if laid upon them. We find by Pliny, that lime was ufed as a manure by the ancient Britons, whofe lands were thereby rendered extremely fertile.

Mr. Evelyn advifes ufing lime a little flacked for cold, wet grounds, and ftiff clays; and obferves, that it is apt to over-heat dry foils.

Chalk operates in nearly the fame manner as lime: but, as Mr. Lifle juftly remarks, if it be laid on clay, it will, in time be loft, and the ground will return again to its former condition of clay; as we have already mentioned under the article chalk. *See* CHALK.

CLAYEY, mixed with clay, partaking of the nature of clay.

CLAY LANDS, fuch as partake of the nature of clay. *See the article* CLAY.

The natural produce of clay lands, with regard to weeds, is goofe-grafs, or wild tanfey, large daifies, thiftles, docks, May-weed, poppies, &c.

CLEARING, a term ufed in threfhing corn, to fignify a heap large enough to winnow.

CLEDGY, ftiff, ftubborn, hard, tenacious, mixed with clay.

CLETCH, a brood, as of chickens, &c.

CLOD, a lump of earth or clay.

CLODDING-BEETLE, a large beetle ufed in fome parts of England for breaking the clods. This operation may be much fooner performed, and at far lefs expence, by the fpikey-roller. *See the article* SPIKEY-ROLLER.

CLOVER, the name of a well known plant, and of which there are a great variety of fpecies; but only three of them cultivated in the open fields for the food of cattle, viz. the red Dutch clover; the white Dutch clover; and the hop-clover.

The firft fort is fufficiently known in England by the name of red clover, and therefore needs no defcription. It is called by Linnæus, *Trifolium caule erecto, foliolis oblongo-ovatis integerrimis, fpicis ovatis, calycibus fetaceis.*

Since red clover has been cultivated in England, great improvements have been made in clay lands, which before produced little except rye-grafs, and other coarfe bents; but, being fown with red clover, have produced more than fix times the quantity of fodder they formerly did: whereby the farmers have been enabled to feed a much greater ftock of cattle, than they could do before, with the fame extent of ground, which has, at the fame time, enriched the foil, and prepared it for corn; and hence it is now common, where the land is kept in tillage, to lay down their ground with clover, after having had two crops of corn, whereby there is a conftant rotation of wheat, barley, clover, or turnips, on the fame land. The clover-feed is generally fown with the barley in the fpring; and when the barley is taken off, the clover fpreads and covers the ground; and this remains two years, after which the land is ploughed again for corn.

Clover is a biennial plant, whofe roots decay after they have produced feeds; but by eating it down, or mowing it, when it begins to flower, it caufes the roots to fend out new fhoots, whereby the plant is continued longer than it would naturally do. The common allowance of feed for an acre of ground is ten pounds. In the choice of the feed, that which is of a bright yellow colour, inclining to brown, fhould be preferred; and the pale coloured thin feed fhould be rejected. The clover feed fhould be fown after the barley is harrowed in, otherwife it will be buried too deep; and after the feeds are fown, the ground fhould be rolled, which will prefs the feeds into the ground; but this fhould be done in dry weather, for moifture will often caufe the feeds to burft; and when the ground is wet, the feeds will ftick to the roller. The above is the method generally practifed by moft people, in fowing this feed with corn: but it will be much better if fown alone; for the corn prevents the growth of the plants till it is mowed and taken off the ground, fo that one whole feafon is loft; and many times, if there be a great crop of corn upon the ground, it fpoils the clover, fo that it is hardly worth ftanding; whereas, when it is fown without any other feed, the plants will come up more equal, and come on much fafter than that which was fown the fpring before under corn.

It is therefore advifable to fow the feed in Auguft, when there is a profpect of rain foon after; for as the ground is, at that feafon, warm, fo the firft fhower of rain will bring up the plants, and thefe will have time enough to get ftrength before winter: and if the clover be well rolled fome time in October, when the ground is not too wet, it will prefs the ground clofe to the roots, and caufe the plants to fend out more fhoots: the fame fhould be repeated in March, which will be found very ferviceable to the clover. The reafon for preferring this feafon rather than the fpring, for fowing the feeds, is, becaufe the ground is cold and wet in fpring, and if much rain fall after the feeds are fown, they will rot in the ground; and many times when the feed is fown late in the fpring, if the feafon fhould prove dry, the feeds will not grow. The other feafon is therefore the fureft, and confequently fhould be preferred.

About the middle of May this grafs will be fit to cut, when the greateft care fhould be taken in the making it into hay; for it will require a great deal more labour and time to dry than common grafs, and will fhrink into lefs compafs; but if it be not too rank, it will make extraordinary rich food for cattle. The time for cutting is, when it begins to flower; for if it ftands much longer, the lower part of the ftems, and the under leaves will begin to dry, whereby it will afford a lefs quantity of hay, and that not fo well flavoured.

Some people cut three crops in one year of this grafs; but the beft way is to cut only one in the fpring, and feed it the remaining part of the year, whereby the land will be enriched, and the grafs will grow muft ftronger.

One acre of this plant will feed as many cattle as four or five acres of common grafs; but great care fhould be taken of the cattle when they are firft put into it, left it fill them with wind and kill them, which is called their being hoven. *See the article* HOVEN.

In order to prevent this accident fome turn them in for a few hours only at firft, and fo ftint them as to quantity; and this by degrees, letting them at firft feed one hour only in the middle of the day, when there is no moifture upon the grafs, and fo every day fuffer them to remain a longer time, until they are fully feafoned to it: but great care fhould be taken never to turn them into this food in wet weather; or if they have for fome time been accuftomed to this food, it will be at leaft proper to turn them out at nights in wet weather, and let them have hay, which will prevent the bad confequences of the green clover. Others give their cattle ftraw while they are feeding upon this grafs, to prevent the ill effects of it; but this muft not be given them in the field, becaufe they will not eat it, where there is plenty of better food. There are others who fow rye-grafs among their clover, which they let grow together, in order to prevent the ill confequences of the cattle feeding wholly on clover; but this is not a commendable method, becaufe the rye-grafs will greatly injure the clover in its growth, and the feeds will fcatter, and fill the ground with bent.

Where the feeds are intended to be faved, the firft crop in the fpring fhould be permitted to ftand until the feeds are ripe, which may be known by the ftalks and heads changing to a brown colour, when it fhould be cut in a dry time; and after being well dried, it may be houfed till winter, when the feeds fhould be threfhed out; but if the feeds are wanted for immediate fowing, it may be threfhed before it is houfed or ftacked; but it muft then be well dried in the field, otherwife the feeds will not quit their hufks.

It has been a common complaint among the farmers, that they could not threfh out thefe feeds, without great labour and difficulty; but this is chiefly owing to their cutting the fpring crop, when it begins to flower, and leave the fecond crop for feed; which ripening fo late in autumn, there is not heat enough to dry the hufks fufficiently; whereby they are tough, and the feeds rendered difficult to get out. This complaint may therefore be entirely removed by leaving the firft crop for feed, as above directed; and then the ground will be ready to plough and prepare for wheat the fame year, which is another advantage.

When cattle are fed with this hay, the beft way is to put it in racks, otherwife they will tread a great deal of it down with their feet. This feed is better for moft other cattle than milch cows, fo that thefe fhould have very little of it, left it fhould prove hurtful to them; though it is not near fo injurious to any fort of cattle when dry, as it is when green.

The fecond fort, namely, the white Dutch clover, grows naturally in moft of the paftures in England, and is generally known among the country people, by the name of white honey-fuckle. Linnæus calls it, *Trifolium capitulis umbellaribus leguminibus tetrafpermis, caule repente.*

This is an abiding plant, whofe branches trail upon the ground, and fend out roots from every joint, fo that it thickens and makes the clofeft fward of any of the fown graffes; and it is the fweeteft feed for all forts of cattle yet known: therefore when land is defigned to be laid down for pafture, with intent to continue fo, it fhould be fown with the feeds of this plant. The ufual allowance of this feed is eight pounds to one acre of land; but this fhould never be fown with corn, for if there is a crop of corn, the grafs will be fo weak under it, as to be fcarce worth ftanding; but fuch is the covetoufnefs of moft farmers, that they will not be prevailed on to alter their old cuftom of laying down their grounds with a crop of corn, though they lofe twice the value of their corn by the poornefs of the grafs, which will never come to a good fward, and one whole feafon is alfo loft; for if this feed is fown in the fpring without corn, there will be a crop of hay to mow by the middle, or latter end of July, and a much better after-feed for cattle the following autumn and winter, than the grafs which is fown with corn will produce the fecond year. The feed of this fort may alfo be fown in autumn, in the manner before directed for the common red clover; and this autumnal fowing, if the feeds grow kindly, will afford a good early crop of hay the following fpring; and if, after the hay is taken off the land, the ground be well rolled, it will caufe the clover to mat clofe upon the ground, and become a thick fward.

The feeds of this white Dutch clover is annually imported from Flanders, by way of Holland, whence it received the name of Dutch clover; not that it is more a native of that country than of this, for it is very common in moift paftures, in every county in England: but the feeds were never collected for fowing in this country, till of late years; nor are there many perfons here, even now, who fave this feed, though it may be done if the fame method, as is practifed for the red clover, be taken with this fort; it fhould therefore be recommended to every farmer, who is defirous of improving his land, to fow carefully an acre or two of this white clover for feed, which will fave him the expence of buying for fome years, when the price is great; and there will be a fure market for any quantity he may have to fpare.

The reader will find a farther account of this grafs under the article PASTURE.

The third fort, namely hop-clover, called by fome yellow meadow trefoil, and by botanifts, *Trifolium fpicis ovalibus imbricatis, vexillis deflexis perfiftentibus, calycibus nudis, caule erecto*, grows naturally among the grafs in the upland paftures of this country; but the feeds are frequently fold in the fhops, and are by many mixed with the other forts of clover and grafs-feeds, for laying down ground to pafture. This plant grows with upright branching ftalks about a foot high, garnifhed with trifoliate leaves, whofe lobes are oblong and heart-fhaped, but reverfed, the narrow point joining the foot-ftalks. The flowers, which are yellow, grow from the wings of the ftalk, upon long foot-ftalks, collected into oval imbricated heads, having naked impalements lying over each other like fcales, fomewhat like the flowers of hops, from whence the plant had the name of hop-clover. But there are two forts of this clover, which grow naturally in England. The other is a much fmaller plant than this, and generally known by the name of nonefuch, or yellow hop-trefoil. *See the article* NONESUCH.

The hop-clover is ftrongly recommended by the following circumftances. 1. It not only grows, but flourifhes on the moft barren fands, and therefore muft be a very proper grafs to cultivate on fuch unfertile foils, where any other grafs that is worth notice will not grow at all. 2. It is not apt to fwell cattle, as the red clover does. 3. In good ground it will continue long, and bear a very good feed or crop, as Mr. Tull, though prejudiced againft clovers, confeffes; and, by its flourifhing both on fands and clay, which have not been ploughed for many years, it feems likely to continue long in any foil.

CLOUGH, a valley between two fteep hills. It alfo fignifies a cliff.

CLOUT, an iron plate on the axle-tree of a carriage.

CLUMP, a number of trees growing together without ſhape or order.

CLUNG, cloſed up, or ſtopped; ſpoken of hens when they do not lay. It is alſo applied to wood, or any other thing that is ſhrivelled, or ſhrunk up, when it is ſaid to be clung.

CLUSTER, a bunch, a number of things of the ſame kind growing or joined together. Alſo a number of animals, or a body of people, collected together.

M. de Chateauvieux has made a very remarkable experiment on ſowing corn in cluſters, which muſt not be omitted here.

“ It is of great conſequence, ſays that ingenious and aſſiduous cultivator, to know which is the moſt profitable way of ſowing beds with corn; I mean, that by which they will be ſtocked with a proper number of plants; for when too much ſeed is ſown, the plants hurt one another; and when too little, the earth is not enabled to produce ſo much as it is capable of doing.

“ The buſineſs, therefore, is to determine what number of plants would be moſt advantageous. Luckily the difference is wide enough between the too great, and the too ſmall number; and the produce of the crop cannot only be diminiſhed by an exceſs one way or the other.

“ But whatever certainty we may acquire with reſpect to this intereſting point, we cannot flatter ourſelves that we ſhall be always able to keep it in our practice. The various accidents to which corn is liable, from the hour of its being ſown till it is reaped, will always fruſtrate the methodical arrangement which we may have intended to give the plants.

“ The difficulty of ſucceeding in this enquiry ought not however to diſcourage us: for it would be attended with ſuch advantages, as would make very ample amends for all the labour beſtowed upon it. Let us then have recourſe to experiments. Thoſe that are made with this view can never be quite uſeleſs. If they do not lead us to the very thing we are in ſearch of, they may at leaſt diſcover to others what may be of ſervice.

“ According to our principles, the diſtance between each plant ought to be equal throughout the whole length of the rows, that all of them may have an equal quantity of earth to draw their nouriſhment from.

“ Several experiments have ſhewn, that ſix inches is not too great a diſtance for the plants to be at from one another. In this caſe it would be ſufficient to ſow one grain of wheat at every ſix inches diſtance. According to this diſpoſition, a field well prepared ought to produce the greateſt crop. The plants will commonly branch out ſo as to have twenty, thirty, or forty ſtalks: I have had ſome with upwards of eighty. It is pity that this exact diſtribution of the ſeed cannot ſubſiſt long. An accident I lately met with ſoon convinced me that it was neceſſary to increaſe the quantity of ſeed, and that very conſiderably.

“ This does not, however, yet hinder me from thinking, that if any eaſy method could be found to have a plant of wheat exactly at every ſix inches diſtance in the rows, it would be the beſt way of ſowing lands. I have often conſidered how this could be reduced to practice, as well to ſatisfy my curioſity, as to enable me to proceed with more certainty in my operations. When a theory is known to be good, we are ſtrongly encouraged to draw all poſſible advantages from it for the practical part; we proceed with confidence and pleaſure.

“ Experience having convinced me that it never would be poſſible to have a plant at every ſix inches in each row, by ſowing only a ſingle grain of wheat at thoſe diſtances, it naturally followed, that the way to have the ground better covered with plants was, to ſow more grains. The next queſtion was, how many grains ſhould or ought to be ſown in each place? Should it be two, three, or more? Experience only could anſwer this queſtion. I therefore tried the following experiment. I ſowed a different number of grains in cluſters, ſix inches diſtant from each other, putting one grain in the firſt, two in the ſecond, and ſo on to the ſixth, which had ſix grains: then I began again, and went on as before, till the whole length of the row was ſowed in this manner. The produce of each cluſter was to ſhew me whether it would be beſt to double, triple, or quadruple the ſeed, which it was plain had been ſown too thin, when a ſingle grain was dropt at every ſix inches.

“ The winter of 1753 was already far advanced when theſe thoughts firſt occurred to me. It was then too late to try this experiment with wheat; but that I might not loſe a year, I did it in the ſpring with barley; not doubting but that corn, which is uſually ſown in March, might furniſh me with ſome future hints for the culture of that which remains longer in the ground.

“ Accordingly on the ninth of April 1754, I ordered another bed to be ſowed with barley in my preſence, and in the manner I have juſt related. I counted all the grains of each cluſter myſelf. They were ſown in three rows. I varied the experiment in the rows next the ſouth, by ſowing no cluſters there of leſs than three, four, five, or ſix grains: which I continued the whole length of the row. At harveſt, all the cluſters in which ſeveral grains had been ſowed, were ſo thick, that they touched one another.

“ What is of moſt conſequence to our culture is, to know the produce of each cluſter. But it will be neceſſary previouſly to obſerve, that the cluſters were ſown in rows extending forty feet in length, and that the beds were five feet wide.

“ Reſults:

The *South row*

ſowed with 6, 5, 4, and 3 grains,
produced 661, 624, 447, and 493 ſtalks.
In all 2225 ſtalks.

“ The *Middle row*,

ſowed with 1, 2, 3, 4, 5, and 6 grains,
produced 48, 72, 147, 204, 219, and 487 ſtalks.
In all 1177 ſtalks.

“ The *North row*

ſowed with 6, 5, 4, 3, 2, and 1 grain,
produce 502, 372, 345, 276, 200, and 92 ſtalks.
In all 1787 ſtalks.

“ Conſequently the whole number of ſtalks in the three rows was 5189. They yielded ſeventeen pounds of grain, beſides a very conſiderable quantity ſhed in cutting.

“ On the footing of this crop, an arpent of thirty-ſeven ſquare toiſes (equal to about one acre and three quarters of a rood Engliſh) would contain at leaſt forty-four beds five feet wide, which was the breadth of the beds on which this experiment was made. The beds would be 222 feet long: the produce of one of them would be ninety-three pounds, eight ounces; and that of the forty-four, 4138 pounds, eight ounces: a very conſiderable crop, and which might be carried ſtill further by other experiments of the ſame kind.

“ The following obſervations deſerve the reader's utmoſt attention. Firſt, by this experiment, I have very nearly effected what I aimed at, viz. to have two or more plants grow ſo cloſe together, as to ſeem but one; and that at ſix inches diſtance from each other. If the three rows had been joined together lengthways, they would have been 120 feet long, and ought to have contained 240 plants only: but the diſtances, which were marked by gueſs, not being exactly ſix inches each, ninety-ſix cluſters were ſown in each row, which made ſixteen cluſters over and above. By this means ſeveral of them were nearer than ſix inches to one another.

“ Two hundred and eighty-eight cluſters were ſown, all of which produced plants, except twenty-five, which either did not ſprout, or the plants periſhed. This deficiency is not very conſiderable; but we muſt obſerve, 1. That almoſt all the places where this happened had been ſown with only one or two grains of corn. 2. That it was in the middle row that the greateſt number of plants was wanting. 3. That the ſouth row, in which the ſmalleſt quantity ſown for any one tuft, was three grains, furniſhed and retained its full number of plants: and laftly, that almoft all thofe which were next to the vacant fpaces, were ftronger than the reft, and thereby made amends for the lofs of the others.

"Secondly, the whole number of the ftalks amounted to 5189, which is after the rate of forty-three ftalks and a quarter to a foot: but it is much more confiderable in the fouth row, which having produced in all 2225 ftalks, the proportion is fifty-five and a half to a foot. The caufe of this difference is eafily feen. The expofition of that row to the fouth being more favourable than that of the others, may have contributed thereto; but it was very plain that it was chiefly owing to none of the clufters in that row being fown with fo few as one or two grains.

"Thirdly, we fee that the increafe of the ftalks was, in general, in proportion to that of the feed; only the clufters that were fown in three grains in the fouth row, produced forty-fix ftalks more than thofe which were fown with four grains; but ftill the general refult of the three rows was exactly in the fame progreffion, as appears by the following recapitulation:

RECAPITULATION.

Stalks produced by 1 grain	140
2 gr.	272
3 gr.	916
4 gr.	996
5 gr.	1215
6 gr.	1650
Total	5189

"Fourthly, the ears were nearly equal, at leaft in two thirds of the length of the rows: the other third furpaffed the reft very confiderably.

"Fifthly, the difference between the produce of the clufters fowed with one, and with fix grains, is extremely great. The former produced but 140 ftalks, the other multiplied to 1650. It is true the number of the clufters of fix grains is greateft, which is fome fmall diminution of this difference.

"Sixthly, I obferved feveral ftalks from which others had fhot out, all as ftrong, and as long, as thofe from which they derived their origin. They proceeded from the firft joint above the furface of the earth, generally at the height of three, four, or five inches, and were two, three, and fometimes four in number. I never perceived this kind of multiplication before; but had till then always obferved it to be at the neck, or point of feparation between the roots which defcend, and the ftalks which afcend, that the ftalks branched out.

"Seventhly, I fufpected, in the fummer, what was the caufe of the great vigour of the plants of this experiment; but I faw it much plainer after harveft: for, upon pulling up fome of the tufts of ftubble, I found their roots innumerable. This fact is ftrictly true. I could not count them upon any one plant that had more than fifteen or twenty ftalks. Thefe roots were in fuch bundles, and fo confufedly interwoven one with another, that after counting feveral hundreds of them I was forced to give up the tafk. Their length and thicknefs was anfwerable to their number.

"I muft now remind the reader of what I faid before, that the feveral accidents which I met with in my firft experiments, fhewed me it was neceffary to increafe the quantity of the feed. I did fo, by fmall degrees, from year to year. It is equally important for the fuccefs of the new hufbandry, not to run into another extreme, by loading the earth with more plants than it can nourifh: the crop would be confiderably diminifhed thereby.

"It appears from this experiment, that the plants of the clufters that were fowed with fix grains, did not hurt one another: on the contrary, their being fown in that manner proved an advantage, fince they produced much more than the others; whence it follows, that we may, without danger, extend the quantity of feed beyond the limits of the new hufbandry. Its principles are not the lefs true; but they leave the farmer at liberty to ufe his own prudence in the application of them, according to the nature of the foil.

"Thofe principles, which fuppofe that every plant is to fubfift till harveft, reduce the feed to a very fmall quantity: but numbers of accidents deftroy many of them. Our reafon ought therefore to tell us, that without deviating too much from the principles we adopt, we may, and fhould, judicioufly ftock our land with a fufficient number of plants, in order to guard againft unavoidable accidents.

"Still I may be afked, what is the fufficient quantity? I anfwer, that our experiment fhews that fowing fix grains together in a clufter, at the diftance of fix inches from each other, all the length of the rows, will not be found too thick. By following this rule, we may be almoft certain that the whole ground will be ftocked with a proper number of plants. This ought, however, to be looked upon only as a general propofition, which it will be often proper to deviate from in the circumftances we are going to mention,

"When the fowing feafon is favourable.

"When the land is well prepared.

"In countries where the winter is feldom fevere.

"When the land is but little liable to infects.

"When the land is not in danger of being hurt by too much drought, or too much wet.

"And laftly,

"When the land is good, and very fertile.

"In all thefe and fuch like cafes, lefs feed fhould be fowed; and, in the contrary cafes, more. Prudence, and a careful ftudy of the nature of the foil, ought to be our guides. Two or three years experience will be fufficient to fhew us the practice that will be beft to follow.

"It will be right to repeat our laft mentioned experiment, and even to vary it. In all probability it will afford us ftill greater lights. It will be right, for example, to fow the clufters with a greater number of grains, beginning with fix, the produce of which is known, and going on to feven, eight, or even more, always in clufters, till we come to a number at which the crop ceafes to yield an equal profit. By this means the two extremes may be known, either of too much, or too little feed; and the juft proportion will then be eafily determined.

"Some farther alterations may likewife be made in this experiment. For example, I placed the grains in the earth fo that they touched one another; they may be placed at fome little diftance, and ranged in a kind of circle of about three inches diameter. It is reafonable to think, that the plants may then make a greater progrefs, as they will not all have one common center: fome of them will be nearer the ploughed alley; their roots will reach it more eafily than before, and will multiply there; which may render the plants more vigorous." *Du Hamel's Culture des Terres, tom.* IV.

CLUSTER-GRAPE, the fmall black grape, generally called the currant.

COAL, the common foffile fuel.

COAL-ASHES. *See the article Coal*-ASHES.

COAL-BALLS, a compofition of culm, or the duft and refufe of pit-coal, mixed up with mud, clay, &c. burnt as fuel.

About Briftol, Briflington, and other places in the weft of England, they commonly make coal-balls of their culm, or fmall refufe-coal, which would not otherwife be faleable.

The method of making thefe balls is, to take a certain quantity of the culm, and an equal quantity of fleech, or mud left by the tide on the fea-fhore: thefe ingredients are firft mixed grofsly with fhovels, and then blended more perfectly with the hand: after which they are moulded into balls of about fix inches diameter.

Thefe balls may either be burnt immediately as foon as they are made, or laid up and kept as long as the owner pleafes, without fuffering the leaft damage.

The inhabitants of Croken-pill, near King Road, about feven miles below Briftol, are fuppofed to make them in the greateft perfection. They feldom ufe any other fuel, and find it anfwers extremely well, being much cheaper than coal, making as good a fire, and lafting longer.

They

They make it a rule to work as much culm into the fleech with their hands, when they mould the balls, as they poffibly can, without making them crumbly.

Thefe balls have not been ufed above thirty or forty years in the above parts; but are now greatly preferred, though they can have coals laid in at three-pence half-penny the bufhel.

In Wales, where thefe coal-balls are alfo made, they ufe clay inftead of the fleech, allowing two parts of culm to one of clay, adding to the heap a fufficient quantity of water, which they temper with it, in the fame manner as if they were making mortar with lime and fand. And after the culm and clay have been fufficiently mixed and tempered together, they form the whole into balls, in the manner above related.

The balls made with clay are not fo pleafant a fuel as thofe made about Briftol with fleech, becaufe the clay is apt to emit a ftinking fmoke, efpecially if the balls are burnt before they are dry; but notwithftanding this inconvenience, which the lower fort of people little regard, they afford the poor a good and cheap fuel.

It is furprizing that fome work of this kind is not undertaken in the neighbourhood of London, as it would greatly tend to leffen the enormous expence to which the poor of the metropolis are every winter fubject, for fuel; and could not fail of rewarding the undertaker for his trouble. Culm might be imported into the Thames very cheap, and nothing could be more fuitable than the river mud to mix with it, in order to form the balls; it would, probably, do better than the fleech, being of a richer, and more combuftible nature.

COAL-SOOT, the foot collected in chimnies, &c. where coals are burnt. A correfpondent of the editors of the Mufeum Rufticum has obliged the world with fome ufeful obfervations on coal-foot as a manure. He obferves that many farmers in fome countries are at a great lofs to find a proper dreffing for their meadows; and to fuch he recommends the ufe of coal-foot, as highly profitable and advantageous; its effects will be very vifible for upwards of three years, during which time no other manure need be laid on the land.

" Coal-foot, fays he, is of a very warm refrefhing nature: it cherifhes, and gives nourifhment to the grafs; it kills the noxious infects that infeft the crop, and protects it from the effects of frofts, fnows, and chilling rains; and, what is ftill of greater confequence, it will kill the mofs that fo often abounds in four meadows.

" I muft not however fail noticing, that foot will not have thefe good effects if the meadow-land fhould be fo damp as to require draining: in this cafe, cuts muft be made acrofs it, in proper directions, previous to the laying on the coal-foot, which would otherwife be of little fervice.

" All rank weeds fhould be carefully grubbed up from among the grafs, and that before they have perfected their feeds; without which precaution, in point of time, the work would be to do over again.

" The general quantity I lay on an acre of meadow-land is twenty-five loofe bufhels: more I find to be rather prejudicial, and lefs does not anfwer all the purpofes we are to expect from this excellent manure.

" The beft time for applying this dreffing, I take to be the beginning of the fpring: about February is the time I generally lay it on; the gentle rains which then, for the moft part, enfue, wafh it into the land, and the following crop is greatly benefited by it. This is very foon vifible from the fine deep verdure which the grafs affumes.

" Some of my meadow-land is particularly fubject to be damaged by frofts, fnows, &c. on this I generally lay the proper quantity of foot in the beginning of November; and fometimes, if the winter is likely to be fevere, I venture to allow thirty bufhels to an acre, which in other cafes I never do.

" Having myfelf found great benefit by ufing this coal-foot as a manure for meadows, I am willing my brother farmers fhould know it, that they may have it in their power to adopt the practice, if they approve of it.

" It will be well worth their while, provided they can have it at a reafonable rate, which they may, if they do not live more than twenty miles from London, by land-carriage, and wherever there is a communication by water, though at almoft ever fo great a diftance.

" Other great towns alfo, where fea or pit-coal is burnt, may fupply the farmers with it; but the misfortune is, that where it is in the greateft plenty, they leaft know the ufe of it.

" Great care however fhould be taken to get it genuine and good, the merchant chimney-fweepers, frequently to increafe the bulk, mixing the fine fifted coal-afhes with it: this is a great fraud, but may eafily enough, with proper care and circumfpection, be difcovered; for the afhes make the foot gritty, and increafe its weight in a very fenfible degree.

" Before I conclude, I muft give my brother farmers a caution; which is, that they never lay the foot on their land in windy weather, as not only great part of it will be loft and wafted, but the remainder will be fo unequally difpofed, as to do rather more harm than good." *Mufeum Rufticum, vol.* I. *pag.* 218.

Coal-foot is alfo an excellent dreffing for green wheat in February; it fhould be fown by hand, in quantity fufficient to blacken the ground. This is frequently practifed in Leicefterfhire, and many other counties. It is of a warm nature, and therefore does moft good on cold, moift, clayey foils.

COB, a wicker bafket to carry on the arm. Hence a feed-cob, or feed-lip, is a bafket for fowing.

COCCIFEROUS *Plants*, fuch as bear berries.

COCK, the male to the hen; alfo the male of any fmall birds.

COCKEREL, a young cock.

COCKLE, the fame with darnel-grafs. *See* DARNEL-GRASS.

COCKSCOMB, a very elegant fpecies of the amaranthus, cultivated in curious gardens for its beauty. The culture of this beautiful plant is the fame with that of the amaranthus. *See* AMARANTHUS.

CODLING, a well known fpecies of apple. *See the article* APPLE.

COFFIN, that part of the horn or hoof of a horfe which appears when he has his foot fet on the ground.

COFFIN-BONE, that bone which lies within a horfe's hoof as in a coffin.

This bone is round upwards, where it receives the little paftern, but grows broader and thinner towards its bottom; it is of a porous open contexture, like a piece of loaf fugar, and is eafily pierced, and often wounded when horfes happen to take up nails or other fharp bodies in the ftreets or roads: accidents to which they are often liable, and are more eafily cured than they would have been, had the bone been hard and folid.

COFFIN-JOINT, that where the leffer paftern joins the foot.

When the coffin-joint is ftrained, a horfe often continues a long time lame, without the owner's difcovering where the lamenefs lies; becaufe a horfe does not, at firft, favour it much on the bending of the foot, only in planting his foot upon the ground: but in time there will grow fuch a ftiffnefs in that joint, that he will only touch the ground with his toe, and it will be impoffible to play the joint with one's hand. The only method of removing this ftiffnefs is bliftering and firing, which generally fucceeds, unlefs the ftiffnefs and contraction has been of long ftanding. *Gibfon's Farriery, vol.* II. *pag.* 372.

COKE, pit-coal, or fea-coal, charred. It is made by burning pit-coal in ovens conftructed for that purpofe, and extinguifhing the fire in the fame manner as is done for charcoal.

COLD, the name of a difeafe to which animals of almoft every kind, particularly horfes, are very fubject.

Colds are caufed by an obftruction of perfpiration: that is, the pores, or outlets of the fkin, are fo far fhut up, that the fteams of perfpirable matter are checked fo that they cannot pafs off in their ufual manner. The confequence of this is, they recoil on the blood, vitiate its quality, overfil the veffels, and affect the head, the glands or kernels of the neck and throat, the lungs, and other principal parts.

It

It would be endlefs to enumerate the various caufes of colds; the moft ufual are, riding horfes till they are hot, and fuffering them to ftand in that condition, where the air is cold and piercing; removing a horfe from a hot ftable to a cold one, and too fuddenly changing his cloathing: hence it is that horfes catch fevere colds after they come out of dealers hands; and by not being carefully rubbed down, when they come in hot, off journeys.

The figns of a horfe's catching cold, are a cough, heavinefs, and dulnefs, which affect him more or lefs in proportion to the feverity of it: the eyes are fometimes moift and watery, the kernels about the ears, and under the jaws fwell, the nofe gleets, and he rattles in his breathing; and when the cold is violent, the horfe will be feverifh, his flanks work, and he will both loath his hot-meat, and refufe his water. When thefe laft fymptoms are attended with a flimy mouth, ears and feet cold, and a great inward forenefs, there is danger of a bad fever.

But when the horfe coughs ftrong, fnorts after it, is but little off his ftomach, pricks up his ears, and moves brifkly in his ftall, dungs and ftales freely, his fkin feels kindly, and his coat does not ftare, he is in no danger, and there will be no occafion for medicines of any kind; but you fhould bleed him about two quarts, keep him warm, and give him feeds of fcalded bran, with as much warm water as he will drink, in order to dilute his blood.

If the diforder fhould increafe, the horfe fall hot, and refufe his meat, bleed him, if a ftrong one, two quarts more; and if you are not fatisfied, without giving medicines, avoid, as you would poifon, a farrier's drench; which is generally compofed of fome hot naufeous powders, given in a quantity of ale: which too often increafes the fever, by over-heating the blood, and palls the horfe's ftomach by its loathfomenefs. And inftead of it, infufe two ounces of annifeeds, with a dram of faffron, in a pint and a half of boiling water; pour off the clear, and diffolve in it four ounces of honey; to which may be added four fpoonfuls of fallad oil: this drink may be given every night; or one of the following balls, provided there is no fever; in which cafe, it always will be more eligible to give two or three ounces of nitre, or fal prunella, every day in his feeds, or water, till it is removed; but fhould the horfe be inclined to coftivenefs, remember that his body fhould be kept open by emollient clyfters, or cream of tartar diffolved in his water, to the quantity of three or four ounces a day.

Take of the frefh powders of annifeed, elicampane, carraway, liquorice, turmeric, and flour of brimftone, each three ounces; juice of liquorice four ounces, diffolved in a fufficient quantity of mountain; faffron powdered half an ounce, fallad-oil and honey each half a pound, oil of annifeed one ounce: mixed together with wheat-flour enough to make them into a pafte.

Or, Take the following from Dr. Brachen.

Take annifeed, carraway-feed, and greater cardamoms, finely powdered, of each one ounce, flour of brimftone two ounces, turmeric in fine powder one ounce and a half, faffron two drams, Spanifh juice diffolved in water, two ounces, oil of annifeed half an ounce, liquorice-powder one ounce and a half, wheat-flour, a fufficient quantity, to make into a ftiff pafte, by beating all the ingredients well in a mortar.

Thefe balls confift of warm opening ingredients; and, given in fmall quantities, about the fize of a pullet's egg, will encourage a free perfpiration; but, in cafe of a fever, fhould be cautioufly continued. They are much more efficacious, and in all cafes fuperior to the farrier's drenches, if diffolved in a pint of warm ale.

This fimple method, with good nurfing and hot mafhes, warm water and cloathing, efpecially about the head and throat, which promotes the running at the noftrils, will anfwer in moft fudden colds; and when the horfe feeds heartily, and fnorts after coughing, moderate exercife every day will haften his recovery.

The fcalded bran fhould be put hot into the manger, for the fteams conduce not a little to promote a running at the nofe, which is often very plentiful, and greatly forwards the cure. His manger fhould be kept clean, by filling it with ftraw; his hay well fhook and fprinkled with water, and given in fmall quantities: for his breathing, at this time, taints the hay, and then he will not touch it.

To a horfe loaded with flefh, a rowel may fometimes be neceffary, as may alfo a gentle purge or two, to fome, when the diftemper is gone off. *Bartlet's Farriery, pag.* 26.

COLD-CHARGE, the name of a medicine much ufed by farriers for curing ftrains, &c. It confifts of vinegar, bole, and the whites of eggs, mixed together to the confiftence of a poultice, and fpread over the part hurt.

COLE, *or* RAPE, the name of a plant greatly cultivated, both on account of its feed, being that from whence the rape-oil is drawn; and alfo for feeding cattle. The botanifts call it *napus fylveftris*, or wild navew.

The marquis de Turbilli, who has done more fervice to agriculture than any other foreign writer, has lately publifhed a memoire on the culture of cole-feed, as practifed by the Flemifh farmers, to whom we are indebted for many valuable improvements in hufbandry.

In the piece above-mentioned, the marquis obferves, that all forts of cole-feed are cultivated in the fame manner; and that all grow more or lefs towards their natural perfection, yield more or lefs feed, and this feed is of a better or worfe quality, according to the nature of the foil on which the cole-feed is fown, the good or bad hufbandry beftowed on it, the favourablenefs of the feafon, and the manner in which it efcapes other accidents to which it is fubject.

Cole-feed, he fays, thrives beft in deep kindly foils; but with plenty of manure, and deep ploughing, it will grow any where. He adds, that he has feen it yield good crops on a dry chalky foil, on which ftreet dirt had been laid.

We muft obferve, that this is a very ufeful piece of knowledge to propagate, as we never yet heard of any farmer in England, who ventured to fow it on fuch a foil. This fhould be attended to by the Bedfordfhire farmers about Dunftable, &c.

Our noble hufbandman next remarks, that in Flanders cole-feed is fown and tranfplanted like cabbages: they give two ploughings to the land before winter; and it is not of much confequence what crop the land was laft under.

In the month of May another deep ploughing is given; the land is harrowed two or three times, and then rolled, in order to make it fine. Towards the eighteenth or twenty-fourth of July, it is again ploughed, harrowed, and rolled till it is reduced to as fine a tilth as poffible: the feed is then fown, being fcattered by the three fingers: the land is lightly harrowed, and afterwards rolled.

The marquis fays, that twenty-four pounds of feed will fow three acres, and the plants on thefe three acres will fill twelve others. Cole-feed is tranfplanted after any crop whatever.

The land intended to receive the cole-feed plants fhould be twice ploughed as foon as the crop is carried off. About ten or fifteen days afterwards it is to be once or twice harrowed, and towards the end of September it fhould have a very deep ploughing. In this laft ploughing there fhould be an open furrow or trench every five bouts. If the field does not lie level, it fhould be ploughed obliquely, fo that there may be an eafy fall for the water.

The beft and moft promifing plants being taken up, and tied in bunches, are carried to the field where they are to be tranfplanted, by the time the laft ploughing is completed, and the workmen are ready for them.

There will always remain a number of plants in the land where they were fown: thefe are generally fed off with cattle; for the farmers never let them ftand to ripen their feeds, unlefs they intend to manure the land for the fucceeding crop.

The feafon in Flanders for tranfplanting cole-feed is the beginning of October. The plants are placed in rows acrofs the furrows. The rows are one foot afunder,

der, and the plants in the rows about fix inches diftance one from the other. The manner in which this work is done is as follows. A certain number of men advance in a parallel line, each having a dibble, or fpade-handle, with two large iron points to it, fix inches afunder: they drive this inftrument into the ground; the women and children follow, who put a plant into every hole, and fettle it at the fame time; which is eafy enough to do, and it faves fome expence.

When all the cole-feed is planted, if the land to which it was removed was not dunged before it was ploughed, it muft be fown with pigeons dung reduced to powder: this, of all other manures whatever, has the moft immediate and proper effect on the vegetation of this plant; fixty bufhels are enough for two acres.

When this is done, the loofe earth in the trenches, or open furrows, is to be thrown with a fhovel amongft the plants in the rows. Early in the fpring, a fpit of earth out of the trenches is, in like manner, to be caft amongft the plants of cole-feed in the rows. This flight tillage gives vigour to the crop, choaks the weeds, and keeps the foil loofe.

The rows of cole-feed form a number of beds, and when it thrives well, the trenches are entirely covered, and the whole refembles a thick copfe.

Here the marquis obferves that cole-feed thrives perfectly well in new-enclofed lands.

The feed is fit to gather about the beginning of July. When it turns yellow, it is reaped like corn, and laid in pretty large gavels on the beds, where it remains three or four days; it is then carried in cloths, in order to prevent any of the feed from being loft, for it is very ready to drop.

In one, or feveral parts of the field, in proportion to its extent, and to the quantity of cole-feed there is, the crop is formed into feveral ftacks. The Flemifh farmers never thatch thefe ftacks; they know fo well how to make them, that the rain does them no damage. The cole-feed heats in the mow, by that means yielding more oil than it would have done, if it had not been ftacked.

In the month of September they make a kind of floor in the field, whereon they threfh and drefs their cole-feed. If a farmer fhould incline to threfh his cole-feed without ftacking, it will be neceffary for him to leave the gavels longer expofed to the air on the beds. Cole-feed may be cut at any time of the day, provided it does not fhed; if it does, it fhould only be cut mornings and evenings. As a whole field does not all ripen at the fame time, it fhould be cut in different portions; being laid in gavels, or heaps, the changes of weather will not affect it. It may fafely be ftacked three or four hours after rain, provided it has previoufly been fome time in gavels, and is judged fufficiently dry.

In order to clean the feed, parchment fieves are ufed, if there is any wind ftirring; but if it be calm, they ufe wind-fans.

Cole-feed fhould not be fown on the fame land above once in five or fix years.

In the neighbourhood of Clermont, in Beauvoifis, the marquis tells us, that they let the cole-feed ripen in the field where it was firft fown; but if they confidered that cole-feed is not fond of moifture, that it fends forth large roots into the earth, and grows to a great height, with numerous wide extended branches, they would be fenfible that the land, being covered with too many plants, muft be impoverifhed; and that plants, which ftand fo clofe together, cannot attain their full fize: thus, in this way, the land is impoverifhed, the weeds are left to perfect and fhed their feeds in it, and not only the crop of cole-feed is very indifferent, but alfo the crops which fucceed it. In order to reftore fuch land to a good condition, it fhould be well manured and fallowed.

Cole-feed extracts fuch a quantity of falts from the earth, that the Flemifh farmers tranfplant it, as well to divide betwixt two pieces of land the loffes in point of quality it occafions to the foil, as to procure better crops. For both thefe reafons, they alfo fometimes tranfplant their cole-feed on land newly broke up.

In the country of Amiens they tranfplant their cole-feed after the plough in clofe furrows: this method is better than that above-mentioned; but it is greatly inferior to the Flemifh method; for the rows are difordered, and the plants crufhed by the horfes feet; and having, befides, no frefh earth laid on them, they cannot grow to fuch fine plants; and, on the other hand, the earth, which is not kept ftirring, cannot receive any confiderable benefit from the influences of the air.

The marquis obferves, that there is, however, a cafe in which this method muft be reforted to; which is, when the plants are grown fo tall, and have fuch long roots, that proper holes cannot well be made for them with a dibble, they fhould be laid in the furrows after the plough, and open furrows, or trenches, fhould be left at the diftances already mentioned; but the earth from thefe trenches is with greater difficulty thrown on the beds, becaufe the cole-feed, in this method, is planted lengthwife, whereas, in the other method of tranfplanting, the plants crofs the beds.

In this effay the marquis de Turbilli relates a very curious fact, which we fhall infert in his own words:

" In the year 1755, I faw, in the neighbourhood of Guife, in France, fome cole-feed tranfplanted into a field, containing about eighteen acres, which had always borne fine corn, but had no great depth of foil.

" At the depth of feven or eight inches from the furface lay a bed of red clay, which the farmers are fo much afraid of mixing with their good earth. This land was firft well dunged, and when the cole-feed was tranfplanted, the red earth out of the trenches was thrown on the beds.

" All the inhabitants of the country flocked to fee this work executed, which was under the direction of a Flemifh farmer. They pretended that he fpoiled the land, and that no corn would grow on it afterwards.

" However, during the courfe of the winter, the red clay became mellow; the rains, which wafhed the dung, ran into the trenches, carrying with it a fediment, and a portion of falts, improving the earth that was in the enfuing fpring to be thrown on the beds amongft the rows of cole-feed, which came on amazingly.

" At the harvefting of the next crop, the inhabitants did not fail coming to fee what fort of corn fucceeded the cole-feed; and being perfectly well convinced that it was much finer than the land was accuftomed to bear, they laid afide their prejudices, and adopted the planting of cole-feed. In the year 1761, there were in that fingle quarter above one hundred acres of tranfplanted cole-feed."

Muft we not, on fuch good authority, allow that the notion of the under-turf earth being poifonous is ideal? If indifcreetly laid over the furface of the land when it either is, or is to be fown, under certain crops, it may be prejudicial, and fo may the beft practices in hufbandry, if injudicioufly followed.

A correfpondent of the editors of the Mufeum Rufticum has given us the following method of cultivating cole-feed in Effex. He begins with obferving, that the great confumption of rape-oil in that country in manufactures, together with the natural richnefs of their land, induces them often to fow the cole-feed or rape-feed, which thrives there extremely well.

" In moift foils, continues he, we fow it on four-bout lands, the large furrows between the ridges ferving to drain off the water.

" We do not truft to the richnefs of our land alone, for we almoft always lay on a confiderable quantity of manure; being of opinion that land cannot be in too good heart for this plant, which requires a great deal of nourifhment, having a very luxuriant growth, and draining the land much: for this reafon, it is in vain to attempt fowing it on poor, hungry, dry foils, on which it will never thrive, nor turn to profit.

" Land cannot be too mellow, nor too much pulverized, for the cole-feed plant; for it not only requires a rich foil, but alfo the land muft be in excellent tilth: we allow land, on which it is to be fown, fometimes three or four ploughings, according to the nature of the foil; if ftiff, it requires more tillage; if a loofe, rich, crumbly loom, lefs ploughing will do.

" In July we harrow the field over, and afterwards fow on it half a peck of feed to the acre broad-caft. As foon as the plant gets out of its feed-leaf, I hoe it as I do do my turnips, thinking this a better way than to let it grow rambling without after culture, as some of my neighbours do.

"This crop is, without care, very apt to be destroyed by slugs, whilst the leaf is young and tender; but to prevent this, I always strew over the young plants a mixture of slaked lime and wood-ashes: about ten bushels of slaked lime, and fifteen of the ashes, will be quite sufficient for an acre: this is the quantity I use.

"I find great benefit from this practice, as it not only burns up the slug, and destroys many pernicious insects, but also greatly helps to forward the crop, insomuch that it gets to a strong head before winter, and yields me plenty of fodder for my cows, sheep, &c.

"A part of my ground will sometimes unaccountably fail; that is, the seeds will not come up; but as the cole-seed plant bears transplanting extremely well, I make my men remove some of the plants, where they stand too thick, to supply the deficiencies: these are sure to take, especially if rain ensues: if it does not, I cause them to be watered, which is soon done, as they seldom fail in great quantities.

"The cole-seed plant is so hardy, that it bears, without injury, the frosts of our severest winters; but the north-easterly winds, if very cold and piercing, will sometimes greatly injure a crop, and there is no guarding against these.

"We sometimes in this county sow cole-seed merely for the sake of the winter feed it affords our cattle; in which case we plough it up early in the spring, and are almost sure of a good crop of sound barley. This is not generally practised, because it requires great care to clear the land of the cole-seed plant, which would otherwise grow up with the barley, and injure it; I, however, and some others, have often practised it to advantage.

"One thing I must observe before I conclude, which is, that cattle must be fed with this plant with great care, or it will have fatal effects: it is best to give them with it, at times, sweet dry hay: this corrects the superabundant moisture of the plants, and serves to dry up the uncorrected and raw juices that would otherwise mix with the mass of blood in the cattle: suckling ewes may feed on it heartily, however, with very little danger; and, in fact, experience will soon direct the young farmer in the management of his cattle in this respect.

"We reap, for the most part, our crops of cole-seed; and as it is very apt to shed, we prepare frames lined with threshing cloths, each drawn by one horse, to receive the heads of the plants as fast as they are cut off.

"When this crop is properly managed, nothing pays better." *Museum Rusticum, vol.* I. *pag.* 237.

Another correspondent of the editors of the above work, gives us the following method of cultivating cole-seed in the fen countries.

He observes, that they make use of no muck or compost, but have recourse to the method of burn-baking, which we have already described under that article. *See* BURN-BAKING.

As soon as the land is burnt, and the ashes spread, it is immediately ploughed, and the seed is sown as soon as possible.

"The quantity we sow, continues he, on an acre is about half a peck, or rather less: it would be proper to draw a light hurdle, stuck with thorn spray, over it, by way of prevention against the fowls. We plough the lands about ten paces wide, that the furrows may carry the water off, where the land lies on a little descent.

"There is one thing to be observed in the ploughing, if the square of the piece will admit of it: you should plough for burning from east to west, and when you plough for sowing, then plough north and south, for these reasons: first, the land will break better for being cross-ploughed; and then the land, when sown, will lie as it were full face to the sun; but this cannot always be done.

"As soon as the cole-seed begins to sprout, it is often all destroyed with what we call a black fly; an insect so small, and being black, the same colour of the land, that it is almost impossible to see it, otherwise than as you walk among the seed, if you look steadily, you will perceive something hop or fly off, like the hopping of a flea: I have very often endeavoured to discover what sort of fly this is, but never could find one, though they will find the seed immediately on its first sprouting.

"It has many more enemies as it advances in its growth: the next is what we call the black canker; it is a small black worm, about a quarter of an inch long, or rather more: this takes possession when it is about the size of a small cabbage-plant, but windy and rainy weather are great helps to the destroying that insect.

"There is yet another enemy, but he appears in a different dress: this is the green caterpillar, more than an inch long, but does not appear till about the latter end of September, and very often destroys a great deal of it; but the frosty mornings generally dispatch him.

"I have now gone through the various steps of the culture of cole-seed to this particular period, with a supposition that we have escaped all those dangers. I will now give you a short sketch how we proceed when we are attacked with those enemies above-mentioned.

"If the small fly eat the first sprout, it is usual to sow the land again; but I would advise the farmer, before he sows, to harrow the land with a light harrow with wooden teeth; for if the harrow be heavy, it will tear up the furrows: my design in this is to raise a fresh mould, by which means the seed will strike much sooner than if nothing was done to it.

"As to the black canker, the only method I can advise is, to let two men take a waggon-rope, each take one end, and draw it over the plant about twice in a place, by which means the canker will be beaten off the plant on to the ground, which seldom rises again.

"As to the green caterpillar, the same expedient, I believe, would be of service to that; but, as I have said before, we are chiefly relieved from it by frosty mornings."

The writer then proceeds to give his readers an account of the uses the cole-seed is put to in the fen countries, when the plant is arrived to its utmost perfection.

"We eat off, says he, with sheep that are about half or three parts fat, to make them fit for the butcher; for cole-seed is the most fattening food for sheep that is known in this part of the world, greatly exceeding turnips, as a sheep will thrive more at cole-seed in one month than it will at turnips in two.

"The usual time of putting them into the seed is about Michaelmas: however, that depends upon the farmer's own conveniency; but if the sheep are poorer than as above described, they must be put in sooner. We generally manage so as to have the seed eaten off by about Old Candlemas, for this reason; if the land be stout and good, there is a chance for the seed to stand for a crop.

"If the farmer finds the seed good enough to stand for a crop, I would advise him, if the stumps or stalks be left high, as where the cole-seed is strong and good is mostly three or four inches off the ground; otherwise he will find his crop will receive great damage by the stumps being left very shagged and torn, which lets in the wet, and rots abundance of them; and even those that do grow have not the vigour as those have that are mowed; for the former is, at it were, spread to the snow and rain, while the latter is wholly secured from them both, and will support the sprouts, that shoot out at the sides, with strength and vigour.

"Cole-seed is a plant that will shed or shale its seed very greatly, if it is not reaped in proper time; from which great losses have been known, where the farmer has thoughtlessly let it stand too long before he begins to reap.

"If the season has been kind, that the crop comes on all together, though we often see the contrary, the farmer is, in either of these cases, as soon as he perceives any part of it to turn brownish, to begin to cut, notwithstanding the generality of the seed will be green; but if you let the whole stand till the last becomes brown, like the first, the first part will be entirely lost.

"But it will perhaps be said, should not the latter part be as ripe as the first? My reply is, as cole-seed is a small a fmall feed, and the ftalks on which it grows are very large, the ftalk will feed that part that is green, after it is reaped, fo as that of the latter will be nearly equal to the firft; by which means both are faved.

"There is a particular method of laying it on the ground, when reaped, different from all other crops; for inftance, fuppofe the people reaping a field from north to fouth, every two men fhould lay in his reaps, with the heads of the feed to each other, but not to touch, the heads and the ends of the ftalks lying eaft and weft. We fhall now proceed to the threfhing.

"The diftance of time between reaping and threfhing depends fo entirely upon the weather, that it is impoffible to give particular directions in that matter, otherwife than that when the feed has lain till the ftalk or ftraw is dead, and turned white, and the feed, fome of it being rubbed out of the cofh, or pod, appears black and plump, and does readily come out, then is the time to begin to threfh.

"Though the bottom of the reaps will be a little greenifh, they muft be not turned to weather the under fide; if you do, it will brufh out a great deal of the top fide: and if the weather fhould prove wet in the time it is threfhing, even in that cafe it muft be turned, but raifed up gently and laid lightly on the ftubs; in that fituation it will dry apace.

"It is always threfhed in the field, upon a cloth about twenty yards long, and eighteen yards wide. To defcribe each perfon's employment, I think, it is not to be done, fo that a perfon that never faw it can have an idea of it; but as it is, I think, if every perfon concerned in a cole-feed fale, for that is the name we give the cloth and people when at work, be clever in their places, a curious piece of mechanifm, if I may be allowed the expreffion, where men and women are made ufe of inftead of wheels and pullies.

"The number of people employed at a cole-feed fale are, generally, about twenty: feven gatherers; thefe are women, great boys and girls: I have faid feven; but where the crop is thin, it requires more, fometimes eight or ten, or more; but where the crop is thick, a lefs number may do; thefe people gather the reaps up with a fickle, for, as their arms cannot reach round the reaps, they would fqueeze it together, and brufh a deal of feed out, if they had no fickle: they put it into a fheet called a bearing-fheet, of which there are two belonging to every fale; it is about ten feet long, and about feven feet wide, and has loops on each fide, through which a light pole is put, and is carried, when filled, by two men to the cloth: thefe are called the bearers.

"When the feed is lain on the cloth, there is a man called the layer-on: he with a fickle lays it on a row, acrofs the cloth, for the threfhers, which are four, two on each fide the row of feed. While the threfhers are threfhing the firft row, or floor, the layer-on lays on another row at a proper diftance from the other: when they have threfhed the fecond once over, they turn to the firft, and threfh it all a fecond time: they have then done their parts: there are two men called fhakers off, that immediately follow the threfhers: the firft of them throws the cole-feed ftraw up; the other ftrikes it as it rifes, which helps to knock out what feed may be left: thefe two men, with wooden forks for that purpofe, convey the ftraw off the cloth, over the bolfter, to a perfon that takes it away; he is called the fack-ftraw.

"After the fhakers off, come two perfons, one of them a woman: they take off the cofhes or pods, and fhort broken ftraws, with rakes made for that purpofe: thefe are called the before and behind cavers. The behind caver muft be a perfon of ftrength and activity, in order to do his work as it ought to be done; for upon him the faving or throwing away of a good deal of the feed depends; fo that he fhould be a nimble brifk fellow, and careful too, or he is by no means fit for that place.

"If there be a good crop, and the plants yield well, the weather bright, and the feed threfh eafy, thirty combs, or one hundred and twenty bufhels, may be threfhed in the day; but fometimes not more than ten or twelve combs.

"Early the next morning the four threfhers throw the feed upon the cloth, when the farmer comes with facks and a waggon, and takes it away, fo that the cloth is cleared and ready againft the people come to work." *Mufeum Rufticum, vol.* I. *p.* 418, *and vol.* II. *pag.* 79.

If this plant be fown for the food of cattle, they will be large enough for feeding by the middle of November, when, if there be a fcarcity of other fodder, this may be eat; but if there be not an immediate want of food, it had better be kept as a referve for hard weather, or fpring feed, when there may be a fcarcity of other green food. If the heads of thefe plants are cut off, they will fhoot again early in the fpring, and produce a good fecond crop in April, which may be either ufed for cattle, or fuffered to run to feed. It is fo hardy as not to be deftroyed by froft, and therefore of great ufe in hard fevere winters, for feeding of ewes: for when the ground is fo hard frozen that turnips cannot be taken up, thefe plants may be eat for a conftant fupply. Mr. Miller fays, he has found, in feveral places where he has fowed this feed, that one acre of land planted with cole will produce nearly as much food as two acres of turnips; that this will afford late food after the turnips are run to feed; and that, if the plants are permitted to ftand for feed, one acre will produce as much as, at a moderate computation, will fell for five pounds, clear of charges.

Partridges, pheafants, turkeys, and moft other fowls, are fo fond of thefe plants, that, if there be any of them in the neighbourhood of the field where they are cultivated, they will flock thither, and lie conftantly among them.

The cakes of cole-feed, which remain after the oil is extracted, are exceeding good food for cattle, and will very foon fatten them. They are indeed apt to render the fat of fuch beafts yellow and rank; but this may be eafily removed by feeding them with dry fodder a fortnight or three weeks before they are killed.

COLE, *Cale*, or *Keal*, fignifies pottage in the northern parts of England and Scotland.

COLEWORT, or *Dorfetfhire-Kale*, is a fpecies of cabbage, formerly much cultivated in gardens, but at prefent little known, cabbage-plants being fubftituted in its room. It is however a very ufeful plant for feeding milch-cattle in the fpring, when there is a fcarcity of herbage; for it is fo hardy that no froft will kill it.

The beft method of cultivating this plant in the fields is, to fow the feeds about the beginning of July, choofing a moift feafon, which will bring up the plants in about ten or fourteen days: the quantity of feed for an acre of land is nine pounds. When the plants have got five or fix leaves, they fhould be hoed in the fame manner as turnips, cutting down all the weeds from among the plants, and alfo thinning the plants where they are too thick; but they fhould be kept thicker than turnips, becaufe they are in more danger of being deftroyed by the fly: this work fhould be performed in dry weather, that the weeds may be killed. About fix weeks after the plants fhould have a fecond hoeing, which, if carefully performed in dry weather, will entirely deftroy the weeds, and make the ground clean, fo that they will require no farther culture. In the fpring they may either be drawn up, and carried out to feed the cattle, or the beafts may be turned into the field to feed upon them as they ftand; but the former method fhould be preferred, becaufe there will then be little wafte; whereas, when the cattle are turned in among the plants, they will tread down and deftroy more than they eat, efpecially if they are not fenced off by hurdles. *Miller's Gard. Dict.*

COLLAR, the part of the harnefs that goes round a horfe's neck.

COLLAR *of brawn*, is the quantity of brawn bound up in one parcel.

COLLATERAL *Bee-Boxes*. *See the article* BEE.

COLLEY *Sheep*, fuch fheep as have black faces and legs. The wool of thefe fheep is very harfh, with hairs, and not fo white as that of other fheep.

COLLIFLOWER. *See the article* CAULIFLOWER.

COLONY, a number of people drawn from the mother country, to inhabit a diftant place. And hence the ingenious

ingenious Mr. White has applied the word to a flock of bees. *See* BEE.

COLT, a foal, or young horse.

Foals are separated from their dams after five, six, or at farthest seven months; experience having shewn, that such as are suffered to suck ten or eleven months, though usually larger and fuller of flesh, are not equal, in other respects, to those that are taken away sooner. After living six or seven months on milk, they are habituated to a more solid nourishment, having bran given them twice a day, with a small quantity of hay, which is increased as they advance in age, and in this manner they are kept in the stable, as long as they express any desire of returning to their dams: but when this uneasiness is over, they are turned into the fields, taking care never to do it fasting. An hour before they are turned to grass, a feed of bran, and some water should be given them; nor should they be exposed to either severe cold or rain: in this manner the first winter must be passed. In May following, they must not only be turned into the fields every day, but may lie in the open air till the end of October, taking care not to let them feed on the after-math; for by accustoming themselves to this remarkably delicate and succulent grass, they would contract a dislike to hay, which, together with bran mixed with barley and oats ground, should be their principal food during the second winter. In this manner they are to be kept till their fourth year, spending the days only in the pastures, during the winter; but both day and night in the summer. When they reach that age, they are to be taken from the pastures, and fed with dry meat; but in this change of food some precautions are requisite; as during the first week to feed them only with straw, and give them proper medicines against worms, which often trouble them from bad digestions and too rank grass.

At weaning young colts, they should be kept in a clean stable, not over warm, which would render them tender, and too sensible of the impressions of the air. They must frequently have fresh litter, and be rubbed often with straw; but not tied nor curried till they are three, or at least two years and a half old; for the roughness of this friction would give them pain, and their skin being too tender to endure it, instead of thriving, they would fall away. The rack and manger should not be too high, lest the necessity of lifting up their heads to reach their food, should occasion them to carry their heads in that manner, which would spoil their chests. When they are a year, or a year and a half old, the hair on their tails should be cut, as the succeeding growth will be stronger and thicker than the former. When they are two years old, they should be separated, and the fillies with the mares, otherwise the former would fruitlessly weaken themselves with the latter. At the age of three years, or three and a half, they should be broke, and rendered docile. In order to this, a light easy saddle should be put on their backs, and continue there three or four hours every day. They should also be used to receive the bit of a small bridle into their mouths, and suffer their feet to be taken up, and some strokes given on the sole, as if shoeing them. If they are designed for draught horses, a harness should be put on their bodies, and afterwards a snaffle bridle should be added. They should then be trotted on level ground, but without a rider, the person only holding the reins, and either the saddle or harness on their backs: and when the saddle-horse easily turns, and freely comes up to him that holds the rein, he should mount on his back, and dismount again immediately, without riding him, till he is four years old, as before that time the weight would be too much for him: but at four years old he may be ridden, and trotted at small intervals. *Buffon's Histoire Naturelle, tom* IV.

COLT-EVIL, a distemper to which young horses are subject, consisting of a swelling in the sheath, occasioned by their having full liberty with the mares before they are able to cover them.

This disease may be easily removed at the beginning, by the use of warm fomentations, made of emollient herbs, &c. but if the swelling be hard and inflamed, bleeding and purging are both necessary; and it may also be proper to tie his yard up to his belly, making a hole for his water to pass free. *Gibson's Farriery, vol.* II. *page* 168.

COLTS-FOOT, *fole-foot*, *horse-hoof*, or *bull-foot*, the name of a very common weed, whose scaly stalks arise in February, bearing one yellow compound flower, which is succeeded by a hairy white down. The leaves come out later. They are shaped somewhat like a horse's hoof, and are downy underneath.

This weed, which delights to grow by the side of rivers, increases so fast by its seeds and rambling roots, every piece of which last will produce a new plant, though they have been broken by the plough, that it cannot be extirpated without much difficulty, and a considerable time. Carefully pulling up the roots every time the earth is stirred, or the least vestige of the plant appears, and preventing its running to seed, are the most effectual means of destroying it in arable land; and this is best accomplished by the horse-hoeing husbandry: but totally to extirpate it, the ground must be laid down long to grass. One of Mr. Lisle's neighbours almost destroyed it by two successive crops of vetches; and he himself is clearly of opinion, that it may be killed by letting the land lie a sufficient time under clover, or rye-grass; because, says he, the roots of the natural grass matting more and more every year, will, in five or six years, so bind the surface of the ground, that the colts foot will not be able to pierce through it, and will therefore die for want of air. He ploughed up broad clover in the beginning of July, and turned up the roots of colt's-foot, in which he observed, between earth and air, many little buds, shot forth, of the bigness of the mid-summer buds in fruit-trees, probably to be the leaves or flowers of the next year; and at the depth of five, six, and even seven inches, he remarked here and there a shoot, of a callous body, like the root itself, from one to four inches long; perhaps destined to be future roots: he experienced that a winter's fallow will not destroy these roots, and that they cannot resist the effect of summer fallows, in which they are turned up, and exposed dry to the sun. It is therefore necessary to pick them as clean as possible, and burn them: for it is not to be supposed, that all the roots which are turned up in a summer fallow will wither of themselves: on the contrary, such of the buds at the joints of these as are buried under ground, will shoot out again if much rain falls, or the season be wet.

COMB, a measure of corn, consisting of four Winchester bushels; but in the fen country the comb generally consists of four bushels, and each bushel of eight gallons and a quart.

COMMON, an open piece of ground used equally by many persons.

The marquis of Turbilli has treated the subject of breaking up commons and waste grounds in so masterly a manner, that it will be necessary to give the substance of what he has advanced on this interesting subject, nearly in his own words.

" Upon the death of my father, says the marquis, which happened in the year 1737, I inherited the lands of Anjou, of which I am now going to speak. They lie contiguous, and form a pretty considerable extent.

" Hills and vales render the country uneven in many places; though, in others, there are spacious plains, with several brooks, and a small river. The soil is of three kinds, bad, middling, and good; but this last is least frequent. Most of the lands, being of a middling quality, are fertilized only by dint of care and manure: wheat grows on one spot, meslin on another, rye on a third; and sometimes it is necessary to sow these three different sorts of grain in the same field; so much does the soil vary: but, in general, we sow more ground with rye, than with any other corn. Buck-wheat, barley, oats, hemp, flax, and other equally useful productions are likewise cultivated in these parts. The vine prospers here very well, especially on the sunny side of banks and higher grounds: our wine, both red and white, is good; our fruit trees thrive well; and so does the white mulberry, of which I made large plantations some years ago. The oak, the elm, the beech, and other forest trees, grow extremely well in these lands. Such is the soil of this district: the climate is mild and temperate, as is the rest of Anjou.

"Three sides of this estate border upon immense tracts of uncultivated heaths, which spread through the greatest part of the province, and belong, some of them to the king, and others to different lords, ecclesiastical and temporal. However, the situation of my house, and of the chief village, is advantageous, being nearly in the center of the whole, and within about six miles of three pretty towns.

"Such was my estate when I took possession of it: not a quarter part of the land was cultivated, and even that very badly: the rest was either abandoned by the husbandmen, or had not been cultivated at all. Most of the meadows along the brooks and rivulets were become marshes, productive of scarce any thing but rushes. The vineyards were ruined, and the woods destroyed. A third part of the farms belonging to the principal parish where my seat is, were un-tenanted, for want of farmers to rent them. The inhabitants of this place were very poor, and did not, in general, raise corn enough of any kind to subsist them half the year: nay, such was their indolence, that they chose rather to stroll about and beg during the other half, than be at the pains of bestowing proper culture upon their land, which, with that culture, would have maintained them decently.

"This deplorable condition of my estate, which I have here represented fairly, without exaggerating any one particular, determined me, early in life, to read attentively all the most approved writers upon agriculture, and to observe carefully every improvement I met with in my travels. Even the campaigns in which I served did not interrupt these inquiries; for agriculture and arms never were by any means incompatible. Under these circumstances, I resolved to execute upon my own property, designs which my knowledge of the place, concern for the unhappy situation of its inhabitants, and regret to see what small returns were made by so large an extent of ground, naturally suggested.

"I plainly foresaw that this undertaking must be a work of time; neither my fortune, nor the number of hands I could procure in the country, allowing me to go beyond the clearing and improving of a certain space every year. Some gentlemen of knowledge, judgment, and public spirit, to whom I communicated my thoughts, approved of them, commended my design, and exhorted me strongly to carry it into execution; representing, besides the advantages which would necessarily accrue to me, the general benefit which such an example might be of to my country, filled, as it is, with numerous tracts of uncultivated land. This last reflection animated me more and more.

"My first care was, to endeavour to extirpate the spirit of indolence, and consequent love of begging, which prevailed among my peasants in general. To this end, I gave public notice of my intended improvements, with a declaration, that I would constantly employ every man, woman, or child above eight years of age, who might not have business of their own to do, on condition of their leaving off begging. At the same time I ordered an account to be taken of such as were not able to work. These I afterwards examined more particularly myself, and found among them several who, though they were not fit for hard labour, were capable of doing many useful things, in which I accordingly employed them. By this means, my list of really helpless people was reduced to a small number, which I provided for, till their relations should be able to keep them by means of what they earned from me. A few, and only a few, of these poor objects, who either had no relations, or such as in truth could not help them, became a dead charge: though this soon lessened, and is now inconsiderable.

"An innumerable multitude of rabbits infested my land. Against these I declared open war; being determined absolutely to destroy them. This has already been several years a-doing, and is not yet entirely completed. Some of them still remain, sheltered in their burrows at the foot of rising grounds, and others make incursions from the neighbouring woods and warrens. However, they do me no great mischief now; and even then I drove them from the place where I wanted to work.

"In the month of June 1737, I begun my improvements with clearing some of the land near my house. This ground was so poor that no farmer would even attempt to make any thing of it, served only to feed a few stinted cows, and was over-run with briars, thistles, and broom, which, being cut up, and laid in heaps, from space to space, were burnt upon the spot, and yielded a considerable quantity of ashes. These were then spread, and immediately turned in by a single plowing, lest their virtue should exhale. During the summer, this land was ploughed several times, different ways, in order to loosen it, and endeavour to destroy the weeds. I had bought for this purpose oxen, which are generally used for ploughing in Anjou; but my horses helped them, especially for harrowing. Here my poor peasants, men, women, and children, were employed to break the clods and pick off the stones; and as I had more dung than my arable lands required, I ordered about half the quantity that is generally used in other places, to be laid upon this ground, which was afterwards sowed at the usual time. This first trial succeeded, and the crop was very good; though most of my neighbours were of opinion that all my labour would be lost.

"In 1738, I undertook another piece of ground, adjoining to the former, and of the same kind. I began in March, proceeded as before, dunged it, and had equal success. The second crop of the former spot was still more plentiful. This summer I gave a thorough fallow to ten acres which had long been under corn, and sowed part of them with hemp and flax, for a purpose which will be mentioned hereafter. I likewise recruited my vineyard, and drained my meadows. Numbers of day-labourers were employed in cleansing the rivulet and brooks which run through them. In the winter of this year an accident happened, which had like to have overset my whole undertaking. The oxen which I used for ploughing, and which were grown lean, it was supposed through labour and fatigue, were on a sudden covered with vermin, which eat into their flesh: several remedies were applied, but in vain, the vermin re-appearing in a few days. We knew not to what cause to ascribe this disorder, which was destroying animals without whose assistance I could not proceed: besides which, the loss would, in itself, have been considerable. They had hitherto been fed with hay only; though the custom of the country was to mix it with an equal quantity of wheat-straw. As I had not yet a sufficiency of this last, I bought some, gave it to them mixed with hay, and allowed them oats from time to time when they had been hard worked. This mended them a little: but they did not recover entirely, or get rid of their vermin, till they fed on green grass, and lay out of doors.

"I begun this year to make new roads and causeys a-cross my meadows, marshes, and rising grounds, for the easier conveyance to and from my fields; the old ways being often impassable in many places. This has been a very long and expensive work; nor it is yet quite finished. I also bought at this time a number of sheep, which have since increased considerably: for, notwithstanding the great extent of this uncultivated land, where many of them might easily have been fed, none were ever kept upon it before. The people of the country thought they could not thrive there, on account of the marshes, and of a plant called white root, very prejudicial to them, found in several parts of the lay-grounds and commons. Most of these weeds was pulled up at a small expence; and the sheep, who are fond of this herb, eat up the rest, which was so little that it could not do them much hurt, though some of them were sick with it. The constant feeding of the sheep, and their dung, afterwards completed the destruction of this noxious plant, and brought up good grass in its stead. This shews how farmers may often get rid of any such bad weed.

"In 1739 I took the next contiguous land, going round my mansion: a method which I have always followed; so that my improvements have been, from year to year, more and more distant from my place of residence. The soil I now fell upon was tough, strong, and only thin grass grew upon it, with here and there a few brambles and other wild productions, which were soon cut up. This ground was broken up only with the plough: some dung was laid upon it, and I sowed it directly with winter oats

oats, which succeeded very well. My improvements of the two last years yielded plentiful crops, not only of corn, but also of hemp and flax. These last were dressed, and given to the wom n and girls to spin; paying them different prices, according to the fineness of the thread. They applied themselves to their work, and by degrees became perfect in it. By this means I accomplished my design of finding employment for these women and girls all the year round, and afforded them the means of procuring an honest livelihood, as well as to those whom age or infirmities rendered incapable of working abroad.

"The business ofthe field was always preferred in the seasons proper for it, and when the weather permitted; keeping in my eye Cato's advice, never to work within doors, while there is any thing to be done without, nor to do that in fair weather, which may be done in wet. I have continued this spinning ever since; and have allotted for the growth of hemp and flax particular spots, which I have inclosed with hedges and ditches, and kept in good heart and fine tilth. They have yielded plentiful annual crops without being rested; only dunging them every other year; for hemp does not impoverish the ground when it is properly cultivated. My vines, meadows, and ways were not neglected.

"In the beginning of this winter I gave my oxen hay mixed with an equal quantity of rye-straw, not having wheat-straw enough to answer that purpose. This succeeded to my wish. My oxen continued in perfect health, free from the vermin I mentioned before, and in better plight than those in the neighbourhood, which were fed with hay and wheat-straw. I have continued to give them this food as long as they lie within doors, and find it answer extremely well. During this time they have no corn, even though they work; and I do not find that this suppressing of their otherwise usual allowance of oats, renders them at all less hearty and vigorous. This quality of the rye-straw may be of great advantage in countries where oxen are used for ploughing.

"In the year 1740, I was obliged to make a considerable addition to my number of servants, and stock of cattle of all sorts, in proportion to the increased extent of my improvements. It may perhaps be thought, that so many servants would eat me out of house and home. This I had guarded against from the beginning. All those employed in my husbandry lived by themselves, in some of the out-houses, where they had their own kitchen, and a certain stated allowance, suited to their usual manner of life; so that they had no sort of connection with the others, whose more immediate business it was to attend me.

"The land which I improved this year was covered with heath, broom, and furze, which had grown very thick and high. In the spring, when the weather was dry, I set fire to this surface, after taking due precautions to hinder the flames from spreading too far. The whole burnt very well, and I was in hopes of being able to plough up this ground without paring off the turf, as I had done with my other land the year before. This would have been a considerable saving; especially as the ashes were ready spread. But I should have considered that different lands require different treatment. Ploughs, stronger than usual, were made on purpose for this work; but the roots of the furze and broom, which had resisted the fire, broke them; and though I doubled the number of my cattle for draught, several of the oxen were ruined by this hard work, in which I persisted with too much obstinacy. In vain did I plough it over and over, and break every clod both before and after sowing it; the broom and furze were not destroyed, but made new shoots every where: the land continued unkindly and sour, and the oats which I sowed in it yielded scarce any crop; in short, repeated ploughings and dunging were necessary during three years, before it could be brought to a good tilth, or those noxious plants be quite extirpated. I came badly off in this experiment: but my former improvements, which I had continued to manure and sow, luckily produced an abundant crop: that of the last year yielded a good quantity of wheat, which kept up my establishment, though it did not compensate for the loss I now sustained. However, this disappointment did not discourage me. It raised the laugh of the whole country at my expence; especially of those who had foretold from the beginning, that I should not succeed. I gave them the hearing, and only resolved not to fall a second time into the same error.

"This year I established a nursery of fruit-trees, and also of forest trees from other countries. This nursery, which succeeded very well, was of great advantage to me afterwards, to fill up the different plantations which I made as my improvements extended. I likewise repaired my woods, which had formerly been destroyed by cattle and deer. I surrounded them with ditches planted with hedges, in order to bring them into regular yearly cuttings; to which end I grubbed up such trees as were stinted in their growth, and filled every empty space, either with young plants, or the seeds of others, according to the nature of the ground. By continuing to do this every year, my woods are now in excellent order, and afford regular cuttings, at the small expence of keeping the fences in repair.

"In 1741, I had the same kind of land to deal with as the year before; but took care not to commit the same fault. Each day's cutting of the heath, broom, &c. was burnt, with proper precautions, as the workmen advanced, and the whole surface was dug by hand as it was cleared. By this means, the ashes of these plants preserved their fertilizing quality, and their roots were pulled up. Women and children shook the earth from off these roots, and turned them, whilst they were drying in the hot weather. These were also laid in heaps from space to space, and burnt upon the spot, where they yielded some ashes, which were spread, and immediately buried with one turn of the plough.

"During the summer, this ground was ploughed several times; each time in a direction different from the former. My cattle were but little fatigued with this work; the heath, broom, &c. was almost entirely destroyed, and the sourness of the land was in a great measure cured. I had then begun to make composts, which were mixed with the dung of the stall and stable, and proved of singular benefit. With their help, I was enabled to manure my newly broken up land sufficiently; that is to say, to lay upon it half the quantity that is generally used of dung for the common run of lands. I sowed this piece with rye, which yielded a plentiful crop. The crops from my former improvements, which I continued to sow without resting them, were likewise very good this year, excepting that of the last, which was also under rye, and yielded but a middling produce. My vineyards were now brought into as good order as any in the province; and I continued draining my meadows, and making roads and causeys.

"The war then calling me into Bohemia and Bavaria, I foresaw that I should be absent some time, and consequently not able to spend part of the year in the country, as I had used to do; to give directions to my people, and see my orders executed. Under these circumstances, that my improvements might not stop, I gave the direction of the whole to an intelligent servant, who had lived with me a long while, and was married to an excellent housewife: and, to interest him the more in the future success of the undertaking, I agreed to allow him half of the profits of every kind; subjecting him to this only restriction, that he should not impoverish the ground by too many crops. In this state things went on till the end of the year 1748.

"In the mean time new pieces of land were broken up every year; but not so extensive as the former; the expence of my campaigns not permitting me to lay out upon them so much money as before. I even streightened myself, not to interrupt the progress of my improvements: which, in general, succeeded very well. I also revived an old method of breaking up land, by cutting off the surface with a paring mattock, and then burning it. *See the article* BURN-BAKING.

"During the whole of this time, I was but two years together without visiting my estate, where my presence was then very necessary. In all the other years, I gladly accepted the leave which was given me to see how my works went on; though I sometimes did not stay above a fortnight among them. However, this was enough to give an eye to every thing that was doing; which is of great consequence in undertakings of this kind.

"Peace being restored, I resumed the personal guidance of my affairs in the beginning of the year 1749, and placed my old servant in a farm which I had to let, where his profits sat him down at his ease. Though he was extremely faithful, and my improvements were carried on very well, yet I found that, for want of due care and attention at certain times, the crops were not equal to what they had been under my immediate direction: a circumstance which plainly shews, that a work like this never thrives so well as in the hands of the owner himself.

"I now resolved to pursue my improvements as before the war, that is to say, to break up larger tracts of ground every year, than had been done of late. Most of my yet uncultivated lands were, and had been from time immemorial, thick covered with high broom, heath, fern, &c. and experience had taught me that these were not to be broken up with the plough alone.

"Of all the methods which I tried, none seemed to me, as I said before, so good as the paring-mattock and burning. I therefore fixed upon this, and, in consequence, sent for the workmen I had formerly employed in trials of this kind: but their number not sufficing for the extent of ground which I purposed to break up this year, I sent for others from a distance, and was weak enough to let these last persuade me to contract with them at a set price, for paring the whole surface. I agreed to give them even more than they ought to have had for doing the work ever so well; for I was not yet thoroughly acquainted with the nature of this business. They began it in March; and, to earn their money the more easily, or rather to rob me, only skimmed off the mere surface, without hardly touching the roots of the plants, which they should have cut up. When this work was done, as they called it, for the burning part did not belong to them, they immediately came to me, and asked for their money, which I simply gave them, not suspecting the cheat, but only thinking they had earned it very soon. When the turf of their cutting was dry, I ordered it to be laid in heaps, and burnt. The small quantity of ashes which it yielded, made me suspect the roguery: but when I found that the roots in the earth broke some of my ploughs, in cutting only a single furrow to cover the seed, and that there was no clearing it of clods, I was thoroughly convinced that I had been the dupe of these people, and that this paring would be of little service. The wheat sowed in this ground rose indeed pretty well, and looked tolerably during part of the winter; but not being able afterwards to strike through the crust formed by the remaining matted roots of the plants, most of it died, and the little that remained scarcely returned the seed: nor could this land be recovered till the next year, even by ploughing, breaking the clods, and dunging.

"The bad success of this experiment, upon which a great deal of money had been thrown away, tried my patience, but did not discourage me. My neighbours began anew to exclaim against my projects, as they called them; and numbers of those people who are determined at all events to oppose every novelty, be it right or wrong, were pleased to vent their sarcasms at my expence. I let them talk on. The roguery of the people who had last pared my ground did not hinder me from still thinking that this was the best way of breaking up new land, especially heaths; and the event has shewed that I was right. This check, which was the last I received, made me resolve to take my measures better for the future.

"The rest of my improvement yielded very good crops this year, during which I continued to mend my roads and meadows. These long winded works, for which only a certain space of time, and a certain sum of money, could be allotted every year, have been continued ever since, and indeed are not yet finished. I likewise bought this year several hives of bees; though I had some before. These useful creatures have multiplied exceedingly; especially in a little garden, where my chief apiary is, situated between meadows and heaths, of the flowers of which they are remarkably fond. Though these industrious insects thrive perfectly all over the country I am speaking of, yet the inhabitants of these parts not only have not a tenth of the number they might keep, but ignorantly follow the old barbarous custom of destroying the bees, when they want their honey, instead of only taking part. *See the article* BEE.

"I did not agree by the piece for breaking up the land I intended to improve in the year 1750, lest I should should be again deceived; but hired proper labourers by the day. They began their work in March, and finished it about the middle of June; cutting all the way deep enough to go under the crust, or net-work, formed by the roots beneath the surface; for I took particular care to see that this was done. When the turf thus pared, to the thickness of about four inches, was dried, piled up, and burnt in heaps from space to space upon this ground, it yielded a considerable quantity of ashes, which enriched the soil for a long time. Wheat was then sowed, and the plough easily turned up the furrow which covered the seed. Women and children easily broke the clods of this ground, which was thereby at once brought into good order; the roots of all the wild plants having been effectually cut through, and their seeds destroyed by the fire. My wheat, by this means un-incumbered with noxious productions of any kind, flourished well, and yielded an excellent crop; as also did such other parts of my land as were under corn. The success of this year revived my hopes. I now perfected my method of making artificial dung, which, as I have already observed, proved of infinite service; and, for manuring my more distant lands, I built upon them perpetual kilns, which have always supplied me with a sufficient quantity of ashes.

"This year I began to plant white mulberries, in order to feed silk-worms, and make the inhabitants acquainted with the management of them. I have since continued to make plantations of this kind every year, and find them answer perfectly well, especially in light soils. Several of them are an useful embellishment to proper parts of my improved lands, and I have alleys of them, which, though not suffered to run up high, form a very pleasing prospect.

"In 1751, I again succeeded perfectly well in my new method of paring and burning. All my cultivated lands now yielded very good crops; and that in particular which I had broke up last year, and since dunged properly, that is to say with half the quantity commonly used upon ground in general, produced more than any other equal space had yet done. From this time I continued to dung all my grounds which were broken up in this manner, every alternate year.

"My improvements were now become so extensive, that I was again obliged to increase the number of my servants, and of my ploughing cattle. The same thing happened more than once after this; but I shall not mention it any more. My cattle too, of different kinds, had multiplied so much, that I had no longer room for them in the old farm-yard, or buildings belonging to it; but plainly saw, that if my improvements were enlarged every year in the manner they had hitherto been, I should soon want more yards, and more buildings, to keep them in. I accordingly marked out proper places for this purpose, and drew plans for more spacious buildings.

"As the cattle in this country are small, I bought some of a larger size in Poictou (from whence we generally have our working beasts), and particularly a fine bull, to try if I could mend our breed, and thereby have of my own oxen strong enough for the plough; by which means I should save the expence of buying them elsewhere. I have not yet succeeded in this, so far as I could wish; probably because my pasture is not yet good enough. However, my bullocks, proceeding from this race, are much stronger and bigger than those I had before, though not large enough to be yoked to the beam, but only before or with others.

"The ground which I broke up in 1752, was pared and burnt in the same manner as that of last year, and produced an equally good crop. My other corn lands did the same; and I have since continued, and still continue, at the time of my writing this, to break up a parcel of heath, or other waste-ground, every year. The success has answered; so that my improved lands now yield me every kind of corn which this country produces. Turky-wheat, buck-wheat, and millet, have done extremely well in some parts of them; and so have flax, hemp, and other productions suited to the different qualities of the soil. In some places I have sowed, at different times, several sorts of trees, such as the oak, the beech, the chesnut, the fir, and others, all of which thrive wonderfully. I have likewise planted new vineyards, and find them answer perfectly well. All these trials convince me more and more, that the very best way of preparing land, is by burning it, as I have already said more than once. Those who were formerly the readiest to blame my undertakings, now see their error, and commend them.

" During this same year 1752, as well as in the course of the following, I drained several marshes, and improved other pieces of uncultivated ground, which, not being of the heath kind, or proper for paring, were broken up, and fitted for their respective crops, whether of corn, or of other plants, as will be more fully related in the second part of this account. I likewise sowed in these, as I had done before in other places, trees of every kind, some of which have succeeded, and others failed, according to the soil, and the manner of preparing it. This also will be more fully noticed hereafter, when I shall speak particularly of the different methods of raising trees from their seeds; and of the means of obviating the three chief difficulties, which must of necessity be guarded against or removed, before one can properly set about breaking up any sort of ground; these are, water, stones, and large roots; each of which I have found it necessary to get rid of, before I could rightly begin any of my improvements.

" I endeavoured this year to make some progress towards perfecting my instruments of husbandry; my new buildings went on according to the plan I had laid down, and were extended from time to time, in proportion as the products of my enlarged improvements, and the increase of my stock of cattle, required more room. I likewise tried to mend the breed of horses in this country, where their chief fault is, that they are too small.

" My sheep were also of too small a size, and yielded but little wool; which indeed is the case throughout all this province. I therefore got from Lower Poictou, in the year 1753, two fine rams, of the large kind, called Flemish; by which means my lambs are much stronger than any other in these parts. Several of the males are almost as large as their sires, and I have given some of them to my neighbours for rams. They have produced a bastard breed, which increases apace, and, though not so large as the Flemish, yields more and better wool than our former breed. I got rid of all my old sheep by degrees, and have now a well-sized flock: nor do I doubt but that if I could conveniently have purchased a whole flock of these large sheep, their breed might have been preserved without degenerating, and increased so as to supply the place of our present inferior species; for our uncultivated lands would feed a much greater number of sheep than we even attempt to raise.

" In 1755, I discovered lime-stone upon my own land. This proved a considerable saving; for I had hitherto been obliged to fetch my lime from a distance of near twelve miles. This stone, if properly searched for, may often be found in places where it it not suspected to lie. It is easily known, by putting a piece of it into the fire till it be calcined, and then dissolving it in water. This discovery, in consequence of which I built a proper kiln, has enabled me to carry on my buildings with less expence than before, and is of signal service in affording an excellent manure for my land.

" I began this year to give premiums for agriculture to the inhabitants of my estate. They were instituted the year before; and I had long used my best endeavours to inculcate a general love of industry, and a relish for improvements. My success had induced several others, both landlords and farmers, to follow my example, as well in amending their already cultivated lands, as in the breaking up of new grounds. I assisted them in their undertakings, giving instructions to some, lending seeds to others, and money and tools to such as were honest, and wanted them. The better to encourage them all, I had given rewards every year to those who distinguished themselves most, and allowed my tenants sixteen shillings for every acre of new ground broken up by them: a regulation which still subsists.

" To fix these people in the industrious disposition to which I at length had brought them, no method seemed to me more proper than to take them on the weak side of almost all mankind, interest and vanity. Accordingly, I notified in the month of January 1754, that I would distribute every year, beginning on the next ensuing festival of the Assumption, two premiums for agriculture; one, to the person who should raise the finest crop of wheat, and the other to him who should have the best field of rye. Each of these premiums consists in a sum of money, not inconsiderable for the country where it is given, and a silver medal, engraved for the purpose, of the size and value of a crown piece. These were, I believe, the first premiums ever proposed in France for this most useful object; though many have been given for much less interesting concerns. On one side of this medal is a sheaf of corn, with two sickles, a scythe, and a flail; over which are the words, *Premium for Agriculture*, and underneath the date. On the other side are my arms, with this inscription round them: *To excite to Industry the Inhabitants of*, &c. I would not put the goddess Ceres of the ancients, or any emblematical figure upon this medal, because, in the first place, the ignorant peasants would not have understood its meaning, and in the next, some of them might perhaps, hereafter, take it for the representation of a saint, and honour it as such; by which means, what I intend only for an object of utility, would become a source of superstition or idolatry.

" A candidate for these premiums must have at least two acres of land sowed with either wheat or rye: they are given to the finest crop as it stands, to avoid all tricks; and if two crops are deemed equally good, the worst soil has the preference. When both the crops and the soils are alike, the largest extent of ground is entitled to the reward. The inhabitants of the place, in general, meet at the parish church on the day appointed; and, after divine service, choose from among themselves five who are not candidates, to inspect all the fields of corn, and mark those which they think the finest. On the next Sunday or holiday, they make their report to the same assembly. If any one complains that his corn has been unjustly passed over un-noticed, proper persons are immediately sent, to examine whether the complaint be just. The assembly then appoint the same five as before, or others if they please, to go and inspect again, with the utmost care, the fields which they had marked, and to judge which two of them, one of wheat, and the other of rye, best deserve the premiums. On the next Sunday or holiday they declare their opinions to a general assembly of the parishioners, as before; and, if no objection be made by any of those whose corn has been marked, this assembly adjudges the premiums accordingly: but if any one of them appeals, other proper judges are immediately chosen, and directed to inspect the spot. On the next Sunday or holiday, till which the decision of the premiums is, in this case, of course put off; these last examiners make their report, and the matter is then determined. All the people thus sent by the assembly, are paid at my expence. In consequence of the decision of the inhabitants, the premiums are delivered publickly on the feast of the Assumption, after the service at church is over. Those who win them, wear the medal, for a year only, fastened with a green ribbon to a button-hole of their coat, and have, likewise for that time, a distinguished seat in the parish church. These marks of distinction cease at the end of the year, when others succeed to them; but the medal remains the property of the person to whom it was adjudged. He may dispose of it as he pleases: yet, though he is no longer allowed to wear it on the outside of his cloaths, there has not been a single instance of any one's selling his medal. They all keep it as a badge of honour.

"These rewards have been productive of fo much good, and have raifed fo extraordinary an emulation among my tenants, that I cannot but advife every gentleman to practife the fame method upon his eftate. I intend to inftitute fome others, for different productions; and as I am far from having a fufficient number of people to manage all my lands, if the whole of them was under culture, I have long thought of giving gratuities to fuch as fhall have a child within the firft year of their marriage, to continue this allowance to them fo long as they fhall have a child from year to year, and to allot a pretty confiderable fum for the family which fhall have moft children. Some may, perhaps, think thefe encouragements for propagating the human fpecies odd, and even fuperfluous: but they will be of a different opinion when informed, as they may be by the minifters of moft country parifhes, that many peafants are unwilling to get children, or at leaft do not choofe to have more than a very fmall number, when they might have a numerous offspring. If my abilities were equal to my will, I fhould already have formed all thefe ufeful eftablifhments. It is generally allowed, and experience has particularly demonftrated it upon my eftate, that an increafe of culture produces an increafe of inhabitants; and that wherever there is room for two, with the means of fubfifting them, a marriage will enfue: but at the fame time that this means of increafing population is encouraged by a more extenfive culture of the earth, I fee no reafon why proper methods fhould not be ufed to induce men likewife to concur in the fame laudable end.

"Ever fince the year 1756, I have continued all my undertakings, and with the fame fuccefs as before. Thofe who faw the condition of my eftate when I firft came to it, in the year 1737, now fcarcely know again a fingle fpot of it; fo much is the face of the country changed. My manfion-houfe, which was formerly furrounded with dreary waftes, vaft commons, and unbounded heaths, now ftands in the middle of well cultivated fields; my improvements are become confiderable both for extent and value; producing all forts of grain, and natural as well as artificial graffes. I have difperfed in them all kinds of fruit-trees, and divided them into fields of proper fizes, feparated by good ditches planted with quick hedges. Alleys of limes, poplars, white mulberries, chefnuts, and various other trees, befides being a confiderable embellifhment to the whole, afford convenient paffes from one field to another, yield food to cattle, and are fown from time to time. I turn every thing to profit; even my drieft foils. Many of my marfhes are drained, and yield good crops. All my meadows, by reafon of their great extent are not yet brought to the ftate in which I wifh to fee them; though a great part of them now produces excellent hay. I have mowed fome of them twice a year, and hope by and by to do the fame to others; for I intend to water them all, by making dams and fluices in the brooks and rivulet which pafs through them.

"My vineyards are in good order; and my woods, which are now in regular cuttings, thrive perfectly. Some of thefe, which I have raifed from the feed, have grown fo prodigioufly, that a ftranger would think them much older than they really are. I have made fome large refervoirs of water, and feveral ponds, intirely new, befides repairing the old ones. All thefe have fucceeded, and yield good fifh. A quarry of mill-ftones, formerly abandoned, now turns to good account, and I have difcovered feveral quarries of free-ftone.

"I have been obliged to make feveral bridges over the brooks and rivulet which divide my meadows and marfhy grounds, and have carried my roads as far as my improvements extend. Some of thefe roads lie over hills, which could not be avoided; though others have been cut through, at a great expence. Moft of my out-houfes, which are pretty fpacious for all my cattle and all the produce of my land, with proper buildings for poultry, barns, granaries, &c. are finifhed; and I have built farm-houfes with the ftones which it was neceffary to take off the lands, in different parts of my improvements, and fettled in them young men, who are now married, and have children. Though my barns are very large, and not few in number, I have the pleafure to find that they would not contain all my laft year's crop of corn: a fatisfaction which I hope to enjoy ftill more amply in the next and following years.

"Thus my eftate, which formerly yielded fcarce any thing, now affords every neceffary for food and raiment. When there, I can, truly fpeaking, keep a very good table, and be decently cloathed, with only the produce of my own improvements. I have no occafion to buy any thing, except falt, fugar, and fpices. My farmers have followed my example, fo far as their means, and the helps which I have given them, have permitted.

"Thefe improvements have, undoubtedly, coft me a great deal of money; but my income from them will foon be proportionably increafed: befides which, it is proper to obferve, that few lands will require fo great an expence to break them up, as mine have done; owing to the uncommon ftubbornnefs, inequality, and unkindlinefs of the foil: nor will it often be neceffary to cut through hills in order to make roads, to lay caufeys over quaking bogs, or to erect fo many new buildings: though, even if all thefe difficulties fhould occur, I would ftill advife gentlemen to undertake the improvement. If they follow the directions here given, and profit by my errors, fo as not to commit the like, I can affure them of fuccefs, at a much lefs expence than it has coft me, who have thoroughly paid for my apprenticefhip. I can alfo promife, that they will lay their money out at better intereft, and on better fecurity, in this, than in any other way: befides which, they will have the heart-felt fatisfaction of contributing to the profperity of their country, to the increafe of population, and to the enriching of others, at the fame time that they enrich themfelves.

"I have already faid, that when I began my improvements, two and twenty years ago, a third part of the farms in my parifh were untenanted, for want of farmers who would rent them; that moft of the inhabitants of my eftate were very poor, and did not, in general, reap corn enough to fupport them half the year; that they were grown fo indolent, that rather than cultivate their ground, which would have afforded them a maintenance, they chofe to beg, like vagrants, in the neighbouring diftricts. Now, their fituation is very different, and they are no longer in that deplorable condition. They are become induftrious, live by their labour, and beg no longer: they would even be at their eafe (a happinefs which I fhall do my utmoft to procure them), were it not for obftacles beyond my power to remedy. The parifh now reaps more corn than it confumes; fo that the farmer here is enabled to fell at the very markets where he ufed to buy. All my farms are tenanted; not a houfe on my eftate is empty, and if I build a new one, it is immediately filled; in fhort, the number of inhabitants in this parifh, for I have an exact lift of all of them, is double what it was in 1737. Such is the hiftory of my improvements, and fuch are the effects with which they have been attended." *Memoire fur les Defrichemens, par.* II.

COMPOST, an ufeful fort of manure, confifting of earth, dung, lime, clay, &c. according to the nature of the foil, well mixed and rotted together, till it forms one united mafs. *See* DUNG-HILLS.

CONE-WHEAT, a fpecies of wheat, called in fome parts of Somerfetfhire, blue-ball. Some of the ears of this wheat have awns, and others none. *See* Plate IV. Fig. 5.

CONIFEROUS, an epithet applied to fuch trees as bear acones, as the fir, pine, cedar, &c.

CONSERVATORY, a place where fruits, &c. are preferved. It is fometimes ufed to fignify a green-houfe. *See the article* GREEN-HOUSE.

CONSOUND, the fame with bugle. *See the article* BUGLE.

CONSUMPTION, a difeafe incident to horfes, confifting in a wafte of mufcular flefh, attended with a flow fever.

When a confumption proceeds from a defect in a horfe's lungs, or any principal bowel, the eyes look dull; the ears and feet are moftly hot; he coughs fharply by fits; fneezes much, and frequently groans with it; his flanks have a quick motion; he gleets often at the nofe, and fometimes throws out a yellowifh curdled matter,

matter, and he has little appetite to hay, but will eat corn, after which he generally grows hot.

As to the cure, one of the principal things is bleeding in ſmall quantities, a pint, or pint and half, for ſome horſes is ſufficient, which ſhould be repeated as often as the breath is more than ordinarily oppreſſed. Pectorals may be given to palliate preſent emergent ſymptoms; but as diſſections have diſcovered both the glands of the lungs, and meſentery to be ſwelled, and often indurated, the whole ſtreſs lies on mercurial purges, and the following ponderous alteratives, given intermediately.

Take native cinnabar, or cinnabar of antimony, one pound, powdered very fine, and add the ſame quantity of gum-guaiacum and nitre: give the horſe an ounce of this powder, twice a day, wetting his feeds.

The ſpring graſs is often extremely ſerviceable, but the ſalt-marſhes are to be preferred, and even to be more depended on than medicines; for great alterations are thereby made in the blood and juices, and no ſmall benefit ariſes from open air, and proper exerciſe.

But it may be worth obſerving, that a horſe frequently relapſes after appearances of amendment; when a yellowiſh gleet, or curdled matter, runs from his noſe, and he grows emaciated, is much addicted to ſweat, heaves much with a reduplicated motion, and has a ſhort rattling cough; under theſe circumſtances there can be little hopes of his recovery, or any future ſervice from him, conſequently, to ſave further expences, the beſt way would be to diſpatch him as an incurable. *Bartlet's Farriery, p.* 76.

CONVOLVULUS, the ſame with bind-weed. *See the article* BIND-WEED.

COOM, the ſoot that gathers over the mouth of an oven; alſo a compoſition of tar and greaſe, with which the axle-trees and boxes of the wheels of carriages are daubed or ſmeared over, in order to leſſen the friction.

COOP, a tumbrel, or cart encloſed with boards, to carry dung, ſand, grains, &c. which would otherwiſe fall out.

COOP, likewiſe ſignifies a pen, or encloſed place, where lambs, poultry, &c. are ſhut up, in order to be fed.

COPPICE, low woods, cut at ſtated times for poles, fuel, &c.

" If you are to plant a coppice, ſays the ingenious Mr. Liſle, it is a good way to ſet your plants in trenches, as one raiſes quickſet hedges, and not to ſow ſeeds, for they are tedious in coming forward, and will tire one's patience in weeding them. I would not ſet above four plants in twelve feet ſquare, and at regular diſtances, ſo that the benefit of ploughing might not be loſt; and then at ſix or ſeven year's growth I would plaſh, by laying the whole ſhoot, end and all, under the earth in the trenches, which would not therefore be choaked, but ſhoot forth innumerable iſſues: this, by great experience, oak, aſh, hazle, and withy, will do.

" In our parks we never ſet leſs than an hundred plants in a double chafed lugg; and, if the earth turned up ſuch rubbiſh and ſtony ſtuff that the edge of earth on which they are to plant, is too narrow for a double chaſe, then they always ſet eighty plants on a ſingle chaſe in a lugg.

" I obſerve the ſedgy graſs comes not up in felled coppices the firſt ſummer; conſequently the young ſhoots have a year's ſtart of that graſs; the next ſummer the ſedgy graſs comes up, and grows ancle high, equal with the two year's ſhoots: but what harm can it then do to the wood? The third year the ſedgy graſs dies, and you ſee no more of it. I ſpeak this, in anſwer to the countryman's objection, who pleads for putting ſome ſort of cattle into coppices to keep down the ſedge, which he pretends otherwiſe will choak and damage the plants. I have experienced this to my coſt.

" It was May the ſixth, in the year 1701, that I bought ſome yearlings; and I aſked the farmer, if I might not put them in the coppice till midſummer; the farmer ſaid, not yet, by any means, for fear they ſhould be oakered, that is, leſt they ſhould bite off the oak-bud before it came into leaf, which might bake in their maws and kill them; but after the oak-bud was in leaf, it would be ſafe enough. The higher coppices are fit for yearlings, and the coppices of the laſt year's growth for hog-ſheep in winter. My ſhepherd ſaid, what the farmer obſerved as to the oak-bud was true; but he thought that the year was ſo backward, that they were not yet come out, and ſo there could be no danger at preſent. Farmer Elton ſaid, his father had loſt abundance of yearlings by the oak-bud, by putting them into the coppices while that was out. I have ſince experienced the ſame, and I have remarked the ſame.

" It is a common ſaying, that calves will not crop in woods: but I put ſix calves into my woods, in November, which very much cropt the yearling-ſhoots. All huſbandmen I told of it very much wondered at it; but the reaſon to me was clear, viz. On firſt putting them in there came three or four days hard froſt, with a ſhallow ſnow, and a rime that laid on the bennetty graſs, ſo that they could not come at the ground, but only met with brier leaves, of which, though I had plenty, they were but thin diet to depend on altogether; yet together with other pickings would have been a noble maintenance for them, if they could have come at the rowet: this ſtreightneſs of fodder brought them to the neceſſity of cropping the young ſhoots, which they afterwards continued to do, having got the habit of it, and finding, when the weather came ſevere, the ſhoots to be toothſome, though the rowet in the coppices would have been ſufficient.

" For a general rule, newly weaned calves are leſs hurtful to newly cut ſpring-woods than any other cattle, eſpecially if there be abundance of graſs; and ſome ſay, colts of a year old will do no harm: but the calves muſt be permitted to ſtay a while longer, and ſurely the later you admit beaſts to graze the better.

" Letting coppice-wood grow to ſixteen or ſeventeen years growth is of great ſervice to young heirs, becauſe by ſo many years growth their backs are caſe-hardened, and able to withſtand the cold, when the coppice is cut, and they muſt ſtand naked, whereas, when coppices are cut at ten and eleven years growth, the barks of the young heirs are ſo tender, that they are ſtarved with cold air and winds. Ivy itſelf, ſays Evelyn, the deſtruction of many a fair tree, if very old, and taken off, does frequently kill the trees by a too ſudden expoſure to the unaccuſtomed cold.

" When coppice-wood is of fourteen or fifteen years growth, it will yield a better price in proportion than young wood, becauſe it will be applicable to more uſes, and particularly in the cooper's buſineſs; for he will uſe the withy and ſome of the aſh for hoops and wine hogſheads; another part of the aſh may ſerve for prong-ſtaves, rake-ſtaves, and rath-pins for waggons, and the reſt may be parcelled out for hurdle and flake-rods.

" Oaken ſtems of fourteen years growth are, in my woods, which in a great meaſure conſiſt of them, as high as the aſh or withy, and meaſure more in the diameter; for oaken ſtems are ſtronger at root, and will hold growing longer than aſh, withy, or hazle. When hazle grows ſpriggy in the body, and ſhoots forth from the ſides of the back, it is a ſign that it has given out, and done growing at the top.

" Coppice-wood, in hedging and hurdling, wears much better and longer, if cut between Michaelmas and Chriſtmas, but ſells beſt in faggots, if cut between Chriſtmas and Lady-day, becauſe it ſhrinks leſs, and is much ſwelled, and looks beſt to the buyer. The method at Crux-Eaſton, and the hill-country adjacent, is only to oblige the buyers to rid the coppice by Midſummer; they think the coppices are not harmed, if rid by the time the Midſummer-ſhoots ſpring up; but they had not rid this year, 1697, by the latter end of July.

" It is obſerved, that coppice-wood, cut for hedging at the latter end of winter, will not endure ſo long by a year as that which is cut at the beginning of winter: which, as I believe, may not only be, becauſe the wood late cut, is cut after the ſap is riſen, or attenuated by the ſun, but alſo oftentimes becauſe it is not cut long enough before ſuch rarefaction is made; for, if a tree, or a cyon cut to be grafted, as Quintery affirms, will endure many weeks of the winter out of the ground, or without being grafted, and, when ſpring ſhall come, it will by virtue of the ſap inherent in it, when attenuated, put

put forth buds for some time, till it dries away; so it follows, that the sap inherent always in the stem of the wood, if not cut so early as to have long time to dry, may be put into motion at spring, so as to effect the abovementioned inconvenience; therefore I hold hedging-wood and fire-faggots should be cut in October.

"It is a common practice of husbandmen to fell their hedge-rows, and small brakes within the grounds, those years they sow the grounds with wheat; but such persons ought well to consider, first, whether such land, after the wheat is off, will not bear a rowet too long for sheep to eat, and, if so, great cattle must be put in to eat up the long rowet, and the sooner the better for their tooth; and then attendance must be given by a cow-keeper by day, before the harvest is in, and consequently the wages dearer, and when you may have many other offices to employ such a person in: therefore, in such case, my advice is to let the hedge rows stand till after the wheat crop be got in, when great cattle may be suffered to feed down the rowet without prejudice to the hedge-rows, and at that time of the year such grass is wanted by night; and, during the future three crops, it is to be supposed the rowet will not be so large, but sheep may overcome it, nor will they very much prejudice the young wood." *Lisle's Husbandry, vol.* II. *p.* 245.

In raising coppices, great care ought to be taken that the wood they are to be composed of be such as is proper for the soil you raise them on, and that it be proper for the uses you design to sell it for, which you must be regulated in by the vent you have; and let the profits resulting from your under-wood regulate the thickness of your standards; for in proportion as they are thicker or thinner, they will do more or less injury to your under-wood. You should likewise consider at what growth you can sell your under-wood; only remember that the older and taller your under-wood is, the better it is both for fuel, and for what standards you leave, because they will be the taller and straiter, by being forced up by the wood that grows about them; though a deep soil contributes much to their spring. It is also necessary, about the time of your felling, to lay out your severals falls, that you may have an annual succession, to yield a yearly profit. But though the seldom felling of coppices yields the more and better wood; yet the frequent cutting of it makes it thicken, and gives room for the seedlings to come up. If many trees grow in the coppice that is to be cut down, fell both them and the underwood together, cutting off the stubs as near the ground as convenient, and those of the underwood a-slope and smooth, and not above half a foot from the ground; and stock up the roots of the timber-trees, if they send forth no shoots, in order to make room for seedlings and young roots to grow.

The under-wood may be cut from the beginning of October to the latter end of February; but February is the best month to cut wood in, where you have but a small quantity to fell, that you may do it before the spring comes on too much: take great care to prevent the carters from brushing against the young standards, and let all your wood be carried out by Midsummer, and made up by the end of April at the farthest; for if the rows and brush lie longer unbound or unmade up, it will spoil many of the young shoots and seedlings. If the winter before you fell, you enclose it so as to keep all cattle out of it, your care and trouble will be well recompensed.

Your elder underwood may be grazed about July, or in winter, but, for a general rule, newly weaned calves are the least prejudicial to new cut wood, where there is abundance of grass; and some fay colts of a year old; but then they must be drove out by the beginning of May at farthest. However, if nothing at all be suffered to come in, it will be better. In this every man's experience must direct him.

If your woods happen to be cropt by cattle, it will be better to cut them down, and they will then make fresh shoots; whereas what has been bit by the cattle, will be otherwise stunted for several years before it will take to its growth. *Mortimer's Husbandry, vol.* II. *pag.* 69.

CORD *of Wood*, a certain quantity of wood for fuel, properly stacked up; so called because it was formerly measured with a cord. The dimensions of a statute cord of wood are eight feet long, four feet high, and four feet broad.

CORE, a disorder incident to sheep, occasioned by worms in their liver, resembling a plaice, or flounder.

A sheep, if chiefly fed with hay, will live a year after being affected with this distemper, by which time he will have a water-bladder as large as an egg, under his throat; at the same time his eyes, mouth, and gums, will be white.

If any sheep in a flock core during the winter, it will be easily seen at shearing-time; for such sheep will be poorer than the rest; their wool also will run into threads, twisting together at the ends, and look somewhat like teats. The last particular is not however a certain sign of a sheep's being cored; for sometimes the wool of very sound sheep will be apt to run together into threads; and the finer the wool the more apt it is to twist together in that manner. There is no method of curing this distemper hitherto known. *Lisle's Husbandry, vol.* II. *pag.* 207.

CORIANDER, the name of a plant formerly much cultivated in England; but at present little of it is sown.

The seeds should be sown in autumn on rich land; and when the plants are come up, they should be hoed out to about four inches distance, every way, clearing them from weeds. By the above management, the plants will grow strong, and produce a greater quantity of good seeds. *Miller's Gard. Dict.*

CORN, a general name for grain that grows in ears, not in pods, as wheat, barley, &c.

If corn be lodged, it may be cut before it is quite ripe; and if blighted, it cannot be cut too soon. But if neither of these accidents happen, both wheat and barley should be suffered to stand till full ripe. The grain will also grow plumper by being left a while in the field after cutting, to take the dew; but the straw will be injured by it; nor must it by any means be laid up damp in the mow, lest it heat, and become what is called mow-burnt; and perhaps take fire. A great number of weeds will produce the same effect, if the corn be housed before their stalks are sufficiently withered.

A correspondent of the authors of the Museum Rusticum tells us, that in the year 1763, he had twenty acres of barley, which was rather weedy at harvest: on which account he was desirous of giving it as much field room as he could conveniently; but the weather promising to be very wet, he was obliged to cart his barley, which he put into the bay of a large barn.

Whilst this work was going forward, he was called away, and in his absence his son got a horse upon the mow to tread it; by which means, the weeds, not being thoroughly dry, caused the barley to heat to so violent a degree, that he was very apprehensive of its firing.

"My men, adds he, were in a violent hurry to get it out of the barn; but this I would by no means consent to. I however ordered one of them to get upon the mow with a cutting-knife, and cut in it a round hole like a well. He began the work; but in about five minutes, being almost overcome by the heat, I sent another to relieve him; and thus they worked spell and spell, till they got to the bottom.

"This round hole saved my barley, and perhaps my barn too; for it formed, as it were, a chimney or flue, to carry off the heat." *Museum Rusticum, vol.* III. *p.* 365.

For the method of preserving corn after it is threshed, *see the article* GRANARY. And for preserving it in the straw, *see* REEK.

CORN-CROWFOOT, a weed very common among the corn. It has an upright stalk; the leaves are of a pale green, and cut into long, narrow, acute segments. The flowers are much smaller and paler than the crowfoot of the pastures: but the seed-vessels are the most remarkable, being covered all over with prickles. *See* Plate V. fig. 33.

CORN-FLAG, a very troublesome weed, multiplying exceedingly by its roots. It has a round compressed tuberous root, which is of a yellowish colour, and covered with a brown furrowed skin, like that of the vernal crocus. From this root arises two flat sword-shaped leaves, which embrace each other at their baſe; and between theſe ariſes the flower-ſtalk, which grows near two feet high, having one or two narrow leaves embracing it like a ſheath. This ſtalk is terminated by five or ſix purple flowers, ſtanding above each other at ſome diſtance, and ranged on one ſide of the ſtalk; each of theſe has a ſheath, which covers the flower-bud, before it expands, but ſplits open lengthways when the flowers blow, and afterwards ſhrivels up to a dry ſkin, which remains about the ſeed-veſſel, till the ſeeds are ripe, which is in the beginning of Auguſt. The flowers come out in the beginning of May, or in June. Some of theſe flowers are white, and others fleſh-coloured.

Corn-flag is extremely difficult to root out, as every part of the root will grow. The beſt manner of extirpating it is that already mentioned under the article coltsfoot. See COLTSFOOT.

CORN-MARYGOLD, the name of a very troubleſome weed, of which there are two ſpecies, one common in corn-fields, and the other in moiſt paſtures. The leaves of the firſt ſort embrace the ſtalks, the upper being jagged, and the lower indented like a ſaw. The ſecond is, by C. Bauhine, called the greater wild daiſy, with a leafy ſtalk. It riſes with ſtalks near two feet high, garniſhed with oblong indented leaves, which embrace the ſtalks with their baſe. Each of theſe ſtalks is terminated by one white flower, ſhaped like that of the daiſy, but four times as large. It flowers in June. *See* Plate V. fig. 34.

The corn-marygold has a perennial woody root, which ſtriking deep requires a conſiderable quantity of food, and therefore muſt be a great enemy to the corn. Conſiderable pains muſt be taken before this weed can be extirpated, as it is highly probable, that, beſides multiplying by its roots, its ſeed will grow, if ploughed in, as that of the garden marygold will do when dug in. Deep and repeated hoeings are therefore neceſſary, before it runs to ſeed.

CORN-PARSLEY, the name of a low branching plant common among corn. The branches grow thick together, and are knotted and crooked. The flowers grow cloſe together after the manner of parſley, and are of a white colour inclining to yellow. The ſeeds are large in proportion to the plant; and are ſet about with little crooked briſtles; which makes them adhere to the ſtockings in great plenty, when the ſeeds are ripe; which is generally about harveſt. *See* Plate V. fig. 35.

CORN-WORM, the inſect lately obſerved in France to be ſo very deſtructive to corn. *See the article* BUTTERFLY.

CORNER-TEETH, the teeth which appear when a horſe is coming five years old. *See the article* AGE.

CORONET, the loweſt part of a horſe's paſtern, which runs round the coffin, and is diſtinguiſhed by the hair which joins and covers the upper part of the hoof.

COSH, the ſame with pods. *See the article* POD.

COSSART, or *Coſſet Lamb*, a lamb left by its dam's dying before it is capable of ſhifting for itſelf; or it is a lamb taken from a ewe that brings two, three, or four lambs at a yeaning, and conſequently is incapable of bringing them all up. The word is alſo applied to a colt, calf, &c.

In either of theſe caſes, if there be not another ewe at liberty to ſuckle it, it muſt be brought up by hand, or periſh. By an ewe at liberty is meant one that has, by ſome accident, loſt her lamb, and has milk enough to ſuckle a lamb yeaned by another.

COSTIVENESS, a complaint to which horſes are often ſubject; ſometimes occaſioned by violent and hard exerciſe, eſpecially in hot weather; and ſometimes by ſtanding long at hard meat, without graſs, or other cleanſing diet, and with very little exerciſe.

The cure for this complaint is eaſy, only by giving him an open diet for ſome time; and if any thing more is wanting, lenitive mild purges are the moſt likely to ſucceed. Such as Glauber's ſalts with lenitive electuary, four ounces of each, diſſolved in warm ale or water, and repeated every other day. This, with ſcalded bran given every day, will ſoon remove the complaint, and carry off the viſcid ſlime engendered in the guts, which is generally the cauſe of his coſtiveneſs.

But there is another kind of coſtiveneſs in horſes, which is much harder to be removed, viz. that which ſeems to be natural, or grown into a habit. We find ſome very good horſes liable to this diſorder; and, when it is of long continuance, they are apt to grow lean and emaciated, feel hot and dry, their hair ſtaring, and there is danger of ſome approaching ſickneſs.

This diſorder is not eaſily removed; nor is it often neceſſary to bring ſuch horſes into a contrary habit; for where this is natural, it may proceed from a more than ordinary ſtrength and rigidity in the ſmall fibres of the ſtomach and guts, which makes them digeſt their aliment well, and retain their excrements longer; and when ſuch a habit can be kept within any proper medium, the horſe will continue in ſtrength and vigour, without any inconvenience; and it is obſervable, that theſe horſes are, for the moſt part, able to endure great fatigue and labour. However, it is proper to give ſuch horſes, at all convenient times, an opening diet. For if this habit happens, by any accident, to grow into an habitual coſtiveneſs, ſo as to produce ill effects, as heat, dryneſs of the conſtitution, little ſcabby eruptions over the ſkin, and a rough coat, it will then be neceſſary to remove it in ſome degree, which cannot be done but by a continual uſe of emollients, joined by a looſe opening diet.

Purging is here alſo neceſſary, and ought by all means to be complied with; but purging in the common way with Barbadoes or other plantation aloes, ſeldom has any great effect longer than the purge is working; for when that is over, the ſame habit of coſtiveneſs generally returns as ſtrong as ever. Scalded bran, and the common opening diet, ſeldom makes any great alteration in theſe horſes. The aloetic purges will ſcarcely work, eſpecially if they are made ſtrong, for they then chiefly run off by urine, which does the creature little ſervice in this caſe. But after the common purges have failed, the following will ſucceed beyond expectation.

Take ſuccotrine aloes, ſix drams; ſpermaceti, half an ounce; fœnugreek-ſeeds in powder, two ounces: make the whole into two balls, with a ſufficient quantity of honey, or common treacle, and give them in a morning faſting.

Let the horſe have ſcalded barley inſtead of ſcalded bran, and the liquor of the barley for his drink, milk warm. This will work very gently, where ſtronger purges have little other effect upon coſtive horſes than to gripe and make them ſick. It ought to be repeated once in four days, and may be continued till he has taken ſix doſes. Let him have an ounce of fœnugreek-ſeeds once a day, in one of his maſhes, and when the purgation is over, continue the uſe of the fœnugreek; and ſometimes give linſeed in the ſame manner, either in his dry or moiſt feeds, until the horſe grows ſmooth and well coated, and his dung moiſt and in good order. *Gibſon's Farriery, vol.* II. *p.* 134.

COTYLEDONS, rinds, or huſks.

COUCH-GRASS, *quick-graſs*, *knot-graſs*, or *dog-graſs*, is one of the worſt of weeds among corn, and one of the moſt difficult to extirpate in arable land; every joint of its long creeping roots being capable of ſoon producing a new plant, after thoſe roots have been broken by the plough. The uſual way of deſtroying it, is by laying the land fallow in ſummer, and frequently harrowing it well over, to draw out the roots, every piece of which ſhould then be burnt, for the reaſon already mentioned. Where this is carefully done, the ground may be ſo well cleanſed in one ſummer, that the remaining roots will not do any great injury to the enſuing crop: but the beſt way is to ſow the land in which this weed prevails with ſuch plants as require the horſe-hoeing culture. The blade of this graſs is ſo rough, that cattle will not feed upon it when green.

COVERT, ſheltered, not open, not expoſed.

COUGH, a convulſive motion of the lungs, being an effort of nature to throw up ſome offending matter.

Horſes are very ſubject to coughs, which are ſometimes occaſioned by colds, and often by the injudicious treatment of an inflammation of the lungs; the conſequence of which is often ſettled habitual coughs, which frequently degenerate into aſthmas, and broken wind.

Nothing has more perplexed practitioners than the cure of settled coughs; the cause of which, perhaps, has been their want of attention to the different symptoms which distinguish one cough from another; for, without strict observance thereof, it is impossible to find out the true method of cure.

Thus, if a horse's cough is of long standing, attended with loss of appetite, wasting of flesh, and weakness, it denotes a consumption; and that the lungs are full of knotty, hard substances, called tubercles, which have often been discovered on dissection.

The following signs denote when the cough proceeds from phlegm, and slimy matter, that stuff up the vessels of the lungs.

The horse's flanks have a sudden quick motion; he breathes thick, but not with his nostrils open, like a horse in a fever, or that is broken-winded; his cough is sometimes dry and husky, sometimes moist, before which he wheezes, rattles in the throat, and sometimes throws out of his nose and mouth great gobs of white phlegm, especially after drinking, or when he begins or ends his exercise, which discharge commonly gives great relief. Some such horses wheeze and rattle to such a degree, and are so thick winded, that they can scarce move on, till they have been out some time in the air; though then they will perform beyond expectation.

These are properly asthmatic cases, and ought to be distinguished in their symptoms from that pursiveness and thick windedness we see in some horses, occasioned by too full, or foul feeding, want of due exercise, or their being taken up from winter's grass. But these two last cases are easily cured by proper diet and exercise; the one by lowering his keeping, and the other by increasing it.

The above asthmatic case proves often very obstinate; but, if it happens to a young horse, and the cough is not of long standing, it is greatly relieved, if not totally cured, by the following method.

If the horse is full of flesh, bleed him plentifully; if low in flesh, more sparingly; which may occasionally be repeated, on very great oppressions, and difficulty of breathing, in proportionate quantities.

As mercurial medicines are found remarkably useful in these cases, give a mercurial ball, with two drams of calomel, over night, and a common purge the next morning: or the following, which is much recommended by Mr. Gibson:

Take gum-galbanum, ammoniacum, and assa-fœtida, of each two drams; fine aloes, one ounce; saffron, one dram; oil of anniseeds, two drams; oil of amber, one dram; with honey enough to form into a ball.

They may be repeated at proper intervals, with the usual cautions. In the intermediate days, and for some time after, one of the following balls may be given every morning:

Take cinnabar of antimony, finely levigated, six ounces; gum-ammoniacum, galbanum, and assa-fœtida, of each two ounces; garlic, four ounces; saffron, half an ounce: make into a paste for balls, with a proper quantity of honey.

These balls are extremely well calculated for this purpose: but if they are thought too expensive, the cordial ball may be given, with an eighth part of powdered squills and Barbadoes tar: or equal quantities of the above, and cordial ball may be beat up together; and where they can be afforded, balsam of Peru, balsam of sulphur, and flower of Benjamin, would undoubtedly, added to the cordial ball, make it a more efficacious medicine, in cases of this sort, as thus:

Take of the pectoral or cordial ball, one pound; balsam of Peru, half an ounce; balsam of sulphur anisated, one ounce; flower of Benjamin, half an ounce: honey as much as is sufficient to form them into a paste: give the size of a pigeon's egg every morning.

Exercise in a free open air is very serviceable, and the diet should be moderate. Horses subject to any inward oppressions of the lungs, should never be suffered to have a belly full; that is, they should never be permitted so to distend their stomach with meat or water, as to press against the midriff; which of course would hinder respiration. Their hay should even be abridged, given in small quantities, and sprinkled with water; and their usual allowance, both of corn and water, should be divided into several portions: by such a regulation in diet, horses may be so recovered as to do great service; and in all disorders of the lungs, it is what should principally be attended to.

The following are the symptoms of a dry cough, or asthma.

The horse afflicted with this cough, eats heartily, hunts, and goes through his business with alacrity, appears well coated, and has all the signs of perfect health; yet he shall cough at particular times almost incessantly, without throwing up any thing, except that the violence of the cough will cause a little clear water to distil from his nose. Though this cough is not periodical, yet some of these horses cough most in a morning, after drinking.

This may properly be stiled a nervous asthma in a horse, as probably it chiefly affects the nerves in the membranous parts of the lungs and midriff; and is a case very doubtful at least, if not incurable: but when the horse is young, the following method may be successful:

Take away first a moderate quantity of blood; then give him two drams of calomel, mixed up with an ounce of diapente, for two nights; and the next morning a purging ball. Keep him well cloathed and littered, and feed him with scalded bran and warm water.

Once in eight or ten days this purge may be repeated, with one mercurial ball only, given over night.

The following balls may then be taken, one every day, about the size of a pullet's egg, the horse fasting two hours afterwards; and should be continued two months, or longer, to be of real service:

Take native cinnabar, or cinnabar of antimony, half a pound; gum-guaiacum, four ounces; myrrh, and gum-ammoniacum, of each two ounces; Venice soap, half a pound: the cinnabar must be finely levigated, as before observed, and the whole mixed up with honey, or oxymel squills.

The following also will be found a useful remedy in obstinate dry coughs:

Take gum-ammoniacum, squills, and Venice soap, of each four ounces; balsam of sulphur, with anniseeds, one ounce; beat up into a mass, and give as the former.

These mercurial and ponderous medicines are well adapted to open obstructions in the lungs, and prevent those little knots, or tubercles, which so frequently ulcerate, and lay the foundation of an incurable malady, or consumption; but the common pectorals alone will avail nothing in old stubborn coughs, their efficacy being lost in the long tour they have to make, before they come to the lungs; and indeed, were it otherwise, without they had such powerful openers joined with them, they would be of little consequence; for where there are expectations from medicines, such are chiefly to be relied on, which have a power of dissolving and attenuating the viscid humours, opening the small obstructed vessels, and promoting all the natural secretions.

Before we conclude this article, it may be necessary to observe here, that some young horses are subject to coughs on cutting their teeth, their eyes also are affected from the same cause. In these cases always bleed, and if the cough is obstinate, repeat it, and give warm mashes; which, in general, are alone sufficient to remove this complaint. But when the cough is an attendant on worms, as it often is in young horses, you must give such medicines as have a power to destroy those animals; particularly mercurial physic, at proper intervals, and intermediately half an ounce of Æthiop's mineral, mixed up with the cordial; or pectoral balls may be given every day. *See* WORMS. *Bartlet's Farriery, page* 51.

But horses are not the only animals subject to this disorder: it is so common among sheep, that one seldom passes near a flock without hearing it in several. They cure this disorder in the Ardennes by throwing up their nostrils with a syringe blanched almonds pounded in wine, for six or eight days successively.

COUPLES, ewes and lambs.

COW, the female of the bull.

Cows are very ſerviceable to the huſbandman for work, and for the ſupply of the family and market. The beſt breed is reckoned that of Yorkſhire, Derbyſhire, Lancaſhire, Staffordſhire, &c. and a good hardy ſort for fatting on barren, or middling ſort of land, are your Angleſey's and Welſh. The hardieſt are the Scotch; but the beſt ſort of cows for the pail, only they are tender, and require very good keeping, are the long-legged, ſhort-horned cow, of the Dutch breed, which is to be had in ſome places of Lincolnſhire, but moſtly in Kent; many of theſe cows will give two gallons of milk at a meal: but in furniſhing yourſelf with cattle, you ought to conſider the goodneſs of your land, and the uſe you deſign your cattle for, as whether for breed, milk, or work.

If for breed, the better your land is, the larger may your kine be; and the cheaper, the more will be your profit: only obſerve, that of what kind ſoever your breed is, that it be the beſt of the ſort, and let your bull be of the ſame country with your cow, for a mixed breed is not reckoned to be ſo good.

The cow ought to have a broad forehead, black eyes, large clean horns, her neck long and thin, a large deep belly, thick thighs, round legs, ſhort joints, a white large deep udder, having four teats, and her feet large. As for the ſize of your cows, as of all other cattle, it muſt be ſuited to the goodneſs of your land, though the largeſt commonly give the moſt milk: and whether you deſign them for breed, fattening, or the dairy, let them be ſuch as come off a worſe ground than your own, if poſſible. The beſt time to breed calves is from three years old to twelve. *See the article* CALVES.

For a fortnight or three weeks before a cow calves, put her into good graſs; or, if it be in winter, give her hay; and be ſure to keep her in the houſe the firſt day and night after ſhe has calved, and let a little of the cold be taken off the water which you give her: the next day, if well, and ſhe be well cleaned, turn her out about the middle of the day, and take her in two or three nights more, giving her water a little warmed every morning, before you turn her out. *Mortimer's Huſbandry, vol.* I. *p.* 225.

COW-LEASE, paſture, or meadow ground, kept for feeding of cows.

COWHERD-MILK, implies milk received from the hands of the cowherd, a perſon whoſe office it is to attend upon, and look after, the herd of cows in places where they run in common.

COWL, a term uſed in ſome counties of England to ſignify a tub.

COW-PARSLEY, the name of a plant common in paſture grounds, and of which cows are ſaid to be very fond. This plant ſhould be rooted out of all paſtures, for it is one of the moſt early plants in ſhooting, ſo that by the beginning of April its leaves are near two feet high. The ſeeds of this plant ſpread greatly over the ground, and as the roots are perennial, ſo they are often very troubleſome weeds to deſtroy.

COW-PARSNIP, *wild parſnip*, *meadow parſnip*, or *madrep*, the name of a weed that grows to near three feet high. The ſtalk is round, furrowed, and hollow. The leaves proceed from a large membrane or ſheath. They grow on long hairy ſtalks, and are divided and downy. The flowers grow in large umbels, are white, and conſiſt of five irregular petals: two oval, ſtreaked, compreſſed ſeeds, ſurrounded by a wing, ſucceed each flower.

COW-WHEAT, by ſome called *fox-tail*, is a pernicious weed in many countries. Its ſeed is ſomething like wheat, and according to Cluſius, ſpoils the meal with which it is ground, by giving it a dark colour, and a bitter taſte: though Mr. Ray ſays he could never perceive any diſagreeable reliſh in the bread with which it was mixed. Mr. Miller ſays it is a delicious food for cattle, particularly for fattening of oxen and cows, and that it may be worth while to cultivate it for that purpoſe.

Its ſeeds ſeldom grow the firſt year, unleſs they chance to be ſown, or ſow themſelves, in the autumn, ſoon after they are ripe.

CRADLE, a part often added to a ſcythe, the better to gather the corn, when low, into ſwarths, when it is mowed.

CRAGG, *cragge*, a name given in Suffolk to the remains of marine ſhells, of various kinds, and in which the greater part of the Britiſh cliffs abound.

This is a very excellent manure for cold, wet, or clay land; ſo that every farmer would do well to ſearch his grounds, in order to know whether he is, or is not, poſſeſſed of this treaſure, which will inſure him of very large crops of corn, though his lands were before worn out by continual labour.

CRAKE, a name given in the northern counties to the crow.

CRAKE-NEEDLE, the ſhepherd's needle; or rather the ſeed-veſſels of it.

CRANE'S-BILL. *See* CROWFOOT, CRANE'S-BILL.

CRAP, a name given in ſome parts of England to darnel; and in others to buck-wheat.

CRATCH, or *critch*, a rack.

CREAM, the unctuous, or oily part of milk.

CUBBITTING, a vice to which ſome horſes are ſubject; conſiſting in their catching hold of the manger, ſucking in of the air, and ſwallowing it down in gulps, till they are often ſo full that they are ready to burſt. Some do it only on their collar reins, and ſome on every poſt and gate they come at.

This vice is more common in London than any where elſe, and may either come upon horſes from very low feeding, while they are young and have appetites, or perhaps by ſtanding much at the crip while they are ſhedding their teeth; for then their mouths are hot, and their gums tender and itching, which may readily make them ſuck in the air to cool their mouths: but young horſes are the more apt to imbibe this ill habit, when they ſtand next thoſe that do it; for young horſes often follow others. Horſes addicted to this vice are but of ſmall value; they drop a great part of their food unchewed, which makes them almoſt always look lean and jaded, with a ſtaring coat, and conſequently few of them are able to endure much labour; beſides their being frequently ſubject to the gripes, and other diſorders, owing to their continual ſucking in the air. There is no method yet known, that has proved effectual in the cure of this vice. *Gibſon on Horſes, vol.* I. *p.* 40.

CRESSES, are of various kinds; but the common garden creſs, the Indian creſs, and the water-creſs, are the ſorts uſed for the table.

The common garden creſs, pretty generally cultivated as a ſallad herb, is moſt eſteemed in the winter and ſpring, becauſe it is one of the warm kind. It is propagated by its ſeeds only. If raiſed in the winter ſeaſon, it muſt be ſown upon a gentle hot-bed, and covered ſo as to defend it from great rains or froſt, both of which are equally deſtructive to it in that ſeaſon. If it be not raiſed till the ſpring, it may then be ſown in warm borders, well fenced from all nipping winds: but if it is to be continued in the ſummer, it muſt be ſown upon ſhady borders; and this ſowing ſhould be repeated every third day, or it will ſoon be too large for uſe, as it grows very faſt at that time of the year.

A curled ſort of this plant is propagated in ſome gardens, more for curioſity, and to garniſh diſhes, than for any real uſe; for the common ſort is full as good. This curled creſs ſhould not be ſown quite ſo thick as the other, and when its plants are come up, they ſhould be thinned, ſo as to leave the remaining ones at leaſt half an inch aſunder, that they may have room to expand their leaves. To preſerve this curled variety unmixed, all ſuch plants of it as ſeem to have a tendency to degenerate muſt be pulled up as ſoon as they are noticed.

The beſt method of ſowing both theſe ſorts of creſſes is in drills, becauſe it will then be eaſieſt to cut them as they may be wanted. Their ſeeds, which are very ſmall, ſhould be but barely covered with earth; and to ſave theſe ſeeds when they are ripe, the plants ſhould be drawn up, ſpread upon a cloth, and dried in the ſun for two or three days. They may then be eaſily beaten out; and they ſhould be kept in a dry place.

The Indian creſs (commonly called naſturtium, which is the right botanic name of the garden creſs, as tropæolum is the proper appellation of this,) is an annual plant, ſeldom propagated otherwiſe than by its ſeeds; though it may be continued through the winter, if kept in pots, and ſheltered in a good green-houſe, and there it may be multiplied by cuttings, as is ſometimes practiſed with the double flowered ſort. But this is not worth while, as the ſeeds ripen every year, and plants are eaſily raiſed from them. They are often raiſed in hot-beds about the end of March, or the beginning of April, and then tranſplanted: but they may be ſown in April, in the places where they are to remain. This, for the ſake of ornament, and that no ſmall one in a kitchen-garden, ſhould be where their ſtalks may find ſupport, for they will climb up to the height of ſix or eight feet, and make a very pretty appearance when their flowers are blown. Thoſe of a deep orange colour, inclining to red, are leſs common now, in this country, than the larger ſort with a pale yellow flower; this laſt being generally preferred on account of it's ſize. Theſe flowers have a warm taſte like the garden-creſs. They are commonly uſed for garniſhing of diſhes, and are frequently eaten in ſallads. Their ſeeds fall off as ſoon as they are ripe, and are excellent when pickled. Some call them capuchin capers.

The water-creſs, which grows naturally in ditches and rills of water in moſt parts of England, is much eſteemed as a ſallad herb in the ſpring of the year. Many people even prefer it to all other ſallatting of that ſeaſon, for its agreeable warm bitter taſte, and becauſe it is reckoned an excellent anti-ſcorbutic, a great cleanſer of the blood, and a good diuretic. The editor of the laſt edition of Mr. Mortimer'sHuſbandry ſays, that water creſſes, freſh gathered, and eat faſting in a morning, have performed wonders in conſumptive caſes; and he judiciouſly recommends to ſportſmen, or others, who ſtay long in the fields in cold weather, to gather them out of the ſprings where they grow, and eat them, as a better cordial to warm the ſtomach, than any dram of ſpirituous liquors.

Water creſſes are eaſily cultivated, by taking ſome of the plants, entire, from the place of their natural growth, early in the ſpring, with all their roots to them, then ſetting them in mud, and letting water in upon them by degrees, ſo as at length to form a kind of pond, if it cannot be continued as a running ſtream; though few ſpacious grounds are without ſome brook or other, along the ſides of which they will grow perfectly well. After they have taken root, they will ſoon multiply, eſpecially if they be not cut the firſt ſeaſon, but ſuffered to ripen their ſeeds; for theſe will fall into the water, and afterwards afford a ſufficient ſupply of plants. If the water is too deep to admit of planting them with eaſe, and if it be not a running ſtream, the beſt way is to throw upon its ſurface, at the places where it is deſired they ſhould grow, ſome of the plants taken from elſewhere juſt as their ſeeds are coming to maturity: for they will there complete their ripening, ſink to the bottom, and produce a plentiful growth of creſſes.

Incautious perſons have, not unfrequently, ſuffered in their health, by eating the leaves of the creeping water parſnip, inſtead of thoſe of the water creſs. To guard againſt this miſtake, which may chance to prove fatal, it is proper to obſerve, that the leaves of the right water creſs are roundiſh, almoſt heart-ſhaped, ſmall, with few indentures on their edges, and of a dark green colour; whereas thoſe of the water parſnip are oblong, pretty ſharp pointed, ſawed at their edges, and of a light green colour.

CRIBBLE, coarſe meal, or that but one degree better than bran.

CROFT, a ſmall field or incloſure. In the northern counties it is uſed as a ſmall cloſe or incloſure, one end of which contains the dwelling-houſe and kitchen garden.

CRONES, old ewes.

CROP, the produce, or the quantity of corn, graſs, &c. growing on any parcel of land.

CROSS-TINING, a method of harrowing land, conſiſting in drawing the harrow up the interval it went down before, and down that which it was drawn up.

CROTCH, a hook.

CROW, an iron bar, with a claw at one end, uſed as a lever, and for making holes in the ground, &c.

CROW-FOOT, or CRANE'S-BILL, the name of a perennial weed common in paſtures. The leaves are divided almoſt to the middle, uſually into ſeven parts. The ſtalk commonly divides into two branches; and each of theſe into two more. From the corner of each diviſion comes a flower-ſtalk, ſupporting two large blue flowers; conſiſting of five roundiſh, intire petals, ſucceeded by a long ſeed-veſſel, reſembling a crane's-bill. This bill-like ſeed-veſſel is thick and rough; but not ſo long as in ſome other plants.

CROWS. *See the article* ROOKS.

CROWN-SCAB, a diſeaſe in horſes, conſiſting in an humour, that breaks out round the coronet; of a very ſharp and itching nature, and attended with a ſcurfineſs. Sharp waters prepared with vitriol are generally uſed for the cure of this diſorder: but the ſafeſt way is firſt to mix equal parts of marſhmallow ointment and yellow baſilicon together, ſpreading the compoſition on tow, and laying it all round the coronet. A doſe or two of phyſic may be very proper, to carry off the humour. *Bartlet's Farriery, p.* 296.

CUCUMBERS, a well known plant, cultivated in moſt kitchen gardens.

Cucumbers, for very early ſhew, that is to ſay, to decorate the table at a time when no prudent man would chooſe to eat them, are nurſed in ſtoves by ſome fantaſtical gentry, who pique themſelves on having this fruit fit to cut in every month of the year. But I ſhall here content myſelf with relating the more rational, and far leſs troubleſome, practice of thoſe who have patience to wait till they can be produced in the natural ſeaſons.

To have as early cucumbers as the not too much forced courſe of vegetation can yield in this country, their ſeeds ſhould be ſown, about the middle of March, or a little later if the ſpring be backward, either under a bell glaſs placed upon a ſpot of hot-bed, or at the upper end of a more regular hot-bed covered with frames, where they will not then take up the room of other plants. It is neceſſary that the due temperature of the hot-bed ſhould be attended to here and when theſe plants are come up, they ſhould be tranſplanted into another moderate hot-bed, at the diſtance of about two inches aſunder. Here they ſhould be covered with bell or hand glaſſes ſet quite cloſe to each other, and they ſhould be ſhaded, and ſparingly watered, until they have taken root. They ſhould alſo be aired, as much as the weather will permit, by raiſing up the ſide of the glaſs oppoſite to the wind, in order to ſtrengthen them, and when they have begun to put out their rough leaves, they muſt be re-tranſplanted on the ridges where they are to remain.

Theſe ridges are made with new horſe-dung, in the ſame manner as before directed for the hot-bed, excepting that they are neither ſo thick nor ſo wide. About two feet four inches will be ſufficient for the breadth of the trenches in which they are made; but their length may be whatever is moſt convenient, according to the number of plants intended for them. The trenches for theſe ridges ſhould be about ten inches deep in dry ground; but very little earth need be dug away for them if the ſoil is wet. About one cart load of dung will make a ridge long enough for five or ſix holes of cucumbers, at the diſtance of about three feet and an half from each other. This ridge of dung, being well beaten down and levelled at top, ſhould be covered with about four inches deep of earth, of which the ſame thickneſs ſhould alſo be laid over its ſides. Hillocks of mould ſhould then be raiſed up in the middle of the ridge, at every diſtance at which the plants are to be ſet; and after theſe have been cloſely covered with the glaſſes during four and twenty hours, in order to warm the earth, and thereby fit it for the reception of the plants, they ſhould be ſtirred up by hand, ſo as to make a little hollow in the middle of each, in the form of a baſon. Four plants ſhould then be ſet, as far as can be from each other, in each of theſe hollows, where they muſt again be watered and ſhaded until they have taken root; and after this they muſt be aired, by raiſing the glaſſes on the ſide oppoſite to the wind, in proportion to the warmth of the weather: but they ſhould be raiſed thus only in the middle of the day, until the plants begin to fill them;

for

for after that, they ſhould be propped up with a forked ſtick on the ſouth ſide, to a height proportioned to the increaſe of the plants, which muſt be carefully preſerved from being ſcorched by the ſun. This will alſo harden and prepare them for the open air, to which they ſhould not, however, be expoſed too ſoon, becauſe we frequently have morning froſts in May, which they would not be able to reſiſt. Rather than run any hazard of this kind, the glaſſes ſhould be kept over them as long as can be without damaging the plants; and this may be for a conſiderable time, if the glaſſes are raiſed all round, by ſetting them on three bricks.

About the end of May, when the weather begins to be ſettled and warm, and rather in a cloudy day which ſeems to promiſe rain, than in a very dry and ſunny one, the plants ſhould be gently turned down from out of the glaſſes; and theſe ſhould then be ſupported over them at the height of four or five inches from the ground, by three forked ſticks, which will hold them up very ſecurely, and prevent their bruiſing the ſhoots of the plants underneath: for it is beſt not to remove the glaſs entirely before the latter end of June or the beginning of July, becauſe they will preſerve a moiſture about their roots much longer than if they were quite expoſed to the open air. The plants thus turned down will have made a conſiderable progreſs by the end of three weeks, eſpecially if the weather has been favourable; and then it is that the ſpaces of ground between the ridges, or along the ſides of the ridge if there be but one, ſhould be dug up, and added to the bed, or beds, that the roots of the plants may be enabled to ſtrike into it; for they will extend themſelves a great way (ſome ſay as far as the vines,) if they are not cramped. The runners of the vines ſhould be laid in exact order, without tumbling them too much, or bruiſing, or breaking of their leaves. Some pin them down gently with little wooden hooks, to prevent their being blown about by the wind. After this, they will require no farther care, except keeping them clear from weeds, and watering them when neceſſary, that is to ſay, when their greater leaves drop and hang down to the ground. But here it is to be obſerved, that, though pretty frequent watering of them increaſes their fruitfulneſs, they are beſt taſted, and wholeſomeſt, when they have had but little water; and, though they ſhould be watered ſometimes in dry weather, they ſhould be carefully defended from rain when it is cold. The ridges thus managed will yield large quantities of fruit, from June till the latter end of Auguſt. Mr. Mortimer recommends nipping of the top ſhoots of cucumber plants after they have put out three or four joints, as a means of making them knit the ſooner for fruit.

It is from cucumbers planted on ridges, like the above, that moſt of the gardeners about London ſave their ſeeds. To this end, they leave a number of the earlieſt and fineſt fruit upon the vines, until their ſeeds are perfectly ripe; and then, when the outer cover begins to decay, they cut them open, and ſcrape out their ſeeds, with the pulp, into a tub, which they cover over with a board, to keep out all filth. They let theſe ſeeds and pulp remain thus for eight or ten days, only ſtirring them well with a ſtick, to the bottom, every day, in order to rot the pulp, and make it ſeparate the more eaſily from the ſeeds. They then pour water into the tub, and ſtir the whole well about, till there ariſes a ſcum, after which they let the ſeeds ſettle to the bottom, and pour off the water. This they repeat two or three times, till the ſeeds are perfectly cleared from the pulp. They then ſpread them upon a mat expoſed to the ſun and open air for three or four days, till they are quite dry, and after this they put them into bags, and hang them in a dry place, where vermin cannot come to them. They will keep good for ſeveral years, but are thought to produce the leaſt luxuriant, and therefore moſt fruitful, plants, when they are three or four years old.

To avoid the trouble of making beds, or ridges, of dung on purpoſe for them, as above deſcribed, (which is undoubtedly the ſureſt way to have early fruit), many people, who are leſs ſollicitous about the earlineſs, or even the great plentifulneſs of theſe crops, than the trading gardeners about London are obliged to be, only dig holes of the ſize of a buſhel, fill them with warm ſtable dung, then ſet in the middle of them four or five cucumber plants, with as much mould as poſſible about their roots, and afterwards earth them up in the form of a baſon, to render the watering of them more effectual. They ſhade them till they have taken root, and cover them for a while with bell or hand-glaſſes, if they have any; or they even truſt them at once to the open air. If the plants thrive, three of them will be ſufficient in a hole; and then the reſt of them may be plucked up, or tranſplanted elſewhere. Some even raiſe them from their ſeeds planted in holes of this kind, without any previous hot-bed, and they do very well, if the ſeaſon be at all favourable.

The time for ſowing the latter crop of cucumbers, commonly called picklers, is the beginning of June. The London gardeners generally ſet theſe between their wideſt rows of cauliflowers, which are four feet and a half aſunder. To this end, they dig ſquare holes about three feet and an half from each other, breaking the earth well, and hollowing the ſurface of each hole, with their hands, till it is like a baſon. They then plant eight or nine ſeeds in the middle of each of theſe ſpots, and cover them with earth to the thickneſs of about half an inch. If the weather is very dry, they water them gently at the end of a day or two. In five or ſix days the plants will appear above ground; and particular care muſt be taken then to defend them from birds, eſpecially ſparrows, which will otherwiſe ſoon pinch them off, and thereby fruſtrate all expectations of a crop: but this danger will be over in little more than a week; for the ſparrows will not meddle with them after they have expanded their ſeed-leaves. Care muſt alſo be taken to continue to water them gently, from time to time, according as the ſeaſon is more or leſs dry; and when they begin to ſhew their third leaf, which is the firſt of their rough ones, all the weakeſt plants ſhould be pulled up, leaving in each hole only four of the moſt promiſing and beſt ſituated. The ground about theſe ſhould then be well ſtirred with a ſmall hoe, to deſtroy the weeds, and earth up the plants, around the ſtems of which the mould ſhould afterwards be gently preſſed down by hand, the better to ſeparate them from each other as much as can be without hurting them. This being done, they are watered a little to ſettle the earth about them, and at ſuch other times as the dryneſs of the weather may render neceſſary: but, above all, they muſt be kept clear from weeds. When the cauliflowers are quite removed, the whole ground ſhould be thoroughly hoed and cleaned, freſh earth ſhould be laid up around the plants, ſo as to deepen the hollows in which they ſtand, that they may the better contain water when it is given them, and their vines ſhould be ſpread out carefully in the order they are to run, in ſuch manner that they may not croſs or be entangled with one another. A little earth ſhould then be laid, and gently preſſed down, between the plants, the better to ſeparate them every way, and a gentle watering now, and as often afterwards as the ſeaſon ſhall require, will forward their growth. With this management, theſe plants will begin to yield young cucumbers, fit for pickling, about the latter end of July, or early in Auguſt.

About fifty or ſixty of theſe holes will be neceſſary for a middling family; becauſe a ſmaller number of them will not afford fruit enough at one gathering to requite the trouble and expence of pickling, and they never are ſo good if they are gathered long before they are put into the vinegar. Fifty holes will ſeldom furniſh more than two hundred cucumbers fit to gather at a time; and this may be repeated twice a week as long as the ſeaſon laſts, which generally is five weeks. What are not wanted for pickling, may be left to grow till they become fit to eat.

Though M. Duhamel has not given us any experiments on the culture of cucumbers according to the principles of the new huſbandry, there can be no room to doubt of their ſucceeding perfectly in that way, ſince M. de Chateauvieux raiſed excellent melons, which are a much more tender fruit, in beds of common earth, in open fields, merely by keeping the ground in fine order by a judicious uſe of the horſe-hoe, without the help of either dung, hot-bed, or glaſſes over them, and they were, in all reſpects, preferable

to

to any in his garden. This furely merits the attention of all kitchen gardeners, and fingularly of thofe near London, where land and labour bear extraordinary prices.

A correfpondent of the editors of the Mufeum Rufticum has given us the following new method of raifing cucumbers, without the help of forcing frames, though the fruit are much finer than any raifed by the other methods yet in ufe. "I procured, fays he, fome of the beft feed of the common prickly cucumbers I could get; and from this feed, in the fpring of the year 1750, I raifed fome plants on a moderate hot-bed, not hurrying them too much in their growth.

"In May, when the danger of the froft was almoft over, I familiarized the plants by degrees to the air, and towards the latter end of the month planted them in the open ground againft a fouth wall.

"In this fituation they throve apace, and as faft as they put forth their runners, I nailed them gently up againft the wall. They did not fend forth many bloffoms till they had run a confiderable height, at leaft five feet; after which the fruit began to fhew itfelf.

"I did not give my plants too much water, and this I have fince found a neceffary precaution.

"The fruit increafed in fize daily, was of a fine green colour, and differed greatly from that of fome other plants raifed from the fame feed, but planted in the common way; the runners being fuffered to trail on the ground.

"When I gathered my firft cucumber, I was exceedingly delighted with its appearance. It was long, thin in proportion to its length, of a beautiful green, not too deep, with a whitifh fummit.

"When I cut it I found the flefh thick and firm, but few feeds, and thofe very fmall, and its flavour extremely delicious.

"Defirous of knowing whether the plant might not be improved by fowing the feeds of fruit raifed in this manner, I pitched upon fome of the fineft cucumbers, not at too great a diftance from the roots, and left them on the vine to perfect their feed.

"In this manner I have raifed cucumbers for my own ufe ever fince, and have the fatisfaction to find, that inftead of degenerating, they have improved furprifingly.

"My neighbours in the country are exceeding glad when I have any feed to fpare for them, and always find their cucumbers that year much better for ufing it, though they do not grow fo large as mine, neither have they fo delicious a flavour, unlefs nailed up againft a wall.

"I am very fenfible that this method cannot, with any degree of convenience, be brought into general practice; yet, in every garden, a few plants may be fo trained to prevent the feed from degenerating; efpecially as one or two plants raifed in this manner would fupply a fufficient quantity of feed for a large garden.

"I muft own, that in my method the plants do not bear fo great a number of cucumbers as in the common way; but then they are, without comparifon, larger, and of an exquifite flavour." *Mufeum Rufticum, vol.* I. *page* 131.

CUCKOW-FLOWER. *See the article* LADIES SMOCK.

CUCKOW-LAMBS, a name given in Hertfordfhire to fuch lambs as are yeaned in April or May, becaufe they fall in cuckow time. They are generally either the lambs of very young, or very old fheep, and occafioned by their taking ram very late in the feafon. Thefe lambs are ufually of the fmalleft fort, and therefore both ewe and lamb fhould have the beft of keeping, in order to fatten the lamb for the butcher; for fuch diminutive lambs are improper to be kept for ftore-fheep. Befides, as thefe lambs are yeaned later than ordinary, it is very likely they will meet with green meat fufficient to fatten them apace, and come in feafon to be fold for the more money; as they are of the youngeft fort, and fatted late. *Ellis on Sheep, page* 79.

CUCKOW-SPIT, a kind of frothy fubftance frequently found on plants, containing one or two infects.

M. Poupart tells us, that as foon as the little creature comes out of its egg, it haftens to fome plant, which it touches with its fundament, and faftens there a drop of white liquor full of air; it drops a fecond near the firft, then a third, and fo on, till it covers itfelf all over with a fcum or froth: this froth defends it from the heat of the fun, and alfo from the attacks of the fpiders, which would otherwife devour it. Mr. Lifle is of opinion, that this froth is nothing more than the nightly dew which falls upon the fork or joint of the plant, and which the little infect, with its probofcis, as with a pair of bellows, works into froth.

CULMIFEROUS *Plants*, fuch as have a fmooth jointed ftalk, and their feeds are contained in chaffy hufks.

CULTIVATION, the art of improving foils, and forwarding or meliorating the produce of the earth, by manual labour, manure, &c.

CULTIVATOR, a name given by foreign hufbandmen to inftruments invented for ftirring the earth, on the principles of the new hufbandry. Thefe inftruments are generally called in England horfe-hoes. We fhall here give a defcription of thofe invented by Meffrs. de Chateauvieux and de Villiers, and defcribe thofe invented in England under the article horfe-hoe. *See* HORSE-HOE.

Defcription of M. de Chateauvieux's *fingle* CULTIVATOR.

M. de Chateauvieux, having remarked the good effects of his plough in ftirring the alleys between the rows of corn, rightly judged, that the inftrument we are now going to defcribe, which is much lighter and fimple in its make, would anfwer the fame end; or at leaft that it might be ufed alternately with that plough, employing this laft only when a greater quantity of earth is to be turned up towards the rows of corn: "for, fays he, it is to be obferved, that the cultivator hardly changes the fituation of the earth, but divides and breaks it in the place it is in, fo as to render it loofe and light, and fit for the roots of plants to penetrate with eafe. This inftrument, like a miner, works chiefly under ground, where it cuts the earth, divides its particles, raifes it up, and lightens it. It has this farther advantage, that one horfe is fufficient to draw it. The cultivator, Plate VII. is compofed of a beam, AB, Fig. 1. the handles CD, and the fhare EF, which is more particularly reprefented in Fig. 2, 3, 4, 5, and 6.

"The beam AB is three feet and a half, or four feet long. Its diameter ought not to exceed three inches at moft; and, if it be fquare, the edges fhould be rounded off. It fhould be pierced with mortifes under the letters G, H, in order to let through the crofs ftaves I, L; in the fame manner as in the fore-carriage of the plough; and is fixed by the keys K, M, or the pins *a*, *b*. The middle of the handles fhould be exactly oppofite to the beam; that is to fay, the fpace between them fhould be equal on both fides. Thefe handles fhould be made flighter than thofe of the plough before referred to, and they fhould be fixed to the beam by a tenon in a mortife, rivetted at N, and fupported behind by the prop P.

"The end A of the fhare, Fig. 3, and the two fins B, C, are made flat. The crooked handle ABC, Fig. 4, fhould be triangular, and fomewhat fharp before, to anfwer the end of a coulter, as in Fig. 2, and 5.

"This fhare is to be let into a grove cut in the under part of the beam, as reprefented in Fig. 7, and 8; and faftened there by a fingle ferrule, as in Fig. 9. If it fhould cut too deep, that may be remedied by altering the pofition of the wheel, as in the plough, or by inferting a very fmall wedge *g*, Fig. 10, between the handle of the fhare and the beam. If it does not cut deep enough, that wedge muft be inferted, as at *h*, Fig. 11, at the other end of the handle.

"When this inftrument is ufed, the beam before defcribed is to be fubftituted in the place of that of the plough, which is to be taken off. The two crofs ftaves I, L, Fig. 1, of the fore-carriage of the plough, are then run through the mortifes G, H, of this beam, which is thereby fixed to that fore-carriage.

" This cultivator is very eaſily guided: the ploughman may hold it upright, or incline it to the right or left, juſt as the intended ploughing may require. The ſhare and its handle enter ſo deep into the earth, as to be quite buried in it, if a deep ploughing is intended to be given: and in that caſe the tail A of the beam touches the ground. Though the ſhare is but ſmall, it ſtirs the earth at leaſt a foot around it: its point ſhould be of ſteel, and ſomewhat inclined towards the earth.

" The ſhare of this inſtrument, like that of the plough, may be brought as near as one pleaſes to the rows of corn, by placing the beam accordingly in the frame."

Deſcription of M. de Chateauvieux's *double* CULTIVATOR.

" This inſtrument, Plate VII. Fig. 12, 13, and 14, has two ſhares. It has a beam AB, and the ſhares CD, EF, Fig. 13, which being exactly like that of the ſingle cultivator, I have only to point out wherein theſe inſtruments differ. The beam of this ſhould be ten or twelve inches longer than that of the other. It has likewiſe two mortiſes more, under the letters G and H, to let through the croſs ſtaves EK, IL, which bear the handles MN, OP of the ſhares. The croſs ſtaves EK, IL, are rivetted permanently to the beam: the handles MN, OP, are moveable upon the croſs ſtaves, to which they are faſtened by the keys R, S, Q, T; ſo that the ſhares may be ſet at a greater or leſs diſtance from each other, according as the quality or ſituation of the ground may require or allow.

" This inſtrument ſtirs the earth extremely well, and does a great deal of work in a little time. Each ſhare being about fifteen inches wide at AC, BD, Fig. 14, and the diſtance between them from A to B, Fig. 14, being about four inches, or, upon occaſion, ſix; and the earth being ſtirred about two inches on each ſide beyond the extent of the outmoſt fins of the ſhares; each cut of this cultivator ſtirs about two feet breadth of ground. This double cultivator requires two horſes, unleſs the ſoil be very light; in which caſe, I fancy one may do, though I have not yet tried it.

" If one had a mind to fix a coulter in the middle of the beam, juſt before the ſhares, I ſee no inconveniency that could ariſe from thence, provided it be a very light one.

" The way to uſe this cultivator, is, to faſten it to the fore-carriage of the plough, by running the two croſs ſtaves V, X, Fig. 13, through the beam A, B.

" I would particularly recommend, not to make the wood work of this cultivator too thick or heavy, and therefore by no means to exceed the dimenſions I have given: for the lighter theſe inſtruments are, the more eaſily they are managed both by men and cattle."

Deſcription of M. de Chateauvieux's CULTIVATOR, *with two Mould-Boards.*

" If, ſays M. de Chateauvieux, I could have imagined, that my propoſing for the uſe of the new huſbandry, ſome other inſtruments beſides the plough, properly called, could have been looked upon as either ſo expenſive or ſo troubleſome as to diſcourage people from practiſing that huſbandry; I ſhould not, by any means, have thought of communicating them to the public.

" But why ſhould not agriculture enjoy the ſame advantages as almoſt all great manufactories, in which every uſeful diſcovery and improvement, either to perfect the manufacture, or to fabricate it in leſs time and with leſs expence, is readily adopted?

" It is with a view to facilitate the various labours of cultivation, to execute them better, more ſpeedily, and with much leſs expence, that I have introduced the uſe of my new inſtruments in the culture of my own lands. If others think proper to do ſo too, they will enjoy the ſame advantages. I offer them, not as things abſolutely neceſſary, for the plough alone may ſuffice; but as things of which I have experienced the good effects during the years 1753 and 1754; and which, for that reaſon, I think it incumbent on me to recommend to thoſe who adopt the new huſbandry.

" The cultivator with two mould-boards differs from the ſingle cultivator before deſcribed, only in the two mould-boards which I have added to it, one on each ſide, and which are repreſented in Plate VII. Fig. 15. A, C, E, H, is the mould-board on the left-hand ſide of the plough; and B, D, G, H, the mould-board on the right-hand ſide. The whole of this Fig. 15, repreſents an entire and a perſpective view of the ſhare and mould-boards.

" The mould-boards are made of plates of iron, either caſt or hammered, about the twelfth part of an inch thick; which is ſufficient to reſiſt the preſſure of the earth. Thicker plates than theſe would render the ſhare too heavy, and it would be much more difficult to give them their proper bent.

" The two mould-boards join to the handle at HL, and lap about an inch one over the other; or elſe they are faſtened together by rivets. They form, in that part, an angle E, H, F, of ſomewhat leſs than ninety degrees, which is ſufficiently acute to ſerve inſtead of a coulter: though a coulter may alſo be uſed upon occaſion, by placing it a little more forward.

" From the lower part L of the handle, the mould-board ſhould paſs underneath the fin L, G, of the ſingle ſhare, and follow the direction of that fin, as at G; being let in beneath, about an inch and an half, according to the pointed line LG, and firmly riveted by three ſtrong rivets.

" The hind part of the mould-boards is fixed and ſupported by the ſtay F, to which they are ſtrongly riveted. This ſtay muſt have exactly the ſame bend as the mould-board.

" Behind the lower part of the handle is another ſtay, M, N, quite cloſe to it, and about two inches below the top of the mould-boards, to which it is riveted at both ends. This ſtay helps to keep them firm: but its chief uſe is to prevent their being raiſed up by the preſſure of the earth againſt their extremities A and B, which would throw their common angle H too forward, and miſplace the ſhare.

" The proper ſlope of the mould-boards cannot be ſo well deſcribed by words, as it may be conceived by the figure, which repreſents at F the convex inſide of the one, and at Q the concave outſide of the other. The diſtance to which the earth is turned over, when the cultivator opens it in order to make a large furrow, depends on the degree of this bending, and the ſpace between the two upper extremities of the mould-boards E, F.

" The hind-moſt part of the mould-boards is cut ſloping at C and D, almoſt in a ſegment of a circle. This ſhape helps to effect a greater diviſion of the earth.

" The plate of iron, before it is bent, ſhould be cut nearly in the ſhape of Fig. 16.

" The ſize of the mould-boards, as well as their proper bending, depends a little upon the quality of the land intended to be cultivated. I have found that, for light ſoils, they need not be bent quite ſo much: ſo that the diſtance from C to D, Fig. 15, may be twelve or thirteen, and even fifteen or ſixteen inches. This ſame cultivator may likewiſe be uſed in ſtiff lands.

" Nothing hinders making theſe mould-boards two or three inches longer, from B to G, and from E to H; or varying ſome of their proportions, as the huſbandman may think beſt.

" This ſhare, with the mould-boards, is fixed to a beam, as in the ſingle cultivator, Fig. 1, where it is faſtened to the fore-carriage by the croſs ſtaves I, L.

" If this deſcription does but convey a ſufficient clear idea of the ſhape and proportions of this cultivator, I will anſwer for its ſucceſs when uſed. I deſcribe it after one of the ſame kind, which I have made uſe of for two years paſt, with very great ſucceſs."

Direction for uſing the CULTIVATOR, *with two Mould-Boards, by M. de* Chateauvieux.

" This cultivator opens the main furrow in the middle of the alley, by turning the earth over on both ſides at the ſame time; and I have found by experience, that as much work is done by that means, by one turn of this inſtrument, as could be done by two, and frequently

quently three turns of the common plough, and that without ufing a greater number of cattle. I muft now prove this propofition; though I am perfuaded that it will eafily be allowed by whoever only cafts any eye upon Fig. 15, Plate VII. which reprefents the fhare of this cultivator." *See the article* ALLEY.

Defcription of a CULTIVATOR *invented by M. de* Villiers.

"This inftrument is compofed of a fhare, Plate VII. Fig. 17, the two fins of which are eight inches and a half afunder at their extremities *a*, *b*. The focket *c*, which is between the two fins, projects fome inches, and the hollow in it is three inches long, and one inch wide. It does not defcend fo low down as the fins, to prevent its touching the earth. The length of this fhare, from the point *d*, to the extremity of the fins *a* or *b*, is from 12 to 13 inches. At the diftance of five inches from the point *d*, is a hole *e*, into which is inferted the crooked point *f*, of the iron fafeguard, Fig. 18, which is ufed in fome countries in order to faften the ear to the fhare of the plough. Upon the fhare is placed a fmall triangular ear *h*, Fig. 20, 21, and 22; fomewhat concave at bottom, that the two fmall ears may join exactly to the fhare at about an inch diftance from the edge of the fins. This ear is about two inches and a half high at *a*, Fig. 21, and is faftened firmly to the fhare by a double and angular fafeguard, which covers its edge as far as *b*. It is fixed at one end by its point, which enters into the hole *e*, Fig. 17, in the fhare, and by four fmall pins faftened to the ear. Fig. 18 and 19, reprefent this fafeguard. The double ear is faftened at its other extremity, by the fheat or upright piece, *e*, *g*, Fig. 21, which paffes through the ground-reft of the hinder part of the ear and beam, and by a piece of iron *c d* bent in a right angle. This piece of iron covers the fore-part of the fheat, and refts upon the tail of the ear, againft which the beam preffes it very tight, by means of a wedge *e*, driven into the fheat. The piece *c d* may likewife ferve to fix two mould-boards from *g* to *c*. It is nine inches high. *f* is another fheat or upright piece, which joins the beam to the ground-reft, to add to the ftrength and folidity of the inftrument, which is increafed alfo by the lower part of the handles being fixed in the ground-reft at *i*, and traverfed by the beam at *k*."

M. de Villiers, in a letter to M. Duhamel gives the following account of his manner of ufing this cultivator.

"Finding it impoffible to plough my alleys well when they were but three feet or three feet and a half wide, without greatly damaging the rows of corn bordering upon them; I refolved to make them four feet wide, and took particular care to have the rows drilled very ftrait: but even then I found only one way of ploughing them well, which is, to open the firft furrow fo near to the bed, that the next furrow within that may come within two or three inches of the neareft row of plants in the bed; turning over the earth of thefe furrows towards the alley. After two or three fuch turns of the plough, the ploughman will be fure not to make any miftake. It is of great importance to cut this firft furrow, by which all the others are directed, quite parallel to the rows. The reft of the work will then go on regularly, and without any of that confufion which would be capable of giving many people a diflike to the new hufbandry. My horfes were led by hand, till they were fufficiently accuftomed to this work: but that was neceffary only for the firft furrow, which they afterwards follow of their own accord, fo that the reft of the alley is ploughed with great eafe.

"The earth of the fecond furrow, which is cut very near to the rows, is turned over in the fame direction as that of the firft; that is to fay, from the bed.

"The third furrow is ploughed the contrary way, and the earth is then turned over towards the rows, fo that the laft furrow is filled up by this ploughing, and a confiderable quantity of well divided earth is turned over to the rows, for the plants to extend their roots in the fpring.

"I then continue ploughing in the fame direction, cutting the furrow that is turned over towards the rows as thick as poffible, till the whole alley is ploughed almoft clofe to the oppofite bed, when, by turning over one large furrow on that fide, the fmall one cut there at firft is filled up. By this means, the firft fpring hoeing is completely executed.

"I begin the fecond ploughing on the fide where I ended the firft, turning the earth over that way, which is the contrary to what was done before: and when I come to the other fide of the alley, I leave there, as was left before on the fide I now begin at, the breadth of a fmall furrow, which I do not plough, but over which I turn the earth of my laft furrow.

"I think this fecond hoeing may be deferred, when the ground does not produce many weeds: and in this cafe I perform it with the cultivator, which I bring almoft clofe to the rows.

"After thus ufing, fometimes the plough, and fometimes the cultivator, according as the condition of the ground feems to require, I finifh all my hoeings by putting two horfes to the cultivator, and drawing it once or twice through the middle of the alleys; becaufe it cuts four or five inches deeper than the plough."

M. de Villiers adds, that he could not always turn the earth over towards the rows, as M. Duhamel directs, becaufe the wheel of his plough, getting too deep in the middle furrow, altered the direction of the fhare. To this M. Duhamel obferves, that he himfelf met with the fame difficulty, and found no other way of remedying it, but by opening a fmall furrow near the rows, by the help of which he turned the earth over towards the alleys, and then filled up that furrow immediately; taking care at the fame time to turn the mould over towards the roots of the plants, fo as to earth them up as much poffible. "I am glad, adds he, that I have had this opportunity of giving M. de Villiers's method, becaufe I think it a good one, and believe it will be of great fervice to fuch as may be inclined to practice the new hufbandry." *Duhamel's Cultures des Terres, tom.* I.

CULTUR, or rather *Coulter*, the piece of iron that cuts the earth before the plough-fhare. *See the article* PLOUGH.

CULTURE, the art of cultivating, improving, or meliorating the foil.

CULVER, a pigeon.

CURB, an iron chain faftened to the upper part of the branches of the bridle, in a part called the eye, and running over the beard of the horfe.

CURB, is alfo the name of a difeafe in horfes, confifting in a fwelling at the junctures of the bones on the hind part of the hock, forming a pretty large tumour over the back part of the hind leg, attended with ftiffnefs, and fometimes with pain and lamenefs.

A curb proceeds from hard riding, ftrains, blows, or kicks. The cure at firft is in general eafily enough effected by bliftering repeated two or three times, or even oftener. If it does not fubmit to this treatment, but grows exceffively hard, the quickeft and fureft way is to fire with a thin iron, making a line down the middle from top to bottom, and drawing feveral lines in a penny form manner pretty deep; and then to apply a mild bliftering plafter or ointment over it. This method will entirely remove it. *Bartlet's Farriery, p.* 262.

CURRANT-TREE, the name of a fhrub well known in the Englifh gardens, and of which there are feveral varieties; but the moft valuable forts, for common ufes, are the white and red Dutch.

Thefe forts may be eafily propagated by planting their cuttings any time from the middle of September to the end of October, upon a fpot of frefh earth, either in rows, at a foot afunder, or in beds, which in the fpring muft be kept very clear from weeds. Thefe may remain one or two years in the nurfery, during which time they muft be pruned up for the purpofes they are defigned for; that is, either to clear ftems about a foot high, if for ftandards; or, if for walls, pales, or efpaliers, they may be trained up flat. They fhould then be planted out where they are to remain, for the younger they are planted,

planted, the better they will succeed; the best season for which is when their leaves begin to decay, that they may take root before winter, so that they may be in no danger of suffering from drought in the spring.

These shrubs are generally planted in rows at about ten feet asunder, and at four distance in the rows, in those gardens where the fruit is cultivated for sale; but the best method is to train them against low espaliers, in which manner they will take up much less room in a garden, and their fruit will be much fairer.

The distance they should be placed for an espalier, ought not to be less than ten or twelve feet, that their branches may be trained horizontally, which is of great importance to their bearing.

Those that are planted against pales or walls, should also be allowed the same distance. If they are planted against a south-east wall or pale, it will cause their fruit to ripen at least a fortnight or three weeks sooner than those in the open air; and those which are planted against a north wall or pale, will be proportionally later; so that, by this method, the fruit may be continued a long time in perfection, especially if those against the north pales are matted in the heat of the day.

These plants produce their fruit upon the former year's wood, and also upon small snags which come out of the old wood; so that in pruning them, these snags should be preserved, and the young shoots shortened in proportion to their strength. The only method, very necessary to be observed in pruning them, is not to lay their shoots too close, and never to prune their snags to make them smooth. This, with a little care in observing the manner of their growth, will be sufficient to instruct any person how to manage this shrub, so as to produce great quantities of fruit.

These plants will thrive and produce fruit in almost any soil or situation, and are often planted under the shade of trees: but the fruit is always best when they are planted in the open air, and upon a light loamy soil. *Miller's Gard. Dict.*

The juice of the currant pressed out, mixed with a proper quantity of sugar, and duly fermented, makes an excellent wine, which is very comfortable to the stomach and nerves.

CURRY-COMB, an iron instrument full of small teeth, used for currying horses.

CURSONS, spurs, or snags, growing on the stems and branches of the apple, currant, and other fruit-trees.

CUSPATED *flowers*, those whose petals or flower-leaves end in a point.

CUTTING-BOX, a machine for cutting fodder, as straw, hay, haulm, &c. into small pieces, commonly called chaff, for the use of cattle.

We have given on Plate VI. Fig. 11. a cut taken from the Museum Rusticum, vol. VI. page 10, of an improved cutting-box. The improvement consists in what the inventor calls a presser, which is a piece of wood as long as the box is wide, with three iron tongues in it, like those of a hay-fork. These tongues are put into the bundle of hay or straw to be cut; and by means of a rope fixed thereto, and extending under the box, the presser is forced down by the left-foot of the cutter, and consequently the bundle kept tight. By this means the chaff is cut with great ease; and after every cut, the operator rises his left-foot, pushes his sheaf or bundle forward with his left-hand, then presses it down again with his foot, and takes another cut. In this manner he continues working, till the whole bundle is reduced to chaff.

This description will be very easily understood by inspecting the figure above referred to, where A is the presser, B a large knot at the end of the rope, which fastens it to the presser. C the rope, DF, the slit in which the rope moves, as the cutter pushes the bundle forward. E the loop in which the cutter puts his left-foot. F the box to contain the hay, straw, &c. The knife is not delineated in this figure, as the manner of placing it is sufficiently known.

A correspondent of the editors of the Museum Rusticum tells us, that he never gives his horses any pure corn, but always makes use of his cutting-box, in which his servants cuts his horse-meat, which consists of unthrashed oats, tares, pease, or beans. They cut off the heads where the corn lies, and take besides a cut or two of the straw to mix with it. This he gives to his horses instead of corn: it being a very nourishing food, and of which they are very fond. Nor is there any danger of their being surfeited with it, which they often are with pure corn; many of their disorders arising from their being over-fed.

"I cannot, continues he, enough commend the use of a cutting-box, though I am persuaded the ploughmen will endeavour to prepossess their masters against it, because the cutting of the horse-meat is pretty tough work, and they do not, in general, love to do more than they can help.

"When oats, beans, pease, or tares, are intended to be thus cut for horse-meat, it is best to mow them before they are quite ripe, as by that means fewer of them will be lost by shaling, and the straw, or stalks, will be of a better quality, and more nourishing for the cattle.

"Care must, however, be taken that the crop be well dried before it is housed, lest it heat in the mow, and take damage, if not set the barn, or stack, on fire." *Museum Rusticum, vol.* I. *p.* 258.

CYDER, or *Cider*, a liquor made from the juice of apples, expressed and fermented.

A Herefordshire planter has given us the following method of making cider in that county, which has been so long famous for this liquor.

"The worse, says he, the apple is for the table, the better it is, in general, esteemed for cider, such as grow all over this county, and are, in a manner, wild, harsh, and crabbed to the taste. These go under various names, as the redstreak, the white and green musts, the gennet-moyl, the stocking apple, the summer and witer fillets, &c. &c. of all which I prefer the first, provided it is a good sort, which is not always the case, particularly in some parts of Worcester and Gloucestershire, where they grow in great plenty.

"I have long laid down from experience, the best mistress, that, first, the more red an apple has in its rind, the fitter it is for cider; that is to say, if it is at all fit; for I have seen an apple of very deep red, by some called sopsy-wine, quasi sopped in wine, which was worth nothing in this intention.

"Secondly, That the paler the rind, the worse the juice.

"Thirdly, I have found it a maxim in general true, that a sweet apple with a tough rind will always yield a good vinous liquor.

"Fourthly, The more yellow the flesh of the fruit, the better and finer coloured will the cider be.

"These few maxims, not too scrupulously adhered to, have been of great service to me in life; for though I have a high opinion of them, I do not absolutely rely on them. There is no rule so general, but an exception may be made to it; but a man of reflection, with a few well-founded rules, will seldom be at a loss how to act in this, or in any other case.

"I seldom suffer my apples to be gathered till they begin of themselves to drop from the trees: nature then tells me they have, for the most part, acquired a proper degree of maturity.

"Great care is taken in the gathering of them, for fear they should be bruised in the operation; and this I have always found a very necessary precaution.

"As they are gathered I have them sorted, according to the several degrees of ripeness they are of, making, in general, three sorts, which a little experience easily teaches to separate properly, the difference being apparent enough at first sight.

"As fast as they are gathered and sorted, they are carried under a shed prepared for the purpose, and laid in large heaps to meliorate: this practice I cannot enough recommend, as being of great service to the liquor, improving its quality, and making it keep, without comparison, better; and all this is caused by a little sweating in the heap.

"Yet

"Yet, good as this practice may be, fome avaricious planters cannot be induced to adopt it, becaufe, fay they, the apples frefh from the tree will yield better; as, of thefe laft, about twenty bufhels will give a hogfhead of cyder; whereas, of the other apples, which have been heaped, it will take about twenty-five to make the fame quantity.

"I fuffer my apples to lie in the heap a longer or a fhorter time, according to the nature of them, fuch as are harfh and folid requiring to lie longer, by feveral days, than thofe that are mellow and pulpy; and the degree of maturity the apples had attained before they were heaped, makes alfo fome difference in this refpect.

"I have already obferved, that I divide my fruit into three feveral forts, according to the ftate of its maturity: I have now to add, that from thefe three fortings I have no lefs than fix feveral kinds of cyder, each different from the other in tafte, flavour, and quality.

"As faft as the fruit is ground (I need not, I think, mention that I ufe the ripeft firft) the pulp is put into a large vat near the prefs: at the bottom of the vat is a tap, through which a confiderable quantity of the prime vinous juice will run without any preffing, induced by its own weight only: this produces my beft cyder; and I always tun it up by itfelf: the pulp is afterwards preffed in the ufual way. The fame procefs is ufed in all the three fortings of apples; by which means I get, as I faid before, fix forts of cyder.

"The firft runnings from the vat I immediately put into the veffels in which it is to remain; only, if it happens, by any accident, to be too foul, I ftrain it firft. I allow here but a fmall vent-hole, and when it has done working, I fill the veffel with fome of the fame liquor referved for that purpofe: I afterwards, by degrees, clofe the vent till it is finally and well ftopped.

"As to the juice, which undergoes the action of the prefs, I put this, as foon as it runs off, into veffels, where I fuffer it to remain about thirty hours, according to the feafon, till the *fæces* are precipitated, or fallen to the bottom; after which I draw it off, and tun it up in the veffels in which it is to remain, with the precautions, however, above-mentioned, when I treated of the firft runnings.

"The kind of veffels I ufe, and which I think by far beft, are upright hogfheads, broader at the upper head than at the bottom; and I often, after my cyder has done fermenting, caft two or three handfuls of wheat-bran into each veffel, which ferves to thicken the head or cream of the liquor, and makes it keep better.

"I am very careful with refpect to the veffels into which I put my cyder, always avoiding new ones, if poffible, as they give the liquor a twang, or bad tafte, and hurt its colour: my ufual way is, to feafon all my new cafks, that I poffibly can, with fmall beer, which I ufe in common in my family, though I live in a cyder country; and if I have not an opportunity of doing this, I fcald them with water, in which a confiderable quantity of apple-pulp has been boiled.

"If a veffel is not fweet, it may eafily be cured, unlefs very bad indeed, by putting fome unflaked lime into it, adding fome cold water, ftopping it clofe, and rolling it about till the noife within is no longer heard.

"I have often found it of great ufe towards enlivening the liquor, to flice about a dozen fweet apples into a hogfhead: I am alfo inclined to think it makes it keep better.

"The beft cyder I ever had was a few years ago, when I put in each hogfhead about three quarts of good wheat firft boiled and hulled, fo as to have, in fome meafure, the appearance of boiled rice.

"When I am obliged to put any cyder into a cafk I fufpect, and afterwards difcover it has given the liquor a bad tafte, I caufe fome muftard feed to be ground in a quern with fome cyder: this mixture, being put into the hogfhead, is often of great fervice, and reftores it to its original good tafte.

"Cyder, when it is tunned, is very apt to lofe that fine mild fpirit which renders it fo pleafant and brifk a liquor; therefore great caution fhould be ufed with refpect to the vent. The wild, furious, and ungovernable fpirit fhould be fuffered to efcape; which may eafily be effected, by leaving a fmall vent open for a few days; after which the barrel muft be clofe ftopped, for if it gets any vent, the liquor will ftand a great chance of being entirely fpoiled; on the contrary, if well bunged, though it may be dead and flat at firft, it will foon recover itfelf, maturate, and be fit for drinking. This particular part of the management of cyder is critical, and depends greatly on the temperature of the air, fo that it is impoffible to give any abfolute directions about it, as fomething muft ftill be left to be learned by experience, and governed by difcretion.

"I muft give one particular piece of advice to fuch as intend making cyder, which is, that they diligently watch the alterations in it upon every change of weather, as a fmall neglect, at fuch times, is often fatal to many hogfheads, and the danger is much greater in fummer than in winter. There is fcarcely any difeafe incident to this liquor, but what may eafily be cured by a timely application: if it is only a little inclined to tartnefs, wheat, managed as above-mentioned, will cure it; and the fame thing is alfo very good to preferve it, when it is drawn out of one cafk into another: the quantity when the liquor is tart is about half a peck to a hogfhead; I have fometimes even put a quart more.

"This fimple remedy will, I fay, often cure the tartnefs I mentioned; but fometimes, when it is very thick and fourifh, it may be neceffary to raife a new fermentation, to purge off the impurities, and make them fubfide: this may be foon done by bruifing the flefh of a few apples to a pulp with fome of the liquor, and putting the whole into the bung-hole of the veffel; this will raife a ferment, and cure the cyder: when that is over, it will be proper to draw it off into another cafk; and it will alfo be a very ufeful precaution, to put into the laft mentioned veffel about a quarter of a peck of wheat, prepared as I have already directed: this will give it new life and fpirits, and make it keep better, and drink much pleafanter.

"I have fometimes alfo ufed another method to cure tart cyder; but it has not always fucceeded with me; why, I cannot fay, as fome people, who live not many miles from me, have great dependence on it. Something may depend on their foil differing from mine, though this may, to fome of your readers, feem to have a very remote analogy to the cafe in hand. The remedy is, to break half a dozen new-laid eggs, and beat them up, fhells and all, till they are brought to a frothy oil: this is put into the bung-hole of a hogfhead, and, as I am credibly informed, fometimes proves a very efficacious remedy: it has fucceeded with me, but not fo often as to induce me to depend much upon it; I mention it, however, as it may prove of more efficacy with others than it has with me.

"An induftrious planter will, by the conftancy of his obfervations and remarks, always have it in his power to cure his own liquor by receipts of his own difcovering; and for this purpofe I would recommend, that he be continually making experiments, and that whatever trials he makes, be in various modes and proportions; for the remedy that may be of no fervice in one form, may poffibly be very efficacious when altered with judgment, which judgment can only be acquired by experience and obfervation.

"It is to be noticed, that, if the cyder is acid, and at the fame time clear, it is in a very dangerous ftate, being but rarely recovered: therefore, in general, when this is the cafe, the cure is fcarcely worth attempting.

"I have often ufed wheat for the recovery of my cyder in other forms, fometimes putting about half a peck, unground, into a hogfhead for it to feed on; at other times I have made dough of coarfe meal with the bran in it, adding fome leaven, ufing no falt, and putting warm cyder, or white wine, inftead of water, in the mixture: this dough I make into lumps about as large as my fift, and thruft them into the bung-hole of the hogfhead, the quantity being about half a peck of the meal to a hogfhead.

"Many mix different kinds of fpice with their liquor, particularly ginger, which they think of great fervice; but I never ufe it now, feldom having found any great effect refulting from it, and being of opinion that it renders

ders the cyder more unwholesome than it can possibly in its own nature be; for, though the ginger may not make any very sensible alteration in the immediate taste of the liquor, it must, I think, strongly impregnate it with its fiery particles, and thereby greatly irritate the mass of blood, and inflame the lungs of such as drink any quantities of liquor wherein it has been infused: others, however, may differ in opinion from me: I know, indeed, many that do so; therefore I only declare my opinion." *Museum Rusticum, vol.* II. *p.* 37.

It is of great importance in the making of cyder, that the fruit be thoroughly ripe. The juices of unripe apples retain their harsh, sour taste, in spite of all endeavours, and never acquire that racy, mellow flavour, which the sun only can bestow. Sweating together in a heap will, indeed, give them an artificial ripeness; but this is not equivalent for that which they receive from nature, which though it receives some assistance from the industry of man, can never be completely imitated by art.

It should, therefore, be the first care of every one concerned in the making of cyder, to let his apples hang upon the tree till they arrive at full maturity. But no certain time can be assigned for this: it varies with the nature of the fruit, and the circumstances of the season. Different apples have different times of ripening; and the same, according to the weather, change their times considerably from one year to another: but signs there always are sufficient to direct the husbandman. The brownness of the kernels, their rattling in the apple, the fragrant smell of the fruit itself, and its spontaneously falling from the tree in calm weather, are certain indications, which, in all kinds, may be depended on. It is, however, an useful caution in this, as in every other case, to err on the right-side, and to let the apples hang too long, rather than too little. Summer fruit, indeed, will suffer by this method, grow pulpy, dry, and mealy, and afford little or no juice. In every other case the rule is good, and in the best fruits, most. The harsher kinds can hardly hang too long, for they daily mend upon the tree: their juices mellow, throw off their crude and watery parts, and consequently, as the crude juices lessen in quantity, the apples improve proportionably in quality. They may hang upon the tree as long as the weather can be expected to continue open: but severe frost should be most carefully avoided, because it destroys the texture of the fruit so much, that even cold water, the only remedy in such cases, will not restore it to its former state: for as all fluids enlarge their dimensions when frozen, the containing vessels of all succulent substances must be thereby burst, and this has upon the fruit an effect similar to a bruise, or any other cause that destroys the vessels, whereby the extravasated liquors soon putrify. From this cause it is that the strongest forest trees are often rent asunder in very severe frosts.

When your apples are fit for gathering, it is essential to choose dry weather for that purpose: for water is a bad ingredient in all vinous liquors, and your fruit should therefore be guarded from it with peculiar care. The wet which adheres to the apples after rain or dew, or even the smaller quantity of moisture which they might contract by falling or lying upon grass, is sufficient to impoverish your cyder in a sensible degree. Gather your fruit therefore in the driest day, and in the driest part of it, when the dew is thoroughly exhaled, and, of choice, gather it by hand. This method may, perhaps, be troublesome and difficult in plantations of great extent, and where the trees are very tall: but wherever it can be used it is of great advantage, and certainly quits cost. You then can choose your apples, and leave upon the tree those which are not of a sufficient ripeness: you save your fruit from bruises, and your trees from the damage they frequently receive by violent unskilful shaking.

The gathering by hand is so essential, especially for winter fruit, which is to be sweated for a considerable time, that it should not by any means be dispensed with; because, as every wounded part of an apple will rot in the sweating, a very great loss must be occasioned, both in the quantity of the fruit, and in the longer time taken up in wiping and rubbing off every speck of rottenness upon each single apple. This last labour is indispensible; because, otherwise, the putrid taint would ever remain in the liquor. Those who plead the want of time, where a great quantity of fruit is to be pressed, may be answered, that it would be more to their advantage to have only half the quantity of good cyder, than the whole of indifferent; and the gathering may certainly be expeditiously performed by means of step-ladders. The apples may be put into baskets, as they are gathered, and thereby be preserved free from hurt, and the tree will not be injured as the support of the ladders here recommended is independant of the tree. However, for those who will follow the contrary practice, the best method is, to cover the ground under the trees with a sufficient thickness of straw to save the apples in their fall, and to lay blankets upon the straw; then, with an easy motion, to shake the boughs successively, removing, at every shaking, the apples already fallen, that they may not be bruised by the next. By these means all your apples are kept dry, and, for the most part, free from bruises; and with a little additional care you may also, in this method, separate the fruits according to their ripeness: for if you proceed regularly from bough to bough, and give each a gentle swing, the ripest will fall first, and the unripe remain upon the tree till more violent motion brings them down.

Windfalls, as they are generally termed, bruised, apples, and those which have not been well ripened, should not by any means be mixed with the choice fruit; for if they are, it would be in vain to expect good cyder: the quantity of it may indeed be large, but it will always be proportionably bad. This fruit need not, however, be thrown away, excepting only that part of it where the bruise appears black and mouldy; for a very little of this would communicate an offensive taste to the whole liquor. The rest will make inferior kinds of cyder; and if care be taken that the windfalls do not lie too long upon the ground, and if keeping cyder be not expected from bruised apples, they will answer tolerably well: nay, Mr. Newburg tells us, in a letter subjoined to Mr. Evelyn's Pomona, that a neighbour of his assured him he had made a quantity of very good cyder with windfalls, which he ripened by sweating them for about a month, that they were beaten off the tree earlier than the season when nature would otherwise have compleated their maturity; but that all the neighbours of this person, who pressed their untimely fruit as soon as it fell, had a crude, austere, indigested liquor, not worth the name of cyder.

The sweating of the apples has, however, been made a matter of some dispute. The writer of the 24th letter in the Dublin Society's weekly observations disapproves of it for choice ripe fruit, and instances his having been informed of some curious gentlemen who carried their thoroughly ripe apples directly from the tree to the grinding mill, without any previous sweating, and obtained from them some of the best cyder they ever tasted. As to the winter fruits, he thinks it probable that the necessity of sweating them might be removed, by leaving them upon the trees, somewhat longer than is necessary to ripen them; "no reason," (says he, without having perhaps sufficiently attended to the benefit which fruit receives from being discharged of its watery parts,) "hitherto appearing to make us think that this fermentation by sweating serves any other use than to increase the degree of maturity which the fruit had acquired upon the tree.—It is indeed possible," continues he, "that it may answer farther purposes, and dispose the fruit to an easier emission of its juices: and as our reasonings upon nature frequently lose their way, where experience does not guide them, it is from trials only that we can form a judgment to be depended on: recourse must therefore be had to actual experiments, which in this case are easy, and will certainly quit cost: for which ever way the question be determined, something must be found very well worth the knowing. Should sweating answer some purpose not to be attained upon the tree, it will, when once discovered, ascertain the nature, the use, and the degree of sweating: or should nothing of this kind appear, it will correct a practice, which, if it does no good, must certainly do

mischief;

mischief: since it is evident to common sense, that if maturity be all that is wanting, it is more perfectly and more naturally attained upon the tree." However, till this is determined by experience, it will be right to continue the practice of sweating every apple: for as to windfalls, and other hard and unripe fruit, it is out of dispute, that as they are deprived of natural maturity, they must be assisted by art.

Upon the whole, there seems in this case, one rule which may be followed for all fruits; namely, to press their juice for fermenting at the time when the fruit itself is in the greatest perfection for eating. Experience teaches us, that there are few apples which do not require time for their being mellowed, before they attain to their highest flavour. The golden pepin, for example, is in its greatest perfection when kept till October; and in favourable years it will retain its flavour and juiciness even till Christmas, or longer. The nonpareil does not attain its chief excellence till near Christmas, and after that it continues in perfection several weeks. It is therefore during the time these apples continue in perfection, that they are fittest to be pressed for cyder; and the same will doubtless hold good of the other sorts, none of which should be pressed before they have attained their highest flavour, nor after they have begun to lose it. A principal advantage accruing from the sweating of apples is, that the fruit is thereby deprived of the watery parts of its juice, which would only weaken the liquor; while its pulp yields a greater quantity of the enriched juice after it has been mellowed.

The material points to be observed in the sweating of apples are, that the fruits be separated according to their different degrees of ripeness, and that the floor on which they are laid be as dry as possible. The more strictly the former of these cautions is observed, the better it will be; and the more the fruit in every heap is alike in its maturity, the sooner the sweating will be over, and the less damage will accrue to the ripest and best apples in the heap. However, if care be taken not to mix any that are very ripe with others that are very green, the injury will not be great: but if this should be neglected, as it too frequently is, either the ripe apples will rot, or the green ones will remain unmellowed; and in either of these cases, the cyder will be considerably lessened in its value. Boarded floors will best answer the intention of the second caution, because they are driest: earthen floors, however, if covered some inches deep with wheat, rye, or oat straw, will do tolerably well. It is likewise essential, for the better preservation of the apples, that they do not touch the walls or sides of the store-room in which they are laid to sweat. To heap them up in the orchard, or any where else upon the grass, or on an uncovered floor where the rains and dews have free access to them, is a sure way to make the cyder weak and watery, and frequently musty and ill-tasted.

Sweating being then undeniably necessary, at least for unripe, hard, and winter fruit, the husbandman, who makes a considerable quantity of cyder, will find a great conveniency in having near his orchard a building, of which his mill and press should occupy the lower floor, and his apples be sweated in that above, from whence they may be conveyed into the mill by a proper trunk. The duration of the time of sweating is best determined by the smell of the fruit; that is, whenever it emits a full scent of the apples, they are fit for the press. Different kinds require different lengths of time, viz. from eight or ten days, to six weeks. The harsher the apple is, the more time it wants.

Apples that have laid any time in heaps, are generally covered with a clammy moisture, proceeding from their sweating. This should be well wiped off; for it is a watery juice, which would impoverish the cyder; and at the same time every bruised and rotten part of the apple should be carefully cut out, and thrown away, and it should be cleared of its stalk; because the former would give a putrid taste, and the latter too much roughness, to the cyder.

The common practice is to carry immediately the apples from the heap where they have been sweated, to the mill, and then to grind them; but if we attend to the length of time during which they will remain in a succulent state after having been sweated, carefully wiped dry, and properly laid up in a place of preservation; we shall find, that, if these directions are duly observed, the fruit will continue in a perfectly sound state, and fit to be made into cyder, till it may be convenient for the husbandman to press it: but before he does this, or rather before he sweats his apples, he should take care to sort them, or at least all the most valuable kinds, and particularly the stire, under-leaf, fox-whelp, and golden pepin, which hitherto have not been found to do so well in mixtures, as each of them does by itself.

The juice of the apples is obtained either by pounding the fruit in a trough, or grinding it in a mill. The former of these is least approved, because it is so tedious as to suit only small quantities, and the work is performed by it unequally, and with waste; much of the liquor being dashed out of the trough by the beating, and some of the apples being hardly broken, when others are reduced to a perfect pomice.

There are several engines used for grinding the apples; but one in particular, resembling a tanner's mill, is used in many parts of England. It consists of a circular trough in which apples are bruised by a large flat stone moved round upon its edge. This engine we have represented on Plate VI. Fig. 8, where M is the stone set upon its edge; N, the spring-tree bar, or that to which the horse is fastened; P, Q, R, the circular trough in which the stone moves; T, L, V, compartments, or divisions for different sorts of apples.

When the apples are ground, some carry them directly to the press; but others empty them out of the trough into tubs, or large, wide, shallow vats. This work is done with most ease by broad wooden shovels: which should also be used to turn the pomice in the vats five or six times a day, to prevent any fermentation; the whole of this operation being chiefly intended to give the pomice a red colour, which afterwards heightens that of the cyder, and brings it to a deep, fine amber. This business is over in two days.

From these vats the pomice is carried directly to the presses, of which there are several kinds: we have given figures of two kinds on Plate VI. where Fig. 9. is the small cyder press, by which the juice is pressed out of the pomice by means of a stone, or block of heavy wood, cut in the form of the frustrum of a cone, and moveable about the center. The pomice is spread upon the bed of the press, where a conical presser is turned round by means of a lever inserted into its base, by which means the juice is forced out and conveyed by notches cut in the bed, to the vessel, by means of a spout, and represented in the figure.

Fig. 10, is a large cyder-press, where A B is the base with its supporters. C, C, the cheeks, which are upright beams, whose lower extremities are sunk in the earth, where they are firmly fixed by cross-bars and masonry. They are connected at the top by two beams, the lowermost of which contains the nut, or female screw. D, is the screw with its wheel; below which is the bearer, or large piece of timber on which the force of the screw is exerted, in order to sink the beams crossing the planks that cover the pomice or cheese, as it is then called. G, G, are the planks on which the pomice is disposed in hair bags, in order to be squeesed: these planks are cut in notches to conduct the liquor to a vessel properly placed to receive it. The bed of this press is supported on a massive work of masonry. It is the wheel which forces down the screw and bearer upon the pomice laid in hair bags upon the bed of the press. This is done by turning the wheel H round; for by that motion the cord is wound round its axis, and by that means the wheel fixed on the bottom of the screw is turned round, and the bearer together, with the cross planks under it, are forced down upon the pomice, laid in bags upon the bed.

These bags hold about two or three bushels, or as much as the mill can grind at once: and these are heaped over each other till the press is full. The larger presses will hold from eight to fifteen bags, which yield, from one to two hundred gallons of liquor, according to the largeness of the cheese. To perform the work neatly, it is necessary to have two sets of these bags; for they clog and fur in pressing, and, consequently, become unfit for use till they have been washed and dried; so that while this is

doing,

doing, either the prefs muft ftand ftill, or another fet be ready to employ it.

Some, inftead of hair-bags, lay long ftraw under the pomice, the ends of which they turn up over it; then cover the pomice entirely with frefh clean ftraw, upon which they fpread another layer of pomice, and fo on, alternately, till the prefs is full. Either of the above methods will do: but thofe who are defirous of doing the work in the neateft and beft manner, generally ufe the bags.

It is ufual to difpofe of all the liquor preffed out of the cheefes, the fame way, and without diftinction: but if the analogy holds, as it furely does, between cyder and other vinous liquors, this muft be a confiderable error. Experience has fufficiently fhewn, that in making wines, there is a very great difference between the firft yieldings of the grapes, and the juices which are afterwards extracted by hard preffings; and this difference is always in favour of the former; fo that, if the fame be true of cyder, the richeft, and choiceft kinds are loft, by an imprudent mixture of the whole.

It is an opinion generally received, and the writer of the letters in the Dublin Society's weekly obfervations, already mentioned, has adopted it; namely, that fummer fruit do not make good cyder. "Summer fruit, or fweet apples, fays he, afford only a weak, pert, windy juice, agreeable enough to the palate from its livelinefs and tartnefs, but in a great degree unwholfome. It has no body, and therefore will not keep, and fcarcely deferves the name of cyder." But Sir Paul Neile, whofe reafoning we fhall give in his own words, judged very differently.

"I affert, fays he, that the beft apples will make the pleafanteft, which in my opinion is the beft cyder; and I account thofe the beft apples, whofe juice is the pleafanteft at the time when firft preffed, before fermentation. I fhall need, befides the experience of the laft ten years, only to fay, that it is an undeniable thing in all wines, that the pleafanteft grapes make the richeft and pleafanteft wines, and that cyder is really but the wine of apples, and not only made by the fame way of compreffion, but, left to itfelf, hath the fame way of fermentation, and therefore muft be liable to the fame meafures in the choice of the materials.

"This truth was not formerly owned, by reafon that in Herefordfhire, and thofe countries where they abound with pepins and hard apples of all forts, they make cyder of both kinds, and ufed them alike; that is, that as foon as they had ground and preffed the apples and ftrained the liquor, they put it into their veffels, and there let it lie till it had worked, and afterwards was fettled again and fined; as not thinking it wholfome to drink till it had thus, as they call it, purged itfelf; and this was the frequent cuftom of moft men in the more fouthern and weftern parts of England alfo. Now, when cyder was thus managed, it is no wonder that when they came to broach it, they for the moft part found their pepin cider not fo pleafant as their moyle or redftreak cyder; but to them it feemed a wonder, becaufe they did not know the reafon of it, which I fhall next explain: for till they knew the reafon of this effect, they had no caufe but to think it was the nature of the feveral apples that produced it; and confequently to prefer the hard apple cyder, and to ufe the other apples, which were good to eat raw, for the table, for which the hard apples were totally improper.

"To fhew that, in Herefordfhire, they know not what was the true caufe why their pepin-cyder was not, as they ufed it, fo good as the cyder made of hard apples, I fay, that for all liquors which are vinous, the caufe that makes them fometimes harder or lefs pleafant to the tafte, than they were at the firft preffing, is the too much fermenting. If wine or cyder by any accidental caufe do ferment twice, it will be harder than if it had fermented but once; and if it ferment thrice, it is harder and worfe than if it had fermented but twice; and fo onward, the oftener it ferments, and the longer it ferments, it ftill grows the harder.

"According to the old method of making and putting up the cyder, they took little care to put up only the clear part of the liquor into their veffels or cafks. Now pepins being a fofter fruit, are in the mill bruifed into fmaller particles, than the harder forts of apples; and confequently more of thofe fmall parts pafs the ftrainer in the pepin cyder, than in the cyder of hard apples. This caufeth a ftronger fermentation, and, according to my former principle, a greater lofs of the native fweetnefs, than in the hard apple cyder; and not only fo, but the lee of the hard apple cyder being compounded of greater particles than the lee of the pepin cyder, every individual particle is in itfelf of a greater weight than the particles of the lee of the pepin cyder, and confequently lefs apt to rife upon fmall motions. When the fermentation of the hard apple cyder is once over, a fecond fermentation feldom happens, unlefs the veffels be ftirred: but in pepin cyder it is otherwife; for if the grofs lee be ftill remaining with the cyder, it need not the motion of the veffel to caufe a new fermentation; but every motion of the air, by a change of weather, will caufe a new fermentation, and confequently make it work till it hath deftroyed itfelf by lofing its native fweetnefs. This alone hath been the caufe why commonly when they broach their pepin cyder, they find it fo unpleafant.

"What firft gave me the hint of this, is that in divers parts they make three forts of wine out of one and the fame grapes; that is, they firft take the juice of the grapes without any more preffing than what comes from their own weight, and the bruifing they receive when put into the vat; which caufeth the ripeft of thefe grapes to break, and the juice, without any preffing at all, makes the pleafanteft and moft delicate wine. The fecond fort they prefs a little, which makes a wine neither fo pleafant as the firft, nor fo harfh as the laft, which is made by the utmoft preffing of the very fkins of the grapes, and is by much more harfh than either of the other two. Now I prefume the caufe of this, at leaft in part, to be, that in the firft fort of wine, which hath little of the fubftance, befides the very juice of the grape, there is little lee, and confequently little fermentation; and becaufe it doth not work long, it lofes but little of its original fweetnefs. The fecond fort, being a little more preffed, hath fomewhat more of the fubftance of the grape added to the juice, and therefore, having in it more of that part which caufes fermentation, ferments more ftrongly, and is therefore, when it hath done working, lefs pleafant than the firft fort, which worked lefs. For the fame reafon the third fort, being moft of all preffed, hath moft of the fubftance of the grape mingled with the liquor, and worketh the longeft: but at the end of the working, when it has fettled and is clear, it is much more harfh than either of the two firft forts. The thought of this made me firft apprehend, that the fubftance of the apple, mingled with the juice, was the caufe of fermentation, which is really nothing elfe but an endeavour of the liquor to free itfelf from thefe heterogeneous parts which are mixed with it: and when there is the greateft proportion of thofe diffimilar parts mingled with the liquor, the endeavour of nature muft be the ftronger, and take up the more time to perfect the feparation, which, when finifhed, leaves all the liquor clear, and the grofs parts, called the lee, fettled to the bottom of the veffel. Nor did this apprehenfion deceive me: for when I began to feparate a confiderable part of the lee from the cyder before it had fermented, I found it to retain a very great part of its original fweetnefs, more than it would have done if the lee had not been taken away before the fermentation; and this not once, but conftantly for feven years.

"The method which I ufed was this: when the cyder was firft ftrained, I put it into a great vat, and there let it ftand twenty-four hours at leaft, but fometimes more, if the apples were more ripe than ordinary: then, at a tap before prepared in the veffel, three or four inches from the bottom, I drew it into pails, and from thence filled the hogfhead, or leffer veffel, leaving the greateft part of the lee behind. During this time that the cyder ftood in the vat, I kept it as clofe covered with hair-cloths, or facks, as I could; that fo too much of the fpirits might not evaporate.

"Now possibly I might be asked why I did not, since I kept it so close in the vat, put it at first in the vessel: to which I answer, that had I put it at first into the vessel, it would possibly, especially if the weather had chanced to prove wet and warm, have begun to ferment before that time had been expired; and then there would have been no possibility to separate any part of the gross lee, before the fermentation had been wholly finished; which keeping it only covered with these cloths was not in danger: for, though I kept it warm in some degree, yet some of the spirits had still liberty to evaporate; which had it been in the hogshead with the bung only open, they would not so freely have done; but in the first twenty-four hours it would have begun to ferment, and so my design had been fully lost: for those spirits, if they had been too strongly reverberated into the liquor, would have caused a fermentation before I could have taken away any part of the gross lee. The great mystery of the whole lies in this; to let so many of the spirits evaporate, that the liquor shall not ferment before the gross lee be taken away; and yet to keep spirits enough to cause a fermentation when you would have it: for if you put it up as soon as it is strained, and do not let some of the spirits evaporate, but suffer the gross lee to be separated by its own weight only, without fermentation, it will ferment too much, and lose its sweetness; whilst on the other hand, if none be left, it will not ferment at all, and then the cyder will be dead, flat, and sour."

Experience taught Sir Paul, that it was necessary to delay the fermentation till late, or till the cold weather had come in, as he informs us, when he says, "It is necessary that the apples have a little time to sweat in the house before the cyder is made; but not too much: for if they be not full ripe before they are gathered, and not suffered to lie a while in the heap, the cyder will not be so pleasant; and if they be too ripe when they are gathered, or lie too long in the heap, it will be very difficult to separate the cyder from the gross lee before the fermentation begins: and in that case it will work so long, that when it fines, the cyder will be hard: for when the apples are too mellow, they will break into so small particles, that it will be long before the lee settles by its own weight only; and then the fermentation may begin before it be separated, and so destroy your intention of taking away the gross lee. And if the apples be not mellow enough, the cyder will not be so pleasant as it ought to be."

To the cause above assigned by Sir Paul Neile for the liquor's fermenting too much, another may be added; namely, that as the summer fruits are fermented earlier than the hard apples, the warmth of the weather hurries the fermentation on too fast, and by this means renders the liquor much less palatable: or it may even hurry it beyond the vinous state, till the acetous fermentation begins. The sweetness of the summer fruits make them likewise more liable to ferment too much; whereas the sour roughness of hard apples retards that operation, and makes a longer time necessary to perfect the vinous fermentation. These causes render it necessary that great care be taken in preparing the juice as directed by Sir Paul, and that there be a cellar in which the heat is suited to carry on as slow a fermentation as possible. If the maker of the cyder is not provided with such a cellar, the juice of the apples may be buried in cold spring water, as before mentioned, and be kept there till the temperature of the weather becomes fit for its being fermented.

"What has been said of the time for making the pepin cyder, may, adds Sir Paul Neile, with due allowances for the nature of the apples, serve for all other summer fruit; as the Kentish-codlin, marrigold, gilly-flowers, summer-pearmains, summer-pepins, Holland-pepins, golden-pepins, and even winter-pearmains. For though they must not be made at the same time of the year, yet they must be made at the time when each respective fruit is in the condition before directed for the pepin. Nay, even in the making of that cyder, you are not tied precisely to that particular time, but, as the condition of the year hath been, you may make your cyder one, two, three, or four weeks later."

When the pressing of the apples is finished, the most careful makers of cyder strain their liquor through a hair sieve, to separate from it the coarsest dregs; which is a practice every way advisable. It must then be left to itself, till it has undergone the necessary fermentation, and deposited its grosser lees. To this purpose some put it immediately into hogsheads, others into large tubs or vats, and the most curious into a vessel intended for that very use, wide at top, and growing narrower all the way down to the bottom, near which is a tap to draw off the liquor. This vessel is fixed upon a stand, or stilling, and frequently contains from five to twenty hogsheads. In these vessels the heavier lees subside, and the lighter form at top a crust, which, by its sinking afterwards, gives timely notice that the ferment is gone off, and that the liquor is fit for racking. Some gentlemen, who spare no pains to make their cyder as fine as possible, think that the excellence of the liquor depends greatly on catching the very instant when this crust breaks; and in order to be sure of it, they set a person to watch and give immediate notice of the crack or noise which the crust makes in breaking. They hold this to be the critical time for racking off the liquor, and maintain, that so much of its spirit is evaporated very speedily after, as to render the cyder irrecoverably vapid. This, therefore, should be carefully attended to; and upon the first appearance of the crust's falling, the cyder, which is then become tolerably fine, should be drawn off the grosser lees, and tunned into the hogsheads. The usual time taken up in this primary fermentation is from thirty-six to forty-eight hours; more or less, according to the weather. Some affirm that they have had good cyder by tunning it directly from the press, without any other caution than leaving room for the liquor to ferment in the hogshead, where it remained from first to last: but this method is liable to many hazards, and successful, where it has been so, only in favourable seasons. The gross lees are apt to rise on every considerable change of weather, and when they do, they set the cyder on the fret, which, should it do no worse, certainly robs it of its spirit, and, when over, leaves it flat and vapid. Besides, repeated experiments have proved, that sourness in all fermented liquors begins ever at the lees, and therefore the more of them is left among the cyder, the more readily it will turn eager.

Here I must observe, that a most important precaution is too often overlooked by many of those who make cyder of winter fruits; for that a sufficient warmth of the air is as essential to ferment the rough juices of hard apples, as it is dangerous to suffer the heat to be too great in the fermenting of cyder made of summer fruits. If the weather is very cold when the hard apples are pressed, the help of fires should be recurred to; or if that has been neglected, or could not be conveniently used, it will be right to carry the cyder to a place warmed considerably by the sun for a short time in the summer, and there to place it out of the immediate reach of the rays of the sun. The bung of the cask must be loosened, because there will arise a degree of fermentation, which will attenuate any viscidity not overcome by the first fermentation. Great care must be taken that this fermentation be not carried beyond the nice point of correcting the rough raw taste of the fruit: for if it goes farther, the liquor will either become vapid, or turn to vinegar. As soon as the desired point is obtained, the liquor should be racked off, especially if much feculence has sunk to the bottom, and it should then be carried down into the vault, where it may be preserved long in perfection.

The choice of proper vessels to keep the cyder in after it has fermented is very material; no liquor being so apt as this to take the taste or tang of the cask. New vessels, though the wood be ever so well seasoned, generally give a disagreeable relish to all liquors, and will do so remarkably to cyder, unless due caution be used before-hand. Frequent scalding with hot water, into which some handfuls of salt have been first thrown, or with water in which some of the pomice has been boiled, and washing afterwards with cyder, are the usual remedies against this evil, and seldom fail of removing

moving it effectually. Of old casks, beer vessels are the worst: they always spoil cyder; as, in return, cyder casks infallibly spoil beer. Canary and brandy casks do well, and all wine vessels tolerably; for, provided the tartar adhering to their sides be carefully scraped off, and they well scalded, there is no danger in using them. The best way of scalding them, is to boil a parcel of dried wormwood in water, and with that and a brush of the same plant to rub and scour their insides. This will correct the acid of the tartar; and so will likewise all vegetable ashes used in the same manner. Those who advise fumigating the casks with brimstone, confidently affirm that the cyder becomes stronger, and keeps better, when the vessels have been thus prepared, and for this reason they tun immediately after the operation, and before the smoak evaporates. To enable such as may choose to examine, by fair trials, how far this is true in fact, I shall here add the neatest method of performance. Melt a pennyworth of brimstone, and dip in it a piece of new cloth, or of canvass, till all the brimstone is imbibed, and the cloth or canvass looks like a piece of searcloth: then roll it close, tie it, and with a wire suspend it at the bung, three parts in four within the vessel; light it, and let it burn till it is ready to fall into the cask, then take it out, and tun without delay. Some add a little powdered cinnamon, cloves, pepper, or other spice to the brimstone for fumigating; but I see no great reason for their so doing.

The best shaped vessels for keeping cyder in are, as advised by captain Sylas Taylor, in a letter subjoined to Mr. Evelyn's Pomona, and by Mr. Worlidge, those of which the barrel-boards are strait, the vessel broader at one end than the other, and standing on the lesser end, with the bung-hole in the top. The advantage of this form is, that in the drawing of the cyder, though but slowly, the skin or cream contracted by its fermentation (as is the case of all strong liquors) descends, and covers the liquor by means of the tapering of the vessel, and thereby preserves to the last the spirits of the cyder, which would otherwise evaporate and waste. A little wheaten-bran cast in after the fermentation, thickens this coat or cream of the liquor, and thereby conduces much to its preservation.

We come now to a point of great importance, and hitherto of as great uncertainty, which has raised among the curious a controversy of long standing, and not likely to be brought to a speedy decision, without a course of regular experiments. Some maintain, that continued fermentation and frequent racking certainly spoil the cyder; whilst others assert, that it can never be good without them. Some rack once, some twice, and others whenever the liquor frets. Some look upon the lees as the food and nourishment of cyder: others, as a cause at hand, upon every change of weather, to set it on the fret, and turn it sour. Every man has a system of his own, and a peculiar practice consequent thereon; and so great is the variety of methods, that nothing certain can be drawn from them but this one general conclusion, that we are still at guess work, and must be obliged to future trials for any rules that can be thoroughly depended on. I shall therefore here relate the several ways now in use, and then give my own general opinion of this matter: but I strongly recommend the making of accurate experiments on each.

One method is, to leave the cyder in the vats some days longer than was before advised, and till it fines in a great measure: then to tun it into hogsheads, where it is to remain without any farther racking. Those who recommend this practice say, that their cyder is thereby rendered the stronger and mellower: and those who object to it reply, that lying on the grosser lees, which cannot all be fallen in the vats, it must be apt to fret, turn foul, and, in unsettled weather, eager.

A second and more common method is, a fortnight after tunning, to rack into other hogsheads. There the cyder undergoes a second gentle fermentation, and while this lasts the bung must be left open; afterwards, when the fermentation lessens, covered only with a wet cloth, or a tile; and when it is quite over, stopped down close with well tempered clay, kept moist, to prevent its cracking, by strewing over it a handful of bay-salt.

To this second racking others add a third in March or April, when the lees have thoroughly subsided. This again is followed by a little fermentation; and for that reason chiefly it is objected to by those who think every fermentation hurtful which is not strictly necessary.

Others, on the contrary, and particularly those of Devonshire, where the strongest cyders are made, look upon thorough fermentation as the great secret to have their cyder fine, light, and free from dregs, and accordingly they not only approve of the above last mentioned method, but proceed much farther, as follows:

At first tunning they do not fill their hogsheads to the bung, but leave an empty space to receive a pailful of fresh cyder from the press: this renews or increases the fermentation, and sets the whole on working with some violence. The froth which rises at the bung is carefully skimmed off, and the waste of liquor thus occasioned is constantly replenished with unfermented cyder. By these means the whole is kept from the fret for a considerable time: for it is not uncommon to have cyder thus managed working for a fortnight. A month after this operation, and the stopping of the vessels, the cyder is racked, and, generally speaking, in two months more a second time: and if it frets, which however is said seldom to happen in this method, it is racked off a third and a fourth time.

To make a proper choice among the several above recited methods, they should be tried together, with the same fruit, of equal ripeness; the cyders should be kept to the same age, and their different qualities should be attentively observed. Just information cannot be obtained in any other way: for the want of accuracy and exactness will render the experiment fruitless and insignificant. Every one will tell you, that his method affords good cyder: but this general expression gives no determinate idea, and forwards knowledge very little. Would gentlemen be at the trouble to keep notes, and minute down all the differences observable in the same cyders under different managements, it might soon be known what method gives the strongest, which the neatest, the roughest, mellowest, or lightest cyders; and every one might then pursue, as his taste or interest should direct, that which would answer best: but till something of this kind be done, only very slow and inconsiderable improvements can be expected.

In the mean time I must observe, in general, that whenever the lees of cyder are in such quantity as that the liquor cannot preserve them from a tendency to putrefaction, as must be the case with the first, and generally the second lees, it is certainly advisable to rack off the liquor; and that, if the cyder is kept in a place not subject to the various changes of the weather, the little fermentations raised by racking cannot be attended with any great danger; nor will the frettings return. But as to the frequently repeated fermentations which are said to be, of choice, the practice of the makers of cyder in Devonshire, they surely are by no means advisable.

The few points which experience has hitherto determined in regard to the making of cyder are, that weak cyder cannot bear above one or two rackings without too great a loss of spirits; that strong cyder made of winter apples will stand several rackings, and thereby grow mellower, and be the sooner fit for drinking; that the more the liquor is fermented, the rougher it will grow; that fermentation is no other way so well promoted, as by putting into the hogshead from time to time some of the liquor fresh drawn from the press; and lastly, that to have a rich, racy, palatable cyder, a little inclining to the sweet, great care must be taken to prevent all future fermentation after the liquor is once become fine. If it should be foul, isinglass will help to fine it, by precipitating the flying lee.

In general, the cyder that is longest in fining is the strongest and most lasting, if it has been made of thoroughly ripe fruit: but, as was before observed in the article of wines, all liquors will be much longer in clearing in mild moist weather, than in cold dry weather or frost.

When the bung-hole of the vessel is closed up, a small vent-hole should be left open, or but loosely stopped with a peg, for several days, till the wild spirit of the liquor be spent;

ſpent; for otherwiſe it will break the caſk, or find ſome other vent, which, though but ſmall, will always abide open, and prove the ruin of the cyder. Many have ſpoiled their cyder by this only neglect, and never apprehended the cauſe thereof. After this wild ſpirit is ſpent, the vent-hole, as well as the bung, ſhould be ſtopped quite cloſe; and then the cyder, though ſeemingly flattiſh at firſt, will ſoon improve, and become briſk and pleaſant.

Deadneſs or flatneſs in cyder, if occaſioned by a two free admiſſion of air into the veſſel, for want of right ſtopping, is remedied by grinding a ſmall parcel of apples, and putting them into the caſk, which ſhould then be ſtopped up cloſe: but care muſt alſo be taken to open the vent ſometimes, or the veſſel will be in danger of burſting. The liquor thus managed muſt likewiſe be drawn off in a few days, either into bottles, or into another caſk, leſt the murk ſhould corrupt the whole maſs; to prevent which, ſome put in only the juice of the newly preſſed apples. The ſame may be done to flat bottled cyder, by adding about a ſpoonful or two of new muſt to each bottle of the dead liquor, and ſtopping it again. Cyder that is dead or flat will often revive again of itſelf, if cloſely ſtopped, upon the revolution of the year, and the approach of ſummer: but cyder which has acquired a deadneſs or flatneſs by being kept in a beer veſſel, cannot be revived again.

Thick cyder may be rendered clear and good by a ſecond fermentation, or, ſometimes, by only throwing into it two or three quite mellow apples. But cyder in which the acetous fermentation has taken place, can never be reſtored. If it be only a little ſouriſh, or drawn off in another veſſel, about a gallon of wheat (blanched is beſt) to a hogſhead of cyder, and ſo in proportion for any other quantity, will both amend and preſerve it: or if it is ſo ſour that the wheat does not anſwer that purpoſe, it may be corrected by egg-ſhells, powdered alabaſter, &c.

Cyder which has contracted any ill flavour or taſte from the veſſel, or from any other cauſe, will be helped by the addition of a little muſtard ſeed ground with ſome of the cyder.

Ginger accelerates the maturation of cyder, gives it more briſk ſpirits, helps fermentation, promotes its duration, and corrects its windineſs.

When the juice is too thin or weak, it is a common and very adviſable practice to give by art that ſtrength which nature had not beſtowed. To this end, raiſins of the ſun, or the lees of rich wines, are uſed with good ſucceſs; as is alſo ſugar. Writers on this ſubject give various directions for the uſe of this ingredient: but it would be needleſs to repeat them here, as it is of very little importance in what manner it be done, the giving a body to the liquor being the only thing wanting, and this a proper quantity of ſugar will effect, in whatever ſhape it is uſed. When the deſign is to colour the cyder, the ſugar is boiled till it becomes brown, and then put into the caſk.

CYTISUS, the name of a plant much cultivated by the old Romans for the food of cattle, and called by ſome ſhrub-trefoil, and by others ſhrub-lucern.

It riſes to the height of five, ſix, or even more feet, with a ſhrubby ſtalk, covered with a greyiſh bark, and divided into many branches, covered with a hoary down while they are young, and garniſhed at each joint with trifoliate leaves ſtanding upon foot ſtalks about an inch in length. There are two or three of theſe at each joint, ſo that the branches are cloſely covered with them. The lobes are ſmall, ſpear-ſhaped, and hoary on their underſide; and theſe leaves remain all the year. The flowers, which are of a bright yellow, blow on foot-ſtalks which ariſe from the ſides of the branches, each foot-ſtalk ſuſtaining four or five flowers; and theſe are ſucceeded by compreſſed moon-ſhaped pods, each containing three or four kidney-ſhaped ſeeds.

The cytiſus may be raiſed either from its ſeed ſown about the middle of October, or in the beginning of April; or if greater ſpeed be deſired, from cutting ſlips, or layers, planted in the ſpring or autumn, ſo as to leave a ſpace of four feet between each plant. Such are the directions of Columella, who adds, that if the ground be well dunged for this planting, and well hoed up round the plants, which ſhould be watered during the firſt fortnight, if rain does not fall, plentiful crops may be obtained from this excellent vegetable, equally fit for horſes, oxen, cows, ſheep, hogs, goats, and poultry. It is alſo ſingularly profitable for bees, whoſe honey it increaſes prodigiouſly. It has the ſame effect upon the milk of cows, beſides greatly improving its quality. In the kingdom of Naples the goats feed upon it, and great quantities of excellent cheeſe are made from their milk. In the iſlands of the Archipelago, the Turks make handles for their ſabres of the wood of this ſhrub, which, when full grown, is as hard as ebony, and of a fine yellow colour. It will bear cutting as often as its ſhoots are about fifteen or eighteen inches long, which may be ſeveral times in the year; for it ſhoots and flowers during eight months in the countries where it grows well, and continues green during the whole winter, if the ſeaſon be at all favourable. Its ſeeds begin to ripen towards the end of Auguſt, and continue to do ſo until the cold ſtops them. It will be fit for cutting at the end of three years at fartheſt, and ſhould be carefully kept clear of weeds, and hoed up between each cutting. If given as green fodder, which it affords during eight months of the year, about fifteen pounds weight of it are ſufficient for the daily food of a horſe, twenty pounds for an ox, and ſo in proportion for other cattle, according to their ſize and ſtrength. When made into hay, it ſhould be given more ſparingly, becauſe it is then more nouriſhing. In this ſtate it ſhould be ſteeped in water, before it is given to cattle, and then be mixed with chaff or ſtraw. The time of cutting it for hay, is when the greater part of its ſeeds begin to grow large; and the manner of making this hay is, to let the ſwarths lie ſome hours in the ſun, till they are faded, and then to dry them thoroughly in the ſhade. *Columella De Ruſtica, Lib.* V. *cap.* 12.

Mr. Miller allows the cytiſus every quality that can recommend it for the feeding of cattle in the countries where it grows naturally, ſuch as the iſlands of the Archipelago, Sicily, and the warmeſt parts of Italy, but is perſuaded that it will not thrive in England, ſo as to be of any real advantage for that purpoſe here; becauſe it cannot bear ſuch hard froſts as we ſometimes have; or if it does not bear them ſo far as not to be abſolutely killed, it will be ſo much damaged thereby, as not to be able to recover its verdure before the middle or latter end of May; nor even then to put forth ſhoots that will bear cutting more than once in a ſummer; beſides, their being ſo woody, if ſuffered to grow to any conſiderable length, as to render that cutting very troubleſome, and of little ſervice by way of fodder. He therefore thinks, upon the whole, that it can never anſwer the trouble and expence of cultivation in this country, where we have many other preferable plants; but that, in hot, dry, rocky countries, of which we have now ſeveral in our colonies, where few other vegetables will thrive, this may be cultivated to great advantage; for it will live there many years, and proſper very well.

D.

DAB-CHICK, a chick newly hatched.

DAFFODIL, the name of a well-known flower, of which there are feveral fpecies. The common fort grows naturally by the borders of woods, and fields, in many parts of England; this hath a large bulbous root, from which come out five or fix leaves, about a foot long, and an inch broad, of a greyifh colour, and a little hollowed in the middle, like the keel of a boat. The ftalk rifes a foot and a half high, having two fharp longitudinal angles; at the top comes out a fingle flower, inclofed in a thin fpatha, or fheath, which is torn open on one fide, to make way for the flower to come out, and then withers and remains on the top of the ftalk. The flower is of one petal, or leaf, being connected at the bafe; but is cut into fix parts almoft to the bottom, and thefe all expand. In the midft of this is fituated a bell-fhaped nectarium, called by gardeners a cup, which is equal in length to the petal, and ftands erect. The flower nods on one fide of the ftalk. The petal is of a pale brimftone colour, and the nectarium yellow. It flowers in the beginning of April; and after the flowers are decayed, it turns to a roundifh capfule, with three cells filled with roundifh feeds, which ripen in July. This fort propagates very faft by off-fets from the root. For the method of cultivating the more curious fpecies of daffodil, *fee the article* NARCISSUS.

DAG, dew hanging upon the grafs.

DAIRY, the occupation, or art of making various kinds of food from milk, particularly butter and cheefe. It alfo fignifies the place where thefe operations are performed.

The following account of managing a dairy was written by a gentleman who has for a confiderable number of years employed himfelf in that bufinefs, and acquired by his induftry a plentiful fortune.

He begins with recommending the cultivation of faintfoin to every perfon concerned in a dairy, as it is obferved to increafe the milk of cows, both in quantity and quality, above any artificial pafture yet known, and therefore he advifes the farmer to keep his cows upon it, and form a five years dairy.

" An acre of the worft land, continues he, will, when improved by this grafs, maintain four cows very well from the firft of April to the end of November, and afford befides a fufficient ftore of hay, to make the greater part of their fubfiftance the four winter months following. You muft buy then about four hundred milch-cows, but take care you chufe them with judgment. I have bought your largeft fort of runts from Wales, for lefs than fifty fhillings a cow, with a good calf by her fide, which I always difpofed of as foon as I could. You will obferve, that I make too good an ufe of the milk to afford the calf his fhare of it: I generally keep thefe cows above twelve months, and then, felling them, fometimes for four pounds a-piece, I ftock myfelf with fuch that are new milched. I obferve this rule every year, and the trouble is fufficiently rewarded by the advantage it brings me; for befides the profit I make by felling dearer than I buy, I avoid the inconvenience of having any thing to do with bulls, and the confequences; fo that I always preferve my cows in their full milk, and find it no uncommon thing for one of thefe milch-cows to be milked twice a day, and afford a gallon and an half at a meal. Four hundred of thefe cows will coft a thoufand pounds; and you will find, that, coming from a poor pafture to a rich, they will profper and increafe both in milk and fize. In eight convenient places about your hundred acres let there be built eight thatched fheds, a little rifing in the middle to carry off the water; the height may be ten feet, and the breadth thirty; each of thefe fheds fhould be a hundred and twenty-five feet long, and, under the higheft part, directly in the middle, you muft raife a flight partition, lathed and plaiftered, which ferves to fupport the ridge of the roof, while the two fides are fuftained by fquare wooden pofts, about eight feet high, and placed at proper diftances.

" On either fide of the partition wall let there be fixed a kind of rack, like thofe in ftables, which is to run the whole length of the fhed, and muft be placed as high as a cow can reach her fodder from. The fhed muft next be divided into ftalls, like thofe for ftone-horfes, and each ftall will be above five feet broad; the length of thefe ftalls muft be exactly fitted to that of a cow, that a crofs bar, being placed at the outward end, may keep the beaft from running backwards: thus every fhed will hold fifty cows, five and twenty on each fide of the partition: to every one of thefe fheds you muft appoint a man, whofe bufinefs it will be to clear the place, and carry off the dung; as alfo to mow the faintfoin every day, and give it to the cows in the rack before-mentioned: this man beginning at one end of his proportion of ground, and going gradually on to the other, the firft place will always be fit to mow again by that time he has gone through his whole divifion. Your cows are thus fed at difcretion, with neither too much nor too little; they are not peftered with the fcorching heats, nor troubled with the ftinging fly, which, in open paftures, often makes them whifk about, and trample down more grafs than they eat. At each end of every fhed you muft build a flight room of brick, thirty feet fquare, and ten feet high, which is to be divided, the crofs-way of the fhed, into two partitions, each fifteen feet broad, and thirty feet long; that which joins the cow-houfe muft be paved with tiles, and is to ferve for a dairy; the other muft be floored and windowed, and is to be a lodging-room for the dairy-maids. Every fhed will require five maids, that is, to every ten cows one dairy-maid; fewer might ferve, but it is better to exceed, than fall fhort, in this particular. Thus each dairy will have two or three maids belonging to it, whofe lodging will be the room adjoining, and whofe care is to extend to the fhed on both fides the partition, to the five and twenty cows which are the neareft to their ftation. All along both fides of the partition, at about a foot above the ground, let there be fixed, clofe to the wall, a ftrong

pipe

pipe of lead, a little lefs than an inch diameter; both which pipes, being fomewhat raifed exactly in the middle of the fhed, muft have a gentle and almoft an invifible defcent from that rifing to the dairies, through the wall of which their nether ends are to be brought, and there wrought into one another, that whatever defcends through them, into either of the dairies, may have iffue but at one mouth. This mouth of the pipes muft be made very fmall, and neatly fitted into the hollow end of a ftrong wooden axle-tree; which, whilft it is turning fwiftly round the mouth of the pipe, may by no means ftrain it by the motion, but receive, into its own hollow, the milk which defcends through the leaden pipes, without fpilling any, and paffes fo far through a wheel, or veffel like a barrel, only much larger in its circumference. The axle-tree, which this veffel is to turn upon, is bored very full of round holes, through which it delivers the milk into the veffel, as faft as it receives it from the pipe.

"The veffel muft be capable of containing, at leaft, three times the quantity of milk, which it is defigned to receive; and there muft be fix wings or thin pieces of wood, glued on edge-ways to the wooden axle-tree, whofe length and breadth muft be fo contrived, as to leave a free fpace of fix inches at either end of the axle-tree, and a foot between their edges lenth-ways, and the fmooth infide of the veffel; in the moft convenient part of which muft be contrived a door, to open and fhut down upon occafion, as clofely as if there was none. This door will perform its work very neatly, if you line the infide and edges with fome kind of cloth, which is commonly ufed in the preffing of cheefe. The other folid end of the axle-tree muft extend itfelf about five feet longer; and the whole length may be fupported by fquare wooden pofts, and turn in their tops, which are to be made hollow, and kept greafed for that purpofe. This end of the axle-tree is to be faftened into a wheel, exactly like thofe which are ufed in many places for roafting of meat. The diameter of this laft wheel muft be within fix inches of the height of the dairy, and two or three large dogs, being put into it at a time, will turn it with extraordinary fwiftnefs: the dogs are eafily taught, and will at laft take delight in the exercife. I have brought up a large buck to the practice of this labour, and it is wonderful to fee the force with which he runs round an hour or two together, and turns a wheel of ten feet diameter; but you muft make your wheel as light as it can poffibly hold together. I have but one thing more to fay, and I finifh this direction: pretty near that fide of every ftall in your fhed, to which the maid muft come to milk the cow that belongs to it, let a hole, as fmall as will ferve the occafion, be contrived by your plumber, in the uppermoft part of the leaden pipe, to fhut and open with a little fcrew, which fcrew, for fear of lofing it, may be faftened by a little iron chain to the body of the pipe. I have endeavoured, in the defcription of all this, to make my meaning as plain as poffible, and hope the reader will, with a little attention, comprehend the whole."

The ingenious Mr. Lifle obferves, that fo much cleaning and fcalding is neceffary, that the dairy farmers fpend as much wood in fire, for that purpofe, during the fummer, as they burn for other purpofes in the winter.

If the milk veffels are not kept clean they will be four, and the cheefe will be four before it can come, and it will eat four and choaky. A cold dairy is a great means of preferving cream from turning four. The milk-houfes fhould alfo be large, for otherwife the fteam arifing from the hot milk as brought in from the cows, will heat the air of the room.

Care fhould be taken when cows begin to give off their milk, to milk them clean; for if this be neglected they will foon grow dry. Cows generally begin to give off the height of their milk about the time of the bloffoming of the wheat, and continue fo till a good aftermath comes on, when their milk will increafe; but cold and rainy weather in the autumn will foon abate their milk again. Perhaps the reafon why the milk of cows abates about wheat bloffoming time is, becaufe about that time the grafs of the field bloffoms alfo, and the flufh of the fap is come to its height and maturity, and then abates, for the roots of the grafs at that time begin to harden and grow dry; nor do they take in the juices of the earth fo freely as they did before, and therefore grow drier and drier, till the feed is hardened. The feed being thus brought to maturity, the roots of the grafs for fome time, till the cold of the winter checks them, ftrike frefh fap roots, or buds, preparative to the enfuing fpring, and which will the next year be the fpring roots and increafe. On thefe new efforts the ftart of the autumn grafs depends, till the cold checks it. This grafs is called the aftermath, and upon the growth of this the cows milk depends.

It has been obferved, that the milk of the hill-country cows do not yield the fame proportion of cream, as that of the vale cows; owing, in all probability, to the poverty of the hill-country cows, which are generally poor in cafe.

Thunder will break the cream, and turn the milk in the milk-pans, fo that no cream can be fkimmed off for butter; nor will the cheefe-curd hold together, but will break afunder.

It is commonly faid, that a quart of cream will make a pound of butter; but this muft be underftood of cream, that hath ftood two or three days to fettle, for three pints of cream juft fkimmed from the milk will, in three days, be reduced to nearly a quart. If you bring in the milk and ftrain it immediately into the pans, without letting it firft ftand to cool, the cream produced by it will be much lefs, than it would have been, if the milk had been fuffered to ftand and cool before ftraining.

In fome parts of Dorfetfhire they fet the milk over the fire in brafs pans to warm, which makes the cream rife, and when a bladdle is formed in the middle, they take the pans from the fire, fkim off the cream, and put it into a tub. After this the dairy-maid, by only putting her hand, and ftirring it about in the tub, brings it prefently to butter, without the help of a churn. The butter made by this method is very rich, but the cheefe made from the fkim-milk very poor. *See the article* Cheese.

The hill-country farms are not fo well adapted to a dairy as thofe in the vale; becaufe the foddering feafon in the former holds fo much longer, occafioned by the rowet-grafs falling of a month fooner, and the fpring-grafs coming a month later than in the vale. *Lifle's Hufbandry, vol.* II. *p.* 139.

A correfpondent of the editors of the Mufeum Rufticum has given the following account of the profits of a dairy kept on twenty acres of land, which he fuppofes to be an addition to a farm, not one by itfelf. Nothing therefore is allowed for the feed which the cattle may accidentally have on the arable land, or turnips, which they may expend in the winter.

EXPERIMENT, 1763.

Food, Produce, and Expences of a Dairy *of four Cows in a Year.*

Their food, four fmall paftures, amounting to fixteen acres, or thereabouts. Two of them I fed in the fpring, rather late before I fhut them up for hay: another, of fix acres, the cows had to themfelves till the others were mown; and then I fhut that up for a rowen (aftermath) crop of hay, cutting it the twentieth of Auguft.

Therefore they had firft that of fix acres, another of two acres, which is common for all my cattle, being never mown; next a five acre piece, after the hay was cleared from it, and then the other field of three acres: befides which, they ran four days in my clover, till finding the butter tafted, I took them out.

It will appear alfo by the following account, that they eat in winter one ton and feven hundred weight of hay, and two loads and a half of ftraw bought for them, befides their fhare of fome which grew on my farm, the whole of which (foft corn ftraw) amounted only to five acres of oats for them and four horfes too; the chief of my lands lying that year fallow.

	4	6	4

In the above account is included nothing for firing, which coſt me very little, as the ſmall buſh-faggots, which I grub up on borders of fields to clear them for the graſs to grow, completely ſerved my dairy this year: theſe are difficult of ſale, fetch but little, and muſt be rooted up if no cows are kept.

The cook in the family managed as dairy-maid: there are in this reſpect great diſadvantages in only keeping four cows, if a dairy-maid is alſo kept to attend them; for ſhe may manage (and they do in this neighbourhood more, in proportion) eight or ten cows, as well as four, which alters the proportion of the expence greatly; and in firing it is but a ſmall addition of wood to the addition of four or five cows.

Profit, four pounds eleven ſhillings per cow				18	5	7½

There are ſome very material obſervations to be made on this account. Is four pounds three ſhillings the value of a cow's feed a twelvemonth? Surely not. Two ſteers, or heifers, may be kept and fatted in the place of one cow: theſe will undoubtedly pay better.

I am aware of the objection, that a dairy is never ſuppoſed to anſwer well without a good dairy-wife to do all the buſineſs of it. This certainly makes a material alteration: but four pounds a cow is, in this neighbourhood, thought pretty near the profit of one, at leaſt as farmers wives own. Yet it muſt be evident, if there was no farther conſideration, a dairy muſt be attended with conſtant loſs: this conſideration is the advantage derived from the hogs, which evidently compoſes the whole profit of a dairy.

I am not yet able, from experiments, to aſſert how many hogs may be kept on a given number of acres without the aid of a dairy: this is neceſſary to be known before the exact profit of cows can be aſcertained. The ſpring litters ſtand greatly in need of the milk and whey, which is then coming on; ſo that few, I doubt, could be bred at that time of the year without them.

I ſhall, every year, make all the obſervations I can on the feeding of them, to be able to judge better for the future.

I ſpeak from experience, and know well that grazing, were it not for the hogs, would be more profitable than four pounds per cow.

I come now to ſpeak of my hogs; and in this point, like the laſt, I ſhall quote a page or two from my manuſcript regiſter of experiments.

EXPERIMENTS, 1763.

Food and Produce of a Sow, and the Pigs bred by her, in a Year.

	Profit	10	1	2

The dairy this year was four cows: all the whey and ſlet milk was thrown into the hogs ciſtern, together with the diſh-waſh and offal of the kitchen, and the drains of about twenty coomb of malt uſed in the family, beſides which, thirteen coomb more I bought for them: all this compoſed their common waſh while lean: for three months in the ſummer, the ſow and the ſeven pigs ran in my clover. Theſe articles, beſides common graſs, (on which, by the bye, they feed as well as ſheep) were all their lean food.

Now, from the above account muſt be deducted the value of the clover-feed, as that certainly was not from graſs-ground, and may be eſtimated. Such deductions I have no objection to, as we may come near the mark in valuing: my calculation, however, does not require them, as the twenty acres were to have been an addition to a farm, not one by itſelf.

	l.	s.	d.
Seven hogs, at fourteen-pence per week, for three months, come to	0	14	0
Thirteen coomb of drains	0	10	4
	1	4	4

But let theſe two articles be ſtated at two pounds one ſhilling and two-pence; the propriety of the ſums mentioned in my calculation for the profit of a ſow will not be impeached thereby.

EXPERIMENT, 1764.

Food, Produce, &c. of Hogs a Year, maintained by a DAIRY *of four Cows.*

The old ſow pigged in April, eleven, and again in November, twelve; the young one ſeven, in January, 1765.

	Profit		14	0	6

Before I make any obſervations on this account, I ſhall explain the price I charge for clover-feed.

I am enabled to do it very clearly this year, as I had none of my own, but hired a field of two acres and three rood, at one pound thirteen ſhillings per acre, from May to Michaelmas. I hired it purpoſely for my horſes, but kept the ten hogs in it for three months.

The price of the clover was four pounds ten ſhillings and ſixpence. The cattle it fed were

Five horſes, three months;
Ten hogs, three months;
Thirty-eight ſheep and lambs, one month;
Two heifers, two months.

The common price of joiſting a horſe is one ſhilling and ſixpence per week in clover; but that I may raiſe the price for the hogs, I will reckon the reſt of the cattle as low as poſſible.

	l.	s.	d.
Five horſes, ſay at three ſhillings and ſixpence per week, for three months	2	2	0
Thirty-eight ſheep and lambs, at two-pence per couple, for one month	1	5	4
Two heifers, at three-pence per week each, for two months	0	8	0
The hogs	0	12	0
	4	7	4

This

This comes as near the truth as any calculation I can make; and I can every year, by hiring clover, keep my hogs as cheap as this, without any affiſtance from arable land of my own. *Muſeum Ruſticum, vol.* IV. *p.* 274.

In a later number of the above work, another correſpondent makes the following remarks.

	l.	*s.*	*d.*
Eleven acres and a half, at fifteen ſhillings per acre, is - - - - - - - - - -	8	12	6
Eight acres and a half of after-graſs, at ſeven ſhillings and ſixpence per acre, for the remainder of the year after being mowed -	3	3	9
	11	16	3
Deduct for the ewes winter-feed, (for ſeventeen, the average in the nine years) at four ſhillings per head - - - - - - - -	3	8	0
To be charged to the annual expence of four cows - - - - - - - - - - - - - -	8	8	3
Expences attending the winter-feed of the ſaid four cows, as it does not appear any part thereof grew on the twenty acres; the average of two years is - - - -	5	0	$7\frac{1}{4}$
One year's expence attending four cows, per his own accounts - - - - - - - -	13	8	$10\frac{1}{4}$
The produce, per ſame accounts, on an average of two years, (making the proper allowance, and three-pence wrong in adding up) is - - - - - - - - - - - -	22	12	$2\frac{1}{2}$
Nett profit on four cows for one year, by his own account - - - - - - - -	9	3	$4\frac{1}{4}$
Thus it appears, admitting his accounts of expences to be for two years. But notwithſtanding the appearance theſe two ſums of four pounds ſix ſhillings and fourpence, and five pounds fourteen ſhillings and ten-pence halfpenny, have of being the expence attending four cows two winters, yet I think, that from April, 1763, to May 6, 1764, includes but one; and in which time it may be reaſonable to apprehend the hay and ſtraw therein mentioned were conſumed for fodder, (except the two hundred weight of hay in the firſt *item*, which, it is very probable, completed the feed of the preceding winter) as it does not appear any remained in ſtock; and that the one pound ten ſhillings, charged for firing, was alſo uſed in that time: therefore, if the firſt article of eight pounds ten ſhillings, and the two laſt, amounting to fifteen ſhillings and one halfpenny, in the expences of 1764, be rejected, all the others, which are divided into two experiments, may very juſtly be looked on to be but one year's expence, and amount to - - - - - - - -	8	12	4
Which being added to the rent - - -	8	8	3
Makes the expence attending four cows one year, excluſive of labour - - - - -	17	0	7
Deduct this from the average produce on two years, amounting to - - - - -	22	12	$2\frac{1}{2}$
Nett profit on four cows for one year is -	5	11	$7\frac{1}{2}$

which is one pound ſix ſhillings and ſeven-pence three farthings per cow per annum, the whey and butter-milk excepted, which, from a cow, can be no great quantity; for, in the account of produce, I obſerve, that the cheeſe, in the year 1763, was ſold for two-pence halfpenny per pound, and in 1764, for two-pence halfpenny, and ſome for two-pence per pound, a price in thoſe years (the ſcarcity of the article conſidered) which indicates it to be not of the beſt ſort, but what is with us called cowherd-milk cheeſe, that is, the night's milk ſkimmed (fleeted), and the morning's milk freſh from the cow, mixed together, and from which method nothing could be for the pigs from it but whey, and what butter-milk came from the cream of half the milk, which amounts to very little from four cows only; therefore the profits ariſing from pigs ſeem evidently to be from ſomething elſe beſide the paſture-land only, as neither grains (drains) peaſe, barley, gurgins (ſhorts) bran, oats, turnips, cabbages, or clover, grew thereon, and all of which, it appears from the accounts, were made uſe of in feeding the pigs. *Muſeum Ruſticum, vol.* IV. *page* 400.

DAISY, the greater, or *ox-eye*, by ſome called *maudlin-wort*, is the name of a perennial weed common in paſtures. The leaves are jagged, and embrace the ſtalk. The flowers are large, and radiated. The ray is white, and the diſh yellow: the ſeeds have no down.

DALLOP, a tuft, or clump.

DAM, a mole, or bank to confine water.

DAMSON, a ſmall black plum, brought originally from Damaſcus; whence the name.

DANDELION, the name of a very troubleſome and well-known weed in the meadows; and which will ſpread greatly, if the flowers are ſuffered to perfect their ſeeds, which are light, downy, and of courſe eaſily blown about by the wind.

DANEWORK, a name given in ſome counties to that ſpecies of elder, generally called dwarf-elder, or wall-wort.

DANK, damp, humid, moiſt, wet.

DAPPLE, marked with various colours.

DARNEL *See* COCKLE.

Annual DARNEL-GRASS, called *white darnel* by Gerrard, and in the ſouthern counties *crap*. This plant is ſo much like the *red darnel-graſs*, that it has been greatly cultivated under the name of *ray-graſs*, or vulgarly *rie-graſs*; but the ſpike is much longer and paler; and has beards, which the ray-graſs is entirely without. It is likewiſe annual; whereas the ray-graſs has an abiding root. Its ſeeds ripen with the corn. *See* Plate VII. Fig. 1.

DAWN, the time when the light of the morning firſt appears.

DAY-BREAK, the dawn, the firſt appearance of light.

DAY-WORK, work impoſed by the day. Day-labour.

DEARTH, ſcarcity; a time when food is dear.

DEATH-WATCH, the name of an inſect that makes a ticking noiſe, ſuperſtitiouſly imagined to prognoſticate death.

DECEMBER, the laſt month of the year.

The earth is now commonly locked up under its frozen coat, ſo that the huſbandman has leiſure to ſit and ſpend what ſtore he has before-hand provided.

Now is the time to houſe old cattle, and to fell all ſorts of timber, and other trees, for building, or utenſils; to cut coppices, &c.

Let horſes blood, fatten ſwine, and kill them. Deſtroy ant-hills.

Plough up your land that you deſign for beans, provided it be not frozen too hard; drain corn fields, where the water ſtagnates, and overflow, or water your meadows.

Put your ſheep and ſwine to the peaſe-rick, and fatten them for the market. Cut hedges, and lop trees. *Mortimer's Huſbandry, vol.* II. *p.* 448.

DECIDUOUS, falling, not perennial: an epithet applied to ſuch trees and ſhrubs as ſhed their leaves in the autumn. Thus the oak, the elm, the beech, &c. are called deciduous trees.

DECLIVITY, inclination or declivity, reckoned downwards; gradual deſcent.

DEFICATION, the act of purifying any liquor from its lees or foulneſs.

DELVING, digging, or the act of turning up the earth with a ſpade.

DEMAIN, or *demeſne*, the land which a man holds originally of himſelf. It is alſo ſometimes uſed as a diſtinction between thoſe lands which the lord of the manor hath in his own hands, or in the hands of his leſſee, and ſuch other lands appertaining to the ſaid manor, as belong to free or copy-holders.

DENSHIRING. *See the article* BURN-BAKING.

DEVIL *in a bush*, or *fennel-flower*, a very troublesome weed among the corn, especially in Italy, France, and Germany, where it abounds much more than in this country. It rises with slender stalks, near a foot high, which sometimes branch out at the bottom, and sometimes are single, garnished with a few very fine cut leaves, somewhat like those of dill. Its flower is generally blue, and its seeds are rough and black. This, together with their being nearly of the same size as the grains of wheat, renders it difficult to separate them from the corn, when the plant has been cut and housed with it; they blacken the meal, and debase its value. The plant is annual, and therefore may be extirpated by rooting it out before it can seed, which is commonly in August.

DEVIL's-BIT, the name of a weed often found among the corn, but more frequently in meadows. It has a strong, thick, fibrous, perennial root, which runs deep into the ground, and sends out several branching stalks, which rise near three feet high. The lower leaves are sometimes almost entire, and at others they are cut into many segments almost to the mid-rib: they are seven or eight inches long, and from three to four broad in the middle, hairy, and sit close to the root. The stalks are covered with stiff, prickly hairs, and garnished with smaller leaves at each joint. The flowers, which are of a pale purple colour, and have a faint odour, appear in June, upon naked foot-stalks at the end of the branches, which decay to the root every autumn.

DEVIL's-GUTS, the same with the lesser bind-weed. *See the article* BIND-WEED.

DEVONSHIRING. *See the article* BURN-BAKING.

DEW, the moisture perceived on the ground, and on the leaves of plants, blades of grass, &c. in the morning.

Those who have made no other reflections on dew than such as present themselves naturally, think that all the moisture one finds in the morning on plants and upon the ground, comes in reality from above; but, when the affair is examined with more attention, one sees that at least a great part of the dew arises from the earth itself and the plants, and keeps hanging to their surface. Mr. Gersten, who hath made a dissertation on this subject in particular, hath even thought that there fell no dew from above on the ground, and that all which we see under the form of dew arose from the earth or plants, on which it keeps hanging in pearls, till the heat of the day hath dispersed it.

This opinion of Mr. Gersten was not new, and we find, in the History of the Academy for 1687, that some persons of the company had advanced, that the dew rose from the earth, and did not descend from above, because they found under glass-bells as much dew as in other places exposed to the air: it is probable, that since that time several persons have been of the same sentiment; one finds even traces of it in ancient authors: but Mr. Gersten did not derive his notion from thence; he had given, in the work which we have cited, a new explication of the risings and fallings of the barometer that did not agree with the descent of dew; this made him think of examining the thing with more attention than had hitherto been done. He had already observed in gardens that the grass was full of a moisture in the evening, and covered with very perceptible little drops, whilst the leaves of trees, and plants that were more raised from the ground, had not the least appearance of it; he remarked moreover, that all the plants had it not equally, that on some it was very abundant, whilst he could scarce perceive it on others.

We shall not relate a great number of experiments that were made by Mr. Gresten, although some of them are extremely curious; but the reader will see by those which we shall give an account of afterwards, that it was necessary, in order to draw certain and exact consequences, to have a knowledge of several facts, the discovery of which was reserved for Mr. Musschenbroek; who after having verified the greatest part of Mr. Gersten's experiments, at first submitted himself to his opinion, but he hath since changed, and is fixed in acknowledging several sorts of dews, of which one more dense than all the others rises from lakes, rivers, and marshes.

And a third falls from above: Mr. Musschenbroek founds the existence of this last on a great number of experiments, which he hath made upon the leaden terras of the observatory at Utrecht; it was not possible that any vapour should rise from this terras of lead, yet several bodies which he exposed there received dew on their upper surface; from whence Mr. Musschenbroek concludes that there is really a dew that falls.

" Several observations and experiments repeated very often, and which always proved uniform, leave no longer any doubt with me concerning the nature of dew, at least with regard to its rising or falling; and I think one may be satisfied that it rises only from the earth and plants; that this moisture, or this vapour, consists of an infinite number of little aqueous globules extremely light with which the air is loaded, and which it carries with it whithersoever it is driven by its fluctuating motion: thus the bodies which are met by this aqueous vapour, receive it in all the parts of their surface, and are immersed all at once. In the experiments of Mr. Musschenbroek where bodies exposed on the leaden terras received dew on their upper surface, it is true, the moisture did not come from the terras, but it rose from the earth, and from the plants round about; it came successively, and by the vehicle of air to the terras of lead; it was afterwards diffused through all the air that was above this terras, and fastened to the bodies which were exposed to receive it: if Mr. Musschenbroek had attended to the time when the dew began to be perceived on the terras, he would have remarked, that it was sensible a long time before at the foot of the tower, on whose summit he made the observation; I even doubt not but, if he had raised a mirrour or piece of glass to six feet above the leaden terras, he would have found drops of dew attached to the inferior surface of the glass, as soon and in as great quantities as on the superior surface: this I cannot doubt of from experiments I have made along the different heights of the steps of a ladder. I placed two ladders opposite each other, joined at their tops, spreading wide asunder at their bottoms, and so high as to reach thirty-two feet. To the several steps of these I fastened large squares of glass, and set them in such a manner that they should not shade or hang over one another. It was plain that, if the dew descended without first rising, the top squares must be first wetted, and that on their upper surface; but on the contrary, if the dew first ascended from the earth, the bottom surfaces of the lower panes must first receive it: and thus in fact it happened; the lower surface of the lowest piece of glass was first wetted, then its upper surface; then the lower surface of the pane next above it, and so on gradually till the whole was wetted to the top of the ladders.

" But, in order to assure myself more certainly, and leave no room for doubt on this subject, I have lately repeated the same experiments at Paris upon a leaden terras. I suspended a glass upon a wooden frame, raised only two feet, and I constantly found drops of dew pretty nearly in equal quantity on the under side as on the upper side of the glass; which is different from the former experiments that were made in the country, where the inferior surface was always sooner and more abundantly moistened than the superior; but the reason of this difference is very evident, for in the country the aqueous vapours rose directly from the earth, and fastened themselves to the under surface of the glass; but it is not so on a terras of lead, and surrounded by lofty buildings: in this case, the air that is loaded with moist vapours cannot arrive thither but by long windings, and a very irregular fluctuation; so that there is no more reason why it should fasten itself to the under than to the upper side of the glass; or, in other words, the vapour doth not rise there perpendicularly as in the country, but is driven in a lateral direction.

" Notwithstanding all I have been saying, I do not pretend that there is but one kind of dew, and deny not but there may be a dew whose parts are gross enough, and have sufficient weight to fall to the ground; yet I think in that case it would be visible, and form what we know by the name of fog: but our inquiry is at present of that kind of dew, so stiled by all, which is imperceptible to the eyes, and becomes sensible only by wetting thofe bodies that are expofed to the air in the night." *Mem. Acad. Roy. Sciences.*

The reverend Dr. Hales, in his treatife of Vegetable Statics, tells us, that in order to find out the quantity of dew that fell in the night, on the 15th of Auguft, at 7. p. m. he took two glazed earthen pans, which were three inches deep, and twelve inches diameter in furface; that he filled them with pretty moift earth, taken from off the furface of the ground, and they increafed in weight by the night's dew 180 grains; and decreafed in weight by the evaporation of the day one ounce + 282 grains.

He fays likewife, he fet thefe in other broader pans to prevent any moifture from the earth fticking to the bottom of them. He adds, the moifter the earth is, the more dew falls on it in a night, and more than a double quantity of dew falls on a furface of water than there does on an equal furface of moift earth: the evaporation of a furface of water in nine hours winter's dry day, is $\frac{1}{31}$ of an inch: the evaporation of a furface of ice, fet in the fhade during a nine hours day, was $\frac{1}{41}$. So here are 540 grains more evaporated from the earth every twenty-four hours in fummer, than fall in dew in the night; that is, in twenty-one days near twenty-fix ounces from a circular area of a foot diameter; and circles being as the fquares of their diameters, ten pounds + two ounces will in twenty-one days be evaporated from the hemifphere of thirty inches diameter, which the funflower's root occupies; which, with the twenty-nine pounds drawn off by the plant in the fame time, makes thirty-nine pounds, that is, nine pounds and three-fourths out of every cubic foot of earth, the plant's roots occupying more than four cubic feet: but this is a much greater degree of drynefs than the furface of the earth ever fuffers for fifteen inches deep, even in the drieft feafons in this country.

In a long dry feafon therefore, efpecially between the tropics, we muft have recourfe, for fufficient moifture to keep plants and trees alive, to the moift ftrata of earth, which lie next below that in which the roots are.

Now, moift bodies always communicate of their moifture to more dry adjoining bodies; but this flow motion of the afcent of moifture is much accelerated by the fun's heat to confiderable depths in the earth, as is probable, he fays, from the twentieth experiment in the faid book.

Now, 180 grains of dew falling in one night, on a circle of a foot diameter = 113 fquare inches; thefe 180 grains being equally fpread on this furface, its depth will be $\frac{1}{159}$ part of an inch $= \frac{180}{113 + 254}$. He adds, that he found the dew in a winter's night to be the $\frac{1}{90}$ part of an inch; fo that if we allow 151 nights for the extent of the fummer's dew, it will in that time arife to one inch deep: and, reckoning the remaining 214 nights for the extent of the winter's dew, it will produce two, thirty-nine inches deep; which makes the dew of the whole year amount to three, thirty-nine inches deep.

And the quantity which evaporated in a fair fummer's day from the fame furface, being as one ounce 282 grains, gives $\frac{1}{40}$ part of an inch deep for evaporation, which is four times as much as fell at night.

He fays likewife, that he found, by the fame means, the evaporation of a winter's day to be nearly the fame as in a fummer's day; for, the earth being in winter more faturated with moifture, that excefs of moifture anfwers to the exceffive heat in fummer.

It is very certain, that fubftances of a very different kind from the ufual and natural matter of the dew, have fometimes fallen in that form. Our Philofophical Tranfactions give an account, that, in the year 1695, there fell in Ireland, in feveral parts of the provinces of Leinfter and Munfter, for a confiderable part of the winter and fpring, a fatty fubftance refembling butter, inftead of the common dew; it was of a clammy texture and dark-yellow colour; and was, from its great refemblance, generally called dew-butter by the country people. It always fell in the night, and chiefly in the moorifh low grounds, and was found hanging on the tops of the grafs, and on the thatch of the houfes of the poor people. It was feldom obferved to fall twice in the fame place, and ufually, wherever it fell, it lay a fortnight upon the ground before it changed colour, but, after that, it gradually dried up, and became black. The cattle fed in the fields where it lay, as well as in others, and received no hurt from it: it fell in pieces of the bignefs of one's finger end, but they were difperfed fcatteringly about, and it had an offenfive fmell, like that of a church-yard. There were, in the fame places, very ftinking fogs during the winter, and fome people fuppofe this no other than a fediment or connection of the heavier matter of thofe fogs. It would not keep very long, but it never bred worms. The country people, willing to have fome good of it, tried it on their children's foreheads, and it always cured them of a fcald-head. *Phil. Tranf.* N° 220.

For the nature and properties of dew, with regard to vegetation, *fee the article* ATMOSPHERE.

DEWLAP, the flefh that hangs down from the throat of oxen.

DIABETES, a morbid copioufnefs of urine, or the making water in too great quantities. This diforder is very common in horfes, and often terminates in death.

Horfes fubject to a diabetes, or profufe ftaling, if old, or of a weak conftitution, are feldom cured; they foon lofe their flefh and appetite, grow feeble, their coat ftaring, and they die rotten. Of a young horfe there are more hopes; but he muft not be indulged with too much water, or moift food. At the fame time give him the following drink:

> Take jefuit's bark, four ounces; biftort and tormentil-root, of each two ounces: boil them in two gallons of lime-water to the confumption of half, and give a pint three times a day.

Let the horfe drink two or three quarts a day of lime-water; and if thefe medicines fhould not fucceed, give a quart of ftrong alum-poffet, three or four times a day.

This method is proper alfo for a horfe who ftales blood; or the following balls may be given for that purpofe, if the bleeding is profufe:

> Take bole armoniac one ounce, Japan earth half an ounce, roch alum two drams, elixir of vitriol one dram; make them into a ball with conferve of rofes, and give it every fix hours.

As this diforder generally proceeds from too violent exercife, over-ftraining, &c. repeated bleedings in fmall quantities are abfolutely neceffary, till the mouths of the veffels clofe up. *Bartlet's Farriery, p.* 165.

DIAPHRAGM, midriff, or fkirt, as fome call it in a horfe or bullock, is a mufcular fubftance that divides the upper cavity or cheft from the lower belly.

DIBBLE, a fetting-ftick, or inftrument to make holes in the ground, for fetting plants, &c.

DIG, a mattock. *See* MATTOCK.

DIGGING, the act of turning up the earth with a fpade.

Was labour confiderably cheaper in England than it is at prefent, and a fufficient number of hands could be found, it would doubtlefs be the beft way to dig by hand all the ground deftined for potatoes, carrots, lucern, &c. many advantages would accrue from this method of tillage; the earth would be loofened to a greater depth, and much better pulverifed; nor would the weeds and grafs be fo apt to grow as in ploughed lands.

DIGITATED, branched out into divifions like fingers.

DIKE, a ditch. It alfo fignifies a dam or mound to hinder inundations.

DILL, the name of an herb cultivated in the kitchen-garden, and nearly refembling fennel.

Dill muft be fown where it is to remain, for it will not bear tranfplanting. The foil fhould be light, and the feeds fown in the autumn, foon after they are ripe; for they feldom grow well if they are kept out of the ground till fpring. When the plants are come up, they fhould be thinned to the diftance of eight or ten inches from each other, that they may have room to put forth their lateral branches; and if they are afterwards kept clear from weeds by good hoeing, they will not require

any

any farther care. When their feeds begin to be formed, fuch of the pods as are intended to be put into pickle for cucumbers (for that is their chief culinary ufe) fhould be cut; and when the feeds of the remainder deftined for fowing are ripe, they fhould be dried upon a cloth, and then beaten out. If they are fuffered to fow themfelves, they will produce in the fpring a multitude of young plants, which will want no other culture than thinning them with a hoe, and keeping them free from weeds.

DINGLE, a fmall clough or valley between two fteep hills.

DITCH, a trench cut in the ground, ufually round the fences of a field.

The mud of ditches affords an excellent manure, as it confifts of the putrid particles of animals and vegetables, mixed with the fineft and richeft mould; and therefore proves a great improvement to any foil, particularly the light and dry. But this mud fhould be expofed to the air for fome time, that the feeds of the weeds generally contained in it may have time to vegetate or putrify, before it be laid on the land.

DOCK, the name of a weed, of which there are feveral fpecies, and all of them remarkable for the largenefs of their leaves; fo that he muft be a very flovenly farmer who fuffers any of thefe plants to grow large. They fhould be plucked up by the roots as foon as they appear, which may be eafily done, as the roots are of the tap, or carrot kind.

DOCKING, the act of cutting off the tails of horfes.

This operation is in general very fuccefsfully executed by the common methods, which are known to every farrier. But fometimes a mifcarriage enfues by an inflammation and gangrene fucceeding. Thefe accidents probably arife from the tendons of the tail fuffering by an injudicious application of the knife or fearing-iron, or in an improper feafon for the operation. Neither the very hot or cold months are proper, for reafons fufficiently obvious. The operation fhould always be performed by incifion, or the chopping engine: the knife being paffed through the tail from above, whilft it lays on the block; for when the cutting inftrument is applied underneath, the blow is given on the tail, which, by bruifing the tendons, may be naturally fufpected to occafion bad fymptoms. The fearing-iron fhould be fmooth, and better polifhed than thofe generally ufed, and ought to be rubbed clean on a woollen-cloth, before it be applied to the ftump; otherwife the fparks, which fly from the iron, are apt to occafion great pain, attended with the fwelling both of the fheath and fundament: nor fhould it ever be applied flaming hot, for then it brings the burnt part away with it, and requires a re-application, in order to form a frefh efchar on the veffels; by which means the bone is frequently left too much expofed, fo that it is often a confiderable time before it is covered.

Farriers feldom apply any thing to the ftump; which need only be anointed with the wound ointment, and when the efchar is digefted off, may be wafhed with allum or lime-water: but if an inflammation enfues, with a difcharge of thin matter, a proper digeftive, compofed of Venice-turpentine, rubbed with the yolk of an egg and tincture of myrrh, fhould be applied, with a poultice of bread and milk over it. The rump fhould be frequently bathed with oil of rofes and vinegar, and a large quantity of blood taken away. If the fundament be at all fwelled, and the inflammation at all fufpected to be communicated to the bowels, let cooling emollient clyfters be injected two or three times a day. Should a gangrene enfue, add Ægyptiacum to your dreffings, and fpirits to the fomentation: and apply over all the ftrong-beer poultice, with London treacle, twice a day. *Bartlet's Farriery, pag.* 323.

DODDED *Sheep*, fheep without horns.

DODDER, the name of fo remarkable a plant, that it cannot eafily be miftaken. It is entirely without leaves, and does not depend upon the ground for nourifhment; but when it is grown up, rots at the bottom, and lives upon the juices of other plants about which it entwines itfelf, by means of threads of a red colour, which it throws out. The flowers are fmall, and come out in roundifh heads or bunches, many of them together, here and there, from the ftem.

DODMAN, a name given in fome of the northern counties to the fhell-fnail.

DODRED *Wheat*, red wheat without beards.

DOG's *Grafs*. *See* COUCH-GRASS.

DOKE, a deep furrow.

DOLE, or *Dool*, a long narrow green in an arable field, left unploughed.

DOLPHIN-*Fly*, the name of an infect very deftructive to beans. *See the article* BEANS.

DOOL, the fame with dole. *See* DOLE.

DOSOME, an epithet appplied to fuch beafts as improve apace. Thus a thriving beaft is called, in the northern counties, a dofome beaft.

DRAGS, a name given in fome counties to the heavieft pair of ox-harrows.

DRAFFE, the grains of malt.

DRAIN, a channel, or trench, cut in the earth, in order to carry, or drain off the water. *See the articles* BOG, MARSH, and MOOR.

When coarfe grafs is produced, the ground is evidently over-charged with moifture, proceeding either from cold, hungry fprings, loaded with fome mineral or acid, which want vent; or elfe from external floods, which, being confined by a ftiff clay, impervious to water, remain upon it, and corrupt the natural nourifhment proper for producing the fweet and richer graffes. When this laft is the cafe, the remedy is eafy, by making proper drains to carry off the fuperfluous moifture. But if the land be fpouty or fpewy, as it is commonly termed, and the moifture arifes from fprings, a deep drain muft be cut in the loweft part, and fmaller drains from that principal ditch to fuch places as appear to be the heads of the fprings, which will be known by their being wetter and loofer than other parts. The drains muft be cut deep enough to reach the bed, whether gravel or fand, through which the water flows; and upon the firft touching of this, the water will be found to run off more freely, and in greater quantity.

The fmaller drains, communicating with the main ditch, fhould be left open for fome time, until the quantity of moifture abate. After this, to make them covered drains, by which the furface is rendered level, and no part of it is loft, they fhould be filled up with fmall ftones to within about a foot and a half of the furface, and then covered with turf, the green fide downward, or with heath, broom, ftraw, or any other thing that can moft conveniently be had, proper to keep the earth from falling in among the chinks of the ftones, through which, if no fuch accident happen, the water will pafs eafily, the drains will prove effectual, and the plough, after the earth that was turned out is laid above all, will go freely over, without being oppofed by the ftones. A foot depth of mould over the drain will be fufficient in pafture-grounds; but this covering fhould be at leaft a foot and a half thick in ploughed lands. Where ftones are fcarce, faggots made of the branches of any kind of trees are fubftituted in their place: but they do not anfwer the purpofe fo well, becaufe they decay and rot, the earth falls in, and the drains are ftopped: though it is highly proper, where thefe are ufed, to line the fides of the drains with brick or ftone, without mortar, to keep the earth from falling in there, and at the fame time give free admittance to the water. It muft be obferved, that, where a great quantity of water is to be difcharged, the main drain into which the fmaller drains are to empty themfelves, fhould not by any means be filled up, even with ftones, unlefs it be both very deep and very wide, and there be a great quantity of ftones to throw into it, left it fhould not be able to difcharge all the water; in which cafe the whole work will prove worfe than ufelefs; a remedy being very difficult on account of the ftones.

The beft time for covering thefe drains is about Michaelmas; becaufe the earth is drieft at that feafon, before the winter rains begin to fall. The digging of them is indeed very laborious work, particularly in marfhes, the foil of which is always of a tough, ftrong quality. It is therefore of great importance, that every means be ufed to leffen that fatiguing labour. The fhovels and ſpades univerſally uſed, are certainly too ſhort. Their length ſhould be ſuch as to give the labourer every advantage ariſing from his own ſtrength. In order to have this, he ſhould ſtand as erect as poſſible: for otherwiſe, he has not only the weight of the earth on the ſpade or ſhovel to raiſe, but alſo that of his own body; whereas, if the ſhovel be of a due length, an eaſy ſhifting of the lower-moſt hand becomes a prop, or point, on which the weight at the end is raiſed, almoſt without bending the body.

Where the ground in which the ſprings are lies on a gentle declivity, Mr. Tull very properly adviſes ploughing it nearly horizontally, by which means each furrow carries off the water, which would otherwiſe ſink into the next ridge. If the clay underneath be at ſo ſmall a depth that the plough can reach it, this will have a very good effect: and as the nearly horizontal direction of the furrow gives the water but a ſlow motion, it will not be ſo apt to waſh away the richer mould, as it would if the furrows were more perpendicular to the declivity. Theſe furrows ſhould, however, have ſlope enough to give the water a current ſufficient to prevent its ſoaking into the ridge underneath.

If the ſprings riſe only at the bottom of a ſloping ground, one large drain, reaching the whole length of the declivity, and cut down to the bed of clay underneath, may be ſufficient, with the help of a channel to carry off the water.

If there is any mineral in the earth, eſpecially a chalybeate, which Dr. Home has experienced to be very prejudicial to vegetation, ſuch mineral, being waſhed out by the ſprings, is lodged in the ſoil, towards the ſurface.

DRAINING *of Land*, the operation of carrying off the water from wet lands. *See the articles* BOG, MARSH, and MOOR.

A correſpondent of the editors of the Muſeum Ruſticum has obliged the public with the following obſervations on the uſes of draining.

" The firſt experiment, ſays he, I made, was upon a piece of ground of about four or five acres, in the front of my houſe, of the ſpringy kind; where the waters, collected from the rains and dews in a large plain of dry land above, broke out upon the declivity of the hill; and not having proper drains and channels, to carry them away, had, by long overflowing, rendered the ground ſo ſoft and boggy, as not to allow the tread of any ſort of cattle, (unleſs in very ſevere froſts;) and thereby made it intirely uſeleſs, and alſo very diſagreeable to the eye. I took the opportunity of a very hard and laſting froſt, to carry on a large quantity of ſtones for making the intended drains: which were laid out in the following manner. A main drain, or trench, was made through the middle of the ground, from a ſmall rivulet (into which it was to empty itſelf), to a little above where the ſprings made their firſt appearance: from thence two drains (one on each ſide) were carried along the ſide of a hill to the two extreme parts of the ground, emptying themſelves into the head of the firſt mentioned drain, which was only made about three feet deep till near the top of it. The branches or ſide drains were better than ſix feet, as I hoped thereby to have cut off all the ſprings: but the declivity of the land being conſiderable, I was obliged to add two drains more below: as ſome of the ſprings had eſcaped under the bottoms of the higheſt branches. I made the drains in the following manner. The bottoms were flagged with a thin tender ſtone (of no other uſe;) the ſides walled with rubbiſh ſtone (the walls being about five inches aſunder, and five inches high;) and the tops covered with a ſtronger kind of rubbiſh ſtone. Upon the covers, I laid ruſhes and reeds, (the then only produce of the ground) to prevent any dirt or ſoil from getting through the openings of them into the drains; and, laſtly, I filled them up with the moſt porous ſubſtances, dug out to near the height of the ſurface.

" I began this work about the end of March, and had finiſhed it about the end of Auguſt. I very ſoon found the good effects of my labour, the ground being grown ſo hard and ſolid before the middle of October, that I was able to carry on, with carts, a very large heap of compoſt, which I had prepared ready for that purpoſe; conſiſting of freſh litter from the ſtables, virgin earth, ſtreet dirt, coal-aſhes, and lime, well incorporated together by frequent turnings. The next ſummer moſt agreeably ſurpriſed me with as fine a crop of hay, both in reſpect of quantity and quality, as any of the neighbouring grounds could boaſt, (above three loads to the acre:) and the aftermath, or ſecond crop, was full as extraordinary as the firſt. In order to know the profit of the latter exactly, I hurdled it off in ſmall parcels: and, having taken in cattle by the week, found the profit better than twenty ſhillings a ſtatute acre. This ground has kept improving ever ſince; and now affords me three crops every year; viz. ſpring paſturage for my milch-cows and early feeders, a moſt plentiful crop of good hay, and an excellent aftermath; without having had any ſuperinduction beſtowed upon it ſince the firſt, which is eleven years ago. When ſtones cannot be conveniently had, the common flat tiles for the bottoms, and the common brick for the ſides, and covers of the drains, will do very well; and, as bricks are more expeditiouſly laid than the rubbiſh-ſtones, I think they will be full as cheap, if proper clay, and fuel for burning them, can be procured upon eaſy terms. The expence of draining this piece of ground was about five pounds per acre. I have drained many acres of the ſame kind of land ſince, with equal ſucceſs; and at a much leſs expence. Another kind of land, which has fallen within my practice of draining, is what I call the four ſpongy land; where there is upon the ſurface a tolerable good mould, for ſix or ſeven inches deep, and below that a ſtiff clay, that will not permit any water to paſs through it; by which means, the ſoil above is ſo ſoaked and chilled, with a conſtant ſurcharge of water, that it is not able to produce any thing but ruſhes, and all the worſt ſpecies of aquatic weeds. As this kind of land is often nearly level, or but gently declining, the firſt ſtep I take, is (by levelling) to find the greateſt fall I can get within any reaſonable diſtance. Then, by the means of iron-rods, (ſuch as are uſed in boring for coals) with a bitt or iron ſcoop at the bottom, I try in ſeveral places the depth of the clayey ſtratum, which ſo obſtructs the paſſage of the water; and alſo what the natures of the ſeveral ſtratums below it are, till I come as low as the level, where I propoſe to begin my drain. If I find, in ſuch ſearch gravel, ſand, ſoft-rock, pinnel, or other porous ſubſtance, I begin the good work immediately, and with full aſſurance of ſucceſs: making a good ſtone or brick drain (as before deſcribed) through the loweſt part of the ground intended to be drained; and then filling it up with all the light porous ſubſtances, that ariſe in the digging of it, or any rubbiſh that can be conveniently procured; taking great care that none of the clay, or hard ſubſtances, be thrown in again; and that the top and ſides of the drain be left lower than the reſt o. the land; that the winter rains may eaſily deſcend to it, and ſo paſs (as through a ſieve) into the channel prepared to receive them. If there be any low parts in the piece of ground, from whence the rain-water cannot deſcend to the main drain, ſmall pebble, or wood drains, ſhould be made from thoſe low parts into it: taking care to fill them up with ſome rubbiſh or light mould. The clay, which is dug out, may be converted (either by burning or laying up in heaps with quicklime) into a moſt excellent tillage, either for corn or graſs land, for the improvement of the ſame ground, or any other where it is more wanted. For the fertility of ſuch land, after ſuch draining, is greater than can be well imagined by thoſe who have not tried it, even without any further improvement. I generally (indeed) ſet on lime immediately afterwards, if the ſeaſon of the year be proper for it: which, I ſay (from experience), is from the middle of April, to the middle of July; being certain, (notwithſtanding ſome great authorities, and the common practice are againſt me) that twenty buſhels ſet upon graſs-land, during that ſeaſon, are more than equal to thirty laid on in the autumn, or winter ſeaſons. About an hundred and ſixty buſhels to an acre are a proper dreſſing. The laſt kind of land, of which I ſhall now treat, is the black peat or mooriſh land, many thouſand acres of which, in this kingdom, are now intirely uſeleſs, though capable of being

being improved to great advantage. Nay, I will venture to affirm, that there is ſcarcely any ſo bad, but that it might, by proper means, and due induſtry, be converted to ſome uſeful purpoſe. For which aſſertion, I have a happy authority, in that beautiful teſtimonial of induſtry, given by Virgil, in his fourth Georgic, to the old Corycian farmer. If theſe kinds of land be nearly upon a level, I uſe the precautions mentioned in the laſt article; and, if I find my level will carry me below, or to the bottom of this black mooriſh or peat-earth, I do not regard the depth of my drains, as the digging is very eaſy, and what is thrown out will nearly pay the expence, by being either dried into peat for fuel, or burnt into aſhes; which, if properly managed, are an excellent dreſſing, either for ſpring-corn, or graſs-land. In the draining of this kind of ground, I make one principal drain through the middle of the piece, (of ſtone or bricks, as before mentioned); and, at about every eighty or a hundred yards, branches from it. Theſe I make rather better than two feet wide at the top; and continue them nearly of the ſame width, till within eight or nine inches of the bottom. Then, with a ſpade (about nine inches broad at the top, and narrowing down to three inches) I make a lower drain; and, upon the ſides or ledges (formed by the narrowing of it), lay large heath-ſods, cut ſquare, and exactly to the width of the upper part: by which means, a cavity is left for the water to run in. Upon thoſe ſods or covers, I throw bruſh-wood, or any kind of light trumpery: and, laſtly, I fill it up with the ſmalleſt of the black ſoil thrown out. Such is the preſerving nature of this black peat or earth, to all vegetables buried in it, that there is no doubt, but drains of this laſt kind will endure for ever, if they be laid deep enough. After the ground is drained and levelled, marl (if to be had near) ſhould be laid on; if not, ſand, gravel, or any kind of light earth. If the firſt, no other ſuperinduction will be required; but if any of the latter over it ſhould be ſpread, a cover of ſome of the fineſt black mould, that is pretty free from any ſtrings or fibres; and then a compoſt made of horſe-dung, coal-aſhes, earth, or clay and lime; and, laſtly, it ſhould be laid down either with graſs-ſeeds alone, or with barley (or oats) and graſs-ſeeds. I laid down a piece (drained and managed as above mentioned) about the beginning of Auguſt laſt, with white clover, yellow clover, and common hay-ſeeds, and though the ſeaſon was ſo remarkably dry and hot, yet the young plants came up very well, and very thick, and, in this preſent ſevere froſt, it affords a verdure, not to be ſeen any where elſe in the neighbourhood; and the piece is conſtantly covered by my cattle, tempted by the look, and the ſweet food it affords them. I am now preparing about five acres of the ſame kind of land, to be laid down with barley and graſs-ſeeds in the ſpring; and hope (if the ſeaſon proves favourable) to have a good crop of both. I had no marl (or even clay) near, ſo was obliged to make uſe of ſand and gravel for my firſt ſtratum.

DRAINING-PLOUGH, a plough for cutting drains, in order to carry off the water from wet ſoils.

Several inſtruments have been invented for performing this neceſſary operation; but as none were found ſufficient to anſwer the intention of the huſbandman, the Society for the Encouragement of Arts, Manufactures, and Commerce, propoſed a premium of fifty guineas for the beſt plough or machine, of the ſimpleſt conſtruction, that ſhould, with the leaſt force, cut a new drain one foot in depth perpendicular, one foot eight inches wide at the top, and ten inches at bottom; both ſides of the drain equally ſlooping, and the earth to be equally thrown out on both ſides. In conſequence of this premium, ſeveral inſtruments for effecting this purpoſe were ſent in to the Society; but upon trial one was found much ſuperior to the reſt, and anſwerable to the Society's advertiſement: and in conſequence of which the premium was adjudged to the author.

This plough, of which we have given four figures on Plate VIII. was made by Mr. Cuthbert Clarke, at Belford, in Northumberland; and anſwered exceeding well in meadow-ground; but could not be drawn in a ſtiff clay with the force of eight horſes. Fig. 1. is a perſpective view of the whole inſtrument ſeen on one ſide. Fig. 2. another view ſeen in front. Fig. 3. a third view ſeen at the tail. Fig. 4. a ſection of the plough, to ſhew the diſpoſition of the three coulters.

Note. The ſame letters refer to the ſame parts in all the four figures; ſo that where any of the parts cannot be ſeen in that figure, the letters will not be found.

A, B, C, are the three coulters.

D, E, F, the nuts and ſcrews that faſten the coulters to the beams.

G, H, I, a wheel, or rather roll, which prevents the plough from going any deeper in the earth. This roll is divided into three parts, by circular pieces of iron, which project beyond the roll; and cut the turf into three parts. The coulters follow in the ſame tract, and finiſh that part of the work.

K, K, the centers on which the roll turns.

L, L, the nut and ſcrews which faſten the iron arbour in which the pivots of the rolls turn to the beams. Theſe arbours are kept in their proper places by means of the two iron braces *f*, *f*.

M, a large iron-hook, to which the chain by which the inſtrument is drawn is faſtened.

N, the tow-chain, or that by which the plough is drawn.

O, the head of the plow into which the beams are mortiſed.

P, Q, R, the three beams.

S, a ſhoe of iron, (the whole part from S to A being of that metal) and into which the hoof of the plough is inſerted.

T, a ſhelf on which the mould riſes after it is cut up by the coulter and fore part of the ſhare, till it is thrown out of the trench by the mould-boards.

V, V, the mould-boards, which throw the earth out on each ſide of the trench.

W, W, a band of iron, which faſtens the after-part of the plough to the main or middle beam.

X, the head of a tenon, which faſtens the mould-boards, and hoof of the plough to the main beam.

Z, Z, the two handles, like thoſe of a common plough.

a, *b*, a piece of board tenoned into the handles, in order to keep the handles in their proper poſition.

c, *d*, repreſents the ſurface of the ground when the plough is at work. Therefore all the parts below that dotted line are under the ground when the drain is cutting.

f, *e*, *g*, ſhews the angle which the coulters make with a line drawn parallel to the horizontal plane; and is nearly equal to forty-five degrees.

The figures are drawn on a ſcale of an inch to a foot; but many of the parts, being drawn in perſpective, cannot be meaſured.

We imagine it will be unneceſſary to ſay any thing farther with regard to the manner of working this plough, as the operation is the ſame as that with the common plough. But it may not be amiſs to obſerve, that the angle *f*, *e*, *g*, being greater than that by which the horſes draw upwards, the plough has too great a tendency to get into the earth; the conſequence of which is, that, when the ſoil is very ſtiff, and conſequently requires a very great force to draw the plough, the inſtrument cannot be held properly by the handles, the force of ſix men not being ſufficient to do this, but the plough will turn entirely over. This was ſufficiently apparent to the committee of the Society, at the firſt experiment, when the ploughs were tried in a ſtiff clay; for the tail of this very plough could not be kept down by ſix men at the handles. If therefore the angle *f*, *e*, *g*, were leſſened to about thirty-three degrees, this difficulty would, in a great meaſure, be removed. However, in marſhy, boggy, and moory ſoils, it will anſwer the intention extremely well, and make a clean trench of the dimenſions required by the Society; and therefore cannot fail of being a very valuable acquiſition in the practice of agriculture.

DRAPE, a farrow cow, or one whoſe milk is juſt dried up.

DRENCH, phyfick, &c. given to a brute by means of a horn, cut properly for that purpofe.

DRILL-PLOUGH, an inftrument for fowing corn in drills, or rows, which is an effential part of the new hufbandry.

The two firft inventions for fowing in this manner were Mr. Worlidge's drill-plough, and Don Jofeph de Lucatello's fembrador, both of which may claim the merit of inventions, and therefore muft not be omitted in this work.

" Befides the ufual method of fowing corn, there are, fays Mr. Worlidge, feveral other ways of difperfing it, as by fetting, and hoeing of it in, &c. This art of fetting corn feems to be very ancient, as appears by Virgil, *Unguibus infodiunt et ipfis fruges.* And hath been a long time attempted to be brought into practice again, as appears by Mr.Platt' Adam's Tool revived." Mr. Worlidge then points out the defects in Mr. Platt's inftruments, and proceeds thus :

" But to remedy and remove all manner of errors and inconveniencies that can be found in fetting of corn, I fhall here give you a plain and perfect defcription of an eafy and feafible inftrument that fhall difperfe your corn, grain, pulfe, of what kind foever, at what diftance, and in what proportion you pleafe to defign, and that with very great expedition, and very little extraordinary charge, expence, or hazard.

" Firft, make a frame of timber, of about two or three inches fquare, the breadth of the frame about two feet, the height about eighteen inches, the length about four feet, more or lefs as you pleafe, as at *u u u u*, Fig. 1. Plate IX. Place this frame on two pair of ordinary wheels, like plough-wheels. The axle-tree of the two foremoft wheels is to lock on either fide, as doth the fore axle-tree of a waggon, for reafons hereafter fhewn. The hindermoft axle-tree, being of iron, and fquare in the middle, muft be fixed to the center of the wheels, that the axis and wheels may move together : then, about the middle of the frame, in the bottom, let there be fixed an iron inftrument, or of wood pointed with iron, like unto a coulter, made a little fpreading at the bottom, in the nature of a fhare, made to pafs through two mortifes on the top, for its greater ftrength ; and made alfo to be wedged higher or lower, according as you will have your furrow in depth, as at *o o* ; the ufe whereof is only to make the furrow : fo that you muft make the point thereof of breadth only to move the earth, and caft it, or force it, on either fide, that the corn may fall to the bottom of the furrow. Then, over this fhare, or coulter, a little behind it, may a wooden pipe be made, to come from the top of the frame to the lower end of the fhare, tapering downward, as at *p*, and as near as you can to the fhare : to deliver the corn immediately, as the ground is opened, and before any earth falls in ; that what earth does afterwards fall in, may fall on the corn. This pipe is to proceed out of a large hopper fixed on the top of the frame, that may contain about a bufhel, as at *q* : but fo that the corn may gradually defcend, according to the quantity you intend to beftow on an acre. At the very neck of the hopper, underneath, in the fquare hollow thereof, muft be fitted in the edge of a wheel of wood, about half an inch thick, and proportioned to the cavity of the neck, as behind the letter *r*. The wheel need not be above two or three inches diameter, and fixed on an axis extending from one fide of the frame to the other : on which axis is alfo to be another wheel, with a groove on the circumference thereof, like the wheel of a fpit or jack, as at *r*, which muft anfwer to another wheel of the like nature and form, fixed on the axis of the hindermoft of the wheels, as at *s* : then fit a line (of filk is beft, becaufe it will not be fo apt to fhrink and reach as hemp) about thefe two wheels, that when the inftrument moves on the hindermoft wheels, by the means of the line, the fmall wheel at the neck of the hopper, may alfo move ; which leffer wheel in the neck of the hopper, may have fhort pieces of thick leather fixed in the circumference thereof, like unto the teeth of a jack-wheel, that upon its motion it may deduce the corn out of the hopper, in what proportion you pleafe : for in cafe it comes too faft, then you may by a wedge at the tenon of the piece whereupon the hopper refts, as at *t*, or at the end of the axis of the leffer wheel, force the wheel and hopper together ; as, in cafe it feeds too flow, then may you remove them by the fame wedges to a farther diftance ; alfo in cafe your line be too flack or too hard, you may prevent either extreme by a wedge in the place where the axis of the wheel moves ; or by a third wheel, about the middle of the line, made to move farther or nearer, as you fee caufe.

" Alfo by means of the iron-rod *v v*, fixed to the foremoft axis that is made to lock, may you guide your engine at pleafure ; which rod is made crooked at the end of the hopper, left that fhould injure its motion.

" And at the turning, you may lift up your engine by the handles at *x* : for whilft you lift it up, the corn feeds not until you fet the fame down again.

" One horfe and one man may work with this inftrument, and fow land as faft or fafter than fix horfes can plough ; fo that you may with eafe compute the expence, in cafe your inftrument be fingle : but you may in the fame frame have two fhares at twelve inches diftance, more or lefs, as you will have the rows of corn diftant the one from the other ; and two pipes out of the fame hopper, and two fmall wheels on the fame axis, with other wheels anfwerable, every whit as eafy to be performed as one ; and then you may double your proportion of land in a day.

" This inftrument will always keep the fame proportion you firft fet it to, which you muft thus contrive. Firft, know the length of the furrow you fow : then caft up how many of thefe furrows at fuch diftance your inftrument is made for (whether a foot, more or lefs) will amount to an acre : then conclude how much to fow on an acre ; as fuppofe a bufhel : then divide that bufhel into fo many parts as you have furrows or diftances in that acre : then take one or two of thofe parts, and put into your hopper, and obferve whether it will hold out, or fuperabound at the end of one or two furrows, and accordingly proceed and rectify the feeder : or you may judge by your own reafon, whether it feed too faft or too flow.

" In cafe it feeds too faft, notwithftanding they be clofe placed together, you may make that wheel at the loweft axis, wherein the line moves, to be lefs than the upper ; then will the motion be flower : and thus may you make it move as flow as you will, by augmenting the upper, and diminifhing the lower wheels wherein the line is ; and make it move fafter by the contrary rule.

" In cafe you drive apace, it feeds apace : in cafe you drive but flow, it feeds but flowly : here is no error.

" When you come to any turning at the land's end, by lifting up the hindermoft part of the inftrument, that thofe wheels touch not the ground, the feeding of the corn immediately ceafeth, until you fet it down again.

" Alfo all the corn you fow lies at a certain depth, none too deep, nor any too fhallow.

" You may place a kind of harrow to follow ; but the beft way is to have on each fide of each furrow, a piece of wood, a little broad at the end, fet aflope to force the earth rounding on the corn. This may be well placed and fitted to the bottom of this inftrument, juft behind the fhare and feeding pipe.

" By this method of fowing any fort of grain or pulfe, may be faved the one half, and in fome places more, which by the other way is either buried fo deep under clods, that it cannot come up, or elfe is fo fhallow, that the cold in the winter, or drought in the fummer killeth it, or elfe lies on the furface as a prey to the fowls of the air : much alfo thereof falls in clufters, twenty or thirty grains where one or two might fuffice, which are common inconveniencies, and ufually happening to the vulgar way of fowing corn : the greater half by far is loft, which in all probability may be faved by the ufe of this very inftrument, which will doubly requite the extraordinary charge and trouble thereof : for here is no corn fowed under clods, but in rows, as the earth is ftirred and moved : it is all at one certain depth and at one certain diftance, and equally covered, below the injury of froft, and heat, and rapine of birds. Alfo by this way corn may be fown in the very middle or con-

Scale of 3 Feet, for Fig. 7 & 8.
J. Hulett sculp.

 D R I

venient depth of the mould, that it may have the ſtrength of the land both below and above the root; whilſt in the other more uſual way, the corn falls to the bottom of the furrow on the gravel, clay, or ſuch like hard ground, where it ſeldom thrives ſo well as what happens to be in the midſt. This way alſo exceeds the way of ſetting corn, where the pins thruſt into the ground harden and faſten the mould, ſo that, unleſs the land be very light, it confines the roots to too narrow a place, which in this way is prevented; as I have obſerved in garden beans, that thoſe hoed in proved better than thoſe ſet with a ſtick.

"By the uſe of this inſtrument alſo may you cover your grain or pulſe with any rich compoſt you ſhall prepare for that purpoſe, either with pigeon-dung dry or granulated, or any other ſaline or lixivial ſubſtance, made diſperſeable, which may drop after the corn, and prove an excellent improvement: for we find experimentally, that pigeon's-dung ſown by the hand on wheat or barley mightily advantageth it in the common way of huſbandry: much more then might we expect this way, where the dung, or ſuch like ſubſtance, is all in the ſame furrow with the corn; whereas in the other vulgar way, a great part thereof comes not near it.

"It may either be done by having another hopper on the ſame frame behind that for the corn, wherein the compoſt may be put, and made to drop ſucceſſively after the corn: or it may be ſown by another inſtrument to follow the former, which is the better way, and may both diſperſe the ſoil, and cover both ſoil and ſeed.

"The corn alſo thus ſown in ranges, you may with much more conveniency go between, and either weed it or hoe it, and earth it up as you think good, and at harveſt it will eaſily repay the charges.

"Alſo the fore-wheels being made to lock to and fro on either ſide, you may have an upright iron-pin fixed to the middle of the axis, extended to the top of the frame: and from thence a ſmall rod of iron to come to your hand, with a crooked neck juſt againſt the neck of the hopper; by means of which iron rod, you may lock or turn the wheels either way, and guide your inſtrument, and rectify it, if it deviate out of its right courſe.

"The hopper muſt be broad and ſhallow, that the ſeed preſs not much harder when it is full, than when it is near empty, leſt it ſow not proportionably.

"Though this inſtrument may at firſt ſeem myſterious and intricate to the ignorant, yet I am confident it will anſwer to every particular of what I have written. Any ingenious wheelwright, joiner, or carpenter, may eaſily make it with very little inſtruction, and any ordinary ploughman may uſe it."

The chief inconvenience in this inſtrument ſeems to be, that the ſeed is liable to be bruiſed as it drops from the hopper, by the wheel in the neck of that hopper.

In the account which is given of the ſembrador, in the Philoſophical Tranſactions, it is juſtly obſerved, that the perfection of agriculture conſiſts in ſetting the plants at proper diſtances, in ground well looſened to a ſufficient depth, that their roots may be able to ſpread, in order to collect the nouriſhment which is neceſſary to produce and ripen their fruit. But this is ſo little obſerved, that almoſt all ſorts of ſeed are commonly ſown by handfuls at random; whence it happens, that corn is ſowed too thick in ſome places, too thin in others, and, frequently, the greater part of it is either not covered at all, or not deep enough; by which means it is not only expoſed to be eaten by birds, but alſo in cold countries to be ſpoiled by froſt, and in hot climates, by the ſun. To remedy theſe inconveniencies, Don Joſeph de Lucatello invented an inſtrument, which, being faſtened to the tail of the plough, drops the ſeed regularly in the furrow, ſaves four parts in five of the quantity which is generally uſed, and becomes the means of procuring a conſiderable increaſe, without employing a perſon purpoſely to ſow.

As a few words will explain the mechaniſm of this inſtrument, which has its merit, though it has not been found to anſwer in common practice, we ſhall venture to give the following ſhort deſcription of it; becauſe ſome of the principles of this may poſſibly ſuggeſt an uſeful hint to an ingenious artiſt.

Fig. 2. Plate IX. is a box of wood: *a*, *b*, *c*, *d*, the cover of that part into which the corn is put, and which is open in Fig. 3. at W: *e*, *f*, *h*, *g*, *k*, *l*, Fig. 2. are the two ſides which cover that part of the box where the cylinder, which is ſtuck round with three rows of little ſpoons to throw out the grains, is turned round. Theſe ſides are taken off in Fig. 3. to ſhew the cylinder R S, and the ſpoons *x*, *x*, *x*. The internal ſhape of theſe ſides is expreſſed in Fig. 4. where may be ſeen the four triangular pieces *p*, *p*, *p*, *p*, and the triangular interſtices *q*, *q*, *q*, which ſerve to convey the corn diſcharged by the ſpoons, to holes which let it out at the bottom of the box. T, is one of the wheels which turn the cylinder; and V the other end of the cylinder, on which the other wheel is to be fixed. The furrow in which the grain has been dropt is to be covered by the next turn of the plough; to which end the mould-board muſt project conſiderably.

In uſing this inſtrument, according to Don Lucatello's method, it muſt be faſtened to the beam of the plough, at ſuch a height that the long projecting nails in the wheels may touch the ground ſufficiently to make them turn round, but not enough for the wheels to reſt upon it, and drag along without turning.

This way of turning the wheels, and conſequently the cylinder, muſt occaſion an unequal diſtribution of the ſeed, wherever the ground is rough and ſtony. For this reaſon, and on account of ſome other inconveniencies attending the uſe of it, the ſembrador is not an inſtrument to be recommended to farmers: but we would here refer to the conſideration of ſuch as are better ſkilled in theſe matters whether an inſtrument leſs liable to this objection, or to the fault which is found in Mr. Worlidge's drill, may not be formed, by placing the ſeed-box of the ſembrador in a frame like that of Mr. Worlidge, with (inſtead of the wheels of the ſembrador, which turn upon the ground) two wheels, grooved like pullies, fixed upon the axis of the cylinder, to be turned with cords, like the ſmall wheel at the neck of Mr. Worlidge's hopper. A ſquare frame, like that, will keep the box more ſteady, and therefore render the diſcharge of the ſeed more regular, than it can be in Don Lucatello's manner.

M. Duhamel obſerves, that the drill-plough invented by M. de Chateauvieux delivers the grain with the greateſt exactneſs, and therefore deſerves much commendation; but that the price of it is too great for moſt farmers. His own, which we ſhall now deſcribe, has, for that reaſon, been the moſt generally uſed.

M. Duhamel's drill is faſtened to the fore-carriage of a common plough. The hind part conſiſts of a plank S S, Fig. 5. Plate IX. at leaſt three inches thick, which is called the table. Underneath this table, and to the bottom part of it, are ſtrongly fixed, as at T, T, T, three ſhares. The beam I, I, is faſtened to the fore-part of the table: and the handles L, L, are let into mortiſes in the back part of the table, in which they are fixed. *a*, *a*, *a*, are three ſloped cavities cut in the table, to receive the ſeed from the cylinder, and convey it through a hole, about an inch in diameter, in the center of each of them, into the hollow *c*, at the back of the ſhare Fig. 6. The form of theſe cavities is more clearly expreſſed by *a*, *a*, *a*, Fig. 7. At *b*, *b*, *b*, *b*, Fig. 5. are fixed four ſtrong ſtandards, to hold the drill-box ſteady.

The ſhares Fig. 6. are made of wood, and terminate at the bottom of their fore-part *a*, in a circular form, covered with iron. In their hind-part *b* is a groove, through which the ſeed drops to the bottom of the furrow. The ſeed is conveyed from the cavities *a*, *a*, *a*, Fig. 7. to this groove *b*, Fig. 6. by means of a thin plate of iron *c*, rounded and fixed to the ſhare, as at *d*. Theſe ſhares are about an inch and a half thick, and their height from *a* to *b* is at leaſt a foot.

As theſe ſhares terminate in a curve at bottom, if they meet with any roots, dung not thoroughly rotted, or any other ſubſtance which they cannot eaſily divide, they force it down to the bottom of the furrow, and by that means are never liable to be choaked: and to prevent this ſtill more effectually, the middle ſhare is placed

ſomewhat

fomewhat more backward than the two others. It is likewife made fhorter, when ufed in land laid out in ridges, in proportion to the greater height of the middle of the ridges. The fhares are generally feven inches afunder.

The four ftandards *b*, *b*, *b*, *b*, Fig. 5 and 7, are placed in fuch a manner, that the blocks *n*, *n*, Fig. 8, in which a groove is cut, anfwer to the middle of this table. On an iron axle-tree which anfwers to the wheels, and which paffes through the centre of the blocks, is fixed the cylinder, or barrel *o*, *o*, which is clofed at its ends, *p*, *s*, and is likewife divided by two partitions *q*, *r*. This barrel is made of thin fplit deal, as are alfo the ends and partitions. *t*, *t*, is a thin board, or plate of tin or thin iron, faftened with hinges, that it may be opened to put the feed into the three partitions *p q*, *q r*, *r s*. In the middle of each of thefe partitions, the barrel is pierced with holes three or four inches afunder, and about a quarter of an inch in diameter. The barrel and the wheels are fo fixed on the iron axle-tree, that they all turn together.

To know whether the holes *u*, *u*, *u*, in the three partitions of the barrel are of a proper fize and number to diftribute the feed in the manner that is defired, let fome, fuppofe half a bufhel, be put into each partition. The blocks *n*, *n*, being placed on each fide, between the two ftandards, whofe inner fides are rounded fo as to fit the groove in the blocks, and the table *S*, *S*, being raifed fo that the wheels do not touch the ground, any one may eafily fee, by giving the wheels a turn or two round with the hand, whether the proper quantity of feed drops behind the fhare; and alter it accordingly.

The barrel being properly fitted, the beam is faftened to the fore-carriage of this drill. As it moves, the barrel turns with the hind wheels, and the feed drops out of the holes *u*, *u*, *u*, Fig. 8. into the cavities *a*, *a*, *a*, Fig. 7, and from thence into the hollow *c*, Fig. 6. in the hind part of the fhare.

When the plowman comes to the end of the field, he lifts up the hind carriage, which is light, and carries it till the horfes are turned for the next furrow.

M. Duhamel does not fix the diameter of the hind wheels, but leaves that to be determined by the length of the fhares. His were fo proportioned, that when the fhares touched the ground, the wheels did not touch it by two inches. He obferves, that this drill anfwered extremely well, where the ground was plowed into an even or level furface: but that the wheels were too fmall when the middle of the ridges was raifed high; becaufe the fhares were then on the higher part of the ridge, while the wheels were in the furrows.

In Fig. 7, are two thin boards *x*, *x*, fomewhat bending, which rife up to about half the height of the barrel. The ufe of thefe is to catch the feeds that may chance to drop from the oblique holes, and guide them into the cavities *a*, *a*, *a*.

It is well known, that when the fore-part of the fhare terminates in a point, it pierces the deeper into the earth, the farther back the beam is placed on the fore-carriage: but as the bottom of thefe fhares is round, they pierce neither more nor lefs when the beam is placed more forward. It is therefore advifeable to place the fore and hind carriage as near as poffible to each other, becaufe the plough then goes eafier, and the draught is lighter to the cattle.

This inftrument is eafily tranfported from place to place by means of two poles *y*, *z*, *z*, Fig. 7. The ends *y* are placed on the fore-carriage, together with the beam, and from thence pafs under the table, fo as to raife the whole from the ground, on which their other ends *z*, *z*, reft. The crofs-bar *k*, *k*, fecures thofe ends, and keeps them at a proper diftance.

M. Duhamel took the firft hint of his feed box from an invention of Mr. Grenville, a gentleman belonging to the king of France's ftables. This was a hollow ball, fixed upon the axle-tree of two wheels, and pierced round the middle with a row of holes, through which the feed dropt as the wheels turned round. Upon a fimilar principle, another gentleman, inftead of fowing under furrow in the common way, contrived a box to turn behind his plough; and that no more than the due quantity of feed fhould be dropped, the lower half of the box moved upon a belt of leather, in the middle of which was fixed a piece of brafs pierced with a hole fuited to the fize of the feed intended to be fown. By this means, the holes in the box could not drop any feed, but when they came oppofite to the hole in the belt. A few grains were indeed fometimes bruifed in their paffage; but, upon the whole, there was a great faving of feed.

According to the above conftruction of M. Duhamel's drill, the fhares muft always pierce to the fame depth, becaufe the whole weight of the hind part of the drill refts continually upon them: confequently, it would be neceffary to have fhares of as many different lengths, as there are depths at which each kind of feed fhould be fown.

We likewife apprehend, that when the fhares have pierced to the depth intended, the weight of the drill may be made to reft on the wheels, by preventing the axle-tree from rifing between the ftandards, beyond fuch a height as fhall exactly regulate the depth to which the fhares are to pierce. This may be effected, by bringing the ftandards *b*, *b*, Fig. 7, nearer to each other; and placing between them, inftead of the blocks *n*, *n*, Fig. 8, two thick pieces of wood, made to flide up and down, with grooves, as in the blocks. Thefe pieces of wood may be fixed between the ftandards, by means of two ftrong iron pins run through the ftandards into them: and to take off the friction of the axle-tree againft thefe pieces of wood, it may be made to turn on two friction wheels, placed in the lower part of them; or rather on four or fix fmall iron rollers turning on their axis in a box inferted in each of thefe pieces, which may be raifed or lowered, by means of a row of holes in the ftandards, through which the iron pins are put, fo as to give the axle-tree room to rife to the height that fhall be thought neceffary to make the fhares pierce to the intended depth, before the weight of the drill fhall reft upon the axle-tree.

That the axle-tree, moving on fuch rollers, will have lefs friction, or require lefs ftrength to make the wheels turn round, even when the weight of the whole inftrument lies upon it, than it has in the blocks, with only the weight of the grain, is evident from the following fact. The gentleman who firft thought of this invention applied it to a roller of four tuns weight, which is now drawn with eafe by two ordinary horfes, even acrofs his plowed grounds.

It appears from this eafy motion of the roller, that there can be no danger of the axle-trees turning, though loaded with the weight of the whole inftrument. Other confiderable advantages will alfo arife from the drill's refting thus upon the wheels; for the labour of the plowman will be greatly leffened, the inftrument will move fteadier and more uniformly, and the draught will be much eafier for the horfes.

Defcription of M. de Chateauvieux's Drill-Plough, *and of its manner of working. Written by himfelf.*

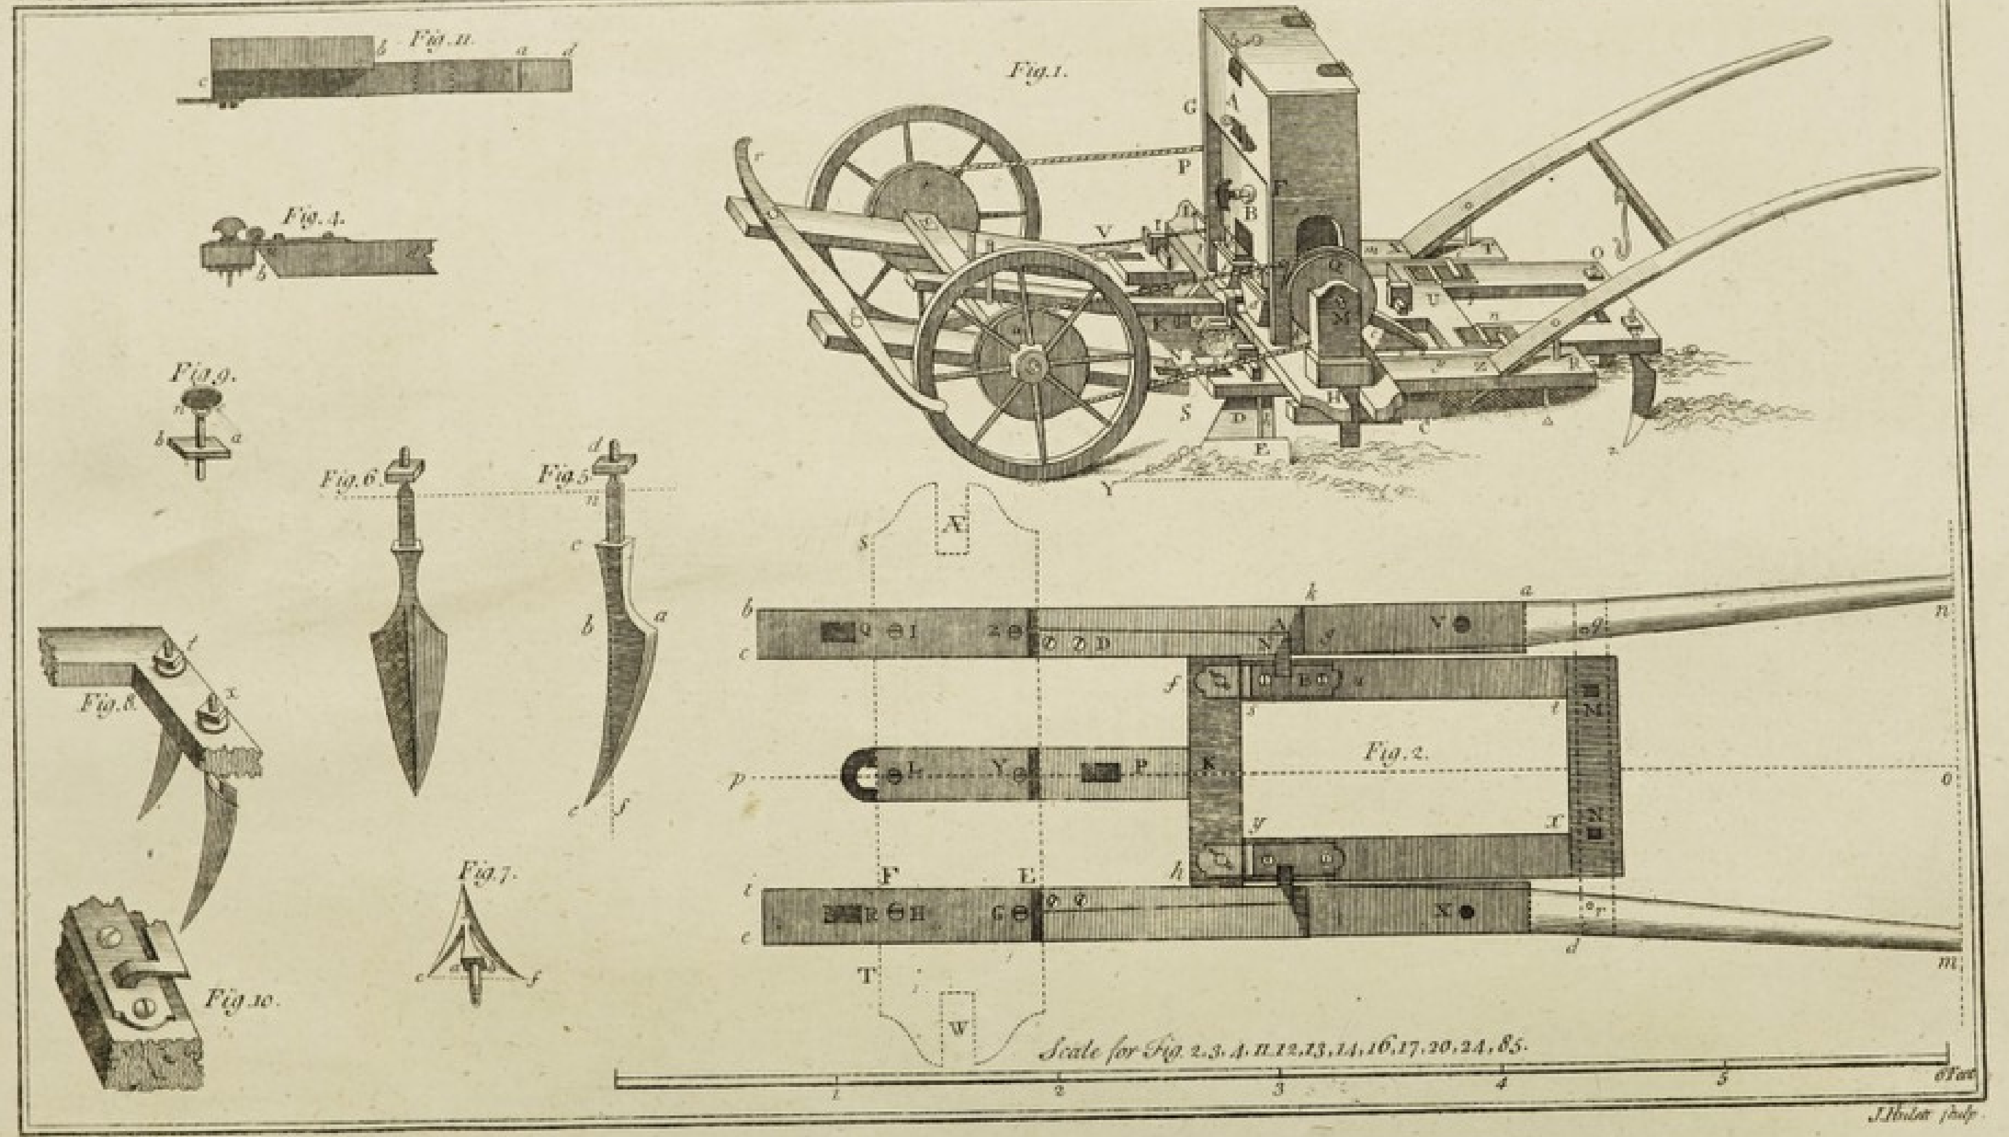
"When I firft fet about conftructing this drill-plough, my defign was to make an inftrument which fhould diftribute the grains of corn one by one, at the diftance of fix inches from each other. I attained this precifion; but foon perceived that it was not the only thing requifite, or even fo neceffary as I had imagined.

"I could, indeed, make my drill diftribute fome grains more than it did in its firft ftate: but I plainly found that the quantity of feed would not yet be fufficient to produce a proper number of plants; efpecially as it muft not be expected that every feed will grow; 1, becaufe, whatever care be taken in chufing the feeds, there will always be among them many which will not fprout at all; 2, becaufe a great number of them will be deftroyed by infects, either before they vegetate, or foon after they fpring up; and 3, becaufe the winter's cold will frequently deftroy feveral of the young plants, and greatly weaken others. Experience taught me, that, to guard againft the effect of thefe cafualties, it was neceffary to fow more feed than I did at firft.

"To this end, and that I might be enabled to increafe the quantity to whatever degree fhould be found moft proper, I enlarged the cavities of my cylinder, fo that I can now fow either more or lefs feed, with equal eafe, by means which fhall be explained in the defcription of this inftrument.

Each

PLATE. X. Facing Drill Plough.



J. Heslet sculp.

" Each of these cavities in the cylinder of my first drill-plough could contain but one grain of corn; but in the present, they are large enough to hold three or four, which, though they touch one another there, are so separated when they fall from thence, and in their passage through the pipes, that they drop at distances from each other in the furrow; for they are not all turned out of the cavities in the cylinder at the same time: besides which, I have observed, that the ground upon which they fall is always more or less uneven, and that this circumstance consequently contributes effectually to separate them.

" I confess that the description which I am going to give is very long, and that this, together with the sight of so many figures as are here represented, may, at first, make people think that my drill is a very complicated machine, and that this complication must render it very defective: but I beg of them not to give way to this prejudice, and to suspend their judgment, till they have studied the instrument thoroughly; after which, I hope they will be sensible that all its mechanism is employed only to procure the movement of the axis, and the play of the valves. I even flatter myself that it will be deemed a simple instrument, by those who rightly consider how few of its parts are moved; a circumstance which prevents its being put out of order in working. The great quantities of land which were sowed in the autumn, with perfect success, ought to remove the diffidence of those who may still incline to doubt whether this drill will always and regularly perform equally well.

" It will perhaps be objected, that the expence of making this drill-plough is too great, and that numbers of farmers, who have not much land, may not be able conveniently to purchase it.

" It is very true that if this instrument could be constructed for a small price, the benefits resulting from it would be the more extensive: but it must also be allowed that this objection does not hold good with respect to all farmers, or to gentlemen who keep ground in their own hands. These will soon be repaid the expence of such a drill, by the saving of seed: and as to the poorer sort, who have, for example, but ten or twelve acres of arable land, the expence will be but trifling, if four or five neighbours, in that case, join to purchase such a drill, which will be more than sufficient to sow all their ground. Or, each parish may come to an agreement, that he who can afford to buy such a drill, may let it out for so much an acre: a method which would be advantageous to all; but particularly to those who, by using it, would sow their land with very little charge.

" But I think, and hope, that when the great advantage of using this instrument is known, no husbandman will be without it merely because of the price; as this consideration can never out-weigh the benefits which will accrue from it in all respects, by lessening the expence of every article in the operation of sowing, and by the farther emoluments which will be reaped at harvest.

" I therefore, in constructing this instrument, paid less regard to the price which it might cost, than to the means of rendering it very solid, by a firm assemblage of all its parts; which was essential, in order to prevent the frequent accidents it would otherwise have been exposed to, in the hands of ignorant peasants, who have no idea of handling things gently, and are still less capable of repairing any mischief done to a very nice machine.

At the same time that I studied strength and solidity in the construction of this instrument, it was not less necessary to take particular care that it should execute well and regularly the purposes for which it is intended, both with respect to the manner of its distributing each grain, and to the movement of the axis, which is always in motion from the moment that the horse stirs, so that the seed runs incessantly.

In describing this instrument, I have first given a general idea of its make and manner of working, that the reader may be thereby enabled the more easily to understand the subsequent minute description of all its parts, with their relation to, and connection with, each other. The method of using it will then follow.

15

General idea of M. de Chateauvieux's DRILL-PLOUGH, *Plate* X.

A (Fig. 1,) is a wooden-box, or hopper, whose bottom is at the height of the line F G. This hopper has four feet, two of which are seen at *k* and *l*. These four feet, which may be called tenons, are fitted into four mortises in the table H L. The bottom F G of this hopper rests immediately upon the seed-box B, which is made of thin plates of brass, and is placed between the bottom of that upper box or hopper, its two sides which have the four feet, and the table H L. B is the front of this seed-box. The corn drops through a hole in the middle of the bottom of the hopper A, into the seed-box B. This seed-box B contains a brass cylinder, which traverses it, and is pierced by and fixed to an iron axis M P, at the two ends of which are firmly fastened two pullies Q and P. The two pivots of the axis are supported by two standards, one of which is seen at M H, and a part of the foot of the other at L. These two standards are fixed to the two ends of the table by two keys, like those of a turner's lathe.

The table upon which all these pieces rest, is itself, at its two ends, supported by, and fastened to the two beams T V, R S. These two beams are fixed in parallel lines, by a traverse X Z. In the middle, U, of this traverse, is pinned the end of another piece of wood, which passes from thence under the table, in a parallel direction with the two beams, and upon which also this table is fastened by two screws.

This instrument has three exactly similar shares, D, K, *e*. Two of these shares, K and D, are fastened to the two beams, at I and *p*; by a tenon and a peg, and the third is fastened in the same manner, towards U, to the piece which runs parallel to the beams. Each of these shares is covered at the bottom with a plate of iron, N, E, C; and the point of one of them, supposed to be in the earth, is seen at Y.

The harrow is composed of three pieces of wood *q* O, O W, W *n*, jointed together by mortises and tenons at O and W, and of two similar iron teeth W *z*, O R. These two teeth are fastened to the harrows by the screws W and O, and the harrow is fastened to the traverse X Z by two hinges near *q* and *n*. Upon the two beams are fastened by two screws, at *m* and *c*, two square springs *m i q* and *c Z n*, of which the two ends *q*, and *n*, press upon the harrow, to make its two teeth enter into the earth.

The fore-carriage is composed of two similar and parallel pieces V *r*, S *s*, upon which is fastened the spring-tree bar *r s*, and the axle-tree *u t* of the two wheels. The drill (of which the manner of working will be explained hereafter) rests upon this fore-carriage, whenever there is occasion for its so doing, by means of a wooden bar *d x*, one of the ends of which, towards *a*, passes through two belts which are fastened to the table, and of which only one is seen here. The other end *x* of this bar, rests upon the middle of the axle-tree of the fore-carriage, between two pins driven into the upper part of that axletree. The fore-carriage is likewise fastened to the drill by hooks and rings, as at *v* and S.

At *t* and *u* are two pullies, which are fastened to the spokes of the wheels by three or four screws. The pullies Q and *u* are encircled by a thong of leather, of the same breadth as the grooves of the pullies, and of which the two ends are buckled together, like a garter. The two other pullies P and *t* are encircled in the same manner by another similar thong.

Manner in which the DRILL *works, Plate* X.

The seed being put into the hopper A (Fig. 1.) the whole machine being drawn by the horse harnessed to the spring-tree bar *r*, *s*, and guided by the seedsman, who holds the two handles; then the three shares D, K, *e* C, open each of them a furrow, and at the same time the pullies *u*, *t*, by their turning, turn, by means of the thongs, the two other pullies Q, P, and consequently likewise the cylinder, which is in the box B, and which, in turning, distributes the seeds equally into three pipes which come out at the bottom of the seed-box. This distribution of the seed is performed by a

X x mechanism

mechanism which cannot be represented here, but will be particularly explained hereafter. The ends of these pipes are seen here at *a* and *b*. These pipes *a* and *b* drop the seeds into two other pipes *d* and *f*. The pipe *a* transmits its contents into the pipe *d*, which terminates behind the share D, at *h*, where it deposits the seeds in the furrow made by this share. In the same manner, the end of the pipe *b* of the box conveys the seed which passes through it into the pipe *f*, which terminates at *g*, behind the share K. And likewise in the same manner, the third pipe of the box, which cannot be seen in this figure, empties its contents into a third pipe, of which part is seen here at *v*, *y*, and which terminates behind the third share *e*, C. The two teeth of the harrow, passing afterward each of them between two of these furrows, cover the seeds which have dropped into the three furrows.

According as screw B, in the fore-part of the box is turned more or less from the right to the left, or from the left to the right, a greater or less quantity of seed drops into each furrow, by a means which will be explained hereafter. But so long as this screw remains in the same situation, the quantity of the seed that is dropped will be constantly the same.

To render the description of this first figure the more distinct and intelligible, some things are passed over here, which will be spoken of hereafter, and among others two traverses which fasten together the two pieces V *r*, S *s*, of the fore-carriage. Also the box B is here made larger than it should be according to the description which will be given of it, in order that the pipes *a* and *b*, *d* and *f* might appear the more distinctly. For the same reason also the out-lets of the pipes *a* and *b* are not here represented as let into the mouths *d* and *f* of the two other pipes, as they should be in fact.

In the following descriptions, that part of a piece which immediately faces the horse, is always called the fore-part of the piece, excepting only the piece named the bin, and its valves, in speaking of which the contrary rule is observed. But, every where, the right or the left side of a piece, is to be understood as of the same side of the horse.

When a machine is to be made from drawings, those drawings, especially when small, cannot, by their scale, point out precisely the exact dimensions of every nice, and oftentimes very important, piece, so as to enable a workman to construct it perfectly. To remedy this defect, all the measures of every piece, and their connection with each other, are here particularly specified in the written description, which is to be looked upon as a surer guide than the measures resulting from the engraved figures: and to render this still more certain, the weight of the nicest pieces is also given.

Description of the two Beams which support the Table and the Hopper, Plate X.

The two beams T V, R S, (Fig. 1,) are represented as if seen from above at *a*, *b*, *d*, *e*, (Fig. 2.) They are exactly similar. Each of them is three feet five inches and a half long, two inches and five-sixths wide (for example from *b* to *c*), and one inch five-sixths thick. All their sides are at right angles to each other.

These two beams are joined by a traverse *f h* (Fig. 2.) and X Z (Fig. 1.) This traverse is two inches and five-sixths wide, measuring it horizontally, one inch and three-twelfths thick, and one foot and a half long, exclusive of two tenons, one at each end, by which it is mortised into the two beams, which are parallel to each other. The upper surface of these beams, and that of their traverse, are exactly even. The distance from *c* to *f* (Fig. 2, Plate X.) is one foot eleven inches and a quarter; and the same from *i* to *h*.

Underneath each beam, and at the distance of five inches from the extremity *a* (Fig. 3.) an iron-pin, seven-twelfths, or two-thirds of an inch in diameter, projects to the length of four inches and one-third. One of these pins is seen at Δ (Fig. 1.) Its other end is driven fast into the middle of the breadth of the under surface of the beam, from which it projects perpendicularly. These two pins are to enter into two holes in the axle-tree of the hind-carriage, which will be spoken of hereafter.

Of the two Handles, Plate X.

Two handles, *k n*, *l m* (Fig. 2.) are fastened to the two beams, each of them by a tenon *d*, (Fig. 3. Plate XI.) five-sixths of an inch thick, which passes through the beam, and is secured underneath it by a wooden pin or peg *d*, about half an inch in diameter. Each handle is likewise supported upon the beam by a wooden prop *p l*, which is seen at R and T (Fig. 1.) Each of these props is three quarters of an inch in diameter, and is driven very tightly into the handle and the beam, at *p* and *l* (Fig. 3, Plate XI.) so as to pass quite through them. The upper end *c* of those props is seen at V and X, in Fig. 2. From the extremity *k* of the handle (Fig. 2, and 3.) to the extremity *a* of the beam, is one foot, and one-third of an inch, and the distance is the same from *d* to *l*, in Fig. 2. The breadth and thickness of the lower end of the handles at *g k* (Fig. 2, Plate X. and 3, Plate XI.) is nearly the same as the breadth of the beams, upon which they rest: but they lessen by degrees from *k* to *n*, and are rounded off, in such manner that the diameter of their upper end *n* is but one inch and a third.

With respect to their position, they form, with the beams, an angle of 40 degrees, as at *c k a* (Fig. 3, Plate XI.) The handle is nearly strait from *k*, to about a third part of its length, and from thence it bends more and more downward, to its end *n*, which is perpendicularly two feet higher than the upper surface *k m* of the beam. This height is expressed by the pricked line *n m*. The space between the handles likewise increases with their length, so that, at their smallest ends, the distance from the outside *m* of the one, to the outside *n* of the other (Fig. 2, Plate X.) is one foot eight inches and a half, and each of them is equally distant from the middle line *o p*.

These two handles are fastened to each other by a traverse *q r*, which is represented in Fig. 1, but is expressed here only by two pricked lines, in order to shew a piece which is under it, and which will soon be spoken of. This traverse is one inch and five-sixths broad, and two-thirds of an inch thick. Its ends, being tenons, are let into mortises in the beams, and fastened there by wooden-pins, at *q* and *r*. One of these ends appears at *q* (Fig. 3, Plate XI.) From the middle of the length of this traverse hangs an iron-hook, as in Fig. 1, Plate X. This hook is about a quarter of an inch thick, and five inches and a half long, from its extremity *e* (Fig. 3, Plate XI.) to its other end, which is fastened to the traverse. The lower end of this hook is put through a small ring fastened to the harrow between the screws of the two teeth, and serves to hold up the harrow when the drill is placed upon its hind-carriage, in order to be removed, as will be said hereafter. The traverse is fixed in the handles at the distance of thirteen inches from their extremity *k* (Fig. 2, Plate X. and 3, Plate XI.) The two handles, which the seedsman holds in his hands by their ends *m n*, serve to direct the drill.

Of the Harrow, Plate X.

The harrow is composed of three pieces of wood *s t*, *y x*, *t x*, (Fig. 2.) and of two teeth fastened to this last. These three pieces are represented at *q* O, O W, and W *n*, and the two teeth at W *z* and O R, in Fig. 1. The two pieces *s t*, *y x*, (Fig. 2.) are each of them fastened to the traverse *s y*, by an iron-hinge, in such manner that the upper surface of the ends *s* and *y* of these two pieces is exactly level with the upper surface of the traverse *s y*. Their two other ends, *t* and *x*, are terminated by a tenon which is pinned into the ends of the traverse *t x*. The upper surface of these three pieces *s t*, *y x*, *t x*, is perfectly even.

The two pieces *s t*, *y x*, are each of them one foot eight inches long, from the end *s*, to the traverse at *t*. They are two inches and one-third broad, measuring over their upper surface, and one inch and two-thirds thick. The fore-end of these pieces towards the hinge makes an angle of about sixty-five degrees, with the upper surface, as is represented in the profile (Fig. 4.) where

where the lines *d a*, *a b*, exprefs this angle. This flope is made, in order that the harrow may the more eafily prefs upon the ground, by moving on its hinges; and for the fame reafon all friction between the fides of the harrow and thofe of the beams is avoided, by leaving an interval of about one-fixth, or one quarter of an inch between them. The lines, or edges *t s*, *x y*, (Fig. 2.) are parallel, and the diftance between them is one foot and five-fixths of an inch. The traverfe *t x* is two inches and nineteen twenty-fourths wide, and one inch and two-thirds thick.

In the middle of the breadth of the upper furface of this traverfe, and cut perpendicularly to that furface, are two fquare holes, M and N, diftant from each other feven inches and a half, from the centre of one to the centre of the other, and both equally diftant from the middle line *o p*.

Of the Teeth of the Harrow, Plate X.

In thefe two holes M N in the travefe of the harrow are faftened, as will foon be feen, two iron-teeth, perfectly alike, fo that it will be fufficient to defcribe one of them. This tooth is fhaped almoft like the head of a lance, if we fuppofe its two fides to be bent towards each other, fo as to form a kind of groove or channel. Thefe two fides, or fins, are feen in perfpective, fideways in Fig. 5, behind in Fig. 6, from above, and from before, in Fig. 7.

The fhank *b d* (Fig. 5.) is five inches and an half long, from its rife at *a b*, to its end *d*; and three quarters of an inch thick at *a b*, where it is made fquare. This thicknefs is increafed a little at *c*, in order to form the fhoulder reprefented at *a b* (Fig, 7.) The diftance from *a b* (Fig. 5.) to this fhoulder *c*, is three inches. The fquare thicknefs of the fhank, from *c* to *n*, is half an inch; which is likewife the fize of the holes M N (Fig. 2.) The reft of the fhank is round, and half an inch in diameter. Its upper end is a fcrew, fitted to receive a nut about half an inch thick, and a little more than an inch fquare. The point *e* does not vary from the direction of the fhank, either to the right or the left, as appears by Fig. 6: but the fide *b e* (Fig. 5.) bends a little forward, fo that the point *e* advances one inch and a quarter beyond the pricked perpendicular *n b f*. The upper and outer extremities *c* and *f* of the fins (Fig. 7.) are two inches and one-twelfth diftant from each other, and equally diftant from the middle of the fhank. The width of each fin, in this part, from *s* to *f*, or from *s* to *c*, is one inch and a half. From thence they leffen by degrees down to their point. The edges of thefe fides, or fins, are almoft fharp, but their thicknefs and ftrength increafe towards their back.

The two teeth of the harrow are placed exactly in the middle of two parallel lines fuppofed to be drawn from the point of the fhares; by which means thefe teeth will enter into the ground at equal diftances from the fmall furrows made by the fhares, into which they will throw back the quantity of earth neceffary to cover the feeds perfectly.

As to the pofition of thefe two teeth, they are faftened in the two holes M and N of the traverfe *t x* (Fig. 2.) as is reprefented by the perfpective view of them in Fig. 8. The fhank of each tooth is run through the holes in the traverfe *x t*; its fhoulder is thruft up clofe to the under furface of this traverfe; and a nut, under which is placed a very thin plate of iron, fixes at the top. The back and point of thefe two pieces fhould face exactly the fore-part of the drill.

Hinges of the Harrow, Plate X.

To return to the hinges *s* and *y* (Fig. 2.) which are exactly alike, and which are feen at *q* and *n* in Fig. 1. Their breadth is one inch and two-thirds, during their whole length, from *v* to *f* (Fig. 2.) The joint *s*, of this hinge, is half an inch in diameter. The claw, from the joint *s* to *f*, is two inches and a quarter long, and is faftened to the traverfe *f b* by a thumb-fcrew reprefented in perfpective in Fig. 9, and which fcrews into a nut *a b*, which is faftened to the bottom of the traverfe, by two nails. This fcrew (Fig. 9.) is one-third of an inch in diameter. It is fcrewed down, by means of a correfponding fcrew in the nut under the traverfe, till its fhoulder *c n*, which is two-thirds of an inch in diameter, preffes upon the claw of the hinge: for which fee alfo Fig. 4. The length of the other claw of the hinge *s v* (Fig. 2.) from the joint *s* to its end *v*, is four inches and a half. The thicknefs of each claw towards the joint, is a quarter of an inch, and from thence that thicknefs leffens by degrees to the end *v*. The claw *s v* is faftened to the piece *s t* by two flat-headed fcrews.

Spring of the Harrow, Plate X.

Upon this claw, and between thefe two fcrews, preffes the end B of a fpring A *z* (Fig. 2.) which forms an angle at A, and is faftened to the beam *a b*, between D and *z*, by two flat-headed fcrews, of which the laft D is two inches and an half diftant from the end *z* of the fpring. Thefe two fprings are feen at *m i e* Z *n* in Fig. 1. The length of this fpring from *z* to A (Fig. 2.) is thirteen inches and a half, and from the angle A to B two inches and a quarter. Its breadth at *z* is one inch and a half; at N it is one inch and one-twelfth; and at B it is thirteen twenty-fourths of an inch. Its thicknefs at *z* is five twenty-fourths of an inch, and from thence that thicknefs diminifhes to A, where it is but one-fixth of an inch. The part A B increafes in thicknefs from A to B, where it has a head, which alone preffes upon the claw of the hinge between the two flat-headed fcrews. This part of the fpring, with its head, is reprefented plainly, in perfpective, in Fig. 10. When this fpring is in its ftate of reft, the whole of its under furface from N to *z* (Fig. 2.) lies exactly flat upon the upper furface of the beam. The end *z* of this fpring is fifteen inches from the end *b* of the beam *a b*. Thefe fprings fhould be made of good well-hammered ftuff, prepared like that which is ufed for the fprings of coaches; by which means they will have a body, and not be fubject to break or bend. If they appear to be too weak, they may be placed a little farther from the joint of the hinge, in which cafe they will the better prefs the teeth of the harrow down into the ground.

Connection of the Beams, with the Table and the Shares, Plate X.

The thicknefs of a quarter of an inch is taken off from the upper furface of each of the two beams, from *z* (Fig. 2.) immediately adjoining to the end of the fpring, to Q, in the one; and from E to F in the other; being, in length, eight inches and two-thirds. In thefe lowered fpaces is placed the table, which will foon be fpoken of, and of which the extent is here indicated by pricked lines. This table is feen at H and L, in Fig. 1. It is faftened to the beams, by four ftrong flat-headed fcrews, at *z*, I, G, and H (Fig. 2.) and is feen in profile in Fig. 3, Plate II. at *i* and *r*. This table refts likewife upon a piece K L (Fig. 2.) of which the end K, being a tenon, is pinned into the middle of the length of the traverfe *f h*; as is alfo feen at U (Fig. 1.) This piece K L (Fig. 2.) is two inches and five-fixths broad, meafuring it horizontally, and one inch and five-fixths thick. Its length is fuch, that its end L reaches, at moft, no farther than the edge Q F of the table. At the end of this piece appears a ring, which is faftened under it, and of which the defcription and ufe will be feen hereafter. The upper furface of this piece K L, from K to Y, is level with the upper furface of the two beams, and the traverfe *f h*: but from Y to its end, a quarter of an inch is taken off from its thicknefs, in the fame manner as from the oppofite parts of the two beams, to fit it for the reception of the under furface of the table. A fide view of this is given in Fig. 11. where *a b* is the profile of this furface, which, from *a* to *b*, is level with the furface *d a* of the traverfe, and from *b*, to its end *c*, is a quarter of an inch lower, that the table may reft upon it.

In the middle of the breadth of the upper furface of this piece K L (Fig. 2.) and perpendicular to that furface, surface, a mortise P is cut quite through it, to receive the tenon which is seen at U, Fig. 1. This mortise is throughout two inches long, and one inch wide. Its end P (Fig. 2.) is three inches and eleven twelfths distant from the traverse *f h*. The two beams are pierced in the same manner by two similar mortises Q and R, of which the ends Q and R are one inch and eleven twelfths distant from the side S T of the table. The tenons which pass through these two mortises are seen at I and *p* in Fig. 1. These three mortises are to receive the tenons of three exactly similar shares, of which the following is the description. These three shares are seen at D, K, and *e* in Fig. 1.

Of the Shares, Plate XI.

The shares are cut out of a plank, and Fig. 12 represents one of their two surfaces. The lines which limit this surface are perpendicular to each other, excepting *i d*; the line *d c* is six inches long; *c f*, nine inches; *f g*, two inches and a quarter; *g l*, five inches and a half; *l m*, two inches; and *h i*, half an inch. This plank is every where an inch thick, except at the edge *e d*, where it forms an acute angle, as at *b*, Fig. 13. which represents the bottom of the plank *c d* (Fig. 12.) The part *g l*, in which is the hole *k*, is the tenon which enters into the mortises P, Q, R, (Fig. 2.) before described. Fig. 14. represents the top of this plank, and of its tenon.

Fig. 15, is a perspective view of an iron share which is fixed under the plank, as in Fig. 17. Its point (Fig. 15.) extends from *e b* to *f*. Its sole, which extends from *c b* to *a c*, and the ears *a b*, *c d*, are all of one piece. Fig. 16 represents a geometrical plan of this share, in which *d f*, and *g h*, are the places from whence the two ears arise.

The length of the point from *e b* to *f* (Fig. 15.) and from *a b* to *c* (Fig. 16.) is four inches. Its height towards *b*, or towards *e* (Fig. 15.) is about one inch and a quarter, and from thence it lessens gradually to *f*, which is the point. Its breadth *a b* (Fig. 16.) is the same as the thickness *c o* (Fig. 13.) of the plank of the share, and it lessens gradually from thence to its point *c* (Fig. 16.) A notch is made in the upper part of this point, between *e* and *b* (Fig. 15.) or between *a* and *b* (Fig. 16.) to receive the lower end of the angular side, *o b c* (Fig. 13.) of the plank.

The sole *e a* (Fig. 15.) or *a d* (Fig 16.) is of the same length and breadth as the bottom *c m*, or *o n* (Fig. 13.) of the plank which it covers. It is about, but not more than two thirds of an inch thick towards *e b* (Fig. 15.) and half an inch thick at its end *a c*.

Towards this end are the two thin iron ears, which lie close to the two sides of the plank, to which they are fastened by a single nail, which passes through the plank, as at *h*, Fig. 17.

This share is also fastened to the bottom of the plank by a flat-headed iron pin, *g h*, Fig. 15. which goes through the share at *n*, and enters into the middle of the thickness of the plank. The head *b* of this pin is flat, and lies even with the bottom of the sole, in the manner indicated by the pricked lines at *a*, Fig. 17. Towards the flat end *c* of this pin is a hole, through which, and through the plank, a smaller pin or nail is driven, as is denoted by the pricked circle in the same figure.

The point of the share, and the bottom of the sole, which rubs upon the ground, should be of steel. The different thicknesses given to the sole, shew that its point inclines a little downward, by which means it enters into the earth very easily.

Fig. 18. represents a perspective view of a thin plate of iron, which is to cover the plank of the share, as in Fig. 20. to preserve it from the friction of the ground, which would otherwise soon wear it out. The thickness of this plate, which should be equal every where, is at most one twelfth of an inch. It is bent at *a b*, Fig. 18. in such manner, that this bending fits close to the sharpened edge *c d*, Fig. 20. of the plank; the angle *b*, Fig. 18. being fitted to the notch *c* (Fig. 20.) in the iron part of the share, and the lower edges *b c*, *a d*, of this plate (Fig. 18.) joining on both sides to the upper edges of the sole of the share, as in Fig. 20. The breadth of this plate from *a* to *b* (Fig. 20.) is about four inches, and each half of its length, from *c* to *a*, or from *d* to *b*, is about seven inches and a half. Fig. 19 is the plan, or bottom, of this plate.

As this plate covers the ears of the share, and at the same time its own angle *c* (Fig. 20) is covered by the point of the share, these two pieces must be put on together. This plate is nailed to the two opposite sides of the plank.

The two ends of this plate extend beyond the hindmost part of the plank of the share, in the proportion of *b b*, Fig. 20: and in this space, between these two ends, is the opening of the pipe through which the seed drops into the furrow, as was said before.

The tenon *l g* (Fig. 12) of the share now described, (and there are three such) enters into one of the three mortises, P, Q, R (Fig. 2) through the bottom of which it is passed, and is fixed above by a wedge driven into the hole *k* (Fig. 12). These shares are situated in such manner, that their point faces directly the fore-part of the drill. One of them is represented as fixed towards the end *b* of one of the beams, in Fig. 3, which exhibits the profile of that beam.

Of the Piece which is placed under the Middle of the Table, and which bears the Middle Share, Plate XI.

The piece K L (Fig. 2, Plate X.) which as been already spoken of, is represented with its bottom upward, and in perspective, at *a b*, Fig. 21. Plate XI. with the share A, and its tenon B, and with the table, which are also inverted in the same manner. Fig. 22. is a geometrical representation of the under side of the same piece, and of part of the table, excepting the share, which is omitted here, and of which only the bottom of the mortise is seen at B.

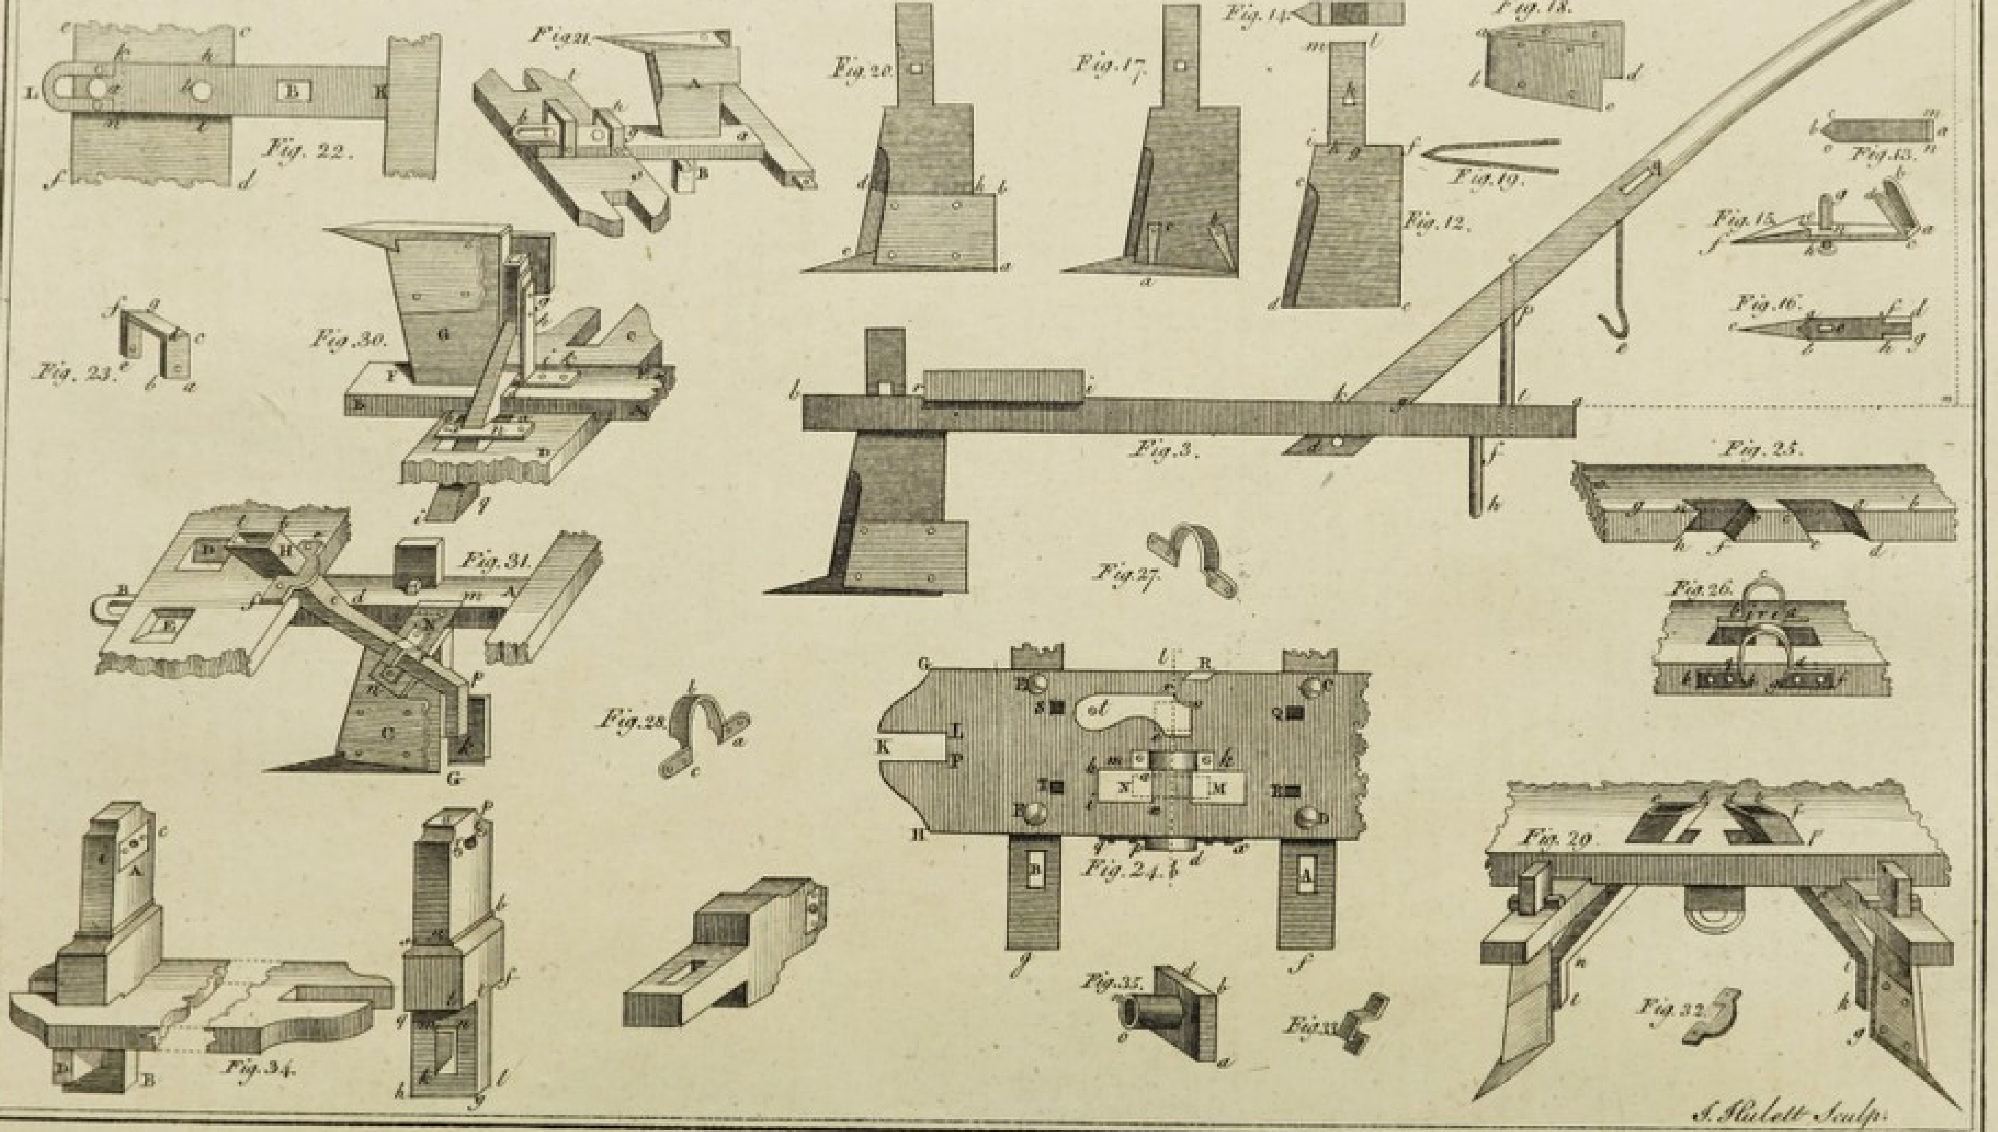
To the end L of this piece (Fig. 22.) is fastened the reign, or bridle before mentioned. This bridle is shaped nearly like a horse shoe; the breadth of each of its branches is three fourths or five sixths of an inch; its total breadth is the same as that of the piece to which it is fastened; its total length is three inches and a half, and its thickness every where is about one sixth of an inch. The whole thickness of the two branches of this bridle is let into the piece of wood to which it is fastened; so that it forms an even surface. This bridle is fastened to the piece by two flat headed screws, which lie even with the branches of the bridle, through and into which they are screwed. It is placed in such manner, that the outside of its circular part L, is one inch and a quarter distant from the edge *e f* the table. It is used only when the drill is put upon its hind-carriage.

a and *b* are the heads of two large flat-headed screws, which pass through the piece K L, and fix it to the table. From the centre of the head *b*, to the edge *c d* of the table, is one inch and two thirds. From the centre of the head *a*, to the edge *e*, *f* of the table, is one inch and one third. These two screws are placed in the middle of the branch of this piece K L. Their diameter is five twelfths of an inch, and that of their head is an inch and a twelfth. These heads are flat, and screw in a level with the wood.

Of the two Bridles which receive the End of the Bar which supports the Drill upon its Hind-carriage, Plate XI.

Underneath this piece K L, are likewise fastened two bridles very like each other. They are represented in perspective by the single figure 23; but both of them may be seen in their proper places, at *g h* and *e f*, Fig. 21. Their place in Fig. 22 is marked only by pricked lines, in order to let the pieces under them be seen. These two bridles are made of a flat piece of iron, one inch and a sixth wide from *a* to *b*, or from *c* to *d* (Fig. 23.) and a very little more than one sixth of an inch thick. They are bent square at *c d* and *f g*, and are pierced with two holes, *h* and *e*, one fourth of an inch in diameter, of which the centers are three fourths of an inch from the ends of the iron. Thus far these two bridles are like each other. What they differ in, is as follows. That which is placed at *g h* (Fig. 21.) is three inches and one sixth high, from its bottom *a*, to the upper surface of its

top



J. Hulett Sculp.

top *c*, or from *e* to *f*, Fig. 23; and this height in the belt which is placed at *e f* (Fig. 21.) is three inches and five twelfths: That which is placed at *g h*, is two inches and five sixths long, from its outside at *c d*, to its outside at *g f* (Fig. 23.) and this part of the bridle placed at *e f*, is three inches and one third.

Both these bridles placed at *g h* and *e f* (Fig. 21.) go over the piece of wood *a b*, to which their ends are fastened by flat-headed screws, which pass through the holes *b* and *e* (Fig. 23.) beforementioned. These ends rest immediately upon the table. As the distance between the ends of the bridle *e f* is exactly equal to the breadth of the piece to which they are fastened, they are applied to the two lateral surfaces of that piece, without being let into it: but as the bridle *g h* is not quite so long, the ends of this are let into those surfaces, as is seen in Fig. 21. and in the pricked plan of these two bridles, *h i*, *k n*, Fig. 22. The end of these bridles stand perpendicular to the table. The bridle *g h*, Fig. 21. is one inch and fifteen twenty-fourths from the edge *t s* of the table; and the bridle *e f* is five inches and eleven twelfths distant from the same edge *t s*.

The use of these two bridles is to receive the end of the bar hereafter described, which serves to support the drill upon its fore-carriage, when the hind-carriage is joined to it: and to prevent this end of the bar from slipping out of these bridles, a moveable iron pin is put through it. This pin is suspended by a piece of pack-thread. It passes through the bridle L (Fig. 2. Plate X. and 22. Plate XI.) and *b* (Fig. 21.) before described.

Of the upper Surface of the Table, Plate XI.

Fig. 24. represents a geometrical plan of the upper surface of the table, one end of which is omitted, as superfluous in this figure, because both its ends are alike. The pricked line *l b* is traced here only to mark the middle of the table, and determine some measures. The fore-ends of the beams appear here at *f* and *g*, with their mortises A and B, into which their shares are fastened. C, D, E, F, are the four large flat-headed screws which fasten the table to the beams. The diameter of these screws towards their head is five twelfths of an inch, that of their head is one inch and a twelfth, and their length is three inches and seven twelfths. They enter into the middle of the breadth of the beams, and the centers of the holes in the tables through which they pass, are eleven twelfths of an inch distant from the nearest edges of the table. The whole breadth of the table, at C D, or E F, is eight inches and two thirds. The two corners G and H are thirteen inches distant from the middle line *l b*, and the end K is one foot three inches and three fourths distant from the same line *l b*. The thickness of this table is every where one inch and two thirds.

At each end of the table is a notch K L P, of which the inner surfaces are perpendicular to each other. These notches are at H and L in Fig. 1. Plate X. Each of them is three inches and three quarters long, from K to L, Fig. 24. and one inch seven twelfths wide from L to P. They are situated in the middle of the breadth of the table. Their use is to receive the lower end of two standards hereafter described (Fig. 34.) of which one is seen at M H, Fig. 1. and the base of the other towards L.

This table has two holes, M and N (Fig. 24.) of which the upper openings are exactly equal, and alike situated, each of them forms a right-angled parallelogram *a b i n*. The side *b i* is parallel to the edge D F of the table, from which it is one inch and a half distant, and its length is three inches and a quarter.

The upper edge of the end *a n* is eleven twelfths of an inch distant from the middle line *l b*, and its length is one inch and eleven twelfths. The inner and parallel sides *a b*, *n i*, of these holes are perpendicular to the upper surface of the table; but their ends *a n*, *b i*, are sloped, in such manner, that each of them forms an angle of fifty or fifty-five degrees towards the line *l b*. This is expressed in the profile of these two holes (Fig. 25.) by the angles *b a d*, *b c e*, and *g o f*, *g n h*, each of which has that measure.

Q, R, S, T, are four mortises, of equal size and depth, cut perpendicularly to the upper surface of the table. Each of them is nineteen twenty-fourths of an inch long, in the same direction as the length of the table, two thirds of an inch wide, and about one inch deep. They are intended to receive the four feet of the hopper, which will be described hereafter. Two of these feet are seen in their mortises at *k* and *l*, Fig. 1. Plate X The centre of each of these mortises is six inches and five twelfths distant from the line *l b* (Fig. 24.) and an inch and three quarters from the edges C E, D F, of the table.

Of the Bridles which receive the End of the Bar which supports the Drill upon its Fore-carriage, Plate XI.

From *k* to F, Fig. 24. is a bridle which is seen in front in Fig. 26. It is made of iron, one inch, or one inch and a twelfth broad, and one sixth of an inch thick. It is bent in a semi-circle at *a c b*, and lies flat upon the table at its end *a* and *b*, which are fastened to it by two flat-headed screws *a* and *b*, Fig. 26. and *k m*, Fig. 24. This bridle is perpendicular to the upper surface of the table. The highest part of the upper side of its arch *c*, Fig. 26. is two inches above the table; and its width, from outside to outside, from *e* to *i*, is two inches and a half. The length of each strait part, or claw, which is fastened to the table, is one inch and a quarter. The centres of the screws *k* and *m* (Fig. 24.) are each one inch and three quarters from the middle line *l b*, and four inches from the edge D F of the table.

d r q (Fig. 26.) is the upright of another bridle, of which the top, or upper surface, is seen at *x d p q*, Fig. 24. the front and side in the perspective figure 27, and the back and sides in the perspective figure 28. The hinder surface of the two claws, represented at *a* and *c* (Fig. 28.) is screwed on to the fore-surface of the table, as at *f g* and *h k*, Fig. 26. by two flat-headed screws, each of which is one inch and seven twelfths long, and near a quarter of an inch in diameter towards its head, which is half an inch in diameter. The middle of this bridle answers to the middle of the length of the table. The under surface of the bridle, and of its wings, answers to the plane of the fore surface of the table, to which it is fastened. The length of each wing is about two inches and a half; their breadth is five sixths, and their thickness a quarter of an inch. The length and thickness of its arched part are equal to those of the wings. The bending of that part is such as is represented at *g d r q h*, Fig. 26. The distance *g h* between the two wings is one inch and eleven twelfths. The greatest width of the bridle, from outside to outside, as at *d q*, is two inches and three fourths; and, lastly, the upper surface of its highest part *r*, is one inch and two thirds above the upper surface of the table.

The use of these two bridles is to receive the end of the bar, which will be described hereafter. This bar is seen at *x d*, Fig. 1, Plate X. where one of the rings appears towards *d*. A wooden wedge *o t* (Fig. 24. plate XI.) is slipped, if there be occasion for it, between this bar and the table, to which last it is fastened by a single flat-headed screw *t*, around which it turns, as around a center. The shape and extent of this wedge is such as is here represented according to the scale. Its thickness, throughout, is seven twelfths of an inch, excepting only at the part *r o e*, where its upper surface inclines from *r*, to *o e*, in such manner, that the edge *o e* is almost sharp, that it may slide, like a wedge, under the end of the abovementioned bar, which passes through the two bridles or belts. The length of this piece is five inches and one twelfth, from the center *t*, to its end *o e*. This center *t* is six inches and one sixth from the edge D F of the table, and four inches and a quarter distant from the middle line *l b*. We shall hereafter see, that the bar which enters into the two belts now described, ought not to fill entirely the belt *a b c*, Fig. 26. but should leave room to introduce under it the wedge just spoken of, which is not to be inserted but when it is intended to make the other end of the bar press hard upon the axle-tree of the fore-carriage, which should never be done at the time of sowing, unless the husbandman would scarcely bury the seed.

Of the two Pipes of the Shares of the Beams, Plate XI.

Through the two holes M and N of the table (Fig. 24.) pass two brass pipes, which descend to, and open at, the back of the shears fastened in the mortises A and B of the two beams. These pipes are seen at *d* and *f* in Fig. 1. from whence they pass through the two holes in the table, and terminate behind the two shares D and K, as is represented in perspective in Fig. 29. These two pipes *f p a i k*, and *o r n l*, (Fig. 29.) are perfectly alike. They are almost square during their whole length; wider towards the end *f d*, than towards the end *k*; and they are made of plates of brass, somewhat less than a twelfth of an inch thick, well soldered together. Their opening at *f d* forms a parallelogram, which is an inch and one sixth wide from *b* to *f*, and an inch and three quarters long from *b* to *d*. The plane or perpendicular projection of these openings in the table, is indicated in Fig. 24. by the pricked lines between the letters M and N, where it is to be observed, that they are both equally distant from the middle line *l b*, and an inch and a half from the edge D F of the table. All the rims of these openings, *f*, *b*, *d*, *b*, *o*, (Fig. 29.) are nearly parallel to the upper surface of the table, above which they rise two inches and two thirds. As these two pipes are alike, and situated in the same manner, one on the right, and the other on the left hand side of the drill, it will be sufficient to apply to one of them, what remains to be said of both. This pipe runs in a strait, but oblique line, from its opening *f d* to *i*, directly behind and under the share, from whence its direction becomes perpendicular, to its other opening *k*, which is at the height of three inches and a quarter from the bottom *g* of the share. From its bending at *i*, to the opening *k*, is three inches. This opening *k* is a square, of which the sides are two thirds, or three quarters of an inch long.

This pipe is held to the side *p* of the hole, by a piece of iron which is under the table; and it is also fastened near the bending *i*, by another piece of iron fixed under the beam. These fastenings are seen in Fig. 30. which represents, in perspective, the bottom C D of the table, E F of the beam on the right-hand side of the drill, and the share G which is fastened to it. *q l* is the upper opening of the pipe, which runs from thence close to the side *a b* of the hole in the table, where it is fastened by a plate of iron, *n x*, about one eighth of an inch thick. In this plate is a notch which fits close to three sides of this pipe. This plate is fastened to the under surface of the table, by two flat-headed screws, *x* and *n*. The pipe continues in the same direction from its upper opening *q l*, to its bending at *e*, behind the share; but from thence to *f*, it follows the direction of the back of this share. It is fastened towards this bending by an iron square, *k i b g*, the thickness of which is about one eighth of an inch. This square is fastened under the beam by two flat-headed screws, *k* and *i*, and to the pipe by two other screws, *g* and *b*, the ends of which screw into a piece of iron, which is soldered to the pipe, and which is seen between the square and the pipe, from *f* to *e*. The beam A B has a shallow notch at *d*, to make room for the passage of the pipe.

Of the Pipe of the middle Share, Plate XI.

The two pipes which terminate behind the two shares fastened near the ends of the beams at Q and R (Fig. 2, Plate X.) have now been described. A third pipe, of nearly the same form, terminates behind the third share, which is fastened at P, in the piece K L. This is the pipe which passes between U and *y*, in order to its terminating behind the share *e* C.

This piece K L is represented in perspective at A B, Fig. 31, Plate XI. which shews its right side, with its share C, and the portion of the middle of the table, where are the two holes D, E, through which pass the two pipes beforementioned.

This third pipe is made like the two others, of plates of brass, of the same thickness and the same shape. Its opening *b l* forms a parallelogram of nearly the same size as the similar openings of the two other pipes. The plane of this opening, or its perpendicular projection, upon the table, is indicated by pricked lines near *o c e*, Fig. 24. where it is to be observed, that the middle of this parallelogram is in the middle line *l b* of the table, and that its side *c e* is five inches and five twelfths distant from the edge D F of the table. The rims of this opening *b l* (Fig. 31.) are raised about two inches above the upper surface of the table. From thence this pipe descends in a strait, but oblique line, towards the share which is behind the table; and at the same time bears to the right to *d* and *c*, where it bends, in order to take the direction of the lateral surface of the piece A B, against which it rests. From thence it continues in this direction to *r*, where it bends again, to *p*, immediately behind the share; and there it is bent again, so as to descend perpendicularly behind this share, down to *k*, which is within three inches and a quarter of the bottom of the share G.

The table is notched at H, to let in one side of the pipe. This notch is also seen at R, in Fig. 24. The pipe is fastened in this place by an iron plate *e f*, Fig. 31. about one eighth of an inch thick, which is fixed upon the table by two flat-headed screws near *e* and *f*. This piece is represented by itself in Fig. 32. *m n*, Fig. 31. is a piece of iron, at least one sixth of an inch thick, fastened by two screws, at N, against the side of the piece of wood A B, into which the thickness of this iron is let, as may be seen at *m*, in such manner that the outward surface of this piece *m n*, is level with that of the piece of wood A B. The pipe is fastened against this piece of iron *m n*, by a belt fixed by two screws to the piece of iron *m n*. This belt is represented by itself in Fig. 33.

Of the Standards, *Plate* XI.

In the notches Æ W at the two ends of the table, Fig. 2. Plate X. are placed two standards, represented in perspective in Fig. 34. Plate XI. with the two ends of the table, of which the middle is suppressed, as needless in this representation. These two standards being exactly alike, it will be sufficient to describe one of them.

In each standard may be distinguished three parts, namely, the head, which reaches from the line *p a*, to the top of the moulding *b d s*; the base, which extends from the top *b d s* of the moulding, to the under part of the shoulder *f u q*; and the tail or tenon, which begins at the bottom of the shoulder.

All the sides of this standard are at right angles to each other, excepting only the two indentures *p* and *a* in the head, and the mouldings at the base. The inner surface A B, which faces the other standard, is every where an even plane.

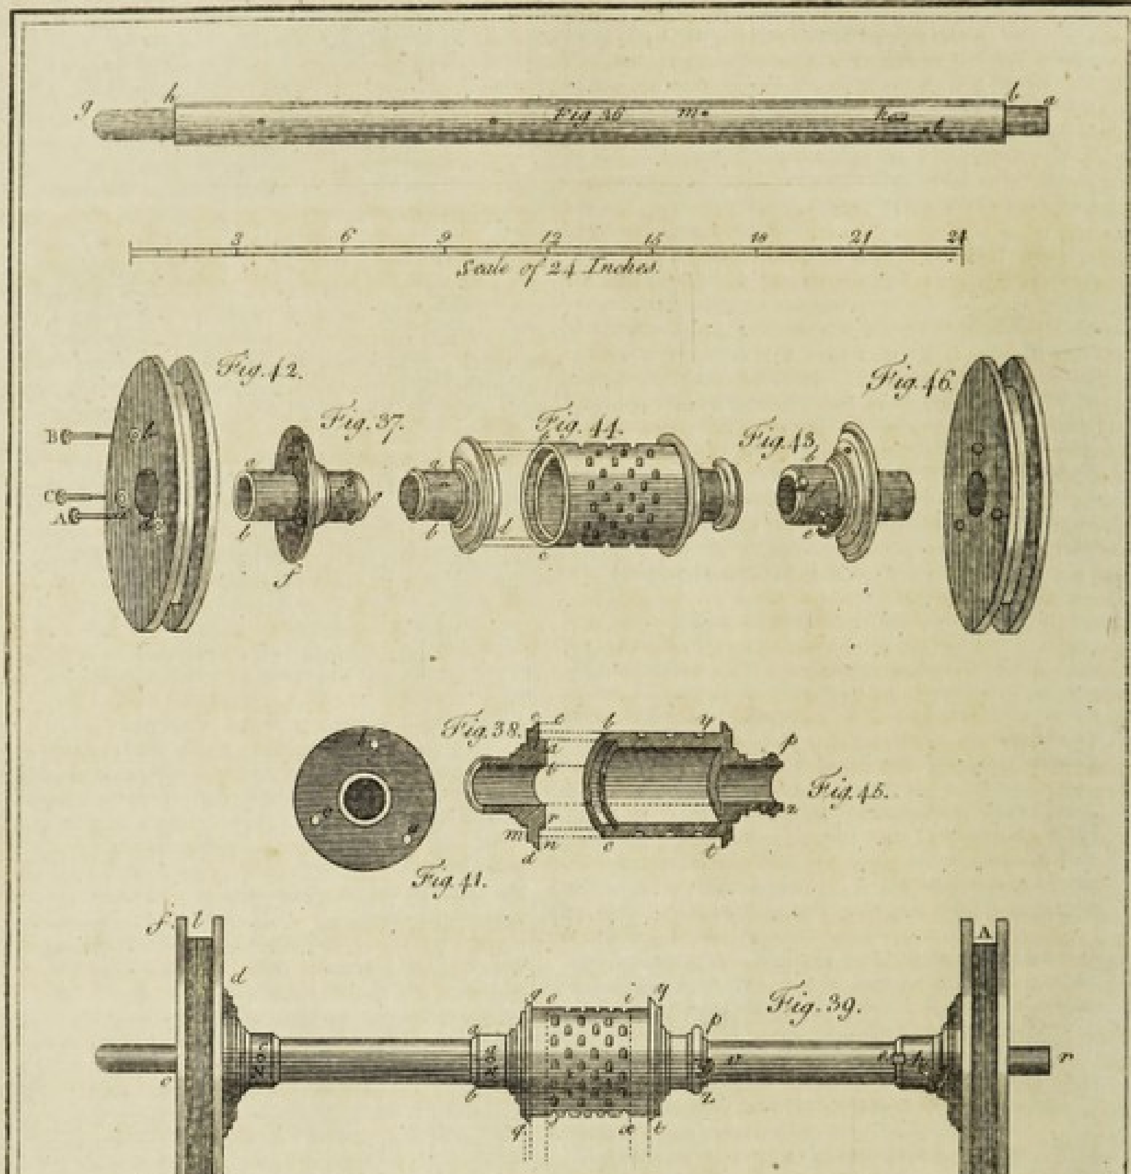
The head is three inches and a quarter wide, from *b* to *d*; two inches and one sixth thick, from *d* to *s*; and seven inches high, from the line *b d* to the line *p a*.

The base is four inches and five sixths wide from *f* to *u*; two inches and five sixths thick from *u* to *q*; and two inches and a half in perpendicular height from *f u* to *b d*.

The tail or tenon, which proceeds from the lower middle of the base, is equal in breadth *g h*, to the breadth *u q* of the base, that is to say, it is two inches and five sixths wide. Its length, *t g*, is six inches and a quarter. Its thickness is the same as the width P L (Fig. 24.) of the notch in the end of the table, which receives this tenon; that is to say, one inch and seven twelfths. The hole or mortise *k n* is in the middle of the breadth of the tenon, and forms a right angled parallelogram, two inches long from *m* to *k*, and eleven twelfths of an inch wide from *n* to *m*. The height of this hole is determined by the thickness of the table, in such manner, that the distance between the bottom *f u q* of the base, to the top *n m* of the hole, is somewhat less than the thickness of the table.

Each standard is fastened to the table, as may be seen in the figure, in the same manner as a common turning lathe is fastened, by a key D, about eight inches and a half long, driven tightly up to its middle, in that part of the mortise which is under the table; and for greater solidity, one of the keys is put in at the fore part of one mortise, and the other at the hind part of the other.

A round hole, one inch and five twelfths in diameter, is bored through the head of the standard, near A. The center or axis of this hole is exactly in the middle of the breadth of the head, and the hole is made through it exactly horizontal to the upper surface of the table, or, in other words, perpendicular to the side of the standard. The pipe *n o* of the ferrule, Fig. 35. is put into this hole. The diameter of this pipe is the same as that of the hole. The pipe *n o*, is of one piece with its scutcheon *a b d*, which



J. Hulett Sculp.

which is one-third of an inch thick: its breadth *ab* is one inch and five-sixths, and its length *bd* is three inches. All its surfaces are at right angles, and parallel to each other. The axis of this pipe is in the middle of its scutcheon, and perpendicular to its surface. Both the scutcheon and the pipe (being but one piece) are bored through with the same hole, which is five-sixths of an inch in diameter; and in the upper surface of the inside of this hole is a grove, which reaches from one end to the other. One end of it is seen at *n*, and its use will soon be shewn. The end *no* of this pipe is put into the hole A of the standard (Fig. 34,) at the inner side A B of this standard, and the scutcheon *abd* (Fig. 35,) is let into this surface at *ci* (Fig. 34,) where it is fastened by two screws, of which the ends are seen at *c* and *i*, in this figure, and at *e* and *r* in the adjoining representation of the outside of the other standard. The two small holes in the schutcheon are female screws, to receive the ends of the screws before mentioned, which are one-third of an inch in diameter, and their heads is two thirds. The outer surface *ci* of the scutcheon is made to lie exactly even with the inner surface of the standard, and the centre of its pipe is at the perpendicular height of five inches, and seven-twelfths above the surface of the table. These two pipes (one in each standard) are destined to receive the two pivots *ab*, *gh*, of an iron axis; and the groove *n*, (Fig. 35,) then becomes useful, by affording the means of introducing a little oil, to keep the pivots from losing their temper by their friction, and to make them turn with the greater ease.

The scutcheon and its pipe should be cast in one piece of good metal, sufficiently hard, but by no means brittle.

Of the Axis, and the Pieces which are fastened to it, Plate XII.

The pivots are of the same diameter as their holes; and their shoulders *b* and *h* (Fig. 36,) are at the same distance from each other as the inner surfaces of the standards, that is to say, two feet.

The axis is represented naked in Fig. 36; but the several pieces represented separately in figures 37, 38, 40, 41, 42, 43, 44, 45, and 46, are to be fastened to it.

Fig. 39, represents all these pieces fixed upon the axis. It is to be observed here, that the long pivot *c* (Fig. 39,) goes through the hole of the standard which is on the left-hand side of the drill, and the pivot *r* through the standard on the right-hand; so that all these figures exhibit a front view of the axis and its pieces.

The pivot *ab* (Fig. 36,) on the right-hand side, is one inch and a quarter long; and that on the left, *hg*, about two inches. The diameter of the axis towards the shoulder *b* and *h* is one inch and a twenty-fourth part of an inch. From thence it thickens gradually to near the middle of its length, in order to facilitate the fixing of the pieces which are to be slipped on, over its two ends. In the middle, its diameter is one inch and an eighth.

The first piece which is slipped over its end *g* (Fig. 36,) is represented in perspective in Fig. 37: a section of it is seen in Fig. 38, and it appears in profile at *gabq* in Fig. 39. It is a hollow cylinder, of which the outer diameter *ab* (Fig. 37,) is one inch and thirteen twenty-fourths of an inch. It has a shoulder, of which the total diameter *cd* (Fig. 38,) or *gq* (Fig. 39,) is three inches and five-twelfths. Its thickness from *a* to *b* (Fig. 38,) is seventeen twenty-fourths of an inch; and the thickness *nm* of the shoulder is one-sixth of an inch. This hollow cylinder and its shoulder are made of the same piece of brass, cast in a mould, and afterwards turned. The diameter of the hollow of this cylinder is the same as that of the middle of the axis, upon which it goes very tightly, and is fastened, as in Fig. 39, by a riveted pin *n*, one-sixth of an inch in diameter, which passes through the axis and the cylinder. This cylinder is placed in such manner that its rim *ab* is eight inches and fifteen twenty-fourths of an inch distant from the shoulder *c* of the axis Fig. 39, or from the shoulder *h* (Fig. 36.)

After this cylinder is firmly fixed, another hollow cylinder, represented in perspective in Fig. 40, is forced over the end *g* of the axis Fig. 36. Its end *g* is put on first, and forced forward, till the edge of its other opening *ab* (Fig. 40,) is about a twelfth part of an inch beyound the shoulder *b* of the axis Fig. 36. The reason for putting it thus a little beyond the shoulder *b*, is, that it may not touch the pipe of the standard when it turns.

This cylinder (Fig. 40,) has, nearly in the middle of its length, a shoulder, of which the flat side *fd*, which is also represented in full view in Fig. 41, forms a circle perpendicular to the axis of the cylinder. This circle or shoulder is four inches in diameter, and a quarter of an inch thick towards its edge; but it is thicker towards the middle, as is seen in its profile at *d* (Fig. 39.) The whole length of the cylinder between its two ends *ab* and *g* (Fig. 40,) is three inches; and the diameter of its thickness at each end, *ab* and *c*, is one inch and five-twelfths: the length *na*, from the end *ab* to the flat side *df* of the shoulder, is one inch and nine twenty-fourths.

This cylinder and its shoulder are of one piece of brass, cast in a mould, and turned in a turner's lathe. When put upon the axis, over which it goes very tight, in such manner that, as was said before, its end *ab* (Fig. 40,) is placed about a twelfth part of an inch within the shoulder *b* of the axis (Fig. 36,) it is fastened by a pin which goes in at the hole *c* (Fig. 40,) and passes through the axis. This pin, waich is of iron, and one-sixth of an inch in diameter, goes tight through the cylinder and the axis, without projecting at either of its ends. This cylinder is represented as pinned at N (Fig. 39.)

Fig. 42, is a wooden pully, of which a part is seen at P (Fig. 1, Plate X.) and of which the hole in its centre is of the same diameter as the end *ab* of the cylinder (Fig. 40, Plate XII.) This end of that cylinder is put through this pully, which is every where one inch and a quarter thick, that is to say, somewhat less than the length of the end *na* of the cylinder (Fig. 40;) so that when the pully is put upon the cylinder, and its side is placed against the shoulder *df*, the end *ab* of the cylinder projects a little beyond the other side of the pully, to prevent its rubbing against the adjoining standard. This pully is represented in profile at *lm* (Fig. 39.) Its extreme diameter, *fk*, is eight inches; and its groove *lm*, which is square, is an inch and a quarter deep, and three quarters of an inch wide. This pully is placed close to the brass scutcheon, to which it is fastened by three screws A, B, C, (Fig. 42,) which screw into the three holes *a*, *b*, *c*, (these being female screws) in the flat part of the shoulder (Fig. 41,) of the cylinder (Fig. 40.) Each of these screws (Fig. 42,) is from a quarter to a third part of an inch in diameter; and their head, which is flat, is about a quarter of an inch thick, and two-thirds of an inch in diameter. These heads are screwed into the holes *ab* and *c*, till they lie even with the surface of the pully on that side.

To the other end *b* of the axis (Fig. 36,) is fitted exactly, though so as to slip on with ease, a third hollow cylinder (Fig. 43,) of which the profile is seen at *b* (Fig. 39.) It is like that which is marked N *d* at the other end of the axis; with this only difference, that the extreme diameter of the end *be* of the cylinder (Fig. 43,) is about two inches. This cylinder is fastened to the axis by a thumb-screw *e*, which goes through a female screw in the cylinder, and of which the end enters into the hole *l* in the axis (Fig. 36,) which is not a female screw: and that the end of the screw may be directed to this hole, without any difficulty, when the cylinder is upon the axis, this last is provided with a small tongue *k*, which goes exactly into the notch *f*, (Fig. 43,) as is seen at *e*, (Fig. 39.)

A pully exactly like the former is fastened to the shoulder of this cylinder, by three similar screws, and in the same manner: observing equally here, that the outer surface of this pully do not rub against its adjoining standard. This pully is seen at Q, (Fig. 1, Plate X.)

It

It is ſometimes neceſſary to take this pully and the cylinder off from the end *r* of the axis (Fig. 39,) which is the reaſon why this cylinder is faſtened by a ſcrew, and not by a pin, like the other. They are taken off, to make room for putting upon the axis the cellular cylinder, which is of caſt braſs, and turned in a lathe.

Of the cellular Cylinder, *Plate* XII.

This cylinder is ſeen in profile, upon the axis, at *p*, *y*, *g*, *q*, *t*, *z*, (Fig. 39,) and in perſpective in Fig. 44. Fig. 45 repreſents its longitudinal ſection. The part of this cylinder which is between the two lines *y t* and *p z*, (Fig. 39) is exactly like the above deſcribed cylinder Fig. 37 and 38, and *g*, *a*, *b*, *q*, (Fig. 39.)

The only difference between them is, that the one is fixed permanently to the axis, by a pin *n*, (Fig. 39;) and the other is faſtened by a ſcrew *v*, which paſſes through a female ſcrew near the end of the cylinder, which is ſtrengthened there for that purpoſe, by a moulding or collar *p z*. The end of this ſcrew enters into a hole *m* in the axis (Fig. 36;) but this hole is not a ſcrew. The other part of the cellular cylinder included between the two lines *y t* and *g q*, (Fig. 39,) is three inches and five-twelfths long; its outward diameter, throughout this length, is two inches and twenty-one twenty-fourths of an inch: and its inner diameter is two inches and a third. This inner diameter is a little wider towards the end *b c* of the cylinder, (Fig. 44 and 45.) It is exactly the ſame as the outer diameter of the projecting part *c d* of Fig. 37, which is to go into, and fit cloſely to, the end *b c* of the cellular cylinder, (Fig. 44;) ſo that the edge of this end *b c* may run quite up to the flat ſide of the ſhoulder of Fig. 37. The pricked lines in Fig. 45 and 38, are intended to expreſs the correſpondence of the parts of theſe two cylinders, which are to be united, by putting the end of one into the end of the other. Fig. 39 ſhews the cellular cylinder joined to the ſhoulder of the other cylinder: in which poſition it is that the cellular cylinder is faſtened to the axis by the ſcrew *v*, as before ſaid: and that the end of this ſcrew may be directed ſtrait to the hole in the axis, whenever this cylinder is put on, two contiguous lines or marks may be made, one upon the edge *p z* of the cylinder, and the other upon the axis.

Of the Cavities of the cellular Cylinder, *Plate* XII.

On the ſurface of this cylinder, between the lines *y t*, and *g q* (Fig. 39,) are ſcooped hollows or cavities, repreſented at large in Fig. 47, N°. 1, and ſeen in profile in Fig. 47, N°. 2. They are ſhaped nearly like a niche, which terminates in a cone at its top, and is rounded gradually deeper and deeper down to its bottom, which is a flat, perpendicular to the loweſt part of the cavity.

To conceive and fix the poſition of theſe cavities upon the cylinder, the two pricked lines *i x*, *o s* (Fig. 41,) muſt be drawn round the cylinder, at equal diſtances from the lines *y t*, and *g q*, and diſtant from each other two inches and one-third, which is the inner breadth of the ſeed-box in which the cylinder is placed, as will be more particularly explained in the deſcription of it.

The breadth between the lines *i x*, and *o s*, muſt then be divided into ſix equal ſpaces, by five other parallel lines drawn round the cylinder. Each of theſe ſpaces marks the width of each row of cavities; and the ſix rows of cavities muſt face exactly the ſix valves of the bin, which will ſoon be ſpoken of.

After this, the places muſt be marked for twelve ſimilar cavities, placed at equal diſtances from each other, in each of the breadths traced round the cylinder; obſerving, that the length of the cavities is to be in the ſame direction as thoſe breadths; and alſo, that the flat end of each cavity muſt be undermoſt, and the rounded end uppermoſt, when the cylinder fronts the fore-part of the drill, which is the view repreſented in Fig. 39; for it is the flat end of the cavities that is to go foremoſt, when the cylinder turns and drops the ſeed.

It is likewiſe to be obſerved, that each cavity ſhould be oppoſite to the interval between two cavities in the next adjoining rows, as they are placed in Fig. 39, 44, and 47.

It will be right to have two or three, or even more, cellular cylinders, equally fitted to the axis (Fig. 39,) but with cavities of different ſizes, in order to be thereby enabled either to ſow more or leſs ſeed, or ſmaller or larger ſeeds, ſuch as barley, lentils, peaſe, beans, millet, oats, &c. for each of which its proper cylinder ſhould be uſed.

The cavities in Fig. 47, N°. 1 and 2, are of a ſize fit for wheat, barley, lentils: for millet, they muſt be much ſmaller; for peaſe, ſomewhat deeper; for oats, there ſhould be but eight or nine cavities in each row, in order that thoſe cavities may be made longer than for wheat, on account of the length of the oat, which is the only ſeed that I have found leſs eaſy to ſow than wheat: the reaſons are, the lightneſs of oats, their not ſlipping eaſily between each other, and their having at one end of the grain a pretty long, flexible, and elaſtic point. Theſe obſtacles ſometimes hinder the grains from entering into the cavities, and the ſeedſman muſt be more careful when he ſows oats, than when he ſows any other kind of grain; though, notwithſtanding theſe difficulties, I have had them ſown pretty well.

To ſow beans, the cylinder muſt have but three rows of cavities, of a length, breadth, and depth proportioned to the ſize of the beans. The bin, which has ſix valves for wheat, ſhould have but three for beans, and theſe valves ſhould be proportioned to the breadth of the cavities, which muſt be placed exactly oppoſite to them, as for wheat.

The following rule will determine the proper ſize of the cavities, by applying, as may eaſily be done, what is here ſaid of wheat to any other kind of grain.

The cavities muſt be large enough to contain three or four grains of wheat, and their depth muſt be ſuch that theſe grains do not riſe above the ſurface of the cylinder, in order that when the cavities filled with ſeeds, paſs under the valves of the bin, the grains may not fall out of the cavities. This will be ſtill better underſtood, after reading the deſcription of the ſeed-box.

Of the Seed-Box, *Plate* XII. *and* XIII.

After unſcrewing and taking off from the axis, the pully A B (Fig. 39) its cylinder *b*, and the cellular cylinder *p z*, *g q*; the ſeed-box (Fig. 48,) is placed upon the axis, by running the bared end of this laſt through a round hole in each of the two parallel ſides of the ſeed-box. The diameter of theſe holes is the ſame as that of the cellular cylinder, which is then to be put over the axis, by paſſing its proper end through the hole in the ſide of the ſeed-box, which it traverſes, and faſtening it in the manner before directed. The pully is alſo then to be replaced. The front of this box is ſeen at B (Fig. 1, Plate X.)

Fig. 49 repreſents the box and the cellular cylinder placed upon the axis, where it is to be obſerved that the outer breadth of the box, expreſſed by the interval between the lines *d e* and *k l*, is exactly the ſame as the length of the cylinder expreſſed in Fig. 39, by the diſtance between the lines or ſhoulders *y t*, and *g q*; ſo that the box is held between theſe two ſhoulders *y t*, and *g q*. It is alſo to be obſerved, that the inner breadth of the box, expreſſed by the interval between the lines *f g*, and *h i*, in Fig. 49, is exactly the ſame as the length of the cylinder expreſſed by the lines *i x*, and *o s*, in Fig. 39.

This braſs-box has neither cover nor bottom, but is formed of four plates, each five twenty-fourths of an inch thick. Fig. 50 repreſents the inſide of the plate F G, (Fig. 48,) which is on the left-hand ſide of the drill, with the pieces which the box contains, and a ſection of the cylinder, lengthways of one of the rows of cavities. Fig. 51 repreſents the outſide of the plate oppoſite to the former, and which conſequently is on the right-hand ſide of the drill.

These two plates (Fig. 50 and 51,) are exactly equal. Each of them forms a parallelogram, of which the length A B (Fig. 50 and 51,) is four inches and eleven

twelfths,

J. Hulett Sculp.

twelfths, and the breadth B E four inches and fifteen twenty-fourths. Both of them are perforated by a large round hole, of the fame diameter as that part of the cylinder in which are the cavities. The centre of this hole is in the middle of the breadth of thefe plates, and the upper extremity *b*, of this hole (Fig. 50 and 51,) is an inch and one-fixth diftant from the upper edge, D A, of the plate. Both the plates have four mortifes, G, H, K, L, (Fig. 51,) the breadth of which is equal to the thicknefs of the plates, and the length about half an inch; though this laft is almoft arbitrary. Both of them have alfo, directly facing each other, a hole at *n* (Fig. 50 and 51,) three twenty-fourths of an inch diameter, and of which the centre at the diftance of five twenty-fourths of an inch from the line D A, and half an inch from the line A B. The inner furface of both the plates is even; and laftly, each of them has, on its outer furface, a fhoulder which projects round the rim of the great hole. One of thefe fhoulders is feen in perfpective in Fig. 48. The profile of one of them is feen between the lines *d e* and *f g* (Fig. 49,) and that of the other between the lines *h i* and *k l*. Fig. 54 reprefents a fection of them both. The thicknefs of this fhoulder, that is to fay, the diftance to which it is to project, has already been determined by the total diftance between the lines *y t* and *g q* (Fig. 39.) When the inner furfaces of thefe two plates (Fig. 50 and 51,) are laid againft each other, their edges and holes, now defcribed, fhould coincide exactly.

What they differ in is, firft, that one of them (Fig. 51,) has a fmall opening M N, which the other has not, and which will be defcribed in its proper place; and fecondly, that the hole *n* (Fig. 50 and 51,) is a female fcrew in Fig. 50, to receive the end of a fcrew which traverfes the box, but is not wormed in that manner in Fig. 51, where the outfide of the plate is hollowed a little around this hole, to make room for the flat head of this fcrew, which will be fpoken of hereafter.

The two plates now defcribed are fixed in their proper places by means of two others (Fig. 55 and 56,) which laft are of equal fize with each other. D E (Fig. 50,) is the profile of Fig. 55, which is the back of the box; and A B (Fig. 50,) is the profile of Fig. 56, which is the front of the box reprefented at A (Fig. 48 and 49.)

The two tenons A and B (Fig. 55,) enter into the two mortifes which are hid near G and H in Fig. 50. The two other tenons C and D (Fig. 55,) are expreffed near G H in Fig. 50, and receive the mortifes G and H of Fig. 51. In like manner the two tenons E and F of Fig. 56, enter into the mortifes hidden near K and L in Fig. 50, where are marked the two other tenons, likewife feen at G and H in Fig. 56, which are to receive the mortifes K and L of Fig. 51. The diftance between the tenons of the fame fide of a plate, and confequently between their mortifes, is arbitrary; as is alfo the length of the tenons, which are pierced, in order to their being fixed very tightly by pins about the twelfth part of an inch thick. Thefe two plates (Fig. 55 and 56,) when rightly placed between the other two plates, fhould be perpendicular to them, aud parallel to each other, as well as to the lateral edges of thofe other plates, and the diftance between them, from infide to infide, fhould be four inches. The upper edges of the four plates, when they are put together, fhould be horizontally level; by which means the bottom of the two largeft plates will reach lower down than the fmaller. Thefe two fmaller plates (Fig. 55 and 56,) are fhaped like a parallelogram two inches and a third wide, and four inches and thirteen twenty-fourths long. This breadth anfwers exactly to the fpace between the lines *i x* and *o s*, (Fig. 39,) and between the lines *f g* and *h i*, (Fig. 49.)

The plate (Fig. 55,) which is feen in perfpective in Fig. 52, has, quite acrofs its inner furface, a folid plint *x* L, which is of the fame piece as the plate, and runs parallel to *f g*, (Fig. 52 and 55.) The bottom of this plint is flat, and its top is arched like a portion of a circle. Its thicknefs from *i* to *n* is nine twenty-fourths of an inch, and its projecture *i x*, (Fig. 52,) is fuch that its edge *x* L meets the furface of the cellular cylinder, as in the profile *d* (Fig. 50.)

The ufe of this plint is to ftrengthen the affemblage of the plates; for which purpofe its ends *x* L, (Fig. 52,) fhould join exactly to the larger plates: and it ferves likewife to prevent the grains of corn from flipping down between the plate and the cellular cylinder.

To the top of the infide of this plate is faftened, by two fcrews *a* and *p* (Fig. 52,) a plate of brafs one-twelfth of an inch thick. Its extent *a*, *p*, *d*, *b*, is a rectangle parallelogram, of which the breadth *a p*, or *d b*, is the fame as that of the plate to which it is faftened; fo that its edges *a b* and *p d* lie clofe to the infides of the two largeft plates (Fig. 50 and 51.) The profile of this plate is feen at *a l b*, (Fig. 50,) where it is inclined from *l* to *b*, in fuch manner that the whole length of its edge *b d*, (Fig. 52,) is almoft clofe to the furface of the cylinder, directly above its axis, as in the profile *b*, (Fig. 50.) But this plate muft not quite touch the cylinder, becaufe it would then obftruct its motion, or at leaft occafion a needlefs and detrimental friction. Its ufe is to hinder the corn which fills the fpace F, from falling down into the fpace M, and to make it pafs only under the piece *r q* (which will foon be defcribed) to drop from thence into three pipes, which begin near *e*, as will be feen hereafter.

The plate Fig. 56, (feen in perfpective in Fig. 53, with fome pieces fixed to it) has, rifing upon its inner furface, four, exactly fimilar fmall partitions, which are of a piece with the plate. Thefe four partitions *c p*, *d e*, *f g*, *h i*, (Fig. 56,) are feen in perfpective at *m s*, *o t*, *q v*, and *r x*, in Fig. 53. The top *r x* of all thefe partitions is rounded like the quarter part of a circle, and the bottom *x v* is flat, and at the fame height as the axis of the cylinder, as may be feen in the profile *e* of one of thefe partitions (Fig. 50.) The two outer partitions *c p* and *h i*, (Fig. 56,) are at the edges of the plate, and the two others *d e*, *f g*, divide the fpace between *c* and *h* into three equal parts. Thefe partitions are about a twelfth part of an inch in thicknefs, and their rounded part terminates in an edge, that the grains which may chance to fall upon it may not lodge there. The height *u r*, (Fig. 53,) or *i h*, (Fig. 56,) of all thefe partitions, is nine twenty-fourths of an inch. The lower ends *s w*, *t æ*, *v a*, *x u*, (Fig. 53,) of all thefe partitions, are in a plane perpendicular to the plate, and parallel to the edges *b a*, *q r*, of this plate (Fig. 56.)

This plate has alfo upon its outer furface a fmall cylinder, which is feen in profile at K, (Fig. 50,) in front at A, (Fig. 49,) and in perfpective at A, (Fig. 49,) and B, (Fig. 1, Plate X.) Its whole length is two-third of an inch, and its diameter is half an inch, excepting its fhoulder at the plate, which is a little more. This cylinder is pierced lengthways with a female fcrew, which goes through the plate perpendicularly to its furface, and through which paffes a fcrew C *q*, (Fig. 50,) five twenty-fourths of an inch in diameter, of which the end is feen at *q*, and the head at C. This head is alfo feen at B, (Fig. 1, Plate X.) The hole is feen at *k* (Fig. 56,) in the inner furface of the plate. The centre of this hole *k* is in the middle of the breadth of the plate, and at the diftance of five twenty-fourths of an inch from its edge *a b*. This fixes the place of the fcrew and of its cylinder; the only ufe of which laft is, by its length, to give the greater ftability and firmnefs to the fcrew, which keeps the bin at a greater or lefs diftance from the cellular cylinder.

Of the Bin and its Valves, Plate XIII.

The bin, which has fix valves, is feen in profile at *q n*, (Fig. 50.) The outfide of this bin is feen in perfpective at *g h n*, (Fig. 53,) with the ends of the valves *a*, *b*, *c*, *d*, *e*, *f*, feparated from each other by partitions. It is fufpended in the box by the axis or fcrew beforementioned (Fig. 50 and 51,) which goes in at the hole *n* in the end (Fig. 51) of the box, then paffes through the hole *n* of the bin (Fig. 50 and 53,) runs quite through the length of the bin, and fcrews into the female fcrew in the plate (Fig. 50,) which, as was faid before, is directly oppofite to the hole *n* in the plate (Fig. 51.) The head of this fcrew, at *n* (Fig. 51,) lies even with the outer furface of this plate.

Fig. 57 repreſents in perſpective the bin alone and its partitions, all made of one piece, or plate of braſs. Fig. 58 repreſents geometrically the fore-part of the bin, which is here turned towards the ſeedſman. Fig. 60 repreſents its back. Fig. 62 its bottom. Fig. 59 one of its utmoſt ſides, or largeſt partitions, both of which are equal and alike. And Fig. 61 the ſide or profile of one of the ſmaller partitions, which are all equal and like to each other.

The whole length of the bin from outſide to outſide, that is to ſay, from *a* to *c*, and from *b* to *d*, (Fig. 58,) or from *c* to *d*, and from *e* to *f*, (Fig. 60,) is the ſame as the breadth of the inſide of the box, or of the ſpace between the lines *i x* and *o s*, (Fig. 39.) or *f g* and *h i*, (Fig. 49.) The bottom of the bin is a parallelogram *s*, *k*, *d*, *b*, (Fig. 58,) or *a*, *b*, *d*, *c*, (Fig. 60,) eleven twenty-fourths of an inch wide at *a c* and *b d*. This bottom is of the ſame thickneſs as the largeſt partitions or ſides *a b*, *c d*, (Fig. 58,) and the five ſmaller partitions; that is to ſay, three twenty-fourths of an inch. Theſe partitions, both great and ſmall, are at equal diſtances from each other, and all their ſides are perpendicular to the bottom of the bin.

The whole length of the two largeſt partitions, (Fig. 59,) from *b*, to the pricked line *g d*, which is perpendicular to *a b*, is one inch and ſeventeen twenty-fourths. Their breadth at *a i* and *b c* is five-ninths of an inch. The line *c m*, parallel to *b a*, is eleven twenty-fourths of an inch long. The notch *l m* is one-twelfth of an inch deep. The angle *a*, *b*, *c*, is of eighty-five degrees. The perpendicular diſtance from the centre of the hole *s*, to the line *g d*, is a quarter of an inch; and the perpendicular diſtance from the ſame centre to the line *a b*, is five-twelfths of an inch. The diameter of this hole is a full twelfth of an inch. The perpendicular diſtance from the centre of the hole *r*, to the line *g d*, is very near, but not quite, one-ſixth part of an inch; and the perpendicular diſtance from this ſame centre to the line *a b*, is five twenty-fourths of an inch. The diameter of this hole is one-ſixth of an inch. Theſe two main partitions, *a b* and *c d*, (Fig. 58,) which have now been deſcribed in the account of Fig. 59, are exactly alike, and pierced in the ſame manner; ſo that if they could be laid flat together, inſide to inſide, their dimenſions and holes would tally perfectly.

It is through the hole *r*, (Fig. 59,) that the ſcrew or axis is paſſed which keeps the bin ſuſpended to the plates, and which was mentioned before. Theſe two holes *r r* are ſeen in Fig. 57, where their axis is indicated by two pricked lines. And it is through the hole *s*, (Fig. 59,) that the ſcrew or axis is paſſed which goes through the valves, next to be ſpoken of, and by which they are ſuſpended in the bin. Theſe two holes *s s* are ſeen in Fig. 57, with their axis, which is indicated by two pricked lines.

Fig. 61 repreſents the profile of the ſmall partitions. Its total height from *ab* to *c d*, is equal to the breadth *d b* of the bottom (Fig. 60,) as is ſhewn in Fig. 58. The ſhape and ſize of theſe ſmall partitions is exactly like, and equal to that part of Fig. 59, which is included between the lines *e*, *f*, *b*, *c*; ſo that their edges would tally in all reſpects, if they were laid one upon the other. The line *c d*, (Fig. 61,) is perpendicular to *c a*.

The edge *m c*, (Fig. 59,) is a bevil, ſloped towards the inſide of the bin, as at *e f*, (Fig. 57,) and *a d*, (Fig. 62.) The like edge *z b*, (Fig. 57,) and *b f*, (Fig. 62,) is ſloped in the ſame manner. All the ſimilar edges *e b*, (Fig. 61,) of the ſmall partitions, which are included between the lines *e f* and *b d*, (Fig. 58,) are bevils on each ſide, and form as many acute edges, as is ſeen in Fig. 62, between the lines *a b* and *d f*. The diſtance between the lines *a b* and *g b*, is five-ninths of an inch.

Fig. 58 is repeated in Fig. 64, with only the addition of the ſix ſprings *a b*, *c d*, *e f*, *g b*, *i k*, *l m*, each of which is faſtened by a ſmall ſcrew, *a*, *c*, *e*, *g*, *i*, *l*, at one of their ends, next to the bottom of the bin, and in the middle of the interval between two partitions. The breadth of theſe ſprings is nearly equal to two-thirds of this interval, and their thickneſs is the ſame as that of a common ſpring of a watch, which is the ſtuff they are made of. Fig. 63 exhibits a front view of one of theſe ſprings. Their length and bending, when in a ſtate of reſt, is repreſented in the profile *c d*, (Fig. 65,) *b a*, (Fig. 66,) ſhews the profile of theſe ſprings in a ſtate of contraction.

Fig. 64 is repreſented in Fig. 67, with only the addition of the ſix valves *c d*, *e f*, *g h*, *i k*, *l m*, *n o*, ſeen in profile in Fig. 65 and 66. Each of theſe ſix valves is, at moſt, one-twelfth of an inch thick, and their total length, *a b*, (Fig. 65.) is one inch and thirteen twenty-fourths. The ſix valves, put together, weigh twenty penny-weights, or five-ſixths of an ounce. When put in their proper places (Fig. 67,) each of them covers one of the before-mentioned ſprings. The breadth of each of them is equal to the whole width of the interval between two partitions, between which they muſt only be able to move. They are all faſtened to the ſame axis *a b*, which, as was ſaid before, paſſes through the holes *s s*, (Fig. 57 and 59.) The diameter of this axis is a full twelfth part of an inch. One of its ends ſcrews at *a*, (Fig. 67,) into one of the aforeſaid holes *s*, and the other end, which has a flat head, is buried at *b*, in the other hole *s*; for which purpoſe the outſide of the plate is pared away a little, around this hole. One of theſe holes is ſeen at *p*, in Fig. 50 and 53. The valves are laid flat in Fig. 67, with their ſprings contracted, as in the profile, (Fig. 66.) When the ſprings are at liberty, they puſh the valves out of the partitions, as far as is repreſented in the profile (Fig. 65.) But they are kept within partitions, by a cover *a b*, (Fig. 69,) which is put into the notch *f m*, (Fig. 59,) and *c d*, (Fig. 61;) and, in ſhort, into all the notches, which are upon a level with each other, from *i e* to *f k*, (Fig. 58.)

Fig. 67 is repeated in Fig. 69, with only the addition of the cover, which is three quarters of an inch wide, as long as the whole breadth of the bin, and not quite a twelfth part of an inch thick. It is faſtened by two ſcrews *a* and *b*, which go into the upper edge of the large partitions, as appears in the profile (Fig. 66 and 70.) Fig. 70 repreſents one of the large partitions of the bin, with the end *c d* of its cover, and the head of one of the ſcrews which faſten it. Fig. 66 repreſents the profile of one of the ſmall partitions of a valve *e f*, of its ſpring *a b*, and of the cover *d c*. This figure ſhews alſo, that the end of the valve cloſes with the loweſt edge of the partition; as may be ſeen more diſtinctly at *d o*, (Fig. 67 and 69.)

Fig. 68 repreſents the back of theſe ſix valves faſtened to their axis.

The end of each valve, *d*, *f*, *b*, *k*, *m*, *o*, (Fig. 67,) is bent a little outward, as in Fig. 71, which is only a repetition of Fig. 62, with the addition of the ſprings of the valves, and their cover.

The whole bin, furniſhed with the ſix valves and their axis, the ſix ſprings and their ſcrews, and the cover and its two ſcrews, but not the axis or ſcrew which ſuſpends the bin in the box, weighs four ounces and a half.

The bin thus completed, and ſuſpended in the box, as was ſaid before in ſpeaking of Fig. 50 and 53, is again covered by thin plate of braſs repreſented in perſpective at *i*, A, *k*, N, P, (Fig. 53,) and of which the profile is likewiſe ſeen at *i*, A, *s*, *k*, (Fig. 50.) This plate is bent at A P, (Fig. 53,) in ſuch manner that its bended part turns inward, over the upper edge of the front of the braſs-box; and its edge, which is ſeen in profile at A *i*, (Fig. 50 and 53,) and fully at *e n*, (Fig. 48 and 49,) is faſtened to the upper part of the outer ſurface of this plate of the box, by two ſcrews *e* and *n*, which go into the holes *l* and *m*, in Fig. 56. This plate, from its bending A P, (Fig. 53,) projects over into the box, inclining down to the bin, which it covers as low as N *k*, where the cover of the bin before-mentioned ends. This plate performs the office of a ſpring, and ſhould therefore be ſcrewed on very tight. It preſſes the bin againſt the end *q* of the ſcrew *q* C, (Fig. 50.) The breadth A P and *k* N of this plate, (Fig. 53,) is the ſame as the breadth of the inſide of the box; ſo that its two edges, A *k* and P N, lie cloſe to the inner ſurfaces of the two large

plates,

plates, (Fig. 50 and 51,) which form the ends of the box.

Of the three Pipes of the Seed-Box, Plate XII. *and* XIII.

Fig. 72 reprefents a perfpective view of the three pipes, which are feen partly at B, D, E, Fig. 48 and 49, Plate XII. and at *a b*, Fig. 1, Plate X. They are made of plates of brafs, about a twelfth part of an inch thick, and are feparated from each other only by a fimple partition. Their front is feen in perfpective, and on the right-hand fide of the drill, in Fig. 72. Their back is fhewn in perfpective, and on the right-hand fide of the drill, in Fig. 53. Their front is reprefented geometrically in Fig. 49 and 73; and their back in Fig. 75. Fig. 74 reprefents geometrically, the fide or profile of the middle pipe, which is inclined with the piece that faftens it to the plate. The profile of the pipes on each fide of this is indicated by pricked lines.

Thefe three pipes, (Fig. 72,) are fet againft the plate (Fig. 56,) in fuch manner that the edges *a b*, *c d*, (Fig. 72,) are applied clofe to it, and in the fame order, at *i r*, *v g*, (Fig. 56.) The edges *g h*, *f e*, (Fig. 72,) are applied in like manner at *p q*, *s e*, (Fig. 56.) The line *b h*, (Fig. 72,) is fet exactly even with *r q*, (Fig. 56.) By this means the anterior furfaces *b c k i*, and *f h l m*, of the two outer pipes, (Fig. 72,) exceed the bottom of the box, as at BD, (Fig. 48 and 49;) and the upper edges *a n*, *d o*, *e p*, *g q*, (Fig. 72,) join to the lower edges of the four partitions (Fig. 56,) at *i*, *g*, *e*, *p*, as is feen in perfpective in Fig. 53, at *x u*, *v a*, *t æ*, and *s w*.

Thefe three pipes, which hold together, are faftened to the plate by means of a fingle brafs fcutcheon A, (Fig. 72,) which is feen directly in front at H, (Fig. 49,) and at A, (Fig. 73.) Its fore part and right hand fide are feen in perfpective at A in Fig. 72; and its fore part and left hand fide at H, (Fig. 48.) Fig. 75 fhews a full view of the back part of it at A; and the whole profile of it, on the right hand fide, is feen at N *u* B L, (Fig. 50,) and at *b d l f*, (Fig. 74.) This fcutcheon is bent at *d* and at *m*. Its breadth is the fame as that of the middle pipe, which is the interval between the other two, as is feen in Fig. 48, 49, 72, 73, 75. Its part *b d*, (Fig. 74,) is foldered or riveted to the lower furface of the middle pipe: from thence it takes an horizontal direction from *d* to *m*, and then afcends perpendicularly from *m* to *f*. This length *m d* is one inch, and the thicknefs of the fcutcheon, throughout, is about a fixth part of an inch, or fomewhat lefs. The thicknefs of the plate, Fig. 56, of which the profile is here at *q l*, Fig. 74, is exactly embraced between the extremity *r i* of the pipe, and the fcutcheon *f l*. The bottom, *q r*, (Fig. 56,) of this plate, refts upon the horizontal part *o l* of the fcutcheon, (Fig. 74;) and this fcutcheon is faftened to the plate by a fcrew *p g*, which goes into the hole *n*, (Fig. 56.) It is to be obferved, that the line *r o*, (Fig. 74,) is equal to the edges *a b*, *c d*, *e f*, *g h*, (Fig. 72,) of which it expreffes the profile; that its farther extent *o a*, (Fig. 74,) is equal to the lines *b i*, *c k*, *f l*, *h m*, (Fig. 72,) of which it expreffes the profile; and that the line *d l*, (Fig. 74,) is in the fame horizontal plane as the line *b h*, (Fig. 72.)

The angle *r*, *i*, *e*, (Fig. 74,) is of one hundred and twenty-fix degrees; and the diftance from *o* to *i* is one third of an inch. The outfide breadth of thefe three pipes, taken together, is the fame as that of the plate; and each of them occupies a third part of that fpace, as in Fig. 53, 56, 73 and 75. Each of them is fquare. The length of the two outer pipes, from the line *b h*, (Fig. 72,) or from the bottom *q r* of the plate, (Fig. 65,) to the line *i m*, (Fig. 72,) or *x o*, (Fig. 56,) is one inch and a twelfth: the length of the middle pipe, (Fig. 74,) from *i*, where it joins to the plate, to its other end *e*, is four inches and five twelfths.

Thefe three pipes are faftened to the plate, as in Fig. 53. The edges *x*, *z*, *v*, T, E, *t*, *l*, D, *s*, *y*, of their upper openings, are circular, that they may fit exactly, and fit clofe to the circumference of the cylinder, which is there indicated by pricked lines, and is fhewn in Fig. 50, by the line *t v f*, which expreffes the profile of thefe edges, againft which the cylinder rubs lightly when it turns.

Manner of working the Seed-box, and of the Pieces which it contains, Plate XIII.

The line or edge *g h* of the fix valves, (Fig. 53,) muft be very near to the furface of the cellular cylinder, tho' not quite fo clofe as to occafion a friction when the cylinder turns; and the lower end of each valve muft anfwer to a row of cavities; fo that the part F of the feed-box, (Fig. 50,) being filled with corn, and the cylinder turning from *b* to *r*, this laft carries with it the grains that fall into the cavities which pafs under the edge of the correfponding valves: thofe that fall from the two valves *a* and *b*, (Fig. 53,) are dropped, by the cavities, into the pipe G, in the fpace between the pricked lines *g s* and *b t*, and are conveyed to the back of the fhare which is on the left hand fide of the drill; thofe that fall from the two next valves, *c* and *d*, are dropped between the pricked lines *b t* and *d v*, into the pipe H, and are conveyed to the back of the fhare which is in the middle of the drill: and thofe that fall from the two laft valves, *e* and *f*, are dropped between the pricked lines *d v* and *b x*, into the pipe M, and are conveyed to the back of the fhare which is on the right hand fide of the drill.

If it happens that feveral grains prefs together at the fame time, at the outlet of any one of the valves, fo as to choak it, that valve immediately gives way, lets them pafs, and is inftantly replaced as before, by means of its fpring which pufhes it back. No grain is ever broken by the valves: fo that if this accident does fometimes happen to a few, it is not during the time of actually fowing the feed, but only when the drill is turned, in order to begin another bout, or when the feedfman, inftead of drawing the drill forward, drags it towards himfelf, and makes the cylinder turn backward.

By loofening the fcrew C *q*, (Fig. 50,) which is at B in Fig. 1, the bin, before preffed againft this fcrew by the fpring or plate A *s k*, (Fig. 50,) is moved farther from the cylinder, the fpace between the cylinder and the end of the valves is increafed, and a greater quantity of corn then paffes at a time. By turning the fcrew C *q* farther in, the bin is pufhed nearer to the cylinder, and fewer feeds are dropped.

To know exactly how much the bin fhould, at any time, be fet nearer to, or farther from the cylinder, there is, at one of the fides of the bin, a fmall fcrew, of which the head *m* paffes through a circular opening M N, (Fig. 51,) in the largeft plate of the box, where it becomes a certain guide, by means of a few equal divifions engraved and numbered at the edge of that opening. The centre of the arch of this opening is the fame as that of the hole *n*, upon which the bin moves.

Of the Hopper, Plate XIII.

Fig. 67. reprefents in perfpective the hopper which is feen at A in Fig. 1, and of which the bottom covers the top of the feed-box. D, (Fig. 76,) is the front, and A the right hand end of the hopper. The boards which form the ends A and B are three quarters of an inch thick; thofe of the fides D and C are feven twelfths of an inch thick; and the thicknefs of the cover is five twelfths of an inch. The fides and ends, which are at right angles to each other, and to the bottom, are joined together by dove-tail tenons; and the bottom is joined to the ends A and B by tenons which go into mortifes in thefe ends, as may be feen on the line *b g*. The four tenons G, H, E, F, enter into the mortifes Q, R, S, T, in Fig. 24, of which the dimenfions have been given. Thofe dimenfions fix the length *g e*, or *k d*, of the hopper, (Fig. 76.)

Its breadth, from outfide to outfide, at *a k*, or *b g*, is feven inches; and its outfide depth *k g*, or *d e*, is eight inches and a half. The height of the legs of the hopper, from the line *b l*, where it refts upon the upper furface of the table, to the line *b g*, which is the under furface of its bottom, is determined by the diftance between the top of the feed-box and the top of the table: it is here eight inches and a fixth. In the middle of the breadth

breadth of the two legs, are two openings, N and P, rounded at their top, to let through them the iron axis which bears the cellular cylinder, and keeps the feed-box steady under the hopper. These two openings are seven inches high, and one inch and three quarters wide. The hopper is fastened to the table by two hooks, one of which is seen entire at L N M, and part of the other at P Q. Each of them moves upon its rivet L, just above the opening of the foot, and is bent from thence to N, to make room for the passage of the axis; after which it hooks into a ring M and Q, fixed upon the table, but not mentioned before.

Towards D is a square opening, an inch and a half wide, cut immediately above the bottom, and through which the hopper may be emptied. This opening is shut by a small plate of iron, or brass, which turns like a latch upon a screw *n*, which fastens it at that end, whilst the other end *r* is slipped down to the small piece of brass or iron *v x*, which is fastened to the box by a screw at *x*, in such manner, that the pricked part of the latch, near *r*, is covered by the end *v* of this last small piece, which is bent for that purpose, so as not to lie quite close to the box, and the edge *r q* of the farther part of the latch rests upon the edge *x* of this small piece.

Of the Fore-carriage, Plate XIV.

Fig. 77 is a perspective view of the fore-carriage without its wheels. It is seen with its wheels in Fig. 1. Plate X. Fig. 80 represents a geometrical plan of the inside of one of the wheels of the fore-carriage, which is seen at *t* Fig. 1, Plate X. and Fig. 81, Plate XIV. represents a section of it. P and Q, (Fig. 77,) are the two fore-ends of the beams, to which the fore-carriage is fastened by hooks and rings.

In Fig. 77, *a d*, and D E, are the two exactly similar pieces which are seen at S *s* and V *r* in Fig. 1. Their length, *a d*, (Fig. 77,) is two feet eight inches; their breadth, *d* A, is two inches and two thirds, and their thickness is two inches. They are parallel to each other, and connected by two traverses, *g h*, *f l*, of which the ends are tenons pinned into mortises in the pieces D E, *a d*. These two traverses are omitted in Fig. 1, Plate X. in order to render that drawing the more simple. The length of these traverses, exclusive of their tenons, is two feet, their breadth is two inches and a quarter, and their thickness one inch. These two traverses are perpendicular to the two other pieces. Their distance from each other, between the farthest outside edge *g h* of the one, Fig. 77, and the farthest outside edge *f l* of the other, is seven inches and a half. The edge *g h* is one foot six inches and a third distant from the two ends B and D.

F G is an axle-tree, of which the middle part *n s* is two inches and seven twelfths square, and of which the upper angles are cut off as in the drawing. The square shoulders of the two ends *s n*, from whence the spindles proceed, project a very little beyond the outside of the pieces D E and *a d*, in order that the nave of the wheels may not rub against these pieces. The spindles *s* G, *n* F, are eigh inches and a third long, and one inch and five twelfths in diameter. This axle-tree is placed upon the pieces D E, *a d*, parallel to the traverses *g h*, *f l*, in such manner, that the distance from the line *s n* to the ends E and A, is a foot and a half. This axle-tree is fastened to the two pieces D E, *a d*, by two iron pins and nuts, *b q*, an inch and a sixth square, of which the screw, which is seven twelfths of an inch in diameter, has a head an inch and a half in diameter, which lies close to the under surface. This screw is represented with its nut in Fig. 78. Upon this axle-tree are fixed two wooden pins, five or six inches long, and five tenths of an inch, or a whole inch in diameter. These pins are perpendicular upon the upper surface of the axle-tree; the space between them is four inches, and this space is in the middle of the length of the axle-tree. This axle-tree is pierced perpendicularly between the two pins, to admit another pin, which will soon be spoken of.

The two wheels, which are placed at F and G, are exactly alike. Fig. 80 represents the inside of one of these wheels, with a pully fixed round its nave, and fastened to its spokes by four screws, each of which goes through the pully and one of the spokes. This pully is seen in profile at *b d*, (Fig. 81,) with two of its screws.

The total diameter, *g b*, of each wheel, exclusive of its iron hoop, is two feet and a half; that of the nave *p q* is four inches and one sixth; that of the pully *b d* is one foot two inches and a sixth; the thickness of the pully is an inch and one third; its grove, which is cut down square, is two thirds of an inch wide, and two thirds or three quarters of an inch deep. The length *p r*, or *q s* of the nave, is six inches; the thickness of the wheel at *i n* is an inch and two thirds, and at *i b* two inches and a quarter. Of the four hooks R, H, T, K, (Fig. 77,) which serve, by means of two rings, to fasten the fore-carriage to the ends of the beams P Q, the two, H and K, are fastened in the usual way, by nailing them, at their flat end, upon the two pieces of the fore-carriage: but the other two, R and T, are shaped like a carpenter's square, of which one end is screwed upon the beam, in order to facilitate the putting on or taking off of the ring. At T, this hook is placed in its proper situation for holding the ring: at R, it is turned the other way, that the ring may be taken off easily.

Of the Pieces which support the Drill upon its Fore-carriage, Plate XIV.

Fig. 82 represents in perspective a piece of wood which supports the drill upon its fore-carriage, when there is occasion to turn it in sowing. This piece may be called the pole. It is seen at *x d* in Fig. 1, Plate X. Its end A, (Fig. 82,) enters into the two bridles or belts *g r h* and *a c b*, (Fig. 26,) which have been spoken of before, and of which one is seen near *d* in Fig. 1. Its other end *q n*, (Fig. 82,) rests upon the axle-tree (Fig. 77,) between the two pins, as is expressed by pricked lines in Fig. 82, and as may be seen at *x* in Fig. 1.

The breadth *q r*, (Fig. 82,) of the lower surface of this piece is an inch and a quarter, throughout its whole length, to its end A; and its thickness throughout its whole length *q s* is an inch and a half. Its upper angles are taken off, from the end *q r* to *s*; but from *s* to A, this piece is shaped like the two bridles or belts into which it is to enter.

Its length from *q* to *s* is one foot seven inches and five-sixths; and from *s* to *t*, it is two inches and seven-twelfths. At *t*, the thickness of a quarter of an inch is taken off from its under surface, as at *t v*; and from *v* to A, its length is five inches and five-twelfths. It is the length *s* A, that goes into the two belts or bridles *g r h*, and *a c b*, (Fig. 26, Plate XI.) and the notch or shoulder *t* is made in order to insert a wedge whenever it is necessary to make the end *q r*, (Fig. 82,) rest upon the middle of the axle-tree, in order to convey the drill the more easily to any distant part, without putting it upon its hind-carriage. This wedge saves the seedsman the trouble of holding up the handles of the drill so high as he would otherwise be obliged to do, to make the end *q r* of this piece (Fig. 82,) rest upon the axle-tree. It is by the help of this piece, that the seedsman, when he comes to the end of each bout of the drill, is enabled very easily to turn it in order to begin another, by lifting the drill up by its handles; for as the end of this piece rests upon the middle of the axle-tree, he makes the drill follow the fore-carriage which is drawn by a horse; and as the distance, in this case, is but five or six feet, there is no occasion for his making use of the wedge. By this means the drill is turned conveniently, and without any loss of time.

The line A *v*, *t s*, are even; but *q s* is inclined at *t s*, and makes with it an angle *t s q* of 166 degrees. *s a* and *g n* are two square pins, fastened by tenons into the middle of the breadth of the under surface *r q s*, perpendicularly to the lower surface *t s*. The pin *s a* is placed near the bending *s*, and the distance between the edges or lines *s a* and *g n*, is fourteen inches and two thirds. The breadth *a o* and *n p* of these pins, is an inch and a quarter; their thickness is two thirds of an inch; the length of *s a* is three inches and a half, and that of *g n* five inches. This pin *g n* is rested against the axle-tree

J. Hulett Sculp.

F G of Fig. 77, and the other, *s a*, (Fig. 82,) is placed near the table of the drill. The ufe of thefe two pins is only to hinder this piece of wood from flipping out of the two belts before defcribed.

Fig. 83 reprefents in perfpective the piece of wood which fupports the drill upon its fore-carriage, when it is placed upon its hind-carriage, in order to be removed from one place to another. This piece neither is, nor can be, feen in Fig. 1, which reprefents the drill in the ftate of actual fowing, and without its hind-carriage. The end A, (Fig. 83,) goes into the belts *e f*, *g h*, (Fig. 21,) before defcribed, like which it is fhaped; and the end B, (Fig. 83,) refts upon the axle-tree, (Fig. 77,) between the two pins. This part of the axle-tree is covered before and beneath by a flip or hook of iron, B E C, (Fig. 83,) which is nailed under the end of the piece A B, as in Fig. 84. The axle-tree, the bar, and its hook, are traverfed by an iron pin, D E, (Fig. 83,) and *d e*, (Fig. 84,) which paffes through the hole in the axle-tree, between the two pins, (Fig. 77.) The length of this piece, A B, (Fig. 83,) is three feet and four inches; its breadth is two inches and a half, and its thicknefs is one inch and a third. The pin F G, which is fufpended here, is put into the ring or bridle L, (Fig. 22,) and goes through the hole immediately underneath it.

Of the Hind-Carriage.

This hind-carriage is fo fimple that it would be needlefs to give a drawing of it. It confifts only of two common wheels, unfhod with iron, two feet eight or nine inches in diameter, fet upon a very fimple axle-tree, in the upper furface of which are two holes, into which are put the two pins before-mentioned, which are under the beams of the drill. One of them is feen at *f h*, (Fig. 3,) and likewife at △, (Fig. 1,) Plate X.

It is neceffary to fix, by proper marks, the refpective places of the feveral fcrews and mortifes of the whole machine, in order that when it is taken to pieces and put together again, none of thefe pieces may be mifplaced, or any of the helixes (or fpiral lines) which the flat-headed fcrews have formed in the wood, be fpoiled.

It is better to make the teeth of the harrow bend a little more than thofe before defcribed, and reprefented in Fig. 5, Plate X. They fhould bend fo that the point *e* of the tooth may project about four inches beyond the pricked line *f*.

Figures 85 *and* 86, *Plate* XIV. *compared with Figures* 2 *and* 31, *Plate* X. *and* XII.

The mortife A in Fig. 85, is the fame as that which is marked Q in Fig. 2. But the end of each beam fhould be made about two inches wider on the infide, and a fecond mortife B, (Fig. 85,) fhould be cut through it, fimilar and parallel to the former, and at the diftance of five-fixths of an inch, or an inch, from it, that the fhare may be faftened in the one or the other, according as it may be found proper to place the two fore-fhares nearer to, or farther from each other, in order to fow the rows clofer than they would be by the fituation of the mortifes Q and R, (Fig. 2:) but then the pipes which anfwer to the back of thefe two fhares fhould be faftened in the manner which will be explained hereafter.

The middle piece K L, (Fig. 2,) fhould project beyond the table, from C to D, (Fig. 85,) about nine inches or a foot, and the belt or bridle L, (Fig. 2,) fhould be fuppreffed. This fame piece fhould have, in its part E F, (Fig. 85,) nearly the fame breadth as the end of the beams H, I; and two mortifes, E F, inftead of one, in which the fhare, thicker than was faid before in its upper part, is to be faftened by two tenons and a key. The pipe which terminates behind this fhare, inftead of paffing fideways, as in Fig. 31, will go ftraiter and more eafily through the hole G, (Fig. 85,) which is feen at K, (Fig. 86,) and from thence through the thicknefs of the fhare, which will be pierced for this purpofe from K to G. The fole of this fhare, from this hole to its bottom, will be of the fame thicknefs as was mentioned before.

Figures 87 *and* 88, *Plate* XIV. *compared with Figures* 29 *and* 30, *Plate* XI.

The upper openings, *f d*, *h o*, (Fig. 29,) of the two foremoft pipes fhould be joined by a good hinge A, (Fig. 87,) well foldered to them, and of which the pin, ending with a ring at one end, may eafily be taken out. By means of this hinge, thefe two pipes may be fet clofer together, or farther afunder, like the legs of a compafs, and be fitted to the different fituations of their fhares. The faftening of the lower end of thefe pipes will be nearly the fame as was defcribed in Fig. 30; with this difference, that inftead of bending the fquare *k i g* of that figure only at *i*, upon its upper furface, and making its part *k i* run lengthways of the beam E F; here, (Fig. 88,) is twifted as it were in its bending, in order that the part *s n* may lie acrofs the beam, and lengthways of the table. In this cafe, if the fhare A be put into the mortife B, the part *s n* muft be flipped farther, till the hole *s* can be faftened at *n*, by the thumb-fcrew which is at *n*: and as this part, being held only by a fingle fcrew, might be apt to loofen and jog, a piece or flip of iron, *a v*, is permanently fixed at its edge, fo as to keep it tight in either of its fituations. The fcrew *n* faftens in a nut funk into the upper furface of the beam, where this nut is permanently fixed, and covered by the table. There fhould likewife be two holes in the other part of the fquare, towards *q*, to ferve for the two different fituations of the fhare. The pipes of the fhares are more eafily made round, as here reprefented, than fquare, as was directed before.

Figure 89, *Plate* XIV. *compared with Figure* 35, *Plate* XI.

Inftead of the fmall groove *n*, (Fig. 35,) in the brafs cylinder, intended for introducing a little oil to that part; a more fimple way will be to bore a perpendicular hole *p*, (Fig. 89,) through the head of the ftandard, down to the fpindle; and this hole may be covered by a fmall plate A, made to turn upon a fcrew or rivet.

Figures 90, 91, 92, 93, *and* 94, *Plate* XIV. *compared with Figures* 50 *and* 53, *Plate* XIII.

As the three pipes or funnels G, H, M, (Fig. 53,) embrace at their upper opening, only a fmall part, *f*, *t*, (Fig. 30,) of the cellular cylinder, fome grains may chance to be loft on the fide where this cylinder is not covered, from *d* to *f*. To prevent this inconvenience, they may be made fo as to embrace the whole lower femidiameter *d f t* of the cylinder in the manner reprefented in Fig. 90, 91, 92, 93, 94.

The firft funnel, which is feen geometrically at A, B B, (Fig. 90,) is reprefented in perfpective, and of a fmall fize, in Fig. 93, where its correfponding parts are marked with the fame letters *a*, *b b*. This is the funnel M of Fig. 53. The fecond large funnel, of which a part appears at D, (Fig. 90,) is feen entire and in perfpective, in Fig. 92, where the fame part is marked *d*. This is the funnel H of Fig. 53. Two fcutcheons *g* and *p* are foldered to this funnel, and faften it, by fcrews, to the fore and hind inner furfaces of the box, as at P G, (Fig. 90.) The third funnel, which does not appear in Fig. 90, and which is like the firft, is reprefented in Fig. 91. This is the funnel G of Fig. 53. Thefe three funnels are made feparately, of very thin plates of brafs, bent, and well foldered; and are afterwards firmly rivetted to each other, fide to fide, as in the perfpective, (Fig. 94.) They are fo tightly joined, that the fcutcheons *g p*, (Fig. 92 and 93,) are alone fufficient to hold them all in their proper places.

Figures 95 *and* 96, *Plate* XIV. *compared with Figure* 66, *Plate* XIII.

In the reprefentation of this part in Fig. 66, the valve *e f* is actually clofed by its fpring *a b*, to the cover *d c*, and in this fituation it is fhut: but when the corn preffes againft this valve, and forces it into the fituation *a b*, (Fig. 95,) a grain may jump fo as to get between the valve and the cover, and thereby hinder the valve from clofing again; fo that more corn would continue to run out. To guard againft this accident, each valve muft have a small tongue *p* immediately below the cover, and the cover must be bent in that place, to receive the tongue when the valves closes. Both of these are represented separately in perspective, in Fig. 96.

Figure 97, *Plate* XIV. *compared with Figures* 50 *and* 51, *Plate* XIII.

Instead of the index *m*, (Fig. 50,) and the graduated opening M N, (Fig. 51,) an easier and more simple way will be, to fasten the end A of a graduated limb or border of a circle, A B, (Fig. 97,) to the bin, in such manner that its other end B may project through a hole in the front of the brass-box. This will mark exactly the situation of the bin.

Figure 98 *compared with Figures* 82, 85, *Plate* XIV. 21, 26, *Plate* XI.

When the middle piece is lengthened, as at C D, (Fig. 85,) there is no occasion for the ring or bridle L, (Fig. 2,) and *f k*, (Fig. 26,) or for the pieces *s a* and *g n*, (Fig. 82;) and then the pole A, of this Fig. 82, will pass through the belt A, (Fig. 98,) and through another belt B, which last goes round it and the piece D. This belt is fixed by two screws under the piece B D. The pin C, which penetrates into the table, will complete the fixing of this pole. The hole K, (Fig. 85, receives the pin F G, (Fig. 83,) which goes through the two pieces C D, (Fig. 85,) and A B, (Fig. 83.)

M. de Chateauvieux's *Instructions concerning the Manner of using* his Drill-Plough.

" This drill is represented in Fig. 1, Plate X. with all its parts put together, in a state fit for working. When the thongs which encompass the grooves of the pullies Q P of the axis in Fig. 1, and those of the fore-carriage *u t*, are stretched properly, and the hopper is filled with corn, a horse is to be harnessed to the spring-tree bar, and an intelligent man, who can walk a good pace, should guide this horse, which should be a mild, tractable creature.

" The seedsman will hold the handles of the drill, in order to direct it: and he will warn the guide whenever he deviates from the strait line in which he ought carefully to keep. He will also observe, from time to time, whether the distribution of the seed is not stopped by some unexpected accident: for he can see the end of the pipes through which the grain should drop; besides which, the corn makes a little noise in passing through the pipes, and he may easily hear it. The seedsman will take particular care that the thongs do not slip out of the grooves of the pullies; and if they do, he will replace them instantly: but this accident is very rare; nor, indeed, does it hardly ever happen, unless the thongs are new, and have not yet been sufficiently stretched. It is proper to observe here, that we have tried hempen ropes, and small iron chains: but thongs of leather are much better than any other thing.

" Care should be taken, that the seed-corn be free from grit, dirt, or little stones; for either of these might damage the valves of the bin. If the corn has been steeped in lime-water, as is the practice of some farmers, in hopes of preserving their crops from smut, it must not be sown till it is so dry that the grains will slip easily over one another.

" The seedsman will be particularly careful to replenish the hopper before it is quite empty.

" He will oil the spindles of the axis once or twice a day; observing that they require most frequent oiling when the drill works in dry ground, which sends up a very fine dust: and he must cleanse the spindles and the pipes in which they turn, every morning, by rubbing off the old oil, and putting on new. He will also, from time to time, cleanse the spindles of the axle-tree of the fore-carriage, and rub them with soap. If any rain happens to fall during the time of sowing, he must wipe the drill very dry, as soon as he has got it home, and particularly about the axis, to prevent its rusting. It is even highly proper to have a leather covering to put over the table and all the parts upon it, and likewise over the standards, the axis, and the hopper. It is easy to conceive the proper cut of this covering.

" The prudent husbandman should always have with his drill, a small box, containing a hammer, a pair of pincers, a turn-screw, thongs, ropes, nails, iron-rings and buckles, a little bottle of oil, and other such like things, in order that, if any of them should be wanted in the field, he may not lose time by being obliged to send home for them.

" The seedsman will observe, when he is going to sow, not to leave the wedge *t*, (Fig. 24, Plate XI.) under the pole, in order that end *c*, (Fig. 1, Plate X.) may not press upon the axle-tree of the fore-carriage. (The only use of the pole, at the time of sowing, is to turn the drill when a second bed is to be sown after the first is finished, and so of others.) It is easy to conceive, that if this end of the pole should make the drill rest upon the axle-tree, it might often happen, that, by its being thereby too much subjected to the motions of the fore-carriage, the stones or clods which the wheels may meet with, would, by raising them higher than the general surface, throw the shares out of the ground, or at least occasion the furrows to be shallower in those places; things which ought by all means to be avoided.

" We have represented but one spring-tree bar, in Fig. 1, because we think a single horse may be used, without any inconvenience, when the ground is not too much loaded with wet: but if the land be too full of water, two horses must be put to the drill, which, in that case, must have a double bar, the manner of ordering which is too well known to need any description. Each horse will then go in a furrow, and they will not poach the bed, as would be the case, in wet land, if the drill was drawn by only one horse, whose steps are determined by the middle of the bed.

" For want of horses, oxen may be used, and the sowing may be performed equally well.

" It is proper to observe, that the quantity of seed distributed by the drill is exactly the same, whether the horses or oxen go fast or slow. If, for example, one bed is sown in ten minutes, and twelve or fifteen minutes are employed to sow another, of equal dimensions, neither more or less seed will be dropped in one, than in the other; because the revolutions of the cylinder, (Fig. 39,) are invariably regulated by those of the wheels of the fore-carriage, whose circumference, be it turned quick or slow, will always describe a line of equal length, and the cylinder turns exactly with these wheels. The only difference that can arise from the greater or less speed of the horse, is the gain or loss of time: but the quantity of seed sown will be constantly the same, so long as the drill remains set in the same manner.

" The greater or less goodness of the soil, its having been well or ill prepared for sowing, its state of dryness or humidity, and several other circumstances which should be carefully attended to, will oblige the husbandman sometimes to vary the quantity of seed. The drill is accordingly made to distribute more or less, by the means before-mentioned, of placing the bin nearer to, or farther from the cellular cylinder, by turning the screw L, (Fig. 50, Plate XIII.) By setting the bin farther off, a greater quantity of seed is dropped; and by bringing it nearer, a less proportion is sown. It will be easy to find the proper distance at which to fix it, in order to its giving out exactly the desired quantity of seed.

" Though this method affords a pretty wide latitude, it may sometimes not be sufficient. This is a case which will very seldom happen, and which we have not yet met with; but if it should at any time take place, the drill may easily be made to distribute still more or less seed, by changing the pullies of the axis, Fig. 39, Plate XII. for others of a larger or smaller diameter, which will either accelerate or retard the motion of the axis, in proportion to their size.

" We will suppose, for example, that the pullies are but of half the diameter of those before described. It is evident that these smaller pullies will make the axis turn round twice, where it turned but once with the former, and that double the quantity of seed will consequently be dropped

dropped on the same length of ground. By the same rule, pullies twice as large will turn the axis but half the number of times, and but half the quantity of feed will of course be let fall, in the same space. The proportion of the feed sown may likewise be increased or diminished, by a greater or less number of cavities in the cellular cylinder; and the changing of this cylinder is soon and easily performed: but, as was said before, there will very seldom be any occasion for these alterations.

"The furrows opened by the shares of the drill, and in which the seeds are deposited, should be of different depths, in different cases; and this may be effected by means of the rings which fasten the drill to its fore-carriage at the hooks R H, T K, (Fig. 77, Plate XIV.) For general use, the diameter of about three inches, from inside to inside, will be sufficient for these rings, and then the furrows are made about three or four inches deep. They will be opened deeper by using rings about four inches in diameter; and it is immaterial whether they are round or oval. With smaller rings, the furrows will be made shallower; and their depth may also be diminished, by making the horse draw with longer traces, or by using a lower horse.

"If very shallow furrows are wanted, or only just the surface of the ground is intended to be opened, the wedge *t*, (Fig. 24,) must be put under the pole. In short, a little practice will soon shew the husbandman how to manage this drill in every respect, and make him thoroughly acquainted with all that is necessary to be known in regard to the distribution and proper covering of the feed, which last part is perfectly well performed by the teeth of the annexed harrow.

"If any thing should still seem obscure to those who have read attentively, and studied the description of each part of this drill, let them but set actually to work, and their ideas of it will soon be perfectly clear. Each part, taken separately, may be made with great ease: their sizes, shapes, and proportions, are pointed out in such manner, that no workman of common understanding can mistake; and when the parts are constructed, there can be no difficulty in putting them together, if the foregoing directions are but observed."

"*Description of a Harness, to yoke Oxen one before another,*" *Plate* XIV.

"The utility of being able to put oxen to this drill, in such manner as to make them go one before another in the furrow, without treading upon the places which are to receive the feed, first put me upon contriving a harness proper for these cattle: for I was not satisfied with those I had seen in different countries. Two of my teams of oxen, harnessed in my new manner, have worked the whole year; several persons have adopted the method; and I am more and more pleased with it. This harness is very simple, and very light, and does not subject the oxen to any irksome confinement.

"Fig. 99 and 100, represent the whole of this harness, that is to say, its plan and a view of it. Fig. 99 shews it to be composed of a yoke A, which the ox bears upon his head, and which is there fastened to his horns by long thongs. The rest of the harness is of leather. The piece B, is the principal part, and that by which the ox is to draw. It rests against his neck, a little below the withers, and sits extremely close to the neck when the ox draws. If it be made of double leather, there is no occasion for the piece of leather D, which serves only to strengthen it when it is single. The thong C fastens in the buckle Q R, which is fixed to the yoke by another thong. The use of these is to hinder the large piece of leather B, from rising above the withers, when the ox tosses his head, or raises his neck. Care should be taken not to stretch the thong C too much, for the ox must not draw by it.

"The thong E E, with their buckles to lengthen or shorten them, serve to make the oxen draw by the yoke, by putting them through the large iron buckles F F, and the leather buckles G G, which must be nailed to the yoke. The length of these thongs is suited to the purpose for which they are intended.

"My traces are made of ropes, and I find them convenient. At one end of them is part of a leathern trace, about fifteen inches long, like the end of the harness of a coach horse. This end is put through the large buckles F F, where it is fastened by the tongue *a a*: so that the trace may easily be shortened or lengthened."

DRILL-RAKE, an instrument invented by M. Vanduffel, for drilling pease, &c.

This instrument, which is chiefly calculated for light grounds, in small inclosures, not exceeding four or five acres. It is a sort of strong plough rake, with four large teeth at *a a*, *b b*, (Plate XV. Fig. 1,) a little incurvated, as represented in the figure. The distance from *a* to *a*, and *b* to *b*, is nine inches. The space, or interval, beteen the two inner teeth, *a* and *b*, is three feet six inches, which is sufficient room for the cultivator or hoe-plough to move in, if conducted with care, before the pease have branched much. To the piece of timber *c c*, forming the head of the rake, are fixed the handles *d*, and the beam *e*, to which the horse is fastened.

It is evident, that when this instrument is drawn over a piece of land made thoroughly fine, and the man who holds it bears upon the handles more or less, according to his discretion, four channels or small furrows, *f*, *g*, *h*, *i*, will be formed; that the distance between the furrows *h i*, and *f g*, will be nine inches: and that the interval *e*, or space contained between the furrows *g*, *h*, will be three feet and a half. It is also evident, that these distances may be preserved with great truth, provided the teeth *a*, *a*, return (when the ploughman comes back, after having ploughed one turn, or about, as they call it) in two of the channels formed before, marked *h*, *h*; so that though he cuts four drills at the first bout, yet, in effect, he only forms two drills each turn, because there are always two drills to be passed over twice, or reploughed, being, in fact, not much more than guids, or marks of direction. Yet even this small work of supererogation repays itself, because it makes the drills more open, distinct and clear.

If the first four channels, formed at one motion by this instrument, are streight and true, all the lines in the field will partake of the same regularity. It will therefore be proper to mark out this first trace of the drill-rake by exact measurement, fixing into the ground, at every distance of ten feet, little flat sticks, labelled with paper; which being finished, the rest may be left to the ploughman.

When the ground-plot of an acre is thus formed into drills (which may be completed in four hours, by one ploughman, a horse, and a boy to lead the horse) you must send two or three women and children into the field, in order to sprain the pease, or scatter them by a single motion of the hand, at a certain distance one from another, into the channels. Use no harrow, which will be apt to draw the seeds out of the lines; but cover them with the flat part of the head of a hand-rake, and press them down gently.

The great excellence of this drill-rake consists in its simplicity; for after the measurement of the parts is once laid down, the meanest carpenter and smith in England can either make or repair it; and if the first four lines formed by it are true, the rest of the lines or rows must be geometrically exact, which is an elegance none can feel, but such as take delight in correct husbandry. *Essays in Husbandry, Essay II. page* 212.

DRONE, the male bee, one that makes no honey. *See the article* BEES.

DROPSY, a disease incident to horses, and generally called the water-farcy. *See* WATER-FARCY.

DROPWORT, the name of a perennial weed common in pasture lands, having winged leaves; the divisions of which are all regular, and sharply indented about the edges. The flowers are white, growing in a bunch like an umbel. Its roots are very remarkable, consisting of a bunch of knobs hanging upon threads; from whence it has the name of filipendula, and dropwort. The flowers have an agreeable smell.

DROUGHT, dry weather, want of rain. It also signifies thirst, or want of drink.

DUB, a pool, or pond of water.

DUCK, the name of a well-known fowl, very necessary for the husbandman's yard, as they require no charge in in keeping; for they live on loſt corn, ſnails, &c. for which reaſon they are very proper for gardens. Once in the year they lay a large quantity of eggs, eſpecially a ſort of duck which turns up its bill more than the common kind. When they ſit they require no attendance except they having a little barley or offal corn near them, that they may not ſtraggle far from their neſts to chill their eggs. They are reckoned to be better hatched under a hen than a duck; becauſe while they are young the hen will not lead them ſo often into the water. Some reckon it very proper to cut off the feathers from their rumps; becauſe when their tails are wet, it often occaſions their drowning. As to the fattening of them, you may do it in three weeks's time, by giving them any kind of corn or grain, and plenty of water. Ground malt, wet either with milk or water, is beſt. *Mortimer's Huſbandry, vol. I. page* 257.

DUN, a colour partaking of brown and black.

DUNG, the excrements of animals, putrified vegetables, &c. uſed in improving land.

Dungs are intended either to repair the decay of exhauſted worn-out lands, or to cure the defects of other ſoils, which are as various in their qualities, as the dungs uſed to meliorate or reſtore them. Some lands are too cold, moiſt, and heavy; whilſt others are too light and dry. To anſwer this, ſome dungs are hot and light, as that of horſes, ſheep, pigeons, &c. Others again are fat and cooling, as that of oxen, cows, hogs, &c. And as the remedies which are uſed muſt be contrary to the diſtempers they are to cure, ſo the dung of oxen, cows, and hogs, ſhould be applied to lean, dry, light earths, to make them fatter and cloſer; and hot and dry dungs to cold, moiſt, and heavy lands.

Dung has two peculiar properties. The one is to fatten the earth, and render it more fruitful; and the other, to produce a certain ſenſible heat, capable of cauſing ſome conſiderable effect; which laſt is ſeldom found but in the dung of horſes and mules, while it is newly made, and a little moiſt.

Horſe-dung, the leaſt fat of any, is the moſt fiery, if taken freſh as it falls, and the moſt apt to excite a ſudden fermentation; for which reaſon it is then fit only for the hot-bed. When this heat is paſt, it may be ſpread on fields where we would have a rank graſs to ſpring: but it ſhould not by any means be admitted into the garden, or where we would wiſh to have good roots, unleſs the ground be very ſtiff, cold, or wet, and then too it ſhould be well rotted, leſt, inſtead of correcting the ſoil, it leave couch, and other pernicious weeds, worſe than the diſeaſe itſelf; the ſeeds of hay, and of other plants, which the horſes eat, coming oftentimes entire from them: for thoſe vegetables which cattle chiefly eat commonly ſpring up from their dung; as long knot graſs from this beaſt; ſhort, clean, and ſweet paſture from ſheep and cows; the ſow-thiſtle from ſwine. Ground mucked with horſe-dung is always the moſt infected of any; and if it be not perfectly conſumed, it makes your roots grow forked, fills them with worms, and gives them an unpleaſing reliſh: but if laid on at the beginning of winter, and turned in at ſpring, it ſucceeds ſometimes with pulſe.

Horſe-dung is greatly improved by being mixed with its oppoſite, cow-dung, which is cold and fat; and this mixture is conſiderably meliorated if mixed with a proper earth, with mud, or with aſhes and urine. Cow-dung alone is the worſt of all dungs to endure wet, becauſe it is the moſt eaſily diſſolved. But either of theſe dungs, either ſingly, or mixed as above, ſhould not be uſed till it is old; nor ſhould it be laid abroad expoſed to the ſun and wind, as is the practice of ſeveral injudicious farmers, who let it lie ſpread on their field-lands during three or four of the ſummer months, till the ſun and air have exhauſted all its virtue: whereas, if it be laid in heaps, mixed with earth, and left in that ſtate till it be rotten, it will be the ſooner brought to a proper temper, will produce a ſweeter graſs when laid on paſture grounds, and will go much farther than in the common way when ſpread before the plough for corn, of which it will then greatly promote the growth.

Mr. Miller ſays he has frequently ſeen new horſe-dung buried as it came from the ſtable, in very cold, moiſt land, and always obſerved that the crops have ſucceeded better, than where the ground was dreſſed with very rotten dung.

Sheeps-dung and deers-dung are nearly of the ſame quality, and are generally eſteemed the beſt of all dungs for cold clays. Some recommend beating them into powder, and ſpreading them very thin over autumn or ſpring crops, about four or five buſhels to an acre, in the ſame manner as aſhes, malt-duſt, &c. are ſtrewed. But this light dreſſing does not laſt long. The moſt common way of conveying it upon land is, by folding of the ſheep themſelves upon it, by which means their urine is ſaved as well as their dung, which ought to be turned in with the plough as ſoon as poſſible, that it may not lie expoſed to the heat of the ſun. In Northamptonſhire, they think it beſt to fold ſheep after July, and to fold them the lateſt upon dry land. In ſome parts of France, where they likewiſe fold their cows and oxen, the place of folding is changed twice every night. In Flanders, they houſe their ſheep at night in places ſpread with clean ſand, about five or ſix inches thick, which, being laid on freſh every night, is cleared out once a week. This mixture of ſand and dung makes an excellent dreſſing for ſtrong land; for the dung and urine of the ſheep is a very rich manure. M. Quintinie thinks it the greateſt promoter of fruitfulneſs in all ſorts of ground. This method of folding ſheep in a covered fold, and of mixing their dung with earth, ſand, &c. according to the nature of the ſoil it is intended for, is likewiſe, very properly, recommended by Mr. Mortimer; who adds, that he has known vaſt crops of rye upon barren lands that have been old warrens, well dunged by rabbits; and large oak and aſh upon the ſame, though the ſoil was very ſhallow.

Next to ſheeps-dung, the preference is generally given to that of ſwine, one load of which will go as far as two loads of other dung. The laying it on too thick may perhaps have occaſioned the old miſtaken notion of its breeding more weeds than any other dung: for all dungs will make weeds ſhoot up; whether they contain within themſelves ſeeds of thoſe plants, not ſo thoroughly digeſted by the animal as to be deprived of their vegetative power, as may ſometimes be the caſe, or by the additional fertility which they communicate to the earth. This dung is beſt when carried from the ſtye directly to the field, where it is a rich manure both for corn and graſs, eſpecially the latter, and for almoſt any ſort of land. Hot ſands and gravel are particularly benefited by it; and it is reckoned a very great fertilizer of fruit-trees. Many good huſbandmen prefer this dung before moſt ordinary ſorts of manure, and to take great care not only to have their hog-yards well paled and paved with pebbles, or other ſtones, or with chalk, which is much the beſt; but alſo to increaſe the quantity of the dung as much as they can, by throwing into the ſtye all the ſtraw, fruit, beans, roots, plants, weeds, &c. which are the refuſe of the garden, with the offals of the kitchen, and every kind of traſh; all which is not only very good for the hogs themſelves, but increaſes their dung to ſuch a degree, that ten or twelve ſwine have yielded ſixty or eighty loads of excellent manure in a year. Some notable farmers will make their hog-yards produce them an annual profit of twenty or thirty pounds. Mr. Worlidge thinks this the beſt of dungs to prevent or cure the canker in trees; and Mr. Mortimer eſteems it beſt for manure, when mixed with horſe-dung; for which reaſon he adviſes placing the hog-ſtye as near the horſe-dunghill as can conveniently be. The farmers in Staffordſhire frequently ſow on poor light ſhallow land, a ſmall white pea, which they never reap, but turn in as many hogs as they think the crop will fatten, and let them lie upon it day and night. The dung and urine of theſe animals enriches the land ſo much, that it ſoon acquires a thick ſward, and continues to be good grazing ground for ſeveral years.

In this light, of reaping a double advantage from the manuring of land, the author of the New Syſtem of Agriculture adviſes huſbandmen to ſow ten or fifteen

acres

acres of their ground with turnip-feed, a little before they fow clover, which, he thinks, is beft done in September: then, towards the beginning of March, to take the beft opportunity to buy three hundred fows, all fuch as will farrow in about a month. Let little ftics, formed of boughs or reeds, be made for them in the moft convenient parts of the clover ground, either in the corners, or under the hedges of thefe fields; and let the fows be kept up, and fed daily with the turnips which were fowed the autumn before. At firft, it will be neceffary to take the trouble of boiling them, tops and all, and of giving them in the troughs with the water not yet cold: they may afterwards be only fcalded; and in a week or ten days the fwine will eat them raw, with the greateft greedinefs and pleafure. In the beginning, or towards the middle of April, thefe fows will farrow; after which they muft not be fed with turnips any longer than till the clover is pretty high, when they and their pigs may be turned in among it. It is impoffible for one who had not feen it, to imagine how eagerly the fwine will graze on clover, which increafes their milk to fuch a degree, that the pigs fhoot forward at a double rate; and, as they leave off fucking, they too take to feeding on the clover, by which they profper fo faft, that, by the end of October, every pig will fetch twenty or five and twenty fhillings, in any market. The treading of great cattle is apt to break the ftalk of clover grafs, and they fpoil, by trampling it down, a much greater quantity than they eat: but fwine are never hurtful this way; and if there be any fear of their rooting up the ground, that may be eafily prevented by a ring in their nofes; though our author fays, he never knew a hog break up an inch of clover. They graze upon it with more pleafure than they could root.

Human ordure is a very fat and hot manure, full of fertilizing falts, and therefore extremely proper for all cold four foils, efpecially if it be mixed with other dung, ftraw, or eath, to give it a fermentation, and render it convenient for carriage. Some do not like to ufe it on account of its bad fmell; and others imagine, that it gives a fetid tafte to plants; but in this they feem to carry their delicacy rather too far. It is ufed with great fuccefs in many parts of France, all over Flanders, and, I believe, not lefs profitably round about London. Mr. Bradley fays, it is kept in pits, made on purpofe, in foreign countries, till it be one, two, three, or four years old: that of four years old is accounted the beft; that of three years tolerable; but the others not fo fit for ufe; and that the perfons concerned in thefe pits pay great regard to the place from whence they have it, preferring that which comes from towns where the moft flefh is eaten, as the ftrongeft and richeft manure. It certainly fhould not be laid on too new, nor in too great quantities, becaufe it is of a very hot nature; but when that heat is tempered by age, putrefaction, and a due mixture with other foils, it becomes a rich and excellent manure. Perhaps it may owe great part of this richnefs to the urine with which it is mixed; for tho' human urine be deftructive to vegetables, whilft it is new, by reafon of its burning fal-ammoniacal fpirit, as Glauber terms it, yet, as in many other moift things, fubject to putrefaction, time will correct that defect, digeft the urine, take of its fiery quality, and fo alter its nature, as to render it an extraordinary fertilizer of every kind of foil. Columella certifies, that old urine is excellent for the roots of trees. Mr. Hartlib commends the Dutch for preferving the urine of cows as carefully as they do the dung, to enrich their lands, and inftances a woman he knew near Canterbury, who faved, in a pale, all the urine fhe could; and when the pale was full, fprinkled it on her meadow, the grafs of which looked yellow at firft, but afterwards grew furprifingly. Similar to this is what Mr. Bradley relates, as of his own knowledge. Human urine was thrown into a little pit conftantly every day, for three or four years. Two years after, fome earth was taken out of this pit, and mixed with twice as much other earth, to fill up a hollow place in a grafs walk. The turf which was laid upon this fpot grew fo largely and vigoroufly, befides being much greener than the reft, that, by the beft computation he could make, its grafs, in a month's time, was above four times as much in quantity as that of any other fpot of the fame fize, tho' the whole walk was laid on very rich ground. The author of the Englifh Improver is therefore very right in faying, that human urine is of great worth, and will fatten land more than is generally imagined by our farmers, whom he advifes to take all opportunities of preferving this, and every fort of urine for their ground, as carefully as is done in Holland.

The dung of all poultry is of a very hot nature, full of volatile falts, and therefore extremely proper for cold lands, being light of carriage, and a little of it going a great way. It is moft commonly ufed for diftant grounds, where it is fprinkled on wheat or barley, after they are come up, or upon the latter at the time of fowing. Mr. Mortimer thinks forty bufhels fufficient for an acre. It is ufed to moft advantage when dried and powdered, and is very efficacious in keeping froft out of the earth. Its effects are fudden, but they do not laft long. Hens dung is very rich, though not fo hot as pidgeons dung, nor is it fo eafy to fow, becaufe it hangs more together, neither can it be fo eafily collected. The opinion that goofe dung is rather hurtful than beneficial to corn or grafs, is an ancient error, as is proved by Mr. Worlidge, who fays, he was credibly informed, that a flock of geefe having made a track a-crofs a field of wheat during the winter, and nibbled the corn clear from the ground in their daily paffage in fuch a manner, that the wheat upon it proved the next year much finer than any other part of the field. He alfo mentions a field which had been given to the town of Sutton, in Northamptonfhire, for feeding geefe, whofe dung rendered it one of the richeft paftures he ever faw, infomuch, that all forts of cattle fed on it very greedily; nor could he hear from any of the inhabitants, that fo much as one beaft received the leaft injury from it. He adds, that his own horfes, kept in a piece of pafture on which geefe lay very much, eat the grafs bareft where the fowls had dunged moft, and that he never found it do them any hurt, except making them too fat.

Perhaps the reafon why the dung of geefe has been faid to occafion barrennefs, flowed from obfervations where it had been laid too thick; for being of a hot fiery nature, it will, if laid on in too large quantities, deftroy the grafs; but if fpread thin in the winter, it will prove a very rich and valuable manure, efpecially if mixed with cooling earth, and left for fome time to putrify.

DUNG-HILLS, heaps of dung collected in the yard, and other places, belonging to a farm.

They are made up of the dung of different animals, of different kinds of ftraw, and other vegetable fubftances; and they have frequently different animal fubftances in their compofitions.

Compoft, or compound dung-hills, are a collection of different matters, as earth, mixed with dung from an ordinary dung-hill, lime, and other manures.

Some perfones make dung hills of this kind, and are of opinion, that the dung and other manures with which they are compounded, are thereby made to enrich a greater quantity of land, than if not mixed with earth; and befides, do not produce the bad effects which fometimes are produced by dung, when taken directly from a dung-hill, and laid upon land.

It will not be amifs that we enquire into the advantages of this kind of dung-hills, which will be a means not only of recommending them, but alfo of pointing out the moft proper method of conftructing them.

The firft thing to be enquired into, is the advantage arifing from the mixing lime, marle, or other manures, with the earth and dung. Lime, as it is a diffolver of all vegetable and animal fubftances, when mixed with dung, will help to diffolve it; and as it communicates an abforbent power to earth, will enable the earth with which it is mixed to attract the vegetable food in greater plenty from the air. But in order to make it produce thefe effects, it is neceffary to mix it with dung and earth; for if the lime is laid in a kind of ftratum above the dung, and below the earth, it will abforb the water that falls upon the dung-hill, and thereby will prevent the dung from receiving a fufficient quantity of water to make it putrify; and will alfo occafion fuch a heat as to burn the dung, and render it ufelefs; and, befides, can have but little influence in diffolving the dung, and communicating to the earth its abforbent quality. If the lime is laid above the earth, and expofed to the air, it will be attended with the fame confequences: it will abforb the water; and though it will attract the vegetable food from the air, yet will be of no more ufe for this end, than if fpread upon as much land as the furface of the dung-hill extends to.

The fame thing may be faid of marle, if ufed inftead of lime; but if marle is ufed inftead of earth, it is probable that the compoft will become very rich, as the marle has a very ftrong abforbent quality, and would be greatly expofed to the influence of the air. A much fmaller quantity than is ufed in the ordinary way, it is probable, would be found fufficient, and its effects would be fooner difcovered. If this is tried, it will be neceffary to carry the dung to the marle-pit, and there form the dung-hill; for marel is fo heavy a body, that it would be too expenfive to carry it firft to the dung-hill, and then to the field.

The advantage of mixing dung with the earth is next to be confidered. This, it is pobable, is the principle advantage of the compound dung-hills, and that the advantages arifing from lime are but trifling. They are often made without lime, and their effects, it is faid, are equally good.

Dung, in the ordinary dung-hills, has its vegetable food fometimes wafhed away by rain, when it falls in large quantities. Now this is prevented by the earth in the compound dung-hill, which abforbs the water, and all the vegetable food which it carries from the dung.

In the ordinary dung-hills, the dung on the furface, it is generally fuppofed, lofes a part of its vegetable food, which is exhaled by the fun, or carried off by the wind. This is prevented, by covering the dung with earth in the compound dung-hill.

But it is probable, that the compound dung-hill receives its principal advantage from the earth being expofed to the influence of the air; and if this be true, the more abforbent that the earth is which is ufed, and the larger that the furface of the dung-hill is, in proportion to its bulk, and the quantity of dung contained, it will be the richer.

This directs us to the proper method of conftructing it, to make it long and narrow, with as many divifions in it as can be made conveniently; for thereby a larger furface is expofed in the fame quantity, and the more vegetable food acquired.

It is proper to obferve further, that earth fhould always be in the bottom of the dung-hill, to receive any of the juices of the dung which the rain may carry downward; that the dung fhould be immediately covered with earth, to prevent the juices from being exhaled, or carried off; and that the earth fhould be expofed for a confiderable time, before any more dung is laid on, that fo it may receive all the benefit from the air which it is capable of, before it is covered.

This kind of dung-hills is made with leaft expence upon the field for which the dung is intended. The head-ridges are commonly high raifed, by the turning of the ploughs upon them, and contain the richeft earth in the field. Thefe are very proper places for the dung-hills. The earth is at hand, and can eafily be thrown upon the dung.

Thofe that treat of dung-hills of this kind commonly recommend earth as oppofite as poffible to the nature of the foil upon which the dung is to be laid. They recommend clay for a light foil, and light earth for a clay foil. Befides, thefe the farmer cannot always command; and, though he can, will frequently find it very expenfive to carry them. It is probable, that there is not fo much in adapting the earth of the dung-hill to the kind of foil, as perfons, at firft fight, are apt to imagine. It is certain, that there cannot be fo much in it, as to anfwer the expence of fetching the earth. It is true, that, in many farms, there are different foils, and therefore the dung may be carried to a foil different from the foil of the field for which it is intended; there the dung-hill may be formed, and from thence carried to the field; but ftill this is an additional trouble and expence; and therefore this method is not to be followed, till, upon a comparative trial, the advantages are found to do more than anfwer the expence.

It is a practice in fome parts of Scotland, to lay clay upon clay land. This practice, it is faid, fucceeds very well, which makes it probable, that it is not very material what kind of earth is ufed for the compound dung-hill, provided it is of the abforbent kind; and, therefore, the farmer need not be anxious about getting earth different from his foil, but may make his compound dung-hill of the earth of the field which he intends to manure.

Farmers, efpecially if they live in countries that do not abound in cattle, may be apt to afk, where they are to get fufficient quantities of dung neceffary for carrying the practice of agriculture ftill nearer to perfection? M. de Tourbilly anfwers this queftion, by pointing out the following method of making an artificial manure.

" Before the winter fets in, fays he, that is about the middle of November at fartheft, hufbandmen fhould cleanfe all the yards, and out-lets belonging to the farm-houfe; lay them fmooth, and, if neceffary, dig away a little of their furface, till it is about a foot lower than the floor of their buildings; then if they have any common or wafte land, let them bring from thence fern, thiftles, and other coarfe weeds, cut down in full fap, at which time they are beft, or occafionally as they are wanted, and lay a bed of them, about two inches thick, upon the places thus prepared. If weeds cannot be got, coarfe wheat or rye ftraw may be ufed in their ftead, in beds about half as thick. A layer of earth, about fix inches deep, fhould be fpread upon this bed of weeds, or ftraw. Earth of a quality proper for the improvement of the foil intended to be manured, is undoubtedly the beft; though any earth, which in this cafe the farmer will dig as near to the houfe as he conveniently can, is preferable to the miftaken practice of paring off the upper foil, or turf, of the neareft common or wafte land, to mix with the artificial manure: for when poor ground has loft its furface or fward, it long remains a barren fpot, before a new foil, capable of affording root and nourifhment for grafs, can be formed upon it. If no proper earth lies nearer at hand, the farmer may take off the furface of any part of his plowed ground which lies too high, and is not at too great a diftance. But, as much as poffible, he fhould adapt the earth mixed with this manure to the nature of the land for which it is intended.

" This bed of litter and earth fhould be let lie about a fortnight, during which all fweepings and filth of the kitchen and houfe fhould be thrown upon it, that nothing may be loft, which can be converted into manure. The wetnefs of the feafon, and the paffing of men, cattle, and carriages, over this bed, will greatly contribute to rot it; to complete which, let the farmer turn in all his cattle of every kind, and drive them backward and forward over it, after rain has fallen. This will foon render it a kind of coarfe mud mixed with litter, which may be cleared away at the end of another fortnight. If it be too liquid, as it often is in rainy feafons, it fhould be laid up in little heaps, upon the fame place, till it be drained. Let it then be carried to a fufficiently capacious hole, or pit, dug for the purpofe in or near a corner of the farm-yard. This pit muft be in a dry place; for no manure fhould ever be laid in water, which would wafh away its unctuous parts, deftroy its heat, diffolve its falts, and even leffen its bulk confiderably, if it run off elfewhere. One load of ftable and other dung fhould be mixed with every two loads of this artificial compoft, as it is laid in the pit. The next day, another bed of litter and earth may be fpread in the yard, &c. as before; and, being managed in the fame manner, will be fit for carrying to the dung-pit in about another fortnight. Thus two fupplies of this artificial dung may be had every month, during the whole winter and part of the fpring.

" This work will not be expenfive: every body, even women and children may be employed at it, and it is done at a time of the year when labourers are leaft wanted in the field. It may be continued in the fummer: though the beds do not rot near fo foon in dry weather; two or three months being fometimes requifite then to bring them to a proper ftate, in the above method. However, this may be confiderably haftened, and much improved, by bringing cattle to lie upon them in the night,

night, unlefs they are in folds. The earth and other fubftances of this manure will be greatly enriched by their dung and urine, before it is carried to the ftercorary.

"As this laft made dung will not be fufficiently rotted by the next fowing feafon, the beft way is to lay it in a feparate pit, to mellow, for the enfuing year; and it will be ftill better, if kept two years. The other dung, made in a wetter feafon, and more thoroughly putrefied at firft, fhould remain about fix months in the pit, to ripen; and be wetted now and then in dry weather. During this time, it heats, ferments, and acquires an excellent quality. It may be made to fuit any foil, and agrees with many lands better than pure dung taken from the ftall or ftable, than which it is milder, lefs fiery, and more lafting. Farmers who have not a large yard belonging to their houfe, may make this compoft in any other p ace that beft fuits their convenience; and the poorer fort of peafants may do the fame. By mixing with it a third part of other dung, they triple their quantity of manure." *Memoirs fur les Defrichemens, p.* 78.

This eafy and profitable method of making artificial dung is likewife recommended by the ingenious author of the Differtation on Agriculture, publifhed in the Memoirs of the truly laudable Society eftablifhed at Berne, for the Improvement of rural Oeconomy.

"There are, fays he, two ways of meliorating land. One of them may be called natural, and the other artificial. The former confifts in a well proportioned mixture of two or three different kinds of earth, the refult of which is a new fort, more favourable to vegetation; and the latter in dung.

"Dung confifts of animal or vegetable fubftances, either actually putrefied, or in a ftate of putrefaction. It operates two ways upon the earth: firft, by conveying nourifhment to the plants which grow in it, as the air and water alfo do; and fecondly, by opening its pores and feparating its parts, by a kind of fermentation, till at laft it is itfelf converted into a kind of fine black mould.

"The only way to have plenty of this ufeful matter, without much expence, is by a mixture of ftraw or litter with the excrements of animals. Manure may be obtained from every part of animals or vegetables: but a quantity fufficient for a large extent of ground would coft too much. I therefore fhall not here fpeak of fawduft, tanner's bark, afhes, foot, linen or woollen rags, fhavings of horn, &c. of which quantities can be had only in the neighbourhood of populous towns; but fhall content myfelf with pointing out the means of increafing dung in countries diftant from great cities.

"Agriculture affords an ample field, and very abundant matter, for the moft ufeful of all experiments. Nothing would contribute more effectually to its improvement, nay, to the reducing of it to fixed and certain rules, than for proper perfons to try upon different pieces of ground, of fimilar fize and foil, fome of the principal methods pointed out by the moft intelligent in this art, and compare the iffue of their trials, and the feveral incidents attending them, during a courfe of years. This is particularly wanted in order to determine the effects, and the quantity moft proper to be ufed, of different manures. To this end, two or three fields of experiment might be fet apart, to be cultivated exactly according to a well chofen and well digefted plan. An exact account fhould alfo be kept of every occurrence, difburfement, and produce. Regularity is the foul of all bufinefs. Such journals, properly methodized, would give us a clear infight into rural Oeconomy, and fet order, affiduity, and frugality in fo advantageous a light, that every one would be forced to acknowledge them to be the fource of riches, and as fuch would be induced to practife them." *Tom.* II. *part* III. *page* 651.

DURZ'D, or *durz'd out*, an epithet applied in the northern counties to corn beaten out of the ears by the wind turning it in the field, or other accidents.

DWARF, an epithet applied to fuch trees and plants as are lefs than the common forts of the fame genus.

Dwarf-trees were formerly in much greater requeft than they are at prefent; for though they have fome advantages to recommend them, yet the difadvantages attending them greatly over-balance; and fince the introducing of efpaliers into Englifh gardens, dwarf-trees have been in little efteem, for the following reafons:

1. The figure of a dwarf-tree is very often fo much ftudied, that, in order to render the fhape beautiful, little care is taken to procure fruit, which is the principal defign in planting thefe trees.

2. The branches being fpread horizontally near the furface of the ground, render it very difficult to dig or clean the ground between them.

3. Their taking up too much room in a garden, efpecially when they are grown to a confiderable fize, for nothing can be fown or planted between them.

It is alfo very difficult to get to the middle of thefe dwarf-trees in the fummer, when their leaves and fruit are on the branches, without beating off fome of the fruit, and breaking the young fhoots; whereas the trees on an efpalier can at all times be come at on each fide, to tie up the new fhoots, or to difplace all vigorous ones, which, if left on, would rob the trees of their nourifhment.

Add to this, the fruit-buds of many forts of pears and apples are produced at the end of the former year's fhoot, which muft be fhortened in order to keep the dwarfs to their proper figure; fo that the fruit-buds are cut off, and a greater number of branches are obtained than can be permitted to ftand; fo that all thefe forts of fruit-trees, whofe branches require to be trained at full length, are very improper to train up as dwarfs.

Thefe evils being entirely remedied by training the trees to an efpalier, hath juftly gained them the preference. *Miller's Gard. Dict.*

DWARF-OAK, the name of a fhrub common in many parts of North America, where it is planted for making hedges and fences. It grows very faft, and becomes fo thick by cutting with fheers, that hardly a bird or moufe can creep through it when in full perfection. The acorns are fown in rows or drills, where the hedge is propofed to be made, which admits of being made of a confiderable height. Such a fence as this would be a fcreen from the winds in winter, as well as a fecurity to the inclofure; and therefore a hedge of this kind would be very ufeful here; and the plant would, perhaps, on further examination, be found capable of being ferviceable in fome other ways. *Mufeum Rufticum, vol.* VI. *p.* 293.

DYER's-WEED. *See the article* WELD.

E.

EADDISH, or *Eddiſh*, roughings, or graſs growing among the ſtubble, after the corn is cut.

EARING, or *Aring*, ploughing, tilling, cultivating.

EARNING, cheeſe-rennet.

EARTH, the ground, conſiſting of different modifications of terrene matter.

The earth, which generally preſents itſelf firſt to the eye, is no particular kind of ſoil, but, uſually, a mixture of the ſoil underneath, with every adventitious ſubſtance, either purpoſely brought to, or accidentally lodged upon it. From theſe cauſes, this ſuperficial earth, commonly called mould, grows and increaſes yearly in depth; oftentimes to ſuch a degree, as to form even conſiderable eminences, eſpecially where there has been a fall of woods and trees, ſuch as birch and beech, which, not being of a conſtitution to remain long in the ground without rotting, as fir, oak, elm, and ſome other timber will do, are pretty ſoon reduced into mould as ſoft and tender as that in which they were ſown or planted.

This ſurface-earth, and alſo the natural under-turf earth, to the depth of about a foot, is generally the beſt and ſweeteſt, being enriched with all that the air, dews, ſhowers, and celeſtial influences can contribute thereto: for that earth is beſt, and it is the ſame with water, which is moſt expoſed to the influences of the ſun and air. The fatneſs of the under-turf earth, drawn up to the ſurface by the kindly warmth of the ſun, ſpends but little of its vigour in the graſs and tender verdure which it produces, provided no rank weeds be permitted to grow and perfect their ſeeds; but maintains its natural force, and is therefore, of all uncultivated moulds, the moſt grateful to the huſbandman.

As the reſt of the ſubjacent earths approach this in virtue, ſo are they to be valued. Of theſe there are ſeveral kinds, diſtinguiſhable by their ſeveral conſtitutions. The beſt of them is black, fat, and at the ſame time porous, light, and ſufficiently tenacious, without any mixture of ſand. It riſes in pretty large pieces, and falls into duſt, of its own accord, after a ſhort expoſure to the air; but without crumbling altogether into duſt, which is the defect of a leſs perfect ſort.

This excellent black mould is fit for almoſt any thing, without much manure. The farmer is not always ſo happy as to meet with it: or if there be a ſmall depth of it, other, leſs fertile, ſoils lie underneath, ſuch as clay, gravel, ſand, &c. which require different treatment, according to their various qualities. Theſe ſoils often appear on the ſurface; and may be ſaid to be almoſt barren, till brought by art to anſwer the purpoſes of the huſbandman. In clays and ſtiff ſoils, the component particles have too cloſe an adheſion to admit the roots of plants with the eaſe requiſite for them properly to ſeek their food: and, on the other hand, ſand, and ſoils of a light nature, are too looſe to give the proper ſtability to plants, or to retain the mixture neceſſary to convey their nouriſhment into them. It will therefore be right, firſt, to ſhew how theſe extremes may moſt properly be corrected, and then point out the means of keeping the ſuperficial mould in conſtant heart, to uſe the language of farmers.

EARTH-BOARD, that part of a plough which turns over the earth. *See the article* PLOUGH.

EAVES, the edges of the roof that over-hang the walls of a building.

EDDER, the ſmall ſhoots of aſh, hazle, oak, &c. uſed for binding the tops of hedges.

EDDISH, the ſame with eaddiſh. *See* EADDISH.

EDGE, the extremity of a border.

EDGE-GROWN, come up uneven, not ripening all together.

EDGINGS, the ſeries of ſmall, but durable, plants, ſet round the edges or borders of flower-beds, &c. The beſt and moſt durable of all plants for this uſe is box, which, if well planted, and rightly managed, will continue in ſtrength and beauty for many years. The ſeaſons for planting this are the autumn, and very early in the ſpring; and the beſt ſpecies for this purpoſe is the dwarf Dutch box. The edgings of box are now only planted on the ſides of borders, next walls, and not, as was ſome time ſince the faſhion, all round borders or fruit-beds, in the middle of gardens, unleſs they have a gravel walk between them, in which caſe it ſerves to keep the border from waſhing down on the walks in hard rains, and fouling the gravel.

In the laſt age, it was alſo a very common practice to plant borders, or edgings, of aromatic herbs, as thyme, ſavory, hyſſop, lavender, and the like. But theſe are all apt to grow woody, and to be in part, or wholly, deſtroyed in hard winters. Daiſies, thrift, or ſea July flower, and chamomile, are alſo uſed by ſome for this purpoſe; but they require yearly tranſplanting, and a great deal of trouble, elſe they grow out of form; and theſe are alſo ſubject to periſh in very hard ſeaſons. *Miller's Gard. Dict.*

EDIFICE, a fabric, a building.

EFT, a newt, or evet.

ELBOW, a name given by horſemen to the hind-part of the fore-leg, pointing towards the briſket.

ELDER, fuel for fire.

ELDER, the udder.

ELDER, is alſo the name of a well-known tree, and is often uſed in making fences, which may be done by taking elder-ſticks, or truncheons, ten or twelve feet long, and ſticking them in the bank ſloping both ways, ſo as to form a kind of chequer work. By this means a fence may be ſooner raiſed than by any other, as the elder is a very quick grower. The wood, when large, is very uſeful for turners and mathematical inſtrument-makers, being nearly equal to the beſt box, and for many uſes ſurpaſſing it. *Mortimer's Huſbandry, vol. I. page 7.*

ELM, the name of a tree too well-known to need any deſcription, being common in almoſt every part of England.

Elms are very proper to be planted in hedge-rows, upon the borders of fields, where they will thrive much better than when planted in a wood, or cloſe plantation, nor will their ſhade be very injurious to whatever grows under them; but when theſe trees are tranſplanted out upon banks after this manner, the banks ſhould be well wrought and cleared from all other roots, otherwiſe the plants, being taken from a better ſoil, will not make much progreſs in theſe places. About Michaelmas will be a good time for this work, for the reaſons before aſſigned; but when they are planted, there ſhould be ſome ſtakes fixed in by them, to which they ſhould be faſtened, to prevent their being diſplaced by the winds; and part of their heads ſhould be taken off, before they are planted, which will alſo be of uſe in preventing their being eaſily overturned by winds; but by no means ſhould their leading ſhoot be ſtopped, nor their branches too cloſely cut off; for, if there are not ſome ſhoots left on to draw and attract the ſap, they will be in danger of miſcarrying.

Theſe trees are alſo proper to plant at a diſtance from a garden or building, to break the violence of winds, for which purpoſe there is not any tree more uſeful; for they may be trained up in form of an hedge, keeping them cut every year; which will cauſe them to grow very cloſe and handſome, to the height of forty or fifty feet, and be a great protection againſt the fury of winds: but they ſhould not be planted too near a garden, where fruit-trees, or other plants, are placed; becauſe the roots of the elm run ſuperficially near the top of the ground to a great diſtance, and will intermix with the roots of other trees, and deprive them of nouriſhment. Nor ſhould they be planted near gravel or graſs walks, which are deſigned to be well kept; becauſe the roots will run into them, and ſend forth ſuckers in great plenty; which will deface the walks, and render them unſightly.

But, for large gardens, where ſhade is required, there is ſcarce any tree ſo proper for that purpoſe, being eaſy to remove, when grown to a conſiderable ſize; ſo that a perſon who is willing to have his plantations for ſhade in a ſhort time, may procure trees of one foot circumference in their trunk, which will be in no danger of ſucceeding, provided they are removed with care. And theſe will take root, and grow again, almoſt as well as young plants, which is what few other ſorts of trees will do; but then they ſhould be ſuch trees as have been thus regularly trained up in a nurſery, and have good roots, and not ſuch as are taken out of hedge-rows, as is by ſome practiſed, which ſeldom riſe with any tolerable roots, and conſequently often miſcarry; and this has been the occaſion of ſo many plantations of theſe trees failing; for although ſome of them may live a few years, yet few of them are of long duration, and they rarely increaſe much in their ſtems, but frequently grow hollow, their heart decaying firſt; ſo that they are ſupported only by their bark or ſhell, for a few years, and the firſt ſevere winter, or very dry ſummer, they are generally deſtroyed.

In planting of theſe trees, great care ſhould be taken not to bury their roots too deep; which is very injurious to them, eſpecially if they are planted on a moiſt loam or clay; in which caſe, if the clay is near the ſurface, it will be the beſt way to raiſe the ground in an hill, where each tree is to be planted, which will advance their roots above the ſurface of the ground, ſo that they will not be in danger of rotting in winter with moiſture.

When theſe trees are propagated by ſuckers taken from the foot of old trees, they are commonly laid into the ground very cloſe in beds, where, in dry weather, they may be frequently watered, to encourage their putting out roots. In theſe beds they are left two years; by which time, thoſe that live will be well rooted, though a great many of them generally die; then they ſhould be tranſplanted into the nurſery.

There are ſome who raiſe the witch elm from ſeeds, which it generally produces in great plenty, and are ripe in April. Theſe ſhould be ſown upon a bed of freſh loamy earth, and gently covered; in dry weather they ſhould be watered, and if the bed is ſhaded from the violent heat of the ſun, it will be of great ſervice to the ſeeds, for I always obſerve the plants to come up better in the ſhade, than when expoſed to the ſun. When the plants come up, they ſhould be carefully cleared from weeds; and after they have ſtood two years in the ſeed-bed, they will be fit to plant out into the nurſery.

Sometimes the common Engliſh elm will produce ſeed; but it is not ſo conſtantly fruitful as the witch elm, which ſeldom fails to produce great quantities, when they have arrived to due maturity; which ſeeds will fall to the ground, and when they light upon a ſpot which is not diſturbed, the plants will come up in great plenty.

The timber of the common Engliſh elm is generally preferred to the reſt; though that of the witch elm is often as good, and is the largeſt tree, when planted on a kindly ſoil; but the Dutch elm affords the worſt timber, and never will grow to the ſtature of either of the other ſorts; ſo that this ſhould not be cultivated for the timber; therefore the beſt way to be ſure of the kinds which a perſon would chuſe to propagate, is to have a nurſery of ſtools, in order to furniſh layers; for when they are grubbed up from hedge-rows, there will often be many ſorts intermixed, eſpecially if the people who go about to gather them, furniſh them; becauſe they take them indifferently, wherever they can procure them; ſo that when they are planted out thus blended together, there will be a conſiderable difference in their growths, which will deface the plantation. *Miller's Gard. Dict.*

A correſpondent of the editors of the Muſeum Ruſticum has favoured the public with the following account of an experiment of planting elms on a ſtiff clay.

"My original deſign, ſays he, was to plant a clump of trees to the north-eaſt, a ſecond to the ſouth-weſt of my houſe, and alſo to plant four rows of elms from the front of my houſe to the village, being about two hundred yards diſtant.

"My firſt buſineſs in this grand affair was to lay a plan of operations: accordingly, I marked out the ground for my two clumps, and my avenue, driving a ſmall ſtake in the ſpot where every tree was to be planted. For the avenue the ſtakes were placed in four rows, two on each ſide, thirty feet diſtant from ſtake to ſtake, the avenue in the middle thirty feet wide, and the rows diſtant twenty-four feet from each other.

"My clumps I planted in triangles, one of the points being to the wind, imagining this form would beſt anſwer the intended purpoſe, each clump conſiſting of about one hundred and fifty trees. This preparation was made by me during the ſummer of the year 1737.

"As ſoon as harveſt was over, the ſame year, I hired ſome labourers, and made them dig a hole ſix feet ſquare, and four feet deep, wherever they found a ſtake, throwing the earth which came out of the hole round its edges.

"When this work was done, I left it in the above ſtate all that winter and the enſuing ſummer, with an intent that the ſtiff obſtinate nature of the clay ſhould be meliorated by the powerful influences of the froſts, ſun, and variable air.

"At the end of the ſummer of 1738, I found I had not loſt my labour, when I came to examine the ſtate of my experiment. The nature of the ſoil, wherever the air could operate upon it, was entirely changed, the clay being much leſs compact, and approaching nearer to the ſubſtance of a ſtiff loam, being crumbly, though cloſe in its texture.

"As ſoon as I found that my land was thus in proper order for planting, I procured from a nurſery-man a ſufficient number of young elm-trees, ordering him to mark the north ſide of every one of them with ſome white paint, previous to his taking them up.

"This was a precaution ſome might think unneceſſary; but my reaſon for doing it was, becauſe I imagined that a tree, removed from its native ſpot, and tranſplanted into another place, muſt thrive better, if, on being removed, it enjoyed the ſame aſpects as before; and indeed ſome ſmall experiment I had before made in this matter ſeemed to confirm me in the opinion.

"As ſoon as I had beſpoke my trees, I employed ſome labourers to fill up the holes above-mentioned with the earth that came out of them; but I firſt ſprinkled ſome ſlaked lime over the bottom of each hole, and mixed lime with the earth as it was thrown in, to the quantity of a buſhel for each hole.

"When this work was done, and the ground appeared level, with a little ſpare earth near each hole, I had my trees planted in the following manner:

"I began planting my trees about the tenth of October, and had finiſhed by the latter end of the month.

"I cauſed, in the firſt place, the roots to be moderately trimmed with a very ſharp knife, each root being cut ſloping, not tranſverſely, the ſlope being undermoſt or next the ground: this was, in ſome meaſure, eſſential, to prevent the moiſture proceeding from rain from ſoaking into the wounded part.

"Having proceeded thus far, I cauſed a tree to be ſet over each hole, upon the ſurface of the ground, round the roots of which ſome under-turf earth was piled, and over that the remainder of the natural ſoil, with which ſome flaked lime had been mixed.

"The upper part of the little hillock, formed round the roots of the tree, was made a little hollow, to convey to the plant as much rain as would be neceſſary to ſupply it with a ſufficient quantity of moiſture.

"I then employed a perſon to ſecure the little mound with brambles, wattled in the ſame manner as are the graves in a country church-yard; my laſt buſineſs being to apply ſome long ſtakes to each tree, by way of ſupporting it, till it had taken firm root.

"In this manner, then, I planted the whole number of my trees; and they ſucceeded to a wonder, for but ten failed; and the bark of thoſe was, on examination, found to have been injured by an aſs which broke into my ground: however, the next year I had them replaced, and the diſadvantage was not great.

"What is moſt remarkable is, that my trees ſtood well the memorable hard froſt, without being, as far as I could find, in the leaſt injured.

"I now, with pleaſure, view the fruits of my former labours; and I cannot find that any perſon, within twenty miles of me, has finer trees, that have been no longer planted.

"I well knew, that the only way to defend the roots of my young trees from the damp, raw, under earth, which had proved fatal to other plantations, was, to raiſe them above it: this I effected, by planting them on the ſurface of the ſoil; and ſuch roots as ſtruck downward found a good warm bed in the earth, which had been ſtirred and mixed with lime: however, as the elm has naturally a ſpreading root, the nouriſhment was chiefly extracted from the upper bed of earth, the main roots being covered by only a few inches of mould, and ſome of them, at this time, lie quite bare and prominent above the earth.

"A great deal depends on ſtaking young trees ſo ſecurely that they ſhall not be ſhaken by every guſt of wind, in ſuch a manner as to diſplace their roots in the earth; for by this means the fibres of the roots of ſuch ſhaken trees are removed from the ſurfaces which ſhould afford them nouriſhment; and either the tree dies, or the mouths of the roots muſt again have time ſo to adapt themſelves to the circumjacent particles of earth, as to be in a capacity of once more extracting their nouriſhment and food from their common mother.

"The trees in my avenue do not now ſeem as if they were planted on the ſurface; for I have, to make the way hard and good, ſince laid many loads of gravel in the middle ſpace, and between the trees: this, together with the trees ſettling a little after planting, as moſt trees do, has made the whole appear near level." *Muſeum Ruſticum, vol.* IV. *page* 154.

Mr. Dodart, in a diſcourſe made before the Paris academy, on the great fecundity of vegetables, and their prodigious increaſe, choſe this tree as an example of it. He obſerved an elm of about ſix inches diameter in the body, and about twenty feet high to the branches; he ordered one of the branches to be cut off, and, without reckoning the ſeeds which had been ſhaken off by the blows of the weapon, or loſt by the fall, he counted the reſt only which remained on. This branch was about eight feet long, and on this there were 16450 ſeeds. Counting in a very moderate way, there muſt be reckoned, at leaſt, ten ſuch branches as this, on an elm of that growth. The product of theſe ten branches will be then 164500 ſeeds.

All the branches which are ſhorter than eight feet, on the ſame tree, taken together, on a moſt moderate computation, muſt be allowed to make a ſurface more than double that of theſe ten branches. The product of this ſurface of the ſhort branches, therefore, will be 329000.

An elm may very reaſonably be ſuppoſed to live a hundred years, and as the elm, here mentioned, was but of twelve years growth, it cannot be ſuppoſed, in that ſtate, to be yet arrived at its middle degree of fertility in ſeeds; therefore the ſmalleſt addition that can be made to the 329000, will bring it to at leaſt 330000, for the mean yearly product of ſeeds of the tree; and to know what is the whole product of an elm in ſeeds, according to this computation, this ſum muſt be multiplied by a hundred, the number of years of the duration of the tree. Thus the ſmalleſt amount will be thirty-three millions of ſeeds, produced by an elm originally raiſed from one ſingle ſeed.

This, however, is no more than the natural produce of the tree, in its wild ſtate; we all know very well, that proper management will make trees yield abundantly more fruit than they naturally would. Thus, if this elm, at a proper ſtage of its growth, had been lopped off at the head, it would have puſhed out infinitely more numerous branches; and a ſet of theſe would have appeared in a circle round the trunk, at about half an inch from the place where it was cut off, and this would have been the caſe in whatever part, or at whatever height, it had been cut. All the trunk of the tree, from the ground up to the beginning of the natural eruption of the branches, being then full of theſe rudiments of branches, placed in circles, and ſeparated by circular ſpaces of about half an inch deep, compoſes ſo many circles of branches, or rudiments of branches, as there are half inches in meaſure from the ground up to the firſt natural rudiments; all theſe rudiments are formed, therefore, all ready to appear in form of complete branches, and all contain, in miniature, their proportion of ſeeds, and any circle of them may be made to ſhoot out and appear, by only cutting off the trunk juſt above them; theſe are all, therefore, to be allowed really to exiſt, and all to be brought into the account of the providence of nature, in the fecundity of the tree, as all are formed and provided for it. There are, therefore, evidently contained, in the elm, ſo many times thirty-three millions of ſeeds, as there are half inches in twenty feet, which was its meaſure from the ground to the firſt branches: that is to ſay, this tree contains actually in itſelf 15840000000 rudiments of ſeeds, or has ſo many bodies incloſed in itſelf, by each, or any one of which, it is capable of multiplying its ſpecies, and of producing ſo great and aſtoniſhing a number of trees. The imagination is ſtartled at being conducted to ſo amazing a ſcene by reaſon.

What are we to think then of the immenſity of the works of the great Creator of the univerſe, when we conſider that every one of theſe ſeeds contains in itſelf a tree, loaded with an equal number of ſeeds, and each of thoſe another tree, loaded in the ſame manner, and ſo on, beyond the utmoſt extent of our capacity; and that conſequently here is a geometrical proportion, or progreſſion of increaſe, the firſt term of which is 1, the ſecond 15840000000, the third the ſquare of that number, the fourth the cube, and ſo on to infinity. Reaſon and imagination are loſt together in the immenſity of ſuch a calculation! *Mem. Acad. Par.* 1700.

ELSHIN, a pail, kit, or bucket.

ENDIVE, or ſuccory, a plant much cultivated in kitchen gardens.

It is propagated by ſeeds, which are longiſh, flat at one end, and roundiſh at the other, not unlike to little bits of ſmall ſtalks. Thoſe of the white, the green, and the curled, which are the ſorts cultivated in the kitchen garden, are of a whitiſh grey colour. The ſeeds of the wild ſuccory, which is uſed for medicinal purpoſes, are black, but of the ſame ſhape as the former. All the ſorts of endive are eſteemed aperitive and diuretic. They will grow in almoſt any ſoil, but thrive by far the beſt in deep, good, and well looſened mould. The management of each ſort is the ſame.

The

The curled endive is the sort now most cultivated in England for sallads in the autumn and winter, during which it may be continued in perfection, so long as the season will permit, by observing the following directions.

The first sowing of endive should be about the middle of June; for that which is sown earlier is apt to run up to seed, especially if the ground be rich, and the situation warm, before the plants have arrived to a proper size for blanching. The second sowing should be in the beginning of July, and the third and last about the middle of the same month. The plants of each of these sowings will be so very different in their growth, that each bed will afford a succession of two or three crops, and the three sowings will of course furnish an uninterrupted supply during the whole season.

The plants must be well weeded, and frequently watered in dry weather, till they are fit to transplant. A spot of rich ground, proportioned to the number of plants intended to be set in it, should then be prepared for them, by thorough digging, and laying of its surface smooth; and, if it be very dry, it must be well watered. The largest plants should be removed first from the seed-bed, and the smaller ones should be left there to gather strength, which they will soon do after the additional room for their farther growth, so as, in their turns, to be fit also for transplanting. Care must be taken not to break their roots in drawing them up from the seed-bed; and if the tops of their leaves are shortened then to nearly equal lengths, and they are spread with all their roots turned the same way, these little precautions will render the regular planting of them much easier, than when their heads and tails are jumbled promiscuously together. They should be transplanted in rows at least one foot asunder, and set ten inches apart in the rows. The earth should be well closed around their roots, and they should be well watered every other evening till they have taken good root, after which they must be kept clear from weeds.

If the plants left in the seed-bed are also well weeded and watered, a second transplantation may be made from thence in about ten days or a fortnight after the first, and the remainder of them will be fit to transplant, in the same manner as before, at about the same farther distance of time.

The plants that were first transplanted will be fit for blanching by the latter end of August at farthest. To do this properly, the gardener should grasp in one hand all the inner leaves of the plant, in regular order, and then collect over them the outside sound ones; for the rotten and decayed leaves, which lie next to the ground, should be pulled off and thrown away. The leaves thus gathered up should be placed as nearly as can be in the natural order of their growth, so as not to cross one another, and when the whole plant is thus collected, it should be tied up very close with a twig of osier, or a strong slip of bass mat, at about two inches below the top. This should be done in a very dry afternoon, when the middle of the plants is perfectly free from dew or rain: for any such moisture tied up in them, would soon make them rot. In about a week after this, these plants should be tied again round the middle, to prevent their heart-leaves from bursting out on one side, which they are otherwise apt to do, as they increase in bulk; and with this management they will be quite blanched in three weeks or a month, from the time of the first tying up. The largest plants should always be tied up first; so that by going over the same ground once a week, and taking them according to their size, the crop will be continued longer than if they were all tied up at once: for they will not hold sound and good above ten days or a fortnight after their blanching has been completed, especially if the season prove wet. For this reason it is most advisable to sow and plant at different times, as before directed. But it is to be observed, that all the plants of the last sowing should be transplanted under pales, walls, or hedges, to screen them from frost; and if the winter be severe, they should also be covered with peas-haulm, or some other light covering, which should be carefully taken off in mild weather: and these borders must likewise be as dry as possible; for endive is very liable to rot, if planted in moist ground in the winter.

Only the plants of the two first sowings are to be tied up in order to blanch them: for, after October, when the nights begin to be frosty, the plants of the late crop would be in great danger of being killed thereby, if they were to be left entirely above ground, even though they should be covered with haulm. The best way of managing these, is to take them up in a very dry day, and with a large flat pointed dibble, plant them in the sides of ridges of earth laid very upright, facing the sun, with only the tops of the plants out of the ground. The plants thus situated will be exposed to as little wet as possible, for rain cannot then lodge upon them, and in about three weeks or a month's time they will be blanched fit for use: but they will not keep good long after that. Fresh ones should therefore be planted in this manner every week or fortnight at farthest, by those who would have a constant supply for the table; and if those which were transplanted from the seed-beds are kept till February or March, before they are thus set to blanch, sallads of endive may be had regularly till the beginning of April, or later. This last planting will continue good longer than that which was made just before the beginning of winter; because, as the days increase in length, the sun grows warmer, and the too great moisture of the earth, which would endanger the rotting of the plants, is more and more exhaled.

When the endive, blanched either way, is fit for use, it should be dug up with a spade, and after its outside green and decayed leaves have been stripped off, it should be thoroughly washed in two or three different waters, to clear it from slugs and other vermin which commonly shelter themselves among its leaves.

If any of the plants should put out flower-stems either before or during the time of their blanching, they should be immediately pulled up, and thrown away.

In order to have good seeds of endive for the next season, some of the largest, soundest, and most curled plants, (a dozen of such will yield seeds enough for any middling family,) should be chosen from among the borders where the last crop was transplanted, before the rest of it is put into the ridges to blanch. These selected plants should be carefully taken up, in the beginning of March, if the weather is mild, otherwise it may be deferred a fortnight longer, and transplanted into a well sheltered place, at the distance of about eighteen inches asunder, in one row, which should be placed pretty near to the fence, whether it be wall, pale, or hedge; but not too near, especially if it be the former, because the danger of frosts and nipping winds is greatest quite close to a wall. These plants should be kept very clear from weeds, a deep stirring or two of the earth will give them great vigour, and when their stems begin to advance in height, they should be supported by a string run along before them, and fastened at each end, either to the fence, or to stakes set up for this purpose. About the beginning of July, these seeds will begin to ripen. As soon as they are quite ripe, the stalks must be cut off, and spread upon a coarse cloth, to dry in the sun. They should then be beaten out, dried again in the sun, and laid up in bags, or paper, in a dry place. But a circumstance of some moment here is, that it would be wrong to wait for the ripening of all the seeds of the same plant, because, such is their irregularity in this respect, the first ripe and best of the seeds will scatter and be lost, before the others are near ripe.

ERSH, the stubble after the corn is cut.

ERGOT, a sort of stub, like a piece of soft horn, placed behind and below the pastern joint.

ESCALLION. *See the article* SCALLION.

ESCALLIOT, a species of onion, much cultivated in gardens.

These plants are propagated by off-sets from the roots, and planting them in a light soil; for though they will grow in almost any ground, they will increase most plentifully there.

The best time for setting is towards the end of January. They must be taken up as soon as their leaves begin to wither; for they will rot if left long after in the ground.

ESPALIERS, in gardening, are rows of trees planted about a whole garden or plantation, or in hedges, so as to inclose quarters or separate parts of a garden; and are trained up regularly to a lattice of wood-work in a close hedge, for the defence of tender plants against the injuries of wind and weather. They are of admirable ufe and beauty in a kitchin garden, ferving not only to fhelter the tender plants, but fcreen them from the fight of perfons in the walks.

The trees chiefly planted for efpaliers, are apples, pears, and fome plums; but the two former are moftly ufed: fome plant efpaliers of apples grafted upon paradife ftocks; but thefe being of a fhort duration, are not fo proper for this purpofe; therefore I fhould rather advife the having them upon crab-ftocks, or (if in fmall gardens, where the trees cannot be allowed to grow fo high) upon what the gardeners call the Dutch ftock, which will caufe them to bear much fooner, and prevent their growing too luxuriant.

In chufing the trees for an efpalier, endeavour, as near as poffible, to plant the feveral forts which are nearly of the fame growth in one line, that the efpalier may be the more regular, and of an equal height, which greatly adds to their beauty; for if you plant trees which fhoot very unequally in the fame line, it will be impoffible to make the efpalier regular: befides, the diftance the trees are to be planted muft be directed hereby; for fome trees, viz. thofe of a larger growth, fhould be planted twenty-five or thirty feet afunder; whereas thofe of fmaller growth need not be above fixteen or eighteen feet diftance from each other.

The width of the walks between thefe efpaliers fhould (in a large garden) be fourteen or fixteen feet at leaft; and, if they are defigned to be carried up pretty high, the diftance fhould be greater, that each fide may receive the advantage of the fun and air, which is abfolutely neceffary, if you would have the fruit well tafted: and if your ground is fo fituated, that you are at full liberty which way to make the efpaliers, I would advife the placing the lines from the eaft a little inclining to the fouth, and toward the weft a little inclining to the north, that the fun may fhine between the rows in the morning and evening, when it is low; for in the middle of the day, when the fun is advanced far above the horizon, it will fhine over the tops of the efpaliers, and reach the furface of the earth about their roots; which is a matter of more confequence than many people are aware of.

The forts of apples proper for efpaliers are the golden pippin, nonpareil, rennette grife, aromatic pippin, Holland pippin, French pippin, Wheeler's ruffet, Pile's ruffet, with feveral others.

The forts of pears proper for an efpalier are fummer and autumn fruits; for fome of the winter pears feldom fucceed well in an efpalier. Thefe trees, if defigned for a ftrong moift foil, fhould be upon quince ftocks; but if for a dry foil, upon free ftocks. Their diftance of planting muft alfo be regulated by the growth of the trees, which are more unequal in pears than apples, and fhould therefore be more carefully examined before they are planted. As for thofe pears upon free ftocks, the diftance fhould never be lefs than twenty-five feet for moderate growing trees; but, for vigorous fhooters, the fpace of thirty or five and thirty feet is little enough, efpecially if the foil be ftrong, in which cafe they fhould be planted at a greater diftance. The particular forts of pears I would recommend for an efpalier, are the jargonelle, blanguette, poir fans peau, fummer boncretien, Hambden's burgamot, poir du prince, autumn burgamot, l'ambrette, gros rouffelet, chaumontelle, beurre du roy, le marquis, creffane, with many others of lefs note, always remembering that thofe pears which are of the melting kind, will do better in efpaliers than the breaking pears, which feldom ripen well on efpaliers: you fhould alfo be careful of the ftocks thefe are grafted on; for if the breaking pears are grafted on quince ftocks, the fruits will be ftony.

I fhall now give directions for making the efpalier, to which the trees are to be trained: but this I would not have done until the third year after the trees are planted; for, while they are young, it will be fufficient to drive a few fhort ftakes into the ground on each fide of the trees, to which the branches fhould be faftened in an horizontal pofition, as they are produced; which ftakes may be placed nearer, or at a farther diftance, according as the fhoots produced may require, and will be fufficient for the three firft years; for fhould you frame the efpalier the firft years the trees are planted, the poles would rot before the efpalier is covered. The cheapeft method to make thefe efpaliers is with afh poles, of which you fhould have two forts; one of the largeft fize, which contains thirteen poles in a bundle, and the other fize thofe of half a hundred; the firft or largeft fize poles fhould be cut about feven feet and a half long; thefe are intended for upright ftakes, and muft be fharpened at the largeft end, that they may, with more eafe, be driven into the ground; thefe fhould be placed at a foot diftance from each other in a direct line, and of an equal height, about fix feet above ground; then you fhould nail a row of ftrait flender poles along upon the tops of the upright ftakes, which will keep them exactly even, and continue to crofs the ftakes with the fmaller poles, and the tops which were cut off from the larger ones, at about nine inches diftance, row from row, from the top to the bottom of the ftakes. Thefe rows of poles fhould be faftened with wire, and the largeft end of the poles fhould be nailed to the upright ftakes, which will fecure the efpalier almoft as long as the poles will endure; whereas, if your faftening is not ftrong, the poles will be continually difplaced with every ftrong wind. When your efpalier is thus framed, you muft faften the branches of the trees thereto, either with fmall ofier twigs, or fome fuch binding, obferving to train them in an horizontal pofition, and at equal diftances; being careful not to crofs any of the branches, nor to lay them in too thick: the diftance I would allow for the branches of pears and apples, fhould be proportioned according to the fize of their fruit; fuch of them whofe fruit is large, as the fummer boncretien, monfieur John, and beurre du roy pears, and the rennette guife, Holland pippin, French peppin, and other large apples, fhould have their branches fix or eight inches diftance at leaft; and to thofe of leffer growth four or five inches will be fufficient.

But, befides this fort of efpalier made with poles, there is another fort that is by many people preferred, which is framed with fquare timbers cut to any fize, according to the ftrength thereof, or the expence the owner is willing to go to; thefe, though they appear more fightly, when well fixed and painted, are not of longer duration than one of the former, provided it is well made, and the poles are ftrong which are fet upright; nor will they anfwer the purpofe better, though they are vaftly more expenfive; for the greateft beauty confifts in the difpofing the branches of the tree, which, efpecially in fummer, when the leaves are on, will entirely hide from the fight the frame of the efpalier: therefore all expence in erecting thefe is needlefs, farther than making provifion to fecure the branches of the trees in a regular order.

Fruit-trees thus planted, and well managed, are much preferable to thofe trained up in any other figure, upon feveral accounts: as, firft, thefe take up very little room in a garden, fo as to be hurtful to the plants which grow in the quarters; and, fecondly, the fruit upon thefe are better tafted than thofe which grow upon dwarfs, the fun and air having freer accefs to every part of the tree, whereby the dampnefs arifing from the ground is fooner diffipated; which is of fingular advantage to fruit-trees. *Miller's Gard. Dict.*

ESSE, a provincial word ufed in Chefhire, to fignify afhes.

ETCH, the fame with erfh. *See* ERSH.

EVERLASTING-PEA, or broad leaved chickling vetch, a perennial plant, which grows naturally in fome parts of England, is eafily cultivated, and the root yields every year a great burden of excellent provender.

Thefe are great inducements for encouraging the cultivation of this plant, which feems adapted to any foil.

" I fowed three years ago, fays a writer in the Mufeum Rufticum, a rood of land, light, and but poor in quality, with this feed: this work was done early in the fpring, the land being prepared as for barley.

" I fowed it not in the broad-caft way, as I fhould have found much more difficulty to keep down the weeds; but I caufed a flight furrow to be drawn the length of the

the land with a light plough; and when the feed was thinly fprained, or rather dropped into this, another was drawn at a foot diftance, in which the feed was dropped in like manner.

"An interval, or fallow fpace, was then left at leaft two feet wide; then two more rows of the vetches, till the whole land was fown. I muft obferve, that I covered the feed by means of a light harrow with wooden tines, drawn backward and forward acrofs the land.

"When the plants came up, I had them well hoed, to clear the ground of weeds; and when they grew a little ftrong, they were fet out with the hoe to about a foot diftance in the rows, that they might have room to fpread and branch.

"The firft year they yielded no great quantity of fodder, but they have fince made me ample amends.

"The fecond fpring they came up very ftrong and vigorous, branching out much; and when I turned a couple of horfes in to feed, they were very fond of it, eating it very greedily, though they were taken out of a good, natural upland pafture.

"This laft fummer the land was almoft entirely covered, and it yielded a great deal of feed indeed: for experiment fake I caufed a few rods to be mowed juft before it flowered, and it made good hay, fweet, without being fticky.

"Before I conclude, give me leave to obferve, that when I had cut a few rods of the everlafting-pea, to make into hay, a fmall quantity of it was, by accident, fpread thin upon the ground, fo as to receive the full action of the fun's rays: this was, in a manner, fpoiled, becoming quite dry, infipid, and brittle, and almoft all the leaves dropping off; but the remaining part, which was dried either in fmall cocks, or thick fwarths, made excellent hay. I am, however, perfuaded that the laft method is by much the beft." *Mufeum Rufticum, vol. I. p.* 468.

EWE, the female fheep. *See the article* SHEEP.

Mr. Ellis, in his Treatife on Sheep, has given us the following fecret, which he pofitively afferts will make ewes take ram, at any time of the year. "Separate, fays he, fix or more of your ewes from the flock, and give to each half a pint of ftrong ale, or the fame quantity of good October, mellow, filky beer, and not that which is fharp by ftalenefs; and for giving it in the eafieft and fafeft manner, you may run the ale or beer through a funnel into the ewe's mouth; and when the ewes have been all thus ferved, put them into a proper place, not too large, nor too narrow, that the ewes may be confined with one or more rams, that have been before a little better kept than ordinary for this purpofe. Out of fix ewes, that I have known to take ram in this manner, not one of them has failed proving with lamb. By the above method, and the affiftance of a fufficient number of hands, an hundred ewes may be thus dofed with ftrong drink, and if rams enough are provided, they will all prefently take ram." *Ellis on Sheep, page* 297.

EXERCISE, a proper agitation given to an animal body, in order to produce falutary effects.

Exercife duly given to horfes that are well fed, is not only the beft means of all others to prevent ill habits, but to preferve them in a perfect ftate of health: for exercife converts the food into good and wholefome nourifhment, it promotes the circulation of the blood, and all the glandular difcharges, fo as greatly to enliven the body, and to make way for frefh fupplies of aliment. It invigorates the fpirits, gives ftrength and firmnefs to the mufcles and finews, and enables a horfe to endure labour. And when exercife is given abroad, in an open free air, it adds greatly to a horfe's vigour, and prevents any difpofition to putrid cohefions in the blood, which a clofe ftagnated air often produce, and this efpecially when horfes are young, and their appetites ftrong; for indeed when horfes grow old, their appetites are more moderate, and reft is oftentimes more agreeable to them than labour. Neverthelefs, exercife is, more or lefs, abfolutely neceffary for all horfes, young or old: for we may obferve, even old horfes, when they lie much ftill, though they are not apt, as young horfes, to turn directly fick, and fall into fevers: yet as their blood grows poor, and languid with age, they become fubject to many infirmities, as fwellings of their fheath and bellies, with other dropfical fymptoms, and fometimes to obftinate eruptions on their fkins, which exercife in a proper degree often prevents.

Horfes, by their natural activity, are every way fuited to exercife and labour, and in that refpect are more ufeful than any other of the brute creatures; only it depends on us, how they are to be treated, both for their own prefervation, and our benefit; and their food ought always to be proportioned according to their exercife. But the time and manner of a horfe's exercife is alfo to be regarded, for if he happens either to be worked at an unfeafonable time, or beyond his ftrength, it will be more injurious to him than if he had not been worked at all. Therefore this general caution is always needful, viz. never to ride a horfe hard, or put him upon any violent exercife when he hath been newly fed, and has his belly full of meat or water; but fhould be moved out at firft gently, and he will naturally mend his pace, as his food and water begins to affuage, when his rider may urge him on to further fpeed, as his bufinefs may require.

I need not tell any one, that when a horfe is hot with riding, or any other fharp laborious exercife, he fhould be cooled by degrees, this being known to almoft every ftable boy, from cuftom and ufe, though it is often neglected, through ignorance or idlenefs, or done with little judgment. And, therefore, when a man has travelled hard upon a journey, or when horfes have been driven hard in a coach or chaife, it is not fufficient, after they come to their bating place, or to the end of their day's journey, to walk them about in hand for half an hour or more, which is ufually done, but their pace fhould alfo be flackened for a mile or two before they come in, and after that, fhould alfo be walked fome time in hand, that they may cool gradually before they are brought into the ftable, with a thin cloth laid over each, if they have been ufed to it. This is the fafeft way with young horfes, that have been kept well, and have worked but little. And when fuch horfes come late to the end of their day's journey, or when the weather is fo bad, that they cannot be walked about in hand, they fhould then be well rubbed all over their bodies and limbs, till they are quite cool, without taking off their harnefs and faddles, and when cloathed; for when all the fmalleft blood veffels are replete and full, as they muft unavoidably be in all ftrong, and efpecially in long continued exercife, and the blood extremely heated, and running like a torrent, any fudden chill or damp will produce ftoppages and obftructions, where the veffels are the moft minute and fmall, or wherever there is the greateft weaknefs and relaxation, fometimes inwardly in the lungs, fometimes in the liver and kidneys, and fometimes in the ftomach and guts, and other membraneous parts; and this is ufually followed with inward pain, and inflammation, or with great dulnefs and heavinefs, which, in the end, often produce many untoward diforders; or if the limbs happen to be weak and relaxed, the blood and juices will foon drop down and ftagnate there, fo as to produce fwellings, and fometimes ulcerations, that are troublefome enough to remove, efpecially in thofe that have been little accuftomed to fuch kind of labour; for habit and ufe, in continued exercife, alters the cafe very much, becaufe that ftrengthens and invigorates the nerves and finews, as we obferve in fome hackney or job horfes, which are fo feafoned to their work, that fcarce any thing can hurt them. Indeed fome of the job horfes, that we fee endure fo much labour, are naturally ftrong, and very hardy, and have at firft been carefully managed by their owners, who are not able to bear the lofs of cattle, as gentlemen or men of fortune; and, therefore, we fee them generally, both begin and end their work with great coolnefs, and when they chance to meet with horfes that they find unable to go through their hard work, they ufually make their bufinefs only a mere play, that they may not lofe their flefh, until they can difpofe of them to the beft advantage. Another neceffary caution for the prefervation of our horfes, is never to feed them too foon, after they have been heated with exercife. *Gibfon's Farriery, vol.* I. *page* 182.

EXOTIC, foreign, not produced in our own country. Thus foreign plants and trees are called exotics, or exotic plants.

EXPERIMENT, a trial of any kind; an eſſay made in order to diſcover an uncertain, or unknown effect.

For the ſeveral experiments made on wheat, barley, &c. *ſee the proper articles* WHEAT, BARLEY, &c.

EXPOSURE, is the ſituation or aſpect of a garden or wall, with reſpect to the ſun and winds, and is therefore as various as the points of the compaſs, being either direct, as eaſt, weſt, north, or ſouth, or declining, as ſouth-eaſt, ſouth-weſt, &c. A garden ſloping to the ſouth is ſaid to have a ſouth expoſure or aſpect, or a wall with trees facing the eaſt, is ſaid to have an eaſt expoſure; the ſouth by eaſt, or ſouth ſouth-eaſt points, are generally reckoned the beſt expoſures for gardens, by reaſon they will enjoy the benefit of the morning ſun, and be leſs expoſed to the injuries of the weſt and ſouth-weſt winds, which in this climate are the moſt violent: the next beſt aſpect is the ſouth, particularly if the land is moiſt, but if it is of a dry nature, its product is very apt to be burnt up in hot ſummers, though it extremely well ſuits winter crops. With reſpect to walls, we would give the preference to the ſouth or ſouth-weſt expoſure for tender fruits; for although the eaſtern aſpect receives the invigorating rays of the ſun in the morning, yet the tender bloſſoms are very liable to be deſtroyed by the dry eaſterly winds, which generally prevail at the time the trees are in flower; therefore a wall with trees inclining a little to the weſtward of the ſouth, hath this advantage, that the bloſſoms receive but little damage from the froſts, which melt before the ſun comes to ſhine on them, and fall off like dew, without doing much harm; however, as there will be contrary aſpects, theſe may be planted with ſuch ſorts of fruits as do not require ſo much heat to ripen them; and wherever there are north aſpected walls, they are only fit for baking pears and plums, morello cherries for preſerving; or ſome duke cherries may be thus continued longer in the ſeaſon, as there is a month difference between the ripening on one ſide of the wall, and on the other.

EYE, the organ of ſight in an animal body; or that which repreſents objects to the mind.

The goodneſs or badneſs of the eyes of horſes is a thing wherein the beſt judges are ſometimes miſtaken; for moſt people regard the clearneſs and tranſparency of the eye, which indeed ought to be conſidered: but it is worth obſerving, that horſes, before they are ſix years old, have not that tranſparency in their eyes which they arrive at afterwards, becauſe while they are young and growing, their juices are viſcid and balſamic; ſo that their eyes look thicker or clearer, in proportion as their blood and juices happen to be more or leſs in a good ſtate. The ſame may be obſerved in all horſes that have colds, when the veſſels of the eyes are full: the eyes at that time look thick, and ſometimes inflamed, and a blow on the eye, or a bite, will have the ſame effect, when there is not the leaſt danger of blindneſs.

It is not, therefore, always the clearneſs of the eye that denotes its goodneſs, but a man is alſo to form his judgment from other indications, particularly from the form and manner of the eye, which includes not only the body of the eye, but the eye-lids, eye-brows, and all the parts belonging to it. Many good eyed horſes have a heavineſs in their countenance, with a lowering-brow, yet great numbers of this aſpect go blind with cataracts when they are about ſeven years old, or between ſeven or eight, and ſometimes later. Theſe are the moſt ſuſpicious where there is a bunch or fullneſs between the upper eye-lid and the eye-brow, with a fullneſs round the under eye-lid; ſo that the eye appears as if it was invironed in a ring. Such horſes are often fleſhy about the head and jaws, which, upon every cold, or rather ſlight accident, expoſes them to defluxions in their eyes.

When the eye is extremely flat or ſunk within its orbit, it is always a bad ſign, even though there be no defluxion or humour upon it: a ſmall pig-eye is none of the beſt, nor a large gogling eye. The one often periſhes for want of nouriſhment, occaſioned by ſome defect in the nerves or the arteries that ſupply it with blood; the other by being too much expoſed to accidents, and by having too great ſupplies of nouriſhment.

That eye is almoſt always weak which is of a longiſh oval figure, eſpecially where the two corners are narrow, like the ſhape of an almond. When the coat or membrane, that riſes from the under part of the eye happens to be large and thick, ſo as to preſs the eye-ball, and the caruncle or kernel on the inward corner next the noſe is ſpongy and moiſt, though there is ſometimes a remedy for this defect, yet ſuch horſes in the end generally go blind.

When the eyes are bad, the muſcles or movers of the eyes are generally weak; ſo if the eye looks dead and lifeleſs, the beſt way of trial is to hold up the horſe's head in the ſame manner as when a drench is to be given, which will draw the eye upward; and if it remains there fixed and immoveable, or has a languid motion, it is a pretty ſure ſign the eye is bad. And this trial will, for the moſt part, hold good whether the eye be moiſt or dry.

Some regard the colour of the eye, which, however, is different according to the difference of colour in horſes; and indeed we are ſo far to regard the colour, that if the iris or circle that ſurrounds the pupil or ſight of the eye be diſtinct, and of a pale variegated cinnamon colour, it always denotes a good eye. For the iris is always moſt diſtinct, where the humours of the eyes are moſt clear and pellucid; and thoſe horſes have the beſt eyes, which in colour reſemble the eyes of a ſheep or goat; but few horſes arrive to that perfection of colour and tranſparency, till they are at leaſt ſix years old or upwards. On the other hand, if the iris or circle round the pupil be of a dark muddy colour, and does not appear diſtinct and variegated, till one approaches near the eye, and if the narrow ſky-coloured verge, which we obſerve more or leſs in moſt horſes on the outſide of the iris, happens to be of a milky hue, it is of no good ſign. Nevertheleſs, wall-eyed horſes have for the moſt part good eyes.

Some in examining the eyes have a regard to the colour of the horſe, which I take to be no ſure way of judging; for as there are good horſes of all colours, ſo there are good eyed horſes of all colours. The grey, eſpecially the pigeon or dove-coloured grey, are the moſt ſuſpected; alſo the iron-grey, and the dun, &c. But I think I may ſay from experience, that whatever colour is the moſt common among the horſes, ſo as to exceed in number, abounds moſt with bad eyes: and I have obſerved as many bad eyed horſes among the black coach breed as any other.

Moſt people in examining a horſe's eyes lead him under a gate-way, or ſome ſhade, that they may ſee perfectly the colour and tranſparency of the eye: but the beſt way is to obſerve his countenance when he comes firſt out of a dark ſtable into a ſtrong light; for if he has any weakneſs in his eyes, he will wrinkle his brow, and look upwards to receive more light; and if the pupil at the ſame time be large, it is a bad ſign; and therefore the beſt way is to look to a horſe's eyes firſt in the ſhade, to obſerve the dimenſions of the pupil, and if that leſſens upon his coming out into a ſtrong light, it is almoſt an infallible ſign that the eye is good.

Some ſuſpect all horſes that ſtartle to have bad eyes; indeed many bad eyed horſes are apt to ſtartle: but a horſe that ſtarts and looks upwards, lifting his feet high when he moves, as if afraid to touch the ground, ſuch is more likely to have bad eyes than one that ſtartles; for many horſes ſtartle merely out of fear, and I imagine not a few from ſome defect in viſion, viz. from ſeeing objects indiſtinctly at ſome diſtance, in all which caſes the eyes may be ſtrong and durable, though many fancy them to be weak. But if a horſe frequently ſtartles when no object is before him that might cauſe him to ſtartle, we may then ſuſpect his eyes to be but indifferent.

Upon the whole, that eye is generally good where the eye-lids are thin, where the outward coat or tunicle of the eye is alſo thin and delicate, where the caruncle next the noſe is ſmall and dry, where the eye is tranſparent and ſprightly, when a horſe has a bold reſolute look, and takes notice of objects without fear. On the other hand, when a horſe moves his ears backwards and forwards, and ſeems ſurpriſed at every noiſe or motion of the hand; when he raiſes his feet high, is uncertain in his walk or ſtep, and unequal in his goings, when his eyes appear full and ſwoln with a fleſhy circle round them, or when they are ſunk or flat, or of a longiſh oval figure, when the outer coat is thick and covers a great part of the eye-ball, and the glands or kernels of the eye are ſpongy and moiſt,

all

all these denote the badness of the eyes, and are often the forerunners of blindness. *Gibson's Farriery, vol.* I. *page* 14.

EYE *of a tree*, a small pointed knot to which the leaves adhere, and from which the shoots or sprigs spring forth.

EYE, among gardeners, implies the small bud or shoot inserted into a tree.

EYE-LID, the membrane that covers the eye.

If the eye-lid of a horse is wounded and cut through, and the cut divides it so as the lips part one from the other, it ought to have a stitch with a strait needle, such as the surgeons use for superficial wounds, and not to be drawn too close, but just so far as to bring the edges together; and this is yet the more necessary when the eye-ball happens to be wounded through the eye-lid, that there may be room for the discharge of the matter. I have observed that the eye-lid requires but one stitch, for when there are more, and these pursed together, as the farriers generally do, and the lips drawn close, such stitches will break in twenty-four hours, and leave the wound in a worse condition than it was at first.

The proper dressing for wounds of the eye, is honey of roses, and tincture of myrrh, viz. one dram of the tincture to an ounce of the other. The best way of using it is to dip a pledgit of lint in this mixture, made warm, and applied to the wound, for tow and hurds are too harsh for the eye. This dressing may be repeated once a day, until the wound is healed up and cicatrised, and it will seldom fail of success. *Gibson's Farriery, vol.* I. *page* 320.

F.

FALLOW, land ploughed, but not sown, being left to rest after the years of tillage.

If the farmer finds that one summer's fallow does not entirely answer the purpose of dividing and loosening the earth, it is his interest to continue it for another. M. Tull confirms this, by instancing a poor man, whom necessity compelled to take this method, because he could not get seed for his ground after he had tilled it the first year. The consequence was, that his crop was worth more than the value of the land it grew on. Mr. Maxwell too mentions another, who, from a like necessity, followed the same course upon almost his whole farm, had such a crop as enabled him to pay many debts, and, by continuing the same practice, came in few years to be in a condition to purchase the farm.

When the husbandman intends to break up any piece of land, the first thing necessary is carefully and judiciously to examine the surface of the ground, and its depth. If the surface be covered with a thick, strong, fibrous turf, and the mould underneath sufficiently deep, his best, and indeed the only right method of proceeding, is excellently well directed by the marquis of Turbilly. But if, on the contrary, the upper mould should be shallow, or so thin turfed as not to be fit for burning, he must observe, whether his soil be of a strong, or of a light quality. Under the former of these are included all deep hard clays, of what colour soever; all stiff binding earths, and such as, after being exposed to the sun, or frost, grow hard and stony; with such as chop and cleave upon their surface in the heat of summer: and under the latter are ranked (the repetition may be excusable here for the sake of perspicuity) all sandy, mouldering, gravelly, mellow soils; all loose and open earth, of what nature soever; all such as are not sticky, but will soon dry after rain; and, instead of lying in great lumps after ploughing, are easily apt to dissolve, and crumble into mould, not being subject to bind by the heats in summer, or frosts in winter.

If, upon examination, the soil is found to be of the stiff kind, particular care must be taken to turn down its surface in the latter end of autumn, that what fibrous roots there are in it may be the more effectually rotted against the summer ploughing, and that the earth may be mouldered, or mellowed, by the winter's frost and rains.

When ploughed land is intended to be fallowed, it should likewise be ploughed in the autumn, as soon as the seed time permits, and laid as rough as may be, especially if it be a stiff soil, that the winter's frost may mellow it.

In the spring, the farmer should take the earliest opportunity that his spring crops will admit of, to give his fallows a second ploughing across the former; after which the ground should be well harrowed, not only to break the clods, but to pull up such roots as are not yet rotted, that they may be gathered into heaps and burnt. It is essentially necessary that this, and all the following ploughings and harrowings be performed in dry weather; because, as the purpose here is thoroughly to loosen the mould, special care should be taken to avoid every thing which might counter-act that intention. The farmer cannot wish for a greater benefit to his husbandry, than moderate showers after each fallow, to bring the seeds of every weed to vegetate, in order that, being turned down by the several ploughing, they may be the more effectually destroyed.

It seems needless to mention when the future ploughings should be given, because the farmer should take every opportunity of repeating both them and the harrowings, in full confidence that he cannot over-do it, especially in strong soils; in which he may also be equally certain, that he cannot err in ploughing too deep: for it is of great consequence, not only that the roots have a sufficient depth of mould to penetrate in, but also that the cold clay be removed to as great a distance as possible from the surface; because, by its retaining the water, the roots of plants are chilled and killed, efpecially in the winter, when they reach fuch ftagnating wet. If any manure is applied to alter the quality of the foil, it cannot be laid on too early in the fummer, that the ploughings may the more effectually mix it with the earth; but if only compoft be ufed for enriching the foil, it need not be fpread till juft before the laft ploughing.

Authors give directions for ploughing land into many different forms, moftly arifing from the different natures of foils, but too often from the particular long eftablifhed cuftom of countries, the reafonablenefs of which is not always fufficiently confidered.

Where there is a defcent for water, all lands fhould be laid flat, becaufe, in that way, the rains will undoubtedly give a more equal nourifhment to the crop, than when they are raifed in ridges. The practice of laying light foils into narrow ridges, for wheat, is certainly owing to want of attention; and even in ftrong land ploughed for winter fallowing and fowing, we are much inclined to think that the beft way would be, inftead of fingle bouts, or narrow ridges, to make the ridges very broad, and lay them up high: for if the ground is level, the water will lie in the parting thoroughs, and, by foaking into the fides of the ridges, make it fo poachy, as to render it very unfit to be worked, till late in the fpring, unlefs the feafon be very dry; or, if there is much defcent, great part of the beft foil will be carried off. For the fame reafons the fides of hills fhould always be ploughed almoft, but not quite, horizontally, that the parting thoroughs, lying open, may ferve for drains to the water: befides which, the ploughing of fuch declivities in this floping manner is by much the leaft laborious both to men and cattle. The furrow here fhould always be drawn oblique, as Columella directs, fometimes a little toward the higher, and and fometimes toward the lower part of the hill, fo that the direction may be altered in each fubfequent ploughing.

The erroneous opinion of thofe who imagine that the furface of the ground is confiderably enlarged by ploughing it into high ridges, and that it therefore affords a larger fpace for the growth of plants, is thus judicioufly refuted by M. Duhamel.

" The produce of a floping furface is not greater than that of a plane equal in extent to the bafe of the flope: for as the plants grow perpendicular to the horizontal bafe, there is no point of the flope which does not anfwer vertically to a point of that horizontal bafe: therefore, fuppofing the furrows of a piece of ground ploughed in broad lands to be fix inches deep, and the ridges fix feet wide; the flope from the bottom of the furrow to the middle of each ridge will be one foot in fix, which is indeed confiderable: but ftill the furface of the ridges will be to that of their horizontal bafe, only as feventy-fix are to feventy-five: a fmall advantage; efpecially when compared to a fixth part of the ground, which is taken up by the furrows, and in which no corn is fowed."

Another, and that very effential, advantage of fallowing, not yet fufficiently infifted on, is the deftruction of weeds, which are one of the farmer's greateft enemies. By weeds, we here mean every plant which grows fpontaneoufly in the field, without having been purpofely fown, and which it is not the hufbandman's intention to cultivate. All thefe fhould be rooted out. It would be needlefs to enumerate them after this general definition; and perhaps equally fo to obferve, what every hufbandman muft know, that cockle, darnel, fox-tail, wild poppies, wild vetches, wild oats, dog's grafs, colt's foot, melilot, knot-grafs, thiftles, and charlock, are the moft hurtful fpecies of thefe noxious growths, and the moft difficult thoroughly to extirpate.

To prevent the increafe of weeds, they fhould be deftroyed before their feed is ripe: but that is not poffible in lands which are ploughed in the common way; becaufe, as they grow intermixed with the corn, and ripen fooner than wheat, their feeds fow themfelves: neither can they be extirpated by refting the land; for the feeds of fome of them will remain found feveral years in the earth. If a field in which there are many poppies, or red-weeds, as they are called in fome places, be fowed with faintfoin, fcarce a poppy will appear the fecond year: but when the faintfoin is ploughed up, even at the end of nine years, the red-weed frequently appears a-new, which can hardly be owing to any other caufe, than that its feeds have remained found in the earth during all that time; for very few of them, in proportion to the quantities which fpring up, can have been brought from the neighbouring grounds, or in dung. This is confirmed by an experiment which M. Duhamel made. He ordered the earth, with which a ditch had been filled fifteen or twenty years before, to be dug out, and fpread upon a piece of ploughed land. Several plants, of different kinds from any that were in the field, fprouted up in the place where this earth was laid. Confequently they were produced by feeds which had remained found in the ground, during the fifteen or twenty years that this earth had lain in the ditch.

This is an important reafon for ploughing thoroughly all lands which are fallowed: for it is certain, that as numbers of feeds fhoot up during the fallow, repeated ploughing will deftroy many of them. But there are feveral kinds of plants, fuch, in particular, as wild oats, and fox-tail, the feeds of which do not fprout till they have remained two or three years in the earth; nor will culture make them grow fooner. Such, at leaft, is M. Duhamel's opinion, as well as that of feveral other very ingenious gentlemen, though it muft be confeffed, that fome late experiments feem to contradict it, and to fhew, that the feeds of thofe plants which he fays require being three years in the ground before they will grow, were only buried fo deep, in the cafe he mentions, as not to be able to vegetate, which they afterwards did when laid within reach of the influences of the air, rain, dew, &c. If fo, though the increafe of weeds may be prevented for feveral years, by ploughing, cutting, pulling them up, &c. yet it is evident, that the repeated ploughing of fallow lands, far from immediately deftroying thefe kinds of weeds, will rather help them to grow, when their feeds are brought within a proper diftance from the furface, and their time of fprouting is come. But then, allowing that fome of their feeds may be thus brought up by each ploughing, for a while, it cannot be long before all of them will have fprouted, after which the ground may be kept quite clear, with proper care.

Hufbandmen have not yet found a more effectual method to deftroy weeds, than by fowing the ground out of feafon; that is to fay, by fowing oats the year that barley fhould be fowed. It has been experienced, that, by this means, fome kinds of weeds have been deftroyed, which, appearing only every third year, never fhews themfelves, in the ufual rotations, but amongft wheat. But the farmer loofes a crop by this means, and ftill has fo many weeds left, that he is obliged to hire people to weed his corn. This is done two ways.

A number of women place themfelves in a row, and, with a hoe made for the purpofe, cut up all the weeds they fee, fuch as thiftles, blue-bottles, poppies, &c. But many of thefe, when young, frequently efcape their notice; in which cafe the hoeing muft be repeated when they are grown larger; and the fmaller weeds, fuch as wild vetches, wild oats, darnel, knot grafs, fox-tail, young poppies, &c. which are at leaft as hurtful as the other, remain in the field. Befides this, in cutting the weeds, it is fcarce poffible not to cut down fome of the corn; and the roots of the thiftles and other biennial plants which are cut, produce two or three new ftalks in lieu of the old one; by which means the evil is increafed.

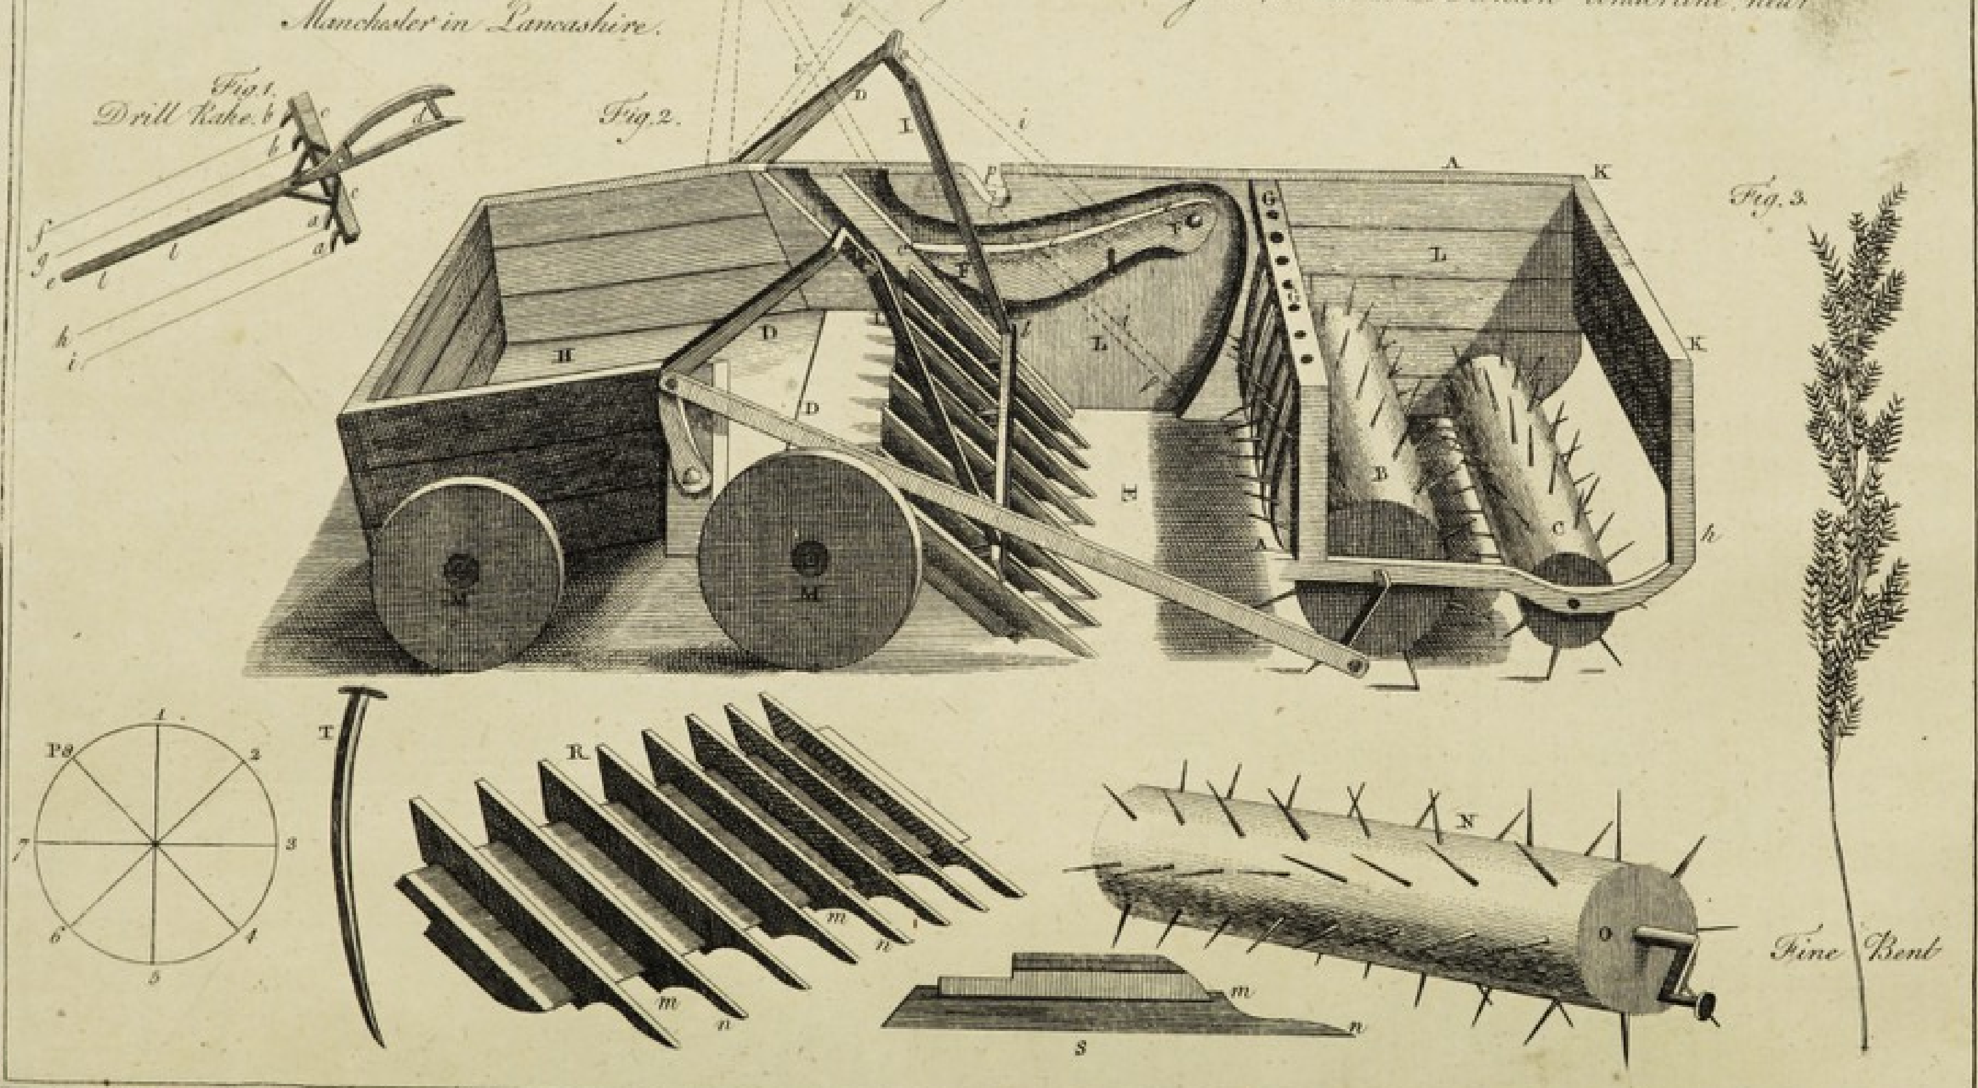
The other method of clearing corn, is by hand-weeding it; but this is feldom practifed by farmers, becaufe it is too expenfive: and indeed the women and children generally employed to do this work, moft commonly pull up a great deal of corn with the weeds; fo that, what with that, and with their trampling, and dragging their bags of weeds over it, they frequently do more hurt than good, efpecially if the earth be moift.

The fureft way to deftroy weeds, is to continue ploughing while the corn grows: but this can be done only in the new hufbandry.

Weeds may be ranked under four general claffes: firft, fuch as have creeping perennial roots: fecondly, fuch as grow in cold wet foils: thirdly, fuch as are of a large fucculent body; and, fourthly, fuch as having fmall feeds, or feeds which ripen before the corn, fow themfelves. Each of thefe require a different treatment.

The

A Fallow-cleaning Machine, Invented by Mr. Aaron Ogden, a Smith at Ashton Underline, near Manchester in Lancashire.



The first sort cannot be destroyed but by repeated summer fallows, by which their roots are cut, and turned up to be withered by the sun and winds, after which they are dragged out by harrows, and should be burnt. This, repeated as often as the farmer conveniently can, especially during a dry season, can scarcely fail to have the desired effect. Colts-foot, which is propagated by the root, and is a very pernicious weed, may likewise be destroyed by sowing the ground with rye-grass, or any plant which, coming up early in the spring, shades and smothers it; for that will kill it in a few years. The second kind are destroyed by draining the earth of its superfluous moisture, and by manuring it with lime, ashes, gravel, shelly sea-land, and other proper correctives for such soils.

The third are extirpated by cutting them down when in full sap and vigour: for the sap being thereby suddenly interrupted in the course of its circulation, stagnates in the roots, and putrifies there. A few weak lateral shoots may be made; but if they are likewise cut in the same manner, the roots will putrify intirely by degrees, and, instead of annoying, will become a manure.

The fourth class can be destroyed only by frequent fallows, and constant cutting, or rather ploughing them down before they run to seed. Some, for instance the wild oats, may be mowed for hay: but it is much more beneficial to the land to plough them in: because, by that means, instead of being exhausted by frequent crops, it is manured by those enemies to useful grain.

FALLOW, also signifies a pale red colour.

FALLOW-CLEANSING *Machine*, an instrument invented by Mr. Aaron Ogden, a smith at Ashton-under-Line, near Manchester, in Lancashire.

This machine, which bids fair to be of very great use in husbandry for cleaning fallows from weeds, &c. which waste the riches of the soil, will be very easily understood from the drawing we have given of it on Plate XV. Fig. 2. Where,

A, A, is the frame; B, the first roller; C, the second ditto, in which last are two cranks to move the arms D, D, which work the rake up the directors fixed on the plank E. The under side of the lower ends, or shares, of these directors, are sharp to cut the clods, and let them come on the upper side. Each alternate heel of the share is longer than the intermediate one, that they may not have more than one half to cut at once.

At the back of the plank E, are two screws to let it loose, that the directors may be set higher or lower. The shares are to penetrate the ground two or three inches, to raise the quicks till the rake I, I, fetches them into the cart H, where a man must be ready with a muck-hook to clear them backward when gathered.

In the rake I, are two teeth for every space of the directors, that stones, &c. may be gathered without damage.

K, K, are two staples, by which the machine is drawn: under them, at *h*, are two hooks, placed low to raise the machine in turning, by the help of the traces; and the axle-tree of the cart should be fixed upon a pin, that it may turn like a waggon.

F, F, are the triggers to throw the rake behind the roots. The long teeth at G, G, are to cleanse the roller C.

I, I, is the rake which gathers up the weeds into the cart H, and is drawn above the trigger F, by the working of the arms D, expressed by the dotted lines at *d d*, *i i i*.

The triggers F, of which there is one on each side, move on the pivots *a*; so that when the points *b*, of the rake I, having been drawn up by the directors E, to the part marked *c*, the trigger, giving way, permits the rake to pass; but immediately falling, the rake returns along the upper surface of the trigger marked *e*, *e*, and of course falls on the weeds when it comes to the end, a little beyond the pivot *a*.

The reader will observe that the boarding is taken away on one side, in the plate, in order to give a more perfect view of the inner parts of the machine; and, in fact, it would, perhaps, be better if all the boarding, marked L, L, L, was taken away, and frame-work put in its stead.

The cart H, might undoubtedly also be made lighter.

The wheels M, M, appear, in the plate, to be made of solid wood; but there is no necessity they should be so.

At N, is another view of the roller C, by which the disposition of the spikes may be easily comprehended.

Suppose the circle O, described by the end of the roller N, to be divided by four strait lines into eight equal segments, as represented at P. Let the same be done at the other end of the roller, and parallel lines be drawn from one corresponding point to the other, the length of the roller: mark the points with figures 1, 2, 3, 4, 5, 6, 7, 8; afterwards draw oblique lines, as from 1, at the end O, to 2, at the other end, and from 2 to 3, &c. on these oblique lines the spikes are to be fixed, at equal distances, in eight circles, described on the circumference of the roller.

The spikes of the small roller B, are fixed in the same manner, except that, the diameter being smaller, there are only six instead of eight rows.

R, is another view of the directors, with the plank E, on which they are fixed; and at S, is a section of a part of the plank, with one of the directors as fixed, in which may be seen the heel *m*, from whence, to the point of the share *n*, is a sharp, cutting edge. See the same letters in figure R.

At T, is one of the long teeth to be seen at G: it is bent towards the roller C, which it serves to cleanse. When the end of the rake *b*, after rising above *c*, is pushed, by the motion of the arms D, D, along the upper part *e*, *e*, of the trigger F, and comes to the end beyond *a*; as it falls, the part of the arm, marked *o*, rests in the notch *p*, till it is again raised by the motion of the roller C, with the rake.

The roller C, is to be one foot diameter, the spikes nine inches long, that they may go through the furrow (if the soil should be too loose) into the hard earth, the more effectually to work the rake, which otherwise might be so over-charged as to cause the roller to drag without turning.

In the rake-ends *b*, there should be pivots, with rollers or pullies on, to go in the groove, to take off the friction; and they would likewise take the triggers more surely as the rake comes back.

The rake should also be hung so far backwarder, that when it is fallen, the arms of it may lie in the same plane, or parallel, with the directors, on which it comes up (which will require the frame to be two inches longer in the model.) This will cause the rake to fall heavier, and drive the teeth into the roots, and bring them up without shattering. These teeth must be made of steel, very fine, and so long as to reach down to the plank on which the directors are fixed, that is to say, six inches long (the directors are to be also made six inches broad above the plank.) The rake-head should also fall a little before the crank is at the extremity, which will cause the rake to push forward to let the teeth come into the roots. The rake-teeth must drop in the same plane with the roller and wheels, or on the surface of the earth. No more space should be given from the roller C, to the long teeth, at G, G, than that the rake may just miss the spikes of the roller C, and fall on the places before mentioned.

As the first roller B, was intended to cleanse the second C, more than any other use, it may be omitted when the machine is made in large, as Mr. Ogden has lately found that the long teeth at G, G, answer the end alone, and this renders the machine about a sixth part shorter.

Now, to suit any sort of earth, there should be to each machine three planks, with directors at different spaces, to use occasionally: in the first, the spaces between the directors should be eight inches wide, in the second six, and the third four. This will answer the same end as having so many machines.

As there may be some objections to the rake not leaving the roots when it has brought them up, Mr. Ogden has several methods for cleansing it; but as he would make it as simple as possible, he chuses to let it be without them at present: but suppose it should bring some roots back again with it, it will probably lose them before it gets back to the extremity; whence they will lie light, and be of but little detriment to the others coming up.

Mr. Ogden would have the first machine made four feet six inches wide, the teeth divided into equal spaces, the outsides into half spaces.

FAN, an inftrument for winnowing corn. *See the article* WINNOWING.

FANTOME CORN, thin, or light corn, that which has but little bulk or folidity.

FARCY, or *Farcin*, a diftemper to which horfes are too often fubject. It is a difeafe of the blood veffels, generally following the courfe of the veins, and, when inveterate, thickens their coat and integuments.

At firft one or more fmall fwellings, or round buds like grapes or berries, fpring out over the veins, and are often exquifitely painful to the touch; in the beginning they are hard, but foon turn into foft blifters, which, when broke, difcharge an oily or bloody ichor, and turns into very foul and ill-difpofed ulcers. In fome horfes it appears on the head only; in fome on the external jugular; in others on the plate-vein, and runs downwards on the infide of the fore-arm towards the knee, and very often upwards towards the brifket; in fome the farcy fhews itfelf on the hind parts, about the pafterns, and along the large veins on the infide of the thigh, rifing upwards into the groin, and towards the fheath; and fometimes the farcy makes its appearance on the flanks, and fpreads by degrees towards the lower belly, where it often becomes very troublefome.

When the farcy appears on the head only, it is eafily cured, efpecially when it is feated in the cheeks and forehead, the blood-veffels being here fmall; but it is more difficult when it affects the lips, the noftrils, the eyes, and kernels under the jaws, and other foft and loofe parts, efpecially if the neck-vein becomes chorded. When it begins on the outfide of the fhoulder or hips, the cure is feldom difficult; but when the farcy arifes on the plate-vein, and that vein fwells much, and turns chorded, and the glands or kernels under the armpits are affected, it is hard to cure; but more fo when the crural veins within-fide of the thigh are chorded, and befet with buds, which affect the kernels of the groin, and the cavernous body of the yard. When the farcy begins on the pafterns or lower limbs, it often becomes very uncertain, unlefs a timely ftop is put to it; for the fwelling in thofe dependant parts grows fo exceffively large in fome conftitutions, and the limbs fo much disfigured thereby with foul fores and callous ulcerations, that fuch a horfe is feldom fit for any thing afterwards, but the meaneft drudgery: but it is always a promifing fign, wherever the farcy happens to be fituated, if it fpreads no farther. It is ufual to affect only one fide at a time, but when it paffes over to the other, it fhews great malignancy; when it arifes on the fpines, it is then for the moft part dangerous, and is always more fo to horfes that are fat and full of blood, than to thofe that are in more moderate cafe. When the farcy is epidemical, as fometimes happens, it rifes on feveral parts of the body at once, forms nafty foul ulcers, and makes a profufe running of greenifh bloody matter from both noftrils; and foon ends in a miferable rot.

From this defcription of the farcy, it will appear how greatly thofe may be difappointed, who depend on fome fingle fpecific drink or ball for a certain cure; for the fymptoms are fometimes fo favourable, that it is eafily conquered by a very fimple management; and when it arifes fuperficially upon the fmaller veffels, it will often go off, with moderate labour, without any other means than bleeding. Such inftances as thefe may eafily give a reputation to things of no great efficacy, and bring them into efteem: but whoever has acquired any true notion of the farcy, will know that this diftemper is not to be conquered but by fuch things as are fitly adapted to the various fymptoms that occur in the different ftages of it. To avoid therefore the perplexity that arifes from the various complications fo ufual in the farcy, we fhall confider it in its different ftates, or degrees, viz. when it feizes only the fmaller veffels; when the larger veins are chorded, and the feet, pafterns, and flanks affected; and laftly, when the farcy, beginning on one fide only, breaks out on the other alfo, and affects the whole body.

When the farcy makes its firft appearance on the head, it rifes on the cheeks and temples, and looks like a net-work, or fmall creeping twigs full of berries. Sometimes it inflames the eye, and fometimes little blifters or buds run along the fide of the nofe. It arifes often on the outfide of the fhoulder, running along the fmall veins with heat and inflammation; and fometimes a few fmall buds appear near the withers, and on the outfide of the hip. In all thefe appearances, the difeafe being fuperficial, and affecting only the fmaller veffels, is eafily conquered by the following method, when taken in time; for the fimpleft farcy, if neglected, may degenerate into the worft fort.

This diftemper then being of an inflammatory nature, and in a particular manner affecting the blood veffels, muft neceffarily require large bleeding, particularly where the horfe happens to be fat and full of blood. This always checks the beginning of a farcy, but is of fmall fervice afterwards; and if a horfe is low in flefh, the lofs of too much blood fometimes proves injurious. After bleeding, let the horfe have four ounces of cream of tartar and lenitive electuary; which may be given every other day for a week, to cool the blood, and open the body; and then give nitre three ounces a day, for three weeks or a month; and anoint the buds and fwellings with the following ointment twice a day.

" Take ointment of elder four ounces, oil of turpentine two ounces, fugar of lead half an ounce, white vitriol powdered two drams; mix together in a gally-pot."

The buds fometimes by this method are difperfed, leaving only little bald fpots, which the hair foon covers again. When they break and run, if the matter be thick and well digefted, they will foon be well: but in order to confirm the cure, and to difperfe fome little lumps, which often remain for fome time on the fkin without hair, give the liver of antimony for a month; two ounces a day for a fortnight, and then one a day for the other fortnight; by following this method, a farcy which affects only the fmall veffels, may be ftopped in a week or ten days, and foon after totally eradicated.

When the farcin affects the larger blood veffels, the cure is more difficult; but let it always be attempted early; therefore, on the plate, thigh, or neck-veins appearing chorded, bleed immediately on the oppofite fide, and apply the following to the chorded vein.

" Take oil of turpentine in a pint bottle fix ounces, oil of vitriol three ounces; drop the oil of vitriol into the oil of turpentine by a little at a time, otherwife the bottle will burft; when it has done fmoaking, drop in more oil of vitriol, and fo on till all is mixed."

This mixture is one of the beft univerfals in a beginning farcy; but where it is feated in loofe flefhy parts, as flanks or belly, equal parts of the oil of vitriol and turpentine are neceffary.

Rub the parts firft with a woollen cloth; and then apply fome of the mixture over the buds, and wherever there is any fwelling, twice a day. Give the cooling phyfick every other day, and then three ounces of nitre every day for fome time. This method muft be continued till the buds digeft, and the chord diffolves; and when the fores run plentifully, the matter digefts well, and the lips and edges are no ways thick or callous, you may expect a fpeedy recovery; yet to confirm the cure, and prevent a relapfe, give the liver of antimony or crude antimony, as before directed; and to heal the fores and fmooth the fkin, drefs with bees-wax and oil.

When the farcy begins on the flanks, or towards the lower belly, it often takes its rife from a fingle puncture of a fharp fpur. The pain and fmarting is one fure fign to diftinguifh the farcy from common accidents: the ftaring of the hair, which ftands up like a tuft all round the buds or blifters, and the matter that iffues from the buds, which is always purulent, and of a clammy greafy confiftence, are other certain figns. After bathing with the mixture above-mentioned till the ulcers are fmooth and healing, fhould the fwelling not fubfide, to prevent the fpreading of the buds, and to difperfe them, bathe with either of thefe mixtures as far as the center of the belly; and at the fame time give a courfe of antimonials, as will prefently be prefcribed.

" Take fpirits of wine four ounces, oil of vitriol and turpentine of each two ounces, white wine vinegar or verjuice, fix ounces."

Or the following:

"Take fpirits of wine rectified four ounces, camphor half an ounce, vinegar or verjuice fix ounces, white vitriol, diffolved in four ounces of fpring water, one ounce; mixed together."

In the lower limbs the farcy lies fometimes concealed for a great while, and makes fo flow a progrefs, that it is often miftaken for greafe, or for a blow or kick; and goes by the general appellation of a humour fettled there. In order to diftinguifh the one from the other, we fhall obferve that a kick, or bruife, is generally attended with a fudden fwelling, or a contufed wound, which for the moft part digefts eafily; the greafe is alfo a fmooth fwelling that breaks out above the bending of the pafterns backwards; but the farcy begins on the paftern-joint ufually with one bud, and runs upwards like a knotty crab-tree.

Very fimple means has fometimes ftopped it, before it has began to fpread; a poultice with bran and verjuice bound round the part, and renewed once a day, will often alone fucceed; and if proud flefh fhould arife, touch it with oil of vitriol, or aqua-fortis, an hour before you apply the poultice; for when the diftemper is local, as we fuppofe it here, it is to be conquered by outward applications.

When the diftemper grows inveterate, and refifts the above method, and the veffels continue chorded, Gibfon recommends the following mixture:

"Take linfeed oil half a pint; oil of turpentine and nitre, of each three ounces; tincture of euphorbium and hellebore, of each two drams; the foldiers ointment, two ounces, or oil of bays; oil of origanum, half an ounce; double aqua-fortis, half an ounce. After the ebullition is over, add two ounces of Barbadoes tar."

Rub this into the chorded veins, and wherever there is a fwelling, once in two or three days; but if the orifices are choaked up with proud flefh, or the fkin fo much thickened over the ulcers as to confine the matter, in either cafe it is neceffary to make an open paffage with a fmall hot iron, and deftroy the proud flefh, after which it may be kept down by touching with oil of vitriol, aqua-fortis, or butter of antimony. A falve may alfo be prepared with quickfilver and aqua-fortis, rubbing any quantity of the former with enough of the latter, to the confiftence of a liniment; fmear the ulcers with this whenever they appear foul, and you will find it preferable to moft other eating ingredients.

Our farriers after opening the buds, put in ufually a fmall quantity of corrofive fublimate or arfenic, which they call coring out the farcy; this may anfwer where the buds are few, and not fituated near large blood veffels, joints, or tendons: others ufe Roman vitriol, or fublimate and vitriol, in equal quantities: but let it be remembered, that many a horfe has been poifoned by thefe medicines ignorantly ufed, and in too large quantities; which fhould be a caution to huntfmen not to fuffer their hounds to feed on the carcafes of farcied horfes, as the greateft part of a pack have been poifoned by that means.

I fhall now mention fome of the defperate methods, and more violent kinds of medicines given by fome internally: thus, from four to eight ounces of lapis caliminaris, to which two ounces of tutty, finely powdered, is added, with other metallic fubftances have been given. Some give a pound of barrel foap boiled in ftale beer; with favin, rue, and other herbs of that intention: others go yet further, being determined to kill or cure, by giving drinks prepared with green vitriol, roche-allum, Roman vitriol, oil of vitriol, boiled in chamber-lie, with hemp-feed, hemlock, and common falt. Thofe who ufe nothing but the decoctions or juices of herbs, fuch as wormwood, rue, or elder particularly, ftand a much better chance for a cure, if given in time; but when the diftemper is grown inveterate, nothing comes in competition with mercurial and antimonial medicines.

The following balls are proper in every ftate of the farcy; and when the diftemper has been in its infancy, before the fkin was much defaced, has often cured it in a week or two, by giving them only once or twice a day: but in an old farcy, they fhould be given for two or three months together.

"Take of native cinnabar, or cinnabar of antimony, eight ounces; long birthwort, and gum-guaiacum powdered, of each four ounces: make into a pafte with honey, and form into balls of the fize of a large walnut, and roll them into liquorice powder."

The tedioufnefs of this courfe has encouraged the giving of mercurials, and indeed, where they are directed with fkill, they muft be attended with fuccefs; the ftronger preparations, as the red and white precipitates, and turbith, being combined with fharp faline parts, may be hazardous and injurious, but the latter given in fmall quantities have been found very fuccefsful in fuch kind of inveterate diforders. Mr Gibfon fays, he has given it to a dram at a dofe, where the limbs have been greatly fwelled; that in forty-eight hours the fores were all dried up, and the limbs reduced; but that it made the horfe fo violently fick for feveral days, and fcoured him to fuch a degree, that it could not be repeated.

One would have thought, that the fuccefs attending this medicine fo fuddenly might have encouraged Gibfon to have made further trials in fmaller quantities; which, had he done, it is more than probable, he would not have been difappointed: for the grand fecret in giving mercurials, as alteratives, is the introducing them into the blood, without operating on the ftomach and bowels; and to do this effectually, they muft be given in fmall quantities, and fo bridled, as to controul their force on the firft paffages: taken in this manner, they will mix gradually with the blood and juices, and operate both effectually and fafely.

The method I would recommend is as follows: give one fcruple, or half a dram of turbith, mixed into a ball, with an ounce of Venice foap, every other night for a fortnight; then abftain a week or ten days, and repeat it again. Should this ball purge, or make the horfe fick, mix it up with two drams of philonium, or with four or five grains of opium, or camphor; with thefe reftrictions, it may be given for fome weeks; but fhould the horfe's mouth be found tender or fore, you muft refrain giving, till that complaint is removed by gentle purges; and then return to it again in fmall quantities; for as the effects of mercurials are very different in the different conftitutions, both of horfes, as well as men, fo the quantity muft be varied in proportion to the operation, which is not intended here to be fenfible, but to work imperceptible on the blood and juices, correcting them as a powerful alterative. During the whole courfe, particular care fhould be taken that he gets no cold.

Two ounces of quickfilver, divided with an ounce of turpentine, and made up into four balls, with diapente, and gum guaiacum, of each two ounces, and a fufficient quantity of honey, have, for this purpofe, been fuccefsfully given, one ball twice a week; but gentle purgatives fhould be interpofed, to prevent a falivation, which fome horfes are very prone to, on taking mercurials, though in fmall quantities.

Dr. Brachen recommends the knots and chords to be rubbed with the mercurial ointment before they break, in order to difperfe them, and, after breaking, to drefs the fores with equal parts of Venice turpentine and quickfilver; if by thefe means the mouth fhould become fore, treat as above. This method feems to be effectual with proper care.

The following is alfo recommended by the fame gentleman.

"Take butter of antimony, and bezoar mineral, of each an ounce, beat up with half a pound of cordial ball, and give the bignefs of a walnut, or three quarters of an ounce every day, for two or three weeks, fafting two or three hours after it."

As moft preparations from antimony are of ufe in the farcy, fo from two drams of antihecticum poterii to half an ounce, may be given with a bit of cordial ball every other day, for fome time; for in thefe obftinate cafes the very crafis of the blood muft be altered, which can only be affected by degrees, and of courfe is a work of time. *Bartlet's Farriery*, p. 178.

WATER-FARCY. *See the article* WATER-FARCY.

FARDING-BAG, the firft ftomach of a cow, or any other ruminating animal.

FARE, *of pigs*, the number a fow bringeth at one time.

FARM, a portion of ground cultivated either by the owner or a tenant.

The ancient writers on hufbandry, who lived in warm countries, where the heat and moifture of the air had fenfible and frequently very dangerous effects on the health of the inhabitants, were very particular in their directions, for the choice of farms or eftates, and of the fpots whereon houfes fhould be built, fo as to avoid the inconveniencies arifing from the climate, or from the quality or fituation of the ground.

Though the temperate air which we enjoy in this ifland renders fuch directions lefs neceffary here, yet as feveral places in it are remarkably fickly, and as, even in the moft healthy fituations, many houfes and villages are built on the leaft healthy fpots, it muft be of confiderable advantage to thofe who can make their choice, to know what foils and places ought to be avoided; and of fuch as are already fixed, to be acquainted with the means of correcting thofe inconveniencies which cannot be totally remedied.

Inftructions of this kind are now full as neceffary in our language, as they ever were in the Greek or Latin, the countries in which Englifh is fpoken being more extenfive, and more various in their climes, than even the Roman empire ever was.

The facrifices of the ancient Romans fhew how attentive they were even in the choice of the ground they encamped upon: much more were they fo in that of the fituation and nature of the place where they laid the foundations of more lafting buildings. They examined the livers of the cattle fed on the fpot, when they offered them in facrifice; and if thefe were livid or corrupted, they offered others, as the unfoundnefs of the firft might be owing to fome cafual diftemper: but if they were often found to be morbid, they concluded that the air, water, or food which the place yielded, would have a like effect on human bodies, and therefore fpeedily left that ground, to fearch for a better fituation. If after repeated trials, they found the livers good, they judged the air and food to be fo likewife, and fettled accordingly. We may ftill obferve the good effect of this precaution, in the healthy fituations of the remains of Roman encampments: for they preferred health to every other confideration.

The Romans had pleafure, as well as profit, in view, when they bought or ftocked a farm; and therefore they laid it down as a rule, that no degree of fertility fhould tempt a man to purchafe in an unhealthy country, nor the pleafanteft fituation in a barren one. "Buy not too haftily," faid the wife Cato, "but view again and again the purchafe you intend to make; for if it be a good one, the oftener you fee it, the better it will pleafe you. Examine how the neighbouring inhabitants fare. Let the country it lies in be a good one; the ways to and from it good; and the air temperate. Let your land, if you can choofe your fituation, be at the foot of a hill, facing the fouth, in a healthy place, where a fufficiency of labourers, of cattle, and of water may be had. Let it be near a flourifhing town, the fea, or a navigable river; or bordering upon a good and well frequented road. Let the buildings upon your ground be ftrong and fubftantial. Do not rafhly condemn the methods of others. It is beft to purchafe from a good hufbandman, and a good improver."

Befides the healthfulnefs of the fituation, three other things fhould be particularly attended to in the choice of a farm or eftate; thefe are the air, the water, and the foil. The air fhould be pure, and temperate; the water wholfome, and eafily come at, and the foil rich.

The knowledge of the healthinefs of the air, is, as lord Bacon obferves, difcoverable rather by experiment, than by reafon or conjecture.

To examine the moifture of the air before a houfe is built, wool, or a fponge, may be hung up in the place, and afterwards compared with fome of the fame, expofed in the fame manner, and at the fame time, in another place. According as they gain more or lefs in weight, the air is more or lefs humid.

The air is liable to greater alterations, from heat and cold, in fome places than in others; and as that inequality in the air is an enemy to health, the moft equal fhould be chofen. This is eafily determined by the thermometer, and by viewing the fituation of the place; for the intermixture of hills and vaillies, though pleafing to the eye, may be held fufpected as to the lengthening of life, becaufe of the variations of heat and cold.

Open places and champaign countries are judged to be healthy, where the foil is dry, not parched or fandy, where wild thyme and other aromatic plants grow fpontaneoufly, and which is not otherwife bare, but interfperfed with trees for fhade. Yet the change of air in travelling, after being accuftomed to it, is healthy: whence many travellers have proved long lived; as, indeed, have alfo fuch as have dwelt conftantly in the fame cottage. A ruddy complexion, clear white of the eye, quick hearing, and diftinct voice, are fet down by Palladius, as marks of the healthfulnefs of the place where thefe circumftances are met with in the generality of its inhababitants.

The ancients were particularly attentive to the quality of their water, and to the eafe of coming at it. They advifed bringing into the farm-houfe the water of a fpring which never dries up; or, if there be no fuch fpring within the farm, to bring running water as near to it as may be; or to dig for well-water, not of a bitter or brackifh tafte. If neither of thefe was to be found, they directed large cifterns to be provided for men, and ponds for collecting and retaining rain water for cattle. They efteemed that running water to be beft for drinking, which had its fource in a hill: fpring, or well-water, from a rifing ground, was deemed the next beft: well-water in the bottom of a valley was held to be fufpicious; and marfhy or fenny water, which creeps flowly on, was by them rightly looked upon as the worft of all.

That water is known to be wholefome, which has no mineral in it, is perfectly clear, has no tafte or fmell, depofits no flimy fediment, leaves no fpots, or incruftation when boiled in copper or brafs veffels, and which boils pulfe in a very little time. "Rain water, fays Sir Thomas Elliot in his Caftle of Health, is the moft fubtile and pure of any other water. The next is that which iffueth out of a fpring facing the eaft, and paffeth fwiftly among great ftones and rocks. The third is of a clear river, which runneth on hard ftones and pebbles. There be divers means to try which is the beft water; for that which is lighteft in poife or weight, is beft; alfo that whereof cometh leaft fcum or froth when it doth boil; alfo that which will fooneft be hot. Moreover, dip linen cloths in fundry waters, and afterwards lay them to dry; and that which is fooneft dry, the water wherein it was dipped, is moft fubtile."

As fprings and well-water pafs through beds of fand, gravel, or fmall ftones, thefe clear it of all impurities, unlefs there be mixed with them fubftances which are foluble in water. If any mineral is mixed with the water, it is unfit for the farmer's ufe. If it be hard, it is thereby rendered unfit for wafhing, and fome other culinary ufes. This is the kind of water which gives flefh boiled in it a red colour. But even the hardeft water may be eafily rendered perfectly foft, and fit for any ufe, by mixing with it a fmall proportion of pot-afh, fixed falt, or, for want of thefe, the afhes of any burnt vegetables.

The animal and vegetable fubftances which are mixed with ftagnating water putrify, and taint that water. This taint is moft effectually carried off by boiling, during which all the putrid particles evaporate: and whatever elfe remains in it will fubfide when it is cold. It may likewife be much mended by having air forced through it by means of Dr. Hales's ventilator; or it may be corrected by mixing with it acids, fuch as vinegar, juice of four fruits, fpirit of nitre, vitriol, &c.

When there is neither running nor fpring water, artificial fprings may be made in the manner thus pointed out by Lord Bacon, who does not indeed fay that he had experienced it himfelf; but it has been repeatedly tried fince his time, and found to anfwer very well. "Upon a hanging ground, where there is a quick fall of rain-water, lay a half trough of ftone, of a good length, three or four feet deep in the ground, with one end upon the high ground, the other upon the low. Cover this trough with brakes, to a good thicknefs, caft fand upon the top of the brakes, and you will fee, after fome fhowers are paft, the lower end of the trough run like a fpring of water." This will continue for a long time after the rain is paft, "as if, fays that great philofopher,

lofopher, the water did multiply itfelf upon the air, by the help of the coldnefs and condenfation of the earth, and the confort of the firft water." A gentleman in France, whofe manfion ftood on a height far from any water, was advifed to make a long ditch, about a fathom deep, in the neighbouring higher grounds, and to fill it with fand; he did fo, and it continued to bring a plentiful fupply of water, for all domeftic purpofes.

M. de la Hire obferves, in the Memoirs of the Academy of Sciences for the year 1703, that rain-water which has been purified by paffing through clean fand, and is afterwards collected in fubterranean refervoirs, will keep a long while without becoming putrid. He thinks this water the beft that can be made ufe of, either for drinking, or for other economical purpofes, becaufe it is not impregnated with any mineral, as fpring waters fometimes are. The only thing requifite in the conftruction of fuch refervoirs or cifterns is, to have a place which will hold water, made of fuch materials as will not communicate any bad quality to the water, which is to remain there a confiderable time. The firft water that falls from the roofs of houfes, when it begins to rain, fhould be thrown away; as having ferved only to wafh the roof, which, in dry weather, is always covered with dung of birds, and other filth. He rejects fnow water for the fame reafon; and likewife the water of rain brought by winds which pafs over places infected with ill fmells, as large cities, finks, &c. He computes, that water enough for the ufe of any family runs off the roof of the houfe which is inhabited by that family.

The buildings on the farm fhould be proportioned to the produce, efpecially as to ftore-rooms. The expence of building fhould be fuch, as that, in cafe of accidents, one, or at moft, two years rent may repair them. The farm-houfe fhould be fomewhat elegant, to give pleafure to its poffeffors, and, as Columella adds, to allure the wife to take delight in it. It fhould be built on the moft healthy fpot of the farm, in a temperate air, fuch as the middle of a hill commonly enjoys, where it is neither ftifling in the fummer, nor expofed to the rage of winds and ftorms in the winter. It may be feated near a quick running river, if the banks are high, and the channel clear of mud: but if the river is large, care muft be taken to fituate it fo that the winds may carry off the vapours in fummer, and the fogs in winter, which otherwife would prove hurtful to the health of men and cattle. The front of the houfe fhould be turned from fuch a river. In a healthy fituation, a houfe fhould front the fouth-eaft, which is fhaded during the hotteft part of the day in fummer, and enjoys the morning fun in winter. A houfe facing wefterly will have the morning fogs longer retained, and will be too much heated by the afternoon fun. In an unhealthy fituation, the front fhould be turned toward the north.

In fouthern climates, where the fun is within a few degrees of being vertical in fummer, and yet the country is fubject to fevere cold in the winter, as is the cafe of fome of our North American colonies, a fouth front is rather convenient: for in the heat of fummer, the fun, being high, paffes over the roof from the eaft fide to the weft, and fhines but little, or not at all, in at the front windows, and very weakly, becaufe obliquely, upon the front wall. But in the winter, being low, it fhines full in at thefe windows, at a time when the cold renders its cheering prefence quite agreeable.

Places in this kingdom intended for defence, before the invention of cannon, were built either on rifing grounds difficult of accefs, or where they could eafily be fecured by moats filled with water. Villages and farm-houfes were moft frequently built in vallies, that they might be fheltered from ftormy winds; or near brooks or rivers, for the conveniency of water. In general, every means have not been ufed to provide againft the inconveniencies of thefe fituations: though as Mr. Worlidge obferves, "were we for the future but duly to obferve the beft fituations of places, and the compleateft methods of building, in fuch houfes as may hereafter be raifed, our England would in a few years appear a kingdom befet and adorned with curious and admirable habitations, poffeffed by noble and ingenious inhabitants."

Houfes built on too lofty a fituation are expofed to the violence of the winter's ftorms, and to the fcorching drought of the fummer: yet we too generally find them without the only fhelter their fituation admits of, which is wood. The reafon of this feems to be, that the inhabitants, finding that trees do not thrive well when they are firft planted on dry heights, are at once difcouraged. But where the plants are fenced from nipping winds while young, and protected from cattle till they become ftrong, fuch ground would be found abundantly favourable to the growth of trees which delight in a dry foil. "Thefe, as Mr. Worlidge expreffes it, would yield a cooling, refrefhing, fweet, and healthy air and fhade during the heat of fummer, and very much break the cold winds and tempefts from every quarter in winter."

One might be apt to think from the unhealthinefs of low and fenny countries, that moats full of water about houfes fhould be prejudicial to health: yet many facts fhew the contrary. In Numb. 310, of the Philofophical Tranfactions, a particular inftance is given of two parifhes which were furrounded with a morafs, and yet were very healthy. Many houfes furrounded with moats are drier than others in a feemingly better fituation; for books and furniture are often lefs apt to grow mouldy in the former, than in the latter. Hence it would feem probable, that the unhealthinefs of low marfhy countries muft arife, rather from the putrefaction of animals and vegetables in flow moving or ftagnating waters, than from a too great moifture of the air, occafioned by the quantity of water evaporated. Of this Dr. Pringle gives a remarkable inftance in his judicious and ufeful Treatife on the Difeafes of the Army, when he fays: "Another caufe of the moifture and corruption of the air were the inundations made about the fortified towns fince the commencement of the war; which were particularly noxious upon letting the water off in the beginning of the fummer, after the preliminary articles of the peace were figned. For thefe grounds, which were once entirely covered, being now half drained and marfhy, filled the air with moift and putrid exhalations. The ftates being made fenfible of this, by the ficknefs that raged at Breda, and the neighbouring villages, gave orders to let in the water again, and keep it penned up till winter."

All phyfical writers point out the great danger to which health is expofed from a moift and warm air; efpecially if it be attended with a putrid vapour. Too much care cannot therefore be taken to guard againft both. The too great moifture may probably be prevented by collecting all the wafte water into deep ditches or ponds. We frequently fee that ponds which have no fupply of water but from rain, retain water during a very dry fummer, when, according to the ufual calculations of evaporations, the whole muft have difappeared in half the time: from whence it feems more than probable, that the quick evaporation of water, in fome cafes, muft arife from a heat reaching to, or affecting the earth under the water; and that, if care be taken to make the ditches or ponds fo deep that the heat of the fun fhall not warm the earth at their bottom, the quantity evaporated will be but fmall, and fuch as will not be prejudicial to the health of the neighbouring inhabitants, if neither animal nor vegetative bodies are fuffered to rot in them. The way to prevent this is by keeping the water free from grafs, or other impurities, which may give fhelter to animals, whofe rotting, as well as that of the grafs, or of thofe impurities, communicates a putrid taint to the exhalations. It is in this cafe neceffary, that the banks of ditches, or ponds, be floped as little as the ftrength or ftiffnefs of the earth will permit.

Though lofty and bleak fituations are too often deftitute of trees, villages built in vallies are as frequently too much crowded with them; which muft be attended with the inconvenience of not having a free circulation of air, to carry off the moifture arifing from the earth, and perfpiring from fo many trees. The antients would have built fuch villages on rifing grounds, to avoid the too fultry heat of the fummer; or they would have preferved a free circulation of the atmofphere, to prevent the bad effects of a ftagnating moift air.

On the firft fettlement of the Englifh in North America, they imitated our cuftom of building in vallies, and near rivers: but experience foon taught them, that fuch places are more subject to the suffocating sultry heat of the summer, and, what they little expected, to a greater severity of frost in the winter, than rising grounds generally are. We have been informed by one of the most curious and intelligent observers of the laws of nature of perhaps any man on that continent, that the cold there, in their hardest frosts, is found to be so severe in the vallies, to a certain height, as sometimes to kill every tender vegetable, while those on the higher grounds escape. This generally takes place to a regular determined height, above which the Americans now build their houses. If we be allowed to offer a conjecture concerning the cause of this, we should say, that the effect of the cold seems to be limitted to the height to which the great moisture of the air arises at that season. In the hard winter of 1739-40, the same happened in this kingdom, when the frost was much less severe in its effect in the hilly countries, than in the low lands.

Dr. Pringle, in his excellent treatise before mentioned, points out the disadvantages of planting so many trees as there generally are in most parts of the Netherlands. The same practice may be as justly blamed in many of the flat moist counties in England, especially where they border on marshes. Their speedy growth tempts the inhabitants to plant, at the sides of their ditches, willows, and other trees, which delight in a moist soil; and these not only prevent a free circulation of air, but also perspire a great deal of moisture. Dr. Pringle confirms this by the following instances.

" At Eyndhoven, two battalions of the guards were quartered in the town, and the third lay without, in the peasants houses, all within the compass of a mile; yet, what was remarkable, this without the town had always three times more sick in the returns, than either of the other two, notwithstanding one of them had been very sickly the year before in Zealand. Now, the height of the ground being alike in all, the difference in point of health could be ascribed to nothing, but to the greater moisture of the cottages; for in all other points, these corps were equal, as in diet, duty, and exercise. A similar case occurred in the cantonment of a regiment of foot, whereof one company being quartered in houses that stood upon a heath, enjoyed a tolerable degree of health, while the rest that dwelt in a wood were remarkably sickly. As a further proof how prejudicial it is to have the air confined by close plantations in so moist a country, it was observable, that the Dutch camp at Gilsen, bordering on our cantonment, but lying on an open heath, preserved a good share of health, while we were at the worst. It was not a little curious to observe, how the agues declined proportionably with the withering and falling of the leaf. At this time less moisture ascends, and by the shedding of the leaves the villages come to be more open and perflated, and of course more dry and healthful. While the troops were very sickly in Zealand, commodore Mitchel's squadron, which lay at this time at anchor in the channel, between South Beverland and the island of Walcheren, in both which places the distempers raged, was neither afflicted with fever or flux, but amidst all that sickness enjoyed perfect health: a proof that the moist and putrid air of the marshes was dissipated, or corrected, before it could reach them; and that a situation open to the winds is one of the best preservatives against the maladies of a neighbouring low and marshy country."

The driest spot in a low flat or fenny country should be chosen for a dwelling-place. Even where there is gravel or sand on the surface, care should be taken that the springs do not rise high. Dr. Pringle points out the necessity of this caution, from what he observed in the lower parts of Brabant, " which is a barren sand, where so little water is seen, that, at first sight, the country is deemed dry and healthful: but the appearance is deceitful; for water is every where to be found at two or three feet from the surface: and in proportion to its distance from thence, the inhabitants are more less free from diseases."

Mr. Worlidge directs, that, in low moist grounds, cellars should be made under the house, with good cielings, or rather arched walls; for that this will conduce much to its dryness and healthfulness. The importance of rendering houses dry appears in many instances mentioned by Dr. Pringle: but we shall give only that in his twelfth page. " One quarter of Ghent, called St. Peter's-hill, stands high above the rest of the country; and in this the barracks, having drains and free air, were quite dry; so that the men who lay there enjoyed perfect health. But the rest who were quartered in the low part of the town, where their barracks were mostly the ground-floors of waste houses without drains, and of course very damp, were all sickly."

The bed-chambers, in such situations, more especially, should be in the driest and most elevated part of the house, and where the morning sun may contribute most to keep them dry. If they are so situated, that the sun does not warm and dry them, they should be frequently aired with fires; the oftener in proportion to the greater dampness of the place: for this has been found to contribute greatly to the health of the inhabitants. We are informed by a gentleman who has experienced it in many instances, that, by this sole precaution, he has preserved several families from the ague, when that distemper was very epidemic in the neighbourhood. How much the dryness of bed-chambers contributes to health is confirmed by what Dr. Pringle observes to have happened at Bruges, where the soldiers that lay in the upper stories kept their health remarkably better than those who were below on the ground floors.

As brick walls render houses drier than those of stone, and of a more equal warmth than plaistering, Mr. Worlidge directs, that, " where bricks can be had, the walls should be built with them, as may be done for little cost, if you raise firm and strong columns at the corners of the house, and where it is necessary to support the main beams. You may build these square, and between them raise the walls with the same materials, and work them up together with the corners and columns, leaving one half of the extraordinary breadth of the column without, and the other within the walls, whereby you will save much charge in materials and workmanship, and yet your house will be firm and strong."

We are too little attentive to the situation of houses with regard to rivers; though a judicious choice in this must be of great consequence to the health of the inhabitants. A quick flowing stream, with a clean channel and dry banks, will rather add to the beauty and healthiness of a country: but oozy banks, over-run with reeds, or other strong coarse grass, should be carefully avoided, as being a shelter to all manner of putrid filth, whence unsalitary vapours must arise. It is a general opinion, that it is safer to dwell on the north than on the south-side of a river; but experience seems to prove the contrary, especially in warm climates. Marshes, which are sometimes overflowed with salt water, are found to be more unwholesome than fresh water marshes. Their neighbourhood should, therefore, be carefully avoided.

The Romans were universally agreed, that it was much better to occupy a small farm than a large one; and laid it down as a rule, that the farmer ought to be stronger than the farm; because in the struggle which will arise between them, if the farm be too strong for the farmer, he must be ruined; that is, if the extent of the farm be such, that he cannot bestow a due culture on every part of it, he must be a loser: for, as Columella remarks, " it is certain, that a large tract of land, not rightly cultivated, will yield less than a small space well cultivated."

A judicious correspondent of the editors of the Museum Rusticum rightly observes, that the stocking of a farm is a point of great importance, and requires as much judgment and foresight as any other point in husbandry.

" The bad success of great numbers, continues he, is owing to their not having a sufficient sum of money to begin with, which inevitably involves them in difficulties, and reduces their profit on every article of their produce. Their farms are understocked; they sell at a constant disadvantage; their fields are not half cultivated; and in a short series of years, unless some lucky hit sets them up, they grow poor, in spite of all possible industry, judgment, and application.

" Even a low and easy rent will seldom remedy the want of mony at setting out.

" The

"The want of judgment, in proportioning the quantity of each particular kind of ſtock to the quantity and nature of the lands of a farm, is alſo attended with great loſs.

"For inſtance; if a farm requires four horſes, or two ploughs, and the farmer keeps only three, or a plough and a harrow, his field cannot be ſufficiently cultivated, even according to the ideas of culture common among farmers; and of courſe in a few years his lands muſt be in very bad order, to his great annual loſs.

"On the contrary, to overſtock himſelf with horſes, is to keep what will inevitably eat him out of houſe and home: the expences attending them are very great, and if they are not kept conſtantly at work, their owner muſt neceſſarily loſe by them. But it will not be amiſs to explain myſelf more particularly on this head.

"I am ſpeaking at preſent of the practice of farmers, ſome of whom overſtock themſelves with horſes, without giving their lands extraordinary ſtirrings on that account. If a farm, which commonly requires three horſes, has four kept, and is conſequently ploughed and harrowed proportionably more, the farmer will be no loſer by his fourth horſe; but the caſe is very different when he is kept without being worked to the beſt advantage of the farm.

"It is not to be at once perceived how much is loſt by not having the number of horſes proportioned to the land; nor can this always be done.

"A farmer may find it neceſſary to keep four horſes, and when he has got them, it is a chance but he could perfectly well manage ſeveral fields more with them; and when a man has an opportunity of hiring additional fields, then ſhould his judgment come into play, to take no more than his old ſtock will manage to advantage, unleſs he has a ſum of money ready to make an addition to it.

"The ſame ill conſequences attend either over or underſtocking a farm with all other cattle: and it would be the farmer's advantage was he always to remember, that three beaſts, of any kind, well fed, pay better than four without their bellies full. On the contrary, not to keep the ſtock neceſſary, is to ſubmit to a conſtant loſs. Both theſe ſorts of conduct are frequently followed, to the great unprofitableneſs of farming.

"The proportion of the paſture and arable lands of a farm is of great conſequence towards the occupier's making a profit of his buſineſs.

"The unprofitable practice of ploughing up paſtures, and not laying them down again, which is ſo univerſal in this country among farmers, whenever their landlords will allow it, tends perpetually to impoveriſh them. They are all, to a man, mad after ploughed lands, and would willingly break up every acre of graſs in their farms.

"So general an opinion among them would make one think the practice really profitable; but the contrary appears beyond all contradiction to be the truth; I mean, according to the culture at preſent purſued in this country.

"Two thirds of the land of a farm in a rich country ſhould be graſs; and a little one had better all be ſo. The vaſt expences of the plough, without doubt, keep many farmers poor, who, if their farms were graſs, would not run half the hazard, and enjoy a much better income.

"Particular points of bad management, for want of ſenſe or knowledge, through ſlovenlineſs, idleneſs, or other obſtructions to any profitable huſbandry, are not what I mean to ſpeak of here, ſince they are ſo very various, and ſo totally ruinous, that no reaſoning can be concluſive, unleſs all ſuch exceptions are made.

"The improper quantity of land in a farm is often againſt the farmer's profit.

"Very large tracks, of two or three thouſand acres, which are common in Norfolk, are too extenſive for one farm. It is impoſſible for one man to cultivate ſuch a quantity of land well: much of it muſt be neglected, and but little perfectly managed.

"Great profit indeed ariſes from moſt of theſe farms; but they take a very large ſum of money to ſtock and manage them properly.

"Very ſmall ones, unleſs the farmer does the whole buſineſs himſelf, are equally liable to objection. The medium, which is ever, in proportion, the moſt profitable, is that quantity of land which will admit of being ſtocked and farmed without the want of either any addition or diminution. What I mean is this:

"Let us ſuppoſe a farm to conſiſt of ſeventy acres of land, twenty of them graſs, and the reſt arable, in a rich country, the land from ten to ſixteen and ſeventeen ſhillings *per* acre; the occupier muſt keep one ſervant, and if he does not work hard himſelf, one labourer all the year, beſides ſome additional help at buſy times.

"I know there are many ſlovenly men, who cultivate (if their management deſerves that name) ſuch farms with fewer hands than I have mentioned; but their conduct can be no rule to good farmers. Four horſes are alſo neceſſary for ſuch a farm.

"Now, for the ſame ſtanding expences of ſervants wages, horſes, &c. the ſame number of ploughs, harrows, tumbrils, waggons, &c. &c. one hundred acres, or better, might be farmed with the ſame proportional profit: in this caſe, therefore, the tenant of ſeventy acres loſes conſiderably for want of thirty or forty more. Indeed we ſeldom meet with a farm nicely proportioned to the ſtock on it.

"There are many very evident reaſons why farming ſhould prove unprofitable to gentlemen who undertake to cultivate a part of their eſtates, whether for their amuſement or convenience, or, generally ſpeaking, even for profit.

"A very fine Norfolk farm, of a large extent of country, the rent exceeding low, and a gentleman willing to be at the expence of marling, in ſuch a caſe, there is no fear of a conſiderable profit, even without perpetual attention: but in common farms, in rich countries, no profit can ariſe to any gentleman that does not give the buſineſs conſtant attention, and deſcend to *minutiæ*; which may be too diſagreeable for him to ſubmit to.

"What I mean by profit, is not making the rent which he might receive from the tenant without trouble, and without hazard, but that additional ſum which is the farmer's profit after his rent and all expences are paid. This is ſcarcely ever made by gentlemen, who farm either for convenience or amuſement; and, excepting graſs grounds, I am perſuaded they loſe conſiderably by keeping land in their hands. The plea of growing enough for family uſe of wheat, oats, &c. is a miſtaken one; they had better by far buy every article, than have any thing to do with the plough.

"When I am told that farming anſwers to gentlemen, who I know do not give the farmer's attention to the buſineſs, I never believe it, or, at leaſt, am perſuaded that no regular accounts are kept. It will not be difficult to produce ſome good reaſons for this incredulity.

"It ſhould be remembered, that the farms which gentlemen keep in their own hands are ſeldom above fifty, ſixty, ſeventy, or an hundred a year, and not often ſo much. It is no eaſy matter for a farmer, with induſtry, ſobriety, and application, to make above a rent profit in ſuch a farm; and I believe but ſeldom ſo much. This is with every advantage of underſtanding his buſineſs, applying cloſe to it, and doing ſome work (if his farm is ſmall, a great deal) himſelf: how unlikely is it therefore that a gentleman, who may probably want theſe advantages, ſhould make near that profit, or, indeed, any at all!

"In the firſt place, a principal part of his buſineſs, his buying and ſelling, is tranſacted by his bailiff, or head ſervant, who muſt be paid for his trouble. He may be lucky enough to meet with an honeſt one; but I would never adviſe any one to let the profit of his farming depend on the honeſty of other people. Suſpicion, to the open generous mind, is irkſome and grating: but the farmer ſhould ſet out with the maxim of Deſcartes—to doubt of his very exiſtence, and ſuppoſe every man a knave till he finds him honeſt.

"But there are many inconveniencies, beſides theſe, in truſting to bailiffs.

The gentleman we muſt certainly ſuppoſe to be ignorant of farming; and he is then, of courſe, in danger of having an ignorant ſervant, without the ability of detecting him. However, the ſingle expence of a bailiff, or a head ſervant, which are much the ſame, is too great to be kept conſtantly

constantly for a small farm; and in their absence the gentleman must depend on himself.

"This is palpably no dependence at all; for can it be expected that he will forego his diversions, his excusions of pleasure, the company of his friends, the joys of society, to attend to his farm? I could almost as soon believe, that his wife would renounce an opera or a ball for the pleasure of dancing attendance on her butter and cheese in the dairy. The rural joys of romance are pretty much out of date now; and, alas! there is great difference between the employment of a farmer's wife in England, and keeping sheep in the plains of Arcadia.

"But to return:

"There are, even in a small farm, a thousand objects which require constant attendance.

"Cattle of no kind will thrive but in the master's eye: every variation of the season to be remarked; the lucky moment for ploughing, harrowing, sowing, reaping, &c. to be caught, and used with diligence and foresight; fences for ever to be attended to; and, in short, a million of other things, which require constant thought and endless application.

"That single article, the employment of labourers, will alone run away with the profit of the whole farm.

"But surely it appears plainly, from what I have said, that the unprofitableness of farming is scarcely ever owing to the art itself, but to the mistakes of those who practise it.

"As I have been so particular in distinguishing several points by which the followers of it lose, I shall now trespass a little longer on your patience, and give my sentiments on the custom of gentlemen's farming, in other respects than that of profit, to those who are not solicitous about it, and in relation to it, to those whose fortunes will not allow an indifference to such a point.

"It is scarcely possible for a gentleman to live in the country without finding many inconveniencies in not keeping a team of farming horses, with waggons, carts, &c. and other implements used in the business of husbandry. While profit is not considered, there will flow a multitude of agreeable circumstances from farming, which will have some relation to almost every particular of a country life.

"In respect of entertainment, what more rational, or more amusing, than country business, without the anxiety of caring for profit! The public good calls loudly to all gentlemen to keep some land in their hands, that experiments may be made, and modes of agriculture pursued, different from the practice of the neighbourhood, for the farmers, at least, to see that their own customs are not the only good ones, and that there are improvements to be made even on their practice.

"All the improvements and new inventions in agriculture come from gentlemen; scarcely one, that I ever heard of is known to have been discovered by farmers.

"I do not wonder at this, for I think it is natural enough; but at the same time, it is a strong reason for gentlemen's farming, whether they make profit by it or not. The expensive use of manures, and introducing a garden culture into the field-husbandry, were the effects, among a hundred other instances, of gentlemen's farming.

"But if the public good was not to be considered, yet the mere amusement of farming to a gentleman of fortune, who has the least taste for country business, must plead warmly for its practice. Such farmers soon make a garden of their estates, at the same time that they improve the value of them.

"What can be more amusing than experimental agriculture? trying the cultivation of the new-discovered vegetables, and all the modes of raising the old ones; bringing the earth to the finest pitch of fertility, and growing plants infinitely more vigorous and beautiful than any in the common tillage; using the variety of new machines perpetually invented, and observing their effects; and, in a small extent of ground, see the growth of an infinite variety of vegetables, unknown in the common practice; perpetually enjoying the neatness of husbandry, that *simplex munditiis* of farming, which gives the most beautiful colouring to every object around, and pleases the refined imagination with the enchanting prospect of all the elegance of nature.

"Those gentlemen of small fortunes, who, if they practice any thing of farming, find it necessary not to be indifferent to profit, have many points to consider.

"Such an one should remember, that though a farm will afford amusement, it will not yield profit without application. A constant attention to every article is highly necessary. He should keep the exactest accounts, and make memorandums of what knowledge he can pick up. For a few years he must employ a bailiff; and he will find that every day and hour will increase his own knowledge, if he is attentive to business." *Museum Rusticum, vol.* IV. *page* 264.

We shall conclude this article with the following

"*Prices of Implements of Husbandry, Corn, and Farming-Work, in the North Part of Hertfordshire, about Hitchin, Baldock, and Stevenage.*

A waggon complete, from 16 to 20 l.

A cart complete, from 8 to 10 l.

A two-wheeled plough complete, with draught-chain, and splinter-bars, or whipple-trees, 3 l.

A wheat two wheeled sowing-plough, as the same wheels serve for both, 1 l. 1 s. 6 d.

A foot, swing, or dray-plough complete, 1 l.

A roller complete, 15 s.

A five-barred harrow ditto, 17 s.

A four-barred harrow ditto, 15 s.

A three-barred harrow ditto, 12 s.

First ploughing per acre, 6 s.

Second ploughing per acre, 5 s.

Harrowing per acre, 6 d.

Rolling per acre, 4 d.

Hoeing turnips per acre, 4 to 5 s.

Hockling, or cutting up and raking haulm, 2 s. 6 d. per acre.

A harvest-man has per month from 33 to 40 s. and his diet.

A ploughman, for a day's work, 8 d.

A labourer, 1 s. per day, and small beer.

Price of threshing per quarter, wheat 2 s. barley 1 s. oats 9 d. pease 1 s. 4 d.

Price of horses, from 5 to 15 l.

Price of cows, from 3 to 8 l.

Price of sheep, from 10 to 20 s.

Hogs, from 5 to 40 s.

Wheat per load, 30 to 35 s. Five bushels make a load, and eight loads, or forty bushels, a waggon-load.

Barley, 24 s. per quarter.

Oats, 16 s. per quarter.

Pease, 17 s. per load.

Thetches, or vetches, 25 s. per load.

Malt, 4 s. 6 d. per bushel.

Note, Our bushel is nine-gallon measure.

Turnip-seed, 3 d. per pound.

Red clover-seed, 4 d. per pound.

Trefoil-seed, 2 d. per pound.

Cinquefoil-seed, 4 s. per bushel.

Wheat-straw, 10 s. per load.

Barley and oat-straw, 6 s. per load.

Cinquefoil-hay, per hundred, 2 s. 6 d.

Clover-hay per hundred, 2 s. 6 d.

Thatching per square, yelming and serving included, 2 s. 6 d.

A carpenter per day, 1 s. 8 d.

A bricklayer ditto, 1 s. 10 d.

Brick at the kiln, 17 s. per thousand.

Plain tiles, 17 s. per thousand.

Pan-tiles, 10 s. per hundred.

Lime, 6 d. per bushel.

Tiling-lath, 2 s. 10 d. per bunch.

Plaistering-lath, 1 s. 5 d. per bunch.

Hurdles per dozen, 8 s.

Faggots, from 6 to 16 s. per hundred.

Making, plashing, and laying live-hedges, and ditching, 4 d. per pole of sixteen feet and a half." *Museum Rusticum, vol.* IV. *page* 78.

FARM-

FARM-YARD, the place adjoining to the farm-houfe, where cattle are foddered, and feveral other neceffary works, belonging to the farm, are performed.

FARTHING-DALE, or *farding-dale*, the fourth part of an acre of land, now generally called a rood.

FATHOM, a long meafure, containing fix feet.

FEABES, or *feaberries*, goofeberries.

FEBRIFUGE, having the power of curing fevers. *See* FEVERS.

FEBRUARY, the fecond month of the year.

This is a principal feed month for fuch as they commonly call lenten grain, and is ufually fubject to much rain or fnow, which is not unfeafonable.

Now fow all forts of grey peafe, fitches, beans, and black oats: in dry weather carry out dung, and fpread it before the plough, and alfo on pafture-ground: this being the principal month for that purpofe.

This is a very proper time for planting trees and quickfets, and alfo to plafh them; to fet willows, plants, or pitchers, and alfo poplars, ofiers, and other aquatics; and to lop trees, or cut coppices.

Sow muftard-feed and hemp-feed, if the fpring prove mild: feed your fwans, and make their nefts where the floods cannot reach them.

Soil fuch meadows as you cannot overflow or water; catch moles, and take great care of ewes and lambs where they are forward. *Mortimer's Hufbandry, vol.* II. *p.* 413.

FEED, the quantity of oats, &c. given to a horfe or other animal.

FEEDING *of cattle. See the article* CATTLE.

FEET, the bafes or fupports of an animal.

The knowledge of the feet is of the utmoft importance in purchafing a horfe. Nor is it enough that the creature have a well-proportioned foot; for if it chance to be thin or weak, the buyer will be difappointed in his expectations; as fuch a foot is liable to be fpoiled in fhoeing, by travelling on hard ftony ground, by too much draught in hot feafons, or by too much moifture in winter. A thin foot is that where the cruft or horn is thin. This may be very eafily feen when the fhoe is taken off, becaufe the verge all round the fole will appear thin, and where it is fo a horfe will winch with the leaft touch of the pincers. The heel and frog are alfo apt to be foft and tender to the touch, and by reafon of the weaknefs natural to fuch a kind of foot, it often turns awry, and one point of the heel ftands higher than the other.

FELL, the fkin or hide of a beaft.

FELLING, the act of cutting or hewing down.

When any tree is intended to be cut down for timber, the firft thing to be taken care of is a fkilful difbranching, or lopping off, fuch limbs, as may endanger it in its fall, many trees being annually fpoiled for want of a previous care of this kind; and therefore in very large arms, chop a nick under them clofe to the bole, and then meeting it with downright ftrokes, it will be fevered without fplitting. Take care alfo to cut the tree as near the ground as poffible, unlefs you defign to grub them up, the doing of which will be of advantage both to the timber and to the wood; for timber is never fo much valued, if it be known to grow out of old ftocks.

M. de Buffon has very juftly obferved, that the trees intended to be felled for fervice fhould firft be ftripped round of their bark, and then fuffered to ftand and die upon the fpot before they are cut. For by this means the fappy part, or blea of the tree, becomes as hard and firm as the heart, and the real ftrength and denfity of the wood has been proved, by many experiments, to be greatly increafed by it.

FEN, a general name for boggy, moorifh, or marfhy land, generally overflowed with water. *See the articles* BOG, DRAINING, MARSH, *and* MOOR.

FEN, is alfo the name of a very pernicious diftemper to which hops are fubject. It confifts of a quick growing mould, or mofs, which fpreads itfelf with great rapidity, and occafions dreadful ravages in the hop-grounds. *See the article* HOPS.

FENCE, a hedge, wall, ditch, bank, or other inclofure, made round fields, woods, gardens, &c.

No foreft trees fhould be admitted into the hedges that divide fields, as their fhade, and wide extending roots, are found very injurious to corn, grafs, and even to the hedge itfelf. But in countries where inftead of hedges, the fences are chiefly made of rough flakes of ftone, piled dry one upon another, or a little earth thrown in between them, to fill up the chafms, a plantation of trees within thefe walls will hide their deformity, and give a warmth which cannot be expected from fuch walls.

The moft ufual way of inclofing land is with a ditch and a bank fet with hawthorn, crabs, black thorn, holly, or white thorn, commonly called quick. Mr. Miller's inftructions in this refpect are very full, and contain among others, the following directions.

"It will be proper before planting to confider the nature of the foil, and what forts of plants will thrive beft in it; and alfo what the foil is from whence the plants are to be taken: for if the ground they are taken from be better than that into which they are to be put, it will be more difficult to make them grow. Thofe which have been raifed on the fpot near the place where they are intended to be fet, will always do beft, if they are to be tranfplanted; and the next to them will be fuch as are taken from a nurfery.

"I would recommend the white thorn, the black thorn, and the crab for outward fences to good ground: but I do not approve of intermixing them.

"The white thorn is the beft quick to plant, becaufe it is the moft eafily procured, is very hardy and durable, and may be rendered the clofeft of any fence, by proper clipping. It, therefore, is preferred to all others for outward fences, or for the divifion of fields, where they are expofed to cattle, &c. It may be raifed either from fets or from feeds. The former is the moft common way of propagating it: for the latter, which may very properly be fown where the hedge is intended to ftand, do not rife till the fecond fpring. The white thorn will thrive on almoft any well loofened foil, except the drieft gravel or fand.

"The black thorn and crab make very good fences, and are to be raifed in the fame manner as the white thorn: but if the kernels of apples or crabs be fown, it is beft to fow the pommace with them; for they will then come up the fooner, that is to fay, the firft year.

"The black thorn is not accounted fo good for fences as the white thorn, becaufe it is apt to run more into the ground, and is lefs certain as to the growing: but, on the other hand, its bufhes are much better, and more lafting, than thofe of the white thorn, or indeed any other fhrub, for dead hedges, or to mend gaps: nor are they fubject to be cropt by cattle, as the others are. The richer the mould is, the better the black thorn will profper: but it will grow on the fame fort of foil as the white thorn.

"The holly makes an excellent fence, and is preferable to all the reft; but it is difficult to be made to grow at firft, and is a flow grower. However, when it does grow, it makes amends by its height, ftrength, and thicknefs. It delights moft in ftrong grounds; but will grow upon the drieft gravel, even among rocks and ftones. It is raifed from fets, or berries, like the hawes of the white thorn, and lies till the fecond fpring before they come up. Thefe two are beft fown in the place where they are intended to ftand. They fhould be well weeded, both before they come up, and afterwards, till they are grown to fuch a fize, as, of themfelves, to kill the weeds.

"French furze will make good hedges upon dry fandy banks, where few other plants will grow: but they muft be kept very clean at the bottom, and never fuffered to grow too high: nor fhould they be clipped either in dry weather, late in autumn, or early in the fpring; becaufe the cutting of them at thofe feafons is apt to make them die in patches, which is irrecoverable; as no new fhoots will here ever proceed from the old wood.

"Alder planted on a bank, the fide of which is wafhed by a river or ftream, will make an extraordinary fence, and preferve the bank from being undermined by the water; becaufe the alder is continually putting forth from the lower roots fuckers, which are of great advantage where the current of the water wafhes away the earth.

"If there is to be a ditch along the hedge, that ditch fhould be at leaft fix feet wide at top, three feet deep, and only one foot and a half over at the bottom, that each fide may have a proper flope: for where its fides are dug too perpendicular, they are very apt to fall in after a hard

froft,

froſt, or heavy rain; and if the ditch is made narrower than here directed, it will ſoon be choaked up in autumn, by the falling leaves, and the growth of weeds: nor will it be a ſufficient defence for the hedge againſt cattle.

"When the bank at the ſide of this ditch is to be planted with quicks, the ſets ought to be about as thick as a gooſe quill, and their tops ſhould be cut off within four or five inches of the ground. They ſhould be freſh taken up, ſtrait, ſmooth, and well rooted. Part of the turf taken off the ſurface of the ground where the ditch is to be dug, ſhould be laid, with the graſſy ſide downward, on the ſide of the ditch, where the bank is intended to be made, and ſome of the beſt mould ſhould be laid upon it, to bed the quick. The ſets of quick, prepared as before directed, are then to be laid upon that mould, a foot aſunder, with their cut ends ſomewhat ſloping upward. When this firſt row of quick is thus laid, it muſt be covered with mould; ſome of the remaining turf muſt then be laid upon that mould with the graſs ſide downward, as before; and more mould muſt afterwards be laid upon this turf. When the bank has, by theſe means, been raiſed about a foot high, a ſecond row of ſets ſhould be laid in the ſpaces between the lower quick, and with their ends turned the oppoſite way, in order to thicken the bottom of the hedge. Theſe are then to be covered in the ſame manner as the former: the bank is to be topped with the bottom of the ditch; and a dry or dead hedge muſt be made on the other ſide, to defend the young plantation from cattle.

"To make theſe dead hedges, ſtakes ſhould be driven into the looſe earth, ſo low as to reach the firm ground. They ſhould be about two feet and a half aſunder. Oak ſtakes are reckoned the beſt, and black thorn and ſallow the next. When they are fixed, ſmall buſhes ſhould be laid at the bottom, but not too thick; for that would make the buſhes rot. The upper part of the hedge ſhould be laid with long buſhes, to bind the ſtakes in, by interweaving them: and, to render this hedge yet ſtronger, it may be eddered as it is called, that is, the tops of the ſtakes may be bound in on each ſide, with ſlender long poles or ſticks. When this eddering is finiſhed, the ſtakes ſhould be driven anew; becauſe the doing of that, together with the weaving of the hedge, will probably have looſened them.

"The quick muſt be kept conſtantly weeded, and ſecured from being cropped by cattle, and in February it ſhould be cut to within an inch of the ground; for this will make it ſhoot ſtrong, and greatly help its growth.

"When a hedge of this kind is about eight or nine years old, it will be proper to plaſh it; the beſt time for which is in October, or February.

"After it has ſtood twenty or thirty years, and there is in it old ſtubs, as well as new ſhoots, thoſe ſtubs ſhould be cut ſloping off within two or three inches of the ground, except the beſt and longeſt of the middle ſize, which ſhould be left to lay down, and ſome of the ſtrongeſt, which ſhould be cut off at the height of five or ſix feet, according to the intended height of the hedge. Theſe laſt may be left to ſerve inſtead of ſtakes, and freſh ſtakes ſhould be put wherever they are wanted. The hedge ſhould be thinned, ſo as to leave on the ſtubs only ſuch ſhoots as are deſigned to be of uſe, that there may be room left to put a ſpade in between them, in order to give the earth as good a ſtirring as poſſible. The ditch alſo ſhould be cleanſed, and its ſlopes carefully repaired; and where the earth has been waſhed from the roots of the quick, or is hollow, it ſhould be faced anew with ſo much of the firſt ſpit of earth as there is occaſion for. The ſecond ſpit of this earth ſhould be laid on the top of the bank: for if it be laid on the ſide, or face of the bank, it will ſlip again into the ditch when wet comes, and perhaps drag down a great deal of the bank.

"Two extremes are to be avoided in the plaſhing of quicks: the firſt is, the laying the plaſhes down too low, and too thick; becauſe that makes the ſap run wholly into the ſhoots, and leaves the plaſhes without nouriſhment, which, with the thickneſs of the hedge, kills them. The ſecond is, not to lay them too high; becauſe this draws all the ſap into the plaſhes, ſtints the ſhoots at the bottom, and renders the hedge ſo thin, that it will neither hinder cattle from going through, nor from cropping of it.

"When the ſhoot deſigned to be plaſhed is bent, give it a ſmall cut with a bill, half through, ſlanting a little downward; then weave it about the ſtakes, and trim off the ſmall ſuperfluous branches that ſtraggle too far out on either ſide of the hedge.

"If the ſtubs are very old, cut them quite down: ſecure the chaſms with a good dead hedge on each ſide, till the young ſhoots are got up tall enough to plaſh; and plant new ſets in the vacant ſpaces.

"If the bank for a fence be without a ditch, and it is intended to make a hedge of quicks, the ſets, prepared as before, ſhould be planted in two rows, almoſt perpendicular, at the diſtance of a foot from each other, in the quincunx order; ſo that, in effect, they will be only ſix inches aſunder." *Miller's Gard. Dict.*

When the plants of the thorn are themſelves ſtinted, or much decayed, as they generally are pretty ſoon, through the unmerciful wounds given them by unſkilful hedgers; inſtead of plaſhing them, the farmer's beſt way will be to dig them up, and plant young ſets in their ſtead. The only inconvenience attending this renewal is the expence of a dead hedge, which is not wanted in plaſhing: but I queſtion much, whether the healthineſs of the plants, when cut ſmooth, and in ſuch a manner as not to retain water, may not ſufficiently compenſate that charge. For the ſame reaſon, it ſeems to be moſt rational to cut the plaſhes upward; becauſe the wound will then be covered from the wet, at leaſt in ſome degree, by the ſlip which remains prominent over it.

Beſides the plants already mentioned for hedges, the ſweet-briar, or eglantine (dog-roſe) is thus recommended by a correſpondent of the ſociety of improvers in the knowledge of agriculture in Scotland, who had tried in vain, in that country, all the methods of fencing uſually practiſed in Hampſhire and Eſſex.

"Obſerving that no creature ate up or deſtroyed the ſweet-briar or eglantine (dog-roſe) I gathered the hips of this plant, and laid them in a tub till March: the ſeeds then rubbed out eaſily, and I ſowed them in ground prepared for garden-peas. By this means I got my crop of peas without prejudice to my briars, which came up the next year; and the year after, when they were about a foot high, I planted them in the following manner.

"After marking out my ditch, I laid my plants about eighteen inches aſunder, upon the ſide graſs, and covered their roots with the firſt turfs that were taken off the ſurface of the intended ditch. The earth ſide of theſe turfs was placed next to thoſe roots, and upon the turfs was laid other earth, taken out of the ditch, which I then finiſhed. In four or five years, theſe plants made a fence which no ſheep, cattle, or horſes could paſs. If old briars are dug up, and divided, they make excellent plants. Where the fences are thin, they may be eaſily thickened, by laying down branches; for theſe will make ſhoots of ſix or ſeven feet in a year. They bear clipping very well.

"In ſandy places, I ſeldom dare to throw all the earth out of the ditch at once, but wait a year, till what I had thrown up is ſettled and ſwarded a little: then I raiſed my bank to the intended height. In the mean time nothing hurts my briars; and in two or three years after they have been planted, nothing can paſs the fence. Sheep ſometimes attempt it: but they ſoon are ſo entangled, that they would lie there till they die, if they were not taken out."

In the hedges which divide the farmer's fields only, fruit trees may be planted; and theſe will yield profit, as well as ornament; or the fruit may be grafted upon a ſtock in the hedge, properly ſuited thereto.

Theſe ſtocks ſhould be pruned up every year, till they are brought out of the reach of cattle, and then they may be grafted with the red-ſtreak, gennetmoil, or any other fruit. If they have proceeded from apple-kernels, they may remain ungrafted, and will yield very good cyder fruit: but then it will be longer before they bear. Alſo, if the leaf, ſhoot, and bud of a natural ſtock, promiſe more than common, a trial may be made, whether that ſtock will not perhaps produce a fine new fruit; and if it be not liked afterwards, it may then be grafted.

Mr.

Mr. Miller reckons the plants raiſed from the kernels of the ſmall wild crab much better for hedges, than thoſe which are raiſed from the kernels of any other ſort of apple; becauſe the former never ſhoot ſo ſtrong as the latter, and therefore may be better kept within the proper bounds of a hedge; and as they generally have more thorns upon them, they are better guarded againſt cattle.

Fences made in marſhy grounds require plants which delight in moiſt ſoils. Of this kind are, particularly, the black alder, the willow, and the poplar: the birch tree, and the aſh will likeways grow very well in ſuch places: but the firſt of theſe, viz. the alder, is reckoned the beſt and moſt profitable.

It likes a ſoil ſo moiſt as few other trees will thrive in, and is propagated either by layers, or planting of truncheons about three feet in length. The beſt time for planting theſe laſt is in February, or the beginning of March, when they ſhould be ſharpened at their larger end, and the ground ſhould be well looſened before they are thruſt into it, leſt the bark ſhould be torn of, which may occaſion their miſcarriage. They ſhould be ſet at leaſt two feet deep, to prevent their being blown out of the ground by violent winds, after they have made ſtrong ſhoots; and they ſhould be keept clear from all ſuch weeds as grow tall, at leaſt till they have got good heads; after this, they will keep down the weeds, and require no farther care.

If alders are raiſed by laying down the branches, this ſhould be performed in October, and by the ſame time twelvemonth they will have roots ſufficient to be tranſplanted, which muſt be done by digging a hole, and looſening the earth in the place where each plant is to ſtand. The young ſets muſt be planted at leaſt a foot and a half deep, and their top ſhould be cut off to within about nine inches of the ground; for this will make them ſhoot out many branches.

The alder tree may be trained into very thick cloſe hedges, to the height of twenty feet and upwards. It will thrive exceedingly on the ſides of brooks, for it grows beſt when part of its roots are in the water, and may, if planted there, as is uſual for willows, be cut for poles every fifth or ſixth year. Its wood makes excellent pipes and ſtaves; for it will laſt a long time under ground, or in water: and it is likewiſe much eſteemed by turners, plough-wrights, &c. and for making ſeveral utenſils neceſſary in agriculture. Its bark yields a good black dye.

All the ſorts of willows, of which Mr. Miller enumerates fourteen, grow beſt in moiſt boggy land, and may be eaſily propagated by planting cuttings or ſets, either in the ſpring or autumn: for theſe readily take root, and are of quick growth.

Thoſe ſorts which grow to be large trees, and are cultivated for their timber, are generally raiſed from ſets about ſeven or eight feet long, ſharpened at their larger end, and thruſt into the ground by the ſides of ditches and banks, where the ſoil is moiſt: but the beſt way is to make holes for them with an iron inſtrument, in order to avoid tearing off their bark. Theſe will afford very profitable loppings every fifth or ſixth year.

The middle ſized, or long leaved red willow *(Salix folio longo ſubluteo non auriculata*, Raii Syn.) and the common ſallow *(Salix folio ex rotunditate acuminato)* C. B. P. 474; willow with a rounded acute pointed leaf, have very pliable ſhoots, and therefore are the fitteſt for baſketmakers, for which reaſon they are much planted in oſier grounds. The cuttings of theſe plants ſhould be about three feet along, and taken from ſtrong ſhoots of the former year. They are commonly thruſt down two feet deep into the ground, and ſhould be about eighteen inches aſunder, if intended only for a fence; but if they are deſigned alſo for an oſier plantation, the rows, in which they may ſtill be at that diſtance, ſhould be three feet aſunder; obſerving always to plant the rows the ſloping way of the ground, eſpecially if tides overflow it; becauſe, if the rows are placed the contrary way, the filth and weeds that will be detained by the ſets will choak them up.

The beſt ſeaſon for planting theſe cuttings, is towards the end of February; for if they are planted ſooner, and a hard froſt comes on, they are apt to peel, which greatly injures them. Theſe plants are cut every year in oſier grounds, and, if the ſoil be good, they will yield ſo great a crop, that the yearly produce of one acre has often been ſold for fifteen pounds: but ten pounds is a common price. It therefore is great pity, that willows are not more cultivated, eſpecially upon boggy land, where few other things will thrive. They will not, however, do ſo well as the alder, in very watery ground. Great care ſhould be taken to ſcreen the young willows from cattle; for they are fond of them, and would ſoon deſtroy them irrecoverably, by nipping off their young ſhoots. In wine countries, the boughs of this tree are uſed either whole or ſplit, according to their ſize, for props to vines; and hoops for barrels are alſo made of them. The large wood, if ſound, is ſold to ſhoemakers for wooden heels, and to turners for many kinds of light ware.

The poplar may be propagated either from layers or cuttings, which will readily take root; and alſo from the ſuckers, which the white ſort, commonly called the abele tree, ſends up in great plenty from its roots. The beſt time for tranſplanting theſe ſuckers, is in October, when their leaves begin to decay. Theſe may be planted in a nurſery for two or three years, to get ſtrength, before they are planted out where they are to remain: but for planting of cuttings, the beſt time is the latter end of February, when truncheons two or three feet long, ſharpened at their lower ends, may be thruſt about a foot and a half deep into the ground, where, if the ſoil be moiſt, they will readily take root, and arrive at a conſiderable bulk in a few years.

The black poplar is not ſo apt to take root from large truncheons: wherefore the better way with this is, to plant cuttings of it about a foot and a half long, and about a foot deep in the ground. Theſe will take root freely, and may afterwards be tranſplanted where they are to remain. This ſort will grow upon almoſt any ſoil, but will thrive beſt in moiſt places. It therefore flouriſhes remarkably on the ſides of rivers, ponds, canals, &c.

Mr. Miller ſays, he has planted cuttings of this tree, which in four years have been bigger in the trunk than a man's thigh, and near twenty feet in height, and this upon a very indifferent ſoil: but in a very moiſt ſoil, it is common for theſe trees to ſhoot eight or ten feet in a ſeaſon: ſo that where a perſon wants to make a ſhelter in a few years, there is ſcarce any tree ſo proper for the purpoſe as this is. The Memoirs of the Berne Society caution us not to plant poplars too much within a meadow, leſt their roots ſhould damage the graſs; to which they add, that their leaves are excellent food for ſheep.

It is rightly obſerved, by the experienced gardener before mentioned, that a conſiderable advantage may be made by planting theſe trees upon moiſt boggy ſoils, where few others will thrive. There are in England many ſuch places, which do not now bring in much money to their owners; whereas, if they were planted with poplars, they would, in a few years, over purchaſe the ground, clear of all expences. But it is a too common opinion, that nothing but corn is worth cultivating in England; or, if timber be planted, it muſt be oak, aſh, or elm; and if the land be not proper for either of theſe, it is deemed of little value: whereas, if the nature of the ſoil was examined, and proper plants were adapted to it, great profit might be made by ſeveral large tracts of land, which at this time lie neglected.

The wood of the poplar, and eſpecially that of the abele, which is much eſteemed on account of its great whiteneſs, is very good for laying floors, where it will laſt many years; but being of a ſoft contexture, it is very ſubject to take the impreſſion of nails, &c. which renders it leſs fit for this purpoſe. It is alſo very proper for wainſcoting rooms, becauſe it is leſs apt to ſwell or ſhrink, than moſt other ſorts of wood. For turnery ware, none is equal to this for its exceeding whiteneſs, and great lightneſs; wherefore trays, bowls, and many other utenſils are made of it; and the bellows makers prefer it for their uſe; as do alſo ſhoemakers, not only for heels, but alſo for the ſoles of ſhoes. It is likewiſe very fit to make light carts; the poles of it are very proper to ſupport vines, hops, &c. and its loppings afford good fuel, which is a valuable article in many countries.

The birch tree, which will grow on almoſt any ſoil, be it ever ſo barren for other plants, thrives equally well in moiſt

moist springy land, or in dry gravel or sand, though the surface be but very shallow. It has succeeded so well, even upon ground which produced nothing but moss, that it has been fit to cut in ten years after planting, when an acre of these trees has sold for near ten pounds, standing, and the after-produce has been considerably increased.

The best way to cultivate this three, is to take young plants of it from the woods, where they naturally grow, and are generally found in great plenty: but in places where no young plants can be procured, they may be raised from seeds, which should be carefully gathered in the autumn, as soon as the scales under which they are lodged begin to open; otherwise they will soon fall out and be lost. These seeds are small, and therefore should not be buried deep in the ground. The autumn is the best season for sowing them; and if this be done in a shady situation, the plants will thrive better than when they are exposed to the full sun.

When young plants of birch are taken from out of woods, in order to be transplanted, they should be carefully dug up, so as not to injure their roots. The ground in which they are to be set will not need any other preparation, than loosening it with a spade or mattock, in the places where the plants are to stand, making holes to receive their roots, and closing the earth hard to them after they are set. If the plants are young, and have not much top, they will not require pruning: but if they have bushy heads at the time of their being transplanted, those heads should be trimmed, or shortened, to prevent their being shaken, and displaced by the wind. After the plants have taken root the only care requisite is, to cut down the great weeds, which would over-hang them. This may be done with a sickle, so as not to cut or injure the young trees: nor need it be repeated oftener than twice in a summer during the two first years; for the plants will afterwards be strong enough to keep down the weeds, or at least to be out of danger from them.

These young birches may be transplanted at any time between the middle of October and the middle of March, when the ground is not frozen: but autumn is the best season for planting them in dry lands, and spring for setting them in a moist soil. The distance at which they should be planted, is six feet square, that they may soon cover the ground, and by standing close draw up each other; for they will not thrive so well, if they are not pretty close, in situations where they are much exposed.

If the plants take kindly to the ground, they will be fit to cut in about ten years; and after that they may be cut every seventh or eighth year, if they are designed for broom makers only; but when they are intended for hoops, for which they are excellent, they should not be cut oftener than every twelfth year. The larger trees are often bought for turners ware; and this wood is also used for making ox-yokes, and other instruments of husbandry. In some of the northern parts of Europe, it is much esteemed for making carriages and wheels, being hard and durable. In France, it is generally used for making wooden shoes. It makes very good fuel; and the author of a dissertation in the Memoirs of the Berne Society says, that its ashes are an excellent remedy for an erysipelas, or St. Anthony's fire: but he does not tell us how they are to be used.

In some places, these trees are tapped in the spring, and the sap is drawn out to make birch wine, which has been recommended for the stone and gravel; as is also the sap unfermented. The bark of the birch-tree is almost incorruptible. Many houses in Sweden are covered with it, and it lasts many years. It frequently happens, that the wood of this tree is entirely rotten, and the bark perfectly sound and good.

To make a plantation of birch in places where the young plants can be easily procured, will not cost above forty shillings an acre, and the after expence of cleaning will not exceed twenty shillings more; so that the whole will not be more than three pounds: and if the land be of so little value as not to be worth attempting to fit it for any other growth, the proprietor cannot make a better use of his money; for when the wood is cut, it will repay the disbursement with interest, and a perpetual stock will remain upon the ground. Mr. Miller says he has seen several of these plantations made upon land which would not let for one shilling an acre, and which has afterwards produced from ten to twelve pounds an acre, clear of the expence of cutting, every twelfth year.

The ash, of which our common sort is the most hardy, most lasting, and finest grained, and consequently the most valuable, will likewise thrive in low and moist places, as well as on high and dry grounds.

The seeds of this tree sown as soon as they are ripe, will come up the following spring; but if they are not sown till the spring, they will remain a year in the ground, which, in the mean time, should be kept clear of weeds, and not disturbed, for fear of turning out the seeds, or burying them too deep. When the plants are come up, they must be carefully weeded during the ensuing summer, and if they make good progress in the seed-bed, they will be fit to transplant by the autumn; the most proper time for which is, when their leaves begin to fall. Great care should be taken not to break or tear off their roots in transplanting them; for which reason it is much better to dig them up with a spade, than to draw them out by hand, as is commonly practised, in order to have the largest only, and leave the others for a second year's growth before they are removed. But the purpose of thus separating them is very easily answered, without the danger of injuring their roots, by digging up all, and then planting them in different rows, according to their sizes. The younger they are planted out, the larger they will grow: and it is of consequence that the soil from whence they are taken, or in which they are raised, be not better than that in which they are to remain: for when any plants are raised in good land, and afterwards transplanted into worse, they very seldom thrive. The best way of all is therefore to sow them on the spot where they are most wanted: for they may easily be thinned afterwards; and it will be found that those which are left standing will grow to a larger size than such as are transplanted.

People who live in the neighbourhood of ash trees, may easily supply themselves with plenty of self-sown plants, if cattle have not been suffered to graze on the land; for if they can come at them, they will eat them up as fast as they appear. If, indeed, the seeds of the ash happen to fall under hedges, where they are protected by bushes, the plants will come up and thrive; and, through the ignorance and inattention of some husbandmen, they are too frequently permitted to grow there till they have destroyed the hedge itself; for there is scarce any tree so hurtful to all kinds of vegetables, as the ash, which robs every plant of the nourishment that is within the reach of its roots. This tree should, therefore, never be suffered in hedge-rows; nor should it ever be permitted to grow near pasture grounds; for if cows eat of the leaves or shoots of the ash, all the butter that is made of their milk will be excessively rank. Such is the quality of the butter which is made about Guildford, Godalmin, and some other parts of Surry, where there are ash trees about all the pastures. In the good dairy countries, not an ash tree is suffered to grow.

This timber is of excellent service to wheel-wrights and cart-wrights, for ploughs, axle-trees, wheel-rings, harrows, &c. It is also used by cabinet-makers, when it is found and knotty; and likewise for oars, blocks for pullies, and many other purposes.

The best season for felling these trees, is from November to February; for if it be done either too early in autumn, or too late in the spring, their timber will be apt to become worm-eaten: but for lopping of pollards, the spring is most eligible for all soft woods.

In countries where there is great plenty of rough flat stones, the fences which bound an estate, or farm, are frequently made with them. It is a pretty common practice in Devonshire and Cornwall, where they build as if were two walls with these stones laid one upon another, first two, and then one between; and as the walls rise, they fill the intermediate space with earth, beat the stones in flat to the sides, which makes them lie very firm, and so proceed till the whole is brought to the intended height. They then plant upon these walls quick hedges, and even timber trees, which thrive exceedingly; and they esteem these fences the best security that can be to their ground and cattle. However, if these stones are laid rough and dry,

dry, they cannot but be disagreeable to the eye, and must certainly require frequent repairs, because they will frequently be forced out of their places, or beaten down by cattle.

To prevent this, let such walls be built in the bottom of a ditch, made wide enough for the purpose, and sloped down on each side. The deformity will then be hid: and as the cattle cannot stand facing the wall, so as to attempt to leap over it, the stones of which it is composed will be the less liable to be beaten down. The earth taken out of the ditch may be spread on the adjacent ground, and its sides may be planted with such trees, or under-wood, as best suit the soil. If a space of several feet, proportioned to the demand which there may be for timber, is left on the inside of the fence, it will be attended with every advantage arising from a supply of that necessary commodity, without prejudice to the arable or more valuable pasture.

Another very strong and durable fence may be formed thus, in grassy places. Dig pieces of turf, four or five inches thick, the breadth of your spade, and about a foot long. Lay these turfs even, by a line, on one side, with the grass outward, at the distance of ten or twelve inches within the mark at which the ditch, afterwards to be dug in the solid ground, is to begin. Then lay in the same manner, but with their grass sides turned out the contrary way, another row of turfs, at such distance as to make a breadth of foundation proportioned to the intended height of the bank. The reason for placing these turfs thus much within what is to be the edge of the solid ground dug away on each side, is to prevent the bank from falling in, if the ground underneath it should be any way defective. A ditch, of what breadth or depth you please, may then be dug; or the ground may be lowered on each side with a slope; in which last case there will be no loss of pasture by the fence, because it may be sowed with hay seeds, and will bear grass on both sides. Part of the earth taken out of the ditches or slopes, will fill the chasm between the rows of the turf, and the rest may be scattered over the adjacent ground. Three, four, or more layers of turf may be thus placed one upon another, and the interval between them filled up as before, till the bank is brought to the desired height; only observing to give each side of it a small slope, for greater strength. The top of this bank should be about two feet and a half wide, and the whole of it should be filled up with earth to a level with the turfs, excepting a little hollow in the middle, to retain some rain. Quick sets should then be planted along this top, and they will soon form an admirable hedge. By this means, a bank four feet high, and a slope only two feet deep, will make, besides the hedge, a fence six feet high, through which no cattle will be able to force their way: for the roots of the grass will bind the turfs so together, that, in one year's time, it will become entirely solid, not a joining will appear, nor a turf can be got out; and it will be yet much stronger, when the roots of the quick shall have shot out among it. The only precautions necessary to be observed here, are, first, not to make this bank when the ground is too dry; because, if a great deal of wet should suddenly follow, it will swell the earth so much, as, perhaps, to endanger the falling of some of the outside, which, however, is easily remedied if it should happen; and, secondly, if the slope be such as sheep can climb up, to secure the young quicks, at the time of planting them, by a small dead hedge, either on or near the top, on both sides. If any of the quicks should die, which they will hardly be more apt to do here than elsewhere, unless, perhaps, in extreme dry seasons, they may be renewed, as in other places, by planting new ones, or by layers from those which remain.

A fence like this will do even for a park; especially if posts and rails, about two feet high, are placed a little sloping over the side of the bank, on or near its top: for no deer will be able to jump over this, nor can they creep through it.

This is one of the best fences to afford shelter for cattle; and if the quick on the bank is kept well clipped, it will form a kind of green wall, pleasing to the eye.

When the bounding fence is only to guard against accidents from without, it may be made in the ha-ha manner; only taking care that the earth be so well rammed down at the back of the wall, as that the stones may be properly supported, and bear equally.

The ingenious author of the Essays on Husbandry recommends the horn-beam plant, as one of the best yet known for making fences, according to the method used in Germany, where such fences are common.

"When the German husbandman, says he, erects a fence of this nature, he throws up a parapet of earth, with a ditch on each side, and plants his horn-beam sets in such a manner, as that every two plants may be brought to intersect each other, in the form of St. Andrew's cross. In that part where the two plants cross each other, he gently scrapes off the bark, and binds them with straw thwart-wise. Here the two plants consolidate in a kind of indissoluble knot, and push from thence horizontal slanting shoots, which form a sort of living palisado, or *chevaux de frise*; so that such a protection may be called a rural fortification. These hedges, being pruned annually, and with descretion, will, in a few years, render the fence impenetrable in every part. *Essays on Husbandry, essay* I. *page* 14.

FENNEL, the name of a well known plant cultivated in kitchen gardens. It is propagated by the seeds, which ripen in autumn, and should be sown soon after. They will come up in the spring, and require no other care than to keep them clean from weeds. This plant will grow in any soil or situation.

FENNY, moorish, marshy, boggy.

FENNY-LAND. *See the articles* BOG, MARSH, *and* MOOR.

FERMENT, the substance used to raise a fermentation, as yeast, wine, lees, leven, &c.

FERMENTATION, an intestine motion excited in vegetable substances, whereby the cohesion of their parts are destroyed, and may easily be separated from one another.

In every fermenting liquor, an intestine motion is generated in all its parts. It is called intestine, because it is excited by the internal principles contained in the vegetable juices; for vegetable juices or infusions made in water, however bright at first, and apparently homogeneous, on being kept in a moderately warm place, in vessels not closely stopped, become turbid, conceive an intestine motion, emit numerous air-bubbles, and discharge a pungent vapour of extreme subtilty.

All bodies which may be so changed by this intestine motion, as to produce wine, are said to be fermentable: and as this was never found to happen in any other than vegetable substances, vegetables alone are said to be fermentable.

The fermentable class of vegetables are extremely various, and might be distributed into as many classes, as they require different methods of fermenting. We shall, however, mention them no further than they relate to the pleasure and profit of the husbandman.

The first class of fermentable substances includes all the pulpous summer fruits, which, when ripe, abound with a tartish sweet juice; such as grapes, apples, pears, elder-berries, gooseberries, rasberries, currants, cherries, plums, and all other summer fruits, provided they be kept free from a tendency to putrefaction.

The second class contains the fresh expressed and native juice of plants, provided they be of a tartish and sweetish taste; such as the juice of the sugar-cane, of liquorice, and other similar plants. To this class may be added all the juices which distil from certain trees when wounded, especially in the spring; as the birch, the plane or maple, the vine, the walnut-tree, &c. The maple has this remarkable property, both in the small kind and in the great, which is called the sycamore, that, being tapped, it will bleed freely in the winter, and its juice will flow very plentifully even after a hard frost. All these juices generally run into a spontaneous fermentation.

The third class comprises those vegetable juices which are formed and inspissated by nature into a certain saponaceous substance, consisting of saline and oily particles; such as honey, manna, and all other juices which are not gummy or unctuous.

The fourth class comprehends all those seeds which, when ripe and dry, may be ground into a fine meal, without their forming an unctuous paste; such are barley, wheat, oats, rye, &c.

Certain phyſical circumſtances are requiſite to render theſe different ſubſtances fit for fermentation; namely, firſt, a perfect degree of maturity ſuitable to each kind. All ſeeds and fruits which are ſo perfect, as, when ſown in fertile ground at a proper ſeaſon, and in a proper climate, to produce a plant of their own ſpecies, are fit for this operation. Another requiſite to fermentation is a moderate proportion of oil: for though fat ſubjects are more apt to grow rancid, than to ferment, yet if they are entirely deprived of their oils, they are hereby alſo rendered unfit for fermentation. Thus, bruiſed almonds, which are rich in oil, will ſcarcely ferment; but they may be ſo far freed from their oil by art, as to be made fitter for this purpoſe. Solubility in water is a third and principal requiſite in fermentable ſubjects.

The methods of preparing each fermentable ſubſtance for fermentation will be given under the articles wine, cyder, and beer.

The juices of ſummer fruits are, of their own nature, greatly diſpoſed to ferment, ſo as immediately to begin this operation, without the addition of any other ferment. Other liquors may, however, ſtand in need of the help of other ferments, to begin this inteſtine motion, which, under proper conduct, proceeds afterwards of itſelf. The chief of theſe ferments is the recent flowers, commonly called yeaſt, thrown up to the top of beer in the act of fermentation: for if this rarified frothy matter be mixed with other fermentable liquors, it greatly promotes their fermentation. The ſame matter become heavier, and ſunk to the bottom, provided it be not too ſtale, ſtill retains the ſame vigour, though in a leſs degree than in its former ſtate. The remains of former fermenting liquors ſticking to the ſides of caſks, have the ſame effect: for caſks thoroughly penetrated by the ſubtilty of wines which they formerly contained, are extremely apt to raiſe a violent and quick fermentation in the freſh liquors put into them. Acid paſte of flour fermented, or bakers leaven, may all be employed for the ſame purpoſe: for though meal may be preſerved freſh and ſweet during years, if it be kept in a dry ſtate, and perfectly free from inſects; yet if it be wrought with water into a ſoft cloſe paſte, and lightly covered in a warm place, it will ſoon begin to heave, be all over full of cavities, change its ſmell, colour, and tenacity, prove acid both to taſte and ſmell; and thus become that proper ferment from which the whole of this operation firſt took its name. When thus prepared, if part of it be mixed with other paſte, freſh and not yet fermented, it will cauſe this to ferment much ſooner, and more ſtrongly, than it would otherwiſe do. Hence, we need not be ſolicitous about a firſt ferment, becauſe nature affords it ſpontaneouſly every where. The great promoters of all the ſtages of this proceſs are warmth, a moderate admiſſion of air, and the addition of actually fermenting matter.

If we take large glaſs bodies, place them upright where they may be kept in an equal heat, and then fill each of them three quarters full with a crude fermentable liquor well prepared for the operation, the orifice being ſlightly covered with a cloth, and a heat kept up to above ſixty degrees, it will be pleaſing to obſerve the ſeveral degrees of fermentation.

The maſs, at firſt reſting, and poſſeſſing a certain ſpace for the veſſel, gradually begins to ſwell, rarify, and conceive an inteſtine motion through its whole body, acting upwards, downwards, and ſideways, in ſtrange circumvolutions, without ceaſing, though with a different force. In the mean time bubbles are every moment formed in every part of the maſs, and conſtantly endeavour to riſe up to the ſurface, where they burſt with a hiſſing noiſe, or often break in the mid-way. Hence the whole maſs froths, diſcharging with an audible ebullition a certain tartiſh ſpirit, which proves acrimonious to the noſe, ſurpriſingly elaſtic, and capable of burſting almoſt any veſſel by its great expanſive force. If a large veſſel full of fermenting muſt, in the height of its action, ſhould diſcharge this condenſed ſpirit through a ſmall orifice, and a ſtrong healthy man ſhould draw in at his noſtrils the vapour ſo iſſuing, he would inſtantly fall down dead; or if he received but little thereof, he would become apoplectic, and remain an idiot his whole life. When this vapour is confined and accumulated in cloſe rooms, it will extinguiſh fire, and ſuffocate animals. Its producing the firſt of theſe effects is a ſign that it is collected in ſufficient quantity to cauſe the other. While candles continue to burn, we need not be afraid that this wild gaſs, as Helmont calls it, will be dangerous to life. It is on account of this ſpirit, that people are obliged to air wine-vaults, where wines are fermenting in the vintage ſeaſon, by ſetting open the windows, lighting fires, and letting in the wind.

In the progreſs of fermentation, the groſſer parts of the maſs begin to riſe to the top, and ſeparate there from the other liquor below, ſo as to collect into a ſpungy cruſt, which exactly covers the liquor underneath, and keeps in the more active parts thereof, in ſuch manner as to prevent their being exhaled and diſſipated before they have performed their effect. Now, it is curious to obſerve how great the agitation conſtantly is every where, even in the ſmalleſt part of the fluid matter, below this cruſt. A greater attrition can ſcarcely be conceived, than that which is here made with the utmoſt rapidity among all the particles. The cruſt being ſucceſſively broke, and raiſed up with a conſiderable noiſe, upon the returns of the exploſions, the exhalations eſcape, while the cruſt, preſently falling together, cloſes again, and prevents the active principles from exhaling otherwiſe. Thus, the formation and continuance of the cruſt is greatly aſſiſting in the due performance of fermentation.

As ſoon as all the groſs parts of the mixture are thus collected at the top, ſome leſs rarified particles of the lower part of the cruſt, being no longer ſuſtained by the light bubbles which cauſed them to aſcend, begin to ſink through the fluid, and are agitated upwards and downwards by bubbles in and about themſelves, by means of which they are again raiſed to the top, from whence, upon the breaking of the bubbles there, they again fall downward; and when they have done this ſeveral times, they at length remain quiet at the bottom. After this, new little maſſes do the ſame; and after ſome continuance thereof, it frequently happens that all the upper cruſt, then grown heavier, or leſs rarified, on account of the air diſcharged, ſinks of a ſudden downward, but ſoon after rolls upward, almoſt entire, with ſuch a force as would ſeem incredible, if it were not ſeen. When the upper cruſt is thus gradually conſumed and fallen to the bottom, the fermentation ceaſes, though the ſame degree of heat be continued; and the liquor, then floating over the fæces which remain at the bottom, becomes tranſparent.

So long as the cruſt remains at top, it is called the flowers of the fermenting liquor, and is the moſt proper and immediate ferment. What falls to the bottom is called lees.

The time requiſite for the perfect completing of fermentation can hardly be determined, becauſe it is different in different liquors, and depends much on the ſeaſon of the year, and heat of the weather. The juice of the palm tree finiſhes its fermentation in a few hours in Africa; and this operation is likewiſe very ſoon ended in Aſia; but in the northern countries, it proceeds ſlower. In the heat of ſummer, it proceeds quick; but in winter more languidly. It is, however, eaſy to know when the fermentation is finiſhed, viz. when the whole ſeries of the phenomena above deſcribed, has ſucceſſively appeared, and is at length ſpontaneouſly gone off. Then the veſſel ſhould be immediately ſtopped down; and the liquor ſhould be kept for ſome time on its lees, a great part of which will be aſſumed and aſſimilated by the liquor, which will thereby become ſtronger and richer in ſpirit than it was before. If the veſſel is not ſtopped down, the ſpirit produced in the fermented liquor will ſoon exhale, and leave behind only a vapid uſeleſs fluid; but if the liquor is kept quiet in a cloſe veſſel, it will gradually become more pure and ſpirituous. The ſweeter and richer the juice is, the longer does the fermentation continue, and the ſtronger and more ſpirituous is the wine or other liquor.

The diſtinguiſhing marks of a vinous liquor are as follow: It has the faculty of inebriating, or of altering the actions of the ſpirits and animal functions, by refreſhing, animating, and exhilirating the drinker: after this, it raiſes the latent paſſions (*in vino veritas*;) and finally, it deſtroys the external and internal ſenſes and voluntary motions, and thus brings on palſy, ſleep, or at laſt death.

Fermentation

Fermentation alſo changes the relaxing, ſaponaceous, cooling, and generally purging virtues of vegetable juices, into ſuch as are ſtrengthening, coagulating, and healing. Thus, the freſh infuſion of malt, before fermentation; ſolution of ſugar or honey in water; the freſh expreſſed juices of ripe ſummer fruits, &c. when plentifully drank, prove flatulent, purgative, weakening, and cooling; but when properly fermented into beer, mead, or wine, they have quite contrary qualities, which they had not before. It is a very ſingular property of fermentation, that it produces from fermented liquor a ſpirit which is convertible into a liquid flame, and yet may be perfectly mixed with water.

The things, which promote fermentation, or tend to the better performance thereof, are free admiſſion and emiſſion of air, a warmth between fifty and ſeventy degrees, and the addition of a proper ferment.

It is found that when ſweet juices are boiled down to a thick conſiſtence, they not only do not ferment in that ſtate, but are not eaſily brought to ferment, when diluted with as much water as they had loſt in the evaporation. Juices and decoctions in general, which have ſuffered much fire, however ſweet, are little diſpoſed to ferment.

One of the chief checks given to fermentation, is the fumes of burning ſulphur, received in a large quantity at ſeveral times, and ſhut up along with the air remaining on the top of the fermenting liquor. If the whole caſk be penetrated and filled with the fumes of burning ſulphur before the fermenting liquor is put in, and if the empty part on the top of the liquor be afterwards well filled with the ſame, and the veſſel cautiouſly bunged down, the fermentation will certainly be ſtopped: and if, after ſome time, it ſhould begin again, from the prevalency of its own cauſe, it may again be ſuppreſſed by the ſame fumes. The ſame end is alſo obtained by mixing with the fermenting matter a large quantity of any powerful acid, ſuch as acid ſpirits of vitriol, or nitre; though theſe at the ſame time prove hurtful to the fermenting liquor. Alkaline ſalts likewiſe, if added in a large quantity to fermenting liquors, immediately excite an increaſe of effervеſcence, which preſently ceaſing, all farther fermentation is ſtopped. But here too fermenting liquor is ſpoiled, ſo that it can ſcarcely be brought again to ferment, though it may to putrify. In the ſame manner, thoſe things which deſtroy acidity by drinking it up, hinder fermention. Thus, chalk, teſtaceous and calcarious ſubſtances, iron, lead, tin, have this effect. Stopping up the containing veſſels ſo cloſe, that nothing can eſcape or enter, will ſtop the fermentation, provided the veſſel be ſo ſtrong as not to be burſt by the force of the confined liquor. This is manifeſt in new malt liquors, which, when included in ſtrong bottles, well corked, effervеſce violently upon receiving the air. The extracting of the elaſtic air ſtops fermentation: too great heat rather diſſipates and throws off the active principles of fermentation, than excites and promotes them; and, laſtly, too great a degree of cold likewiſe ſtops fermentation.

FERN, the name of one of the worſt of weeds, and one of the moſt difficult to deſtroy where it has a deep ſoil to root in. Mr. Mortimer ſays, he has ſeen its root eight or ten feet deep in ſome grounds; and adds, that the beſt way of killing it is by cutting it often while it is in graſs; that the moſt proper ſeaſons for this purpoſe are the ſpring, midſummer, and Michaelmas: that is, when the circulation of the ſap is ſtrongeſt. Moſt of the roots being then cut aſunder, and thereby deprived of the channels through which nature intended to convey the ſap, will bleed to death, or, if it ſtagnates in them, they will ſoon rot. The fern itſelf, if cut when full of ſap, and left to rot upon the ground, will greatly improve the ſoil, and mellow it ſo as to prevent its binding: or, if it be burnt when ſo cut, it will yield a much greater quantity of ſalt, than any other vegetable. If it be ploughed up, plentiful dunging of the land, and ſprinkling it well with aſhes, have been found to kill this weed: but the moſt certain cure for it is urine. In ſeveral parts of the North, where they keep their fern under, and deſtroy a great deal of it by mowing it frequently when green, they alſo find that rolling of it is of great ſervice; and when they burn it, the poor people make the aſhes of it up into balls, with a little water, dry them in the ſun, and uſe them in waſhing their linnen, for which they think them nearly as good as ſoap. Often treading down theſe plants, and feeding Scotch ſheep on them, is ſaid to be almoſt an infallible way of killing the fern.

Trees planted among fern will thrive very much, though it be on a hot gravel; the fern ſhading their roots, and keeping them moiſt and cool.

FERTILE, fruitful, abundant, plenteous.

FERTILITY, fecundity, abundance, fruitfulneſs.

FESCUE, the name of a genus of graſs, of which there are ſeveral ſpecies; as the flote-feſcue, the ſheep's feſcue, &c. *See the articles* FLOTE-FESCUE, SHEEP'S FESCUE, &c.

FESTING-PENNY, earneſt given to ſervants when hired.

FETLOCK, the tuft of hair that grows behind the paſtern-joint of many horſes; thoſe of low ſize have ſcarce any ſuch tuft.

FETTERS, chains for the feet.

FEVER, a diſeaſe that frequently attacks ſeveral ſorts of cattle, particularly horſes.

The ſymptoms which denote the horſe to be afflicted with a fever, are great reſtleſſneſs, the creature ranging from one end of the rack to the other; his flanks heat; his eyes are red and inflamed; his tongue parched and dry; his breath hot, and of a ſtrong ſmell; he loſes his appetite, and nibbles his hay, but without chewing it, and is frequently ſmelling to the ground; the whole body is hotter than ordinary (though not parched, as in ſome inflammatory diſorders) he dungs often, little at a time, uſually hard, and in ſmall bits; he ſometimes ſtales with difficulty, and his urine is high coloured; he ſeems to thirſt, but drinks little at a time and often; his pulſe beat full and hard, to fifty ſtrokes and upwards in a minute.

The firſt intention of cure is bleeding, to the quantity of two or three quarts, if the horſe is ſtrong and in good condition; then give him a pint of the following drink four times a day; or an ounce of nitre mixed up into a ball with honey, may be given thrice a day, inſtead of the drink, and waſhed down with three four horns of any ſmall liquor.

> Take of baum, ſage, and chamomile flowers, each a handful; liquorice root ſliced, half an ounce; ſalt prunel, or nitre, three ounces: infuſe the whole in two quarts of boiling water, and when cold ſtrain it off; then ſqueeze into it the juice of two or three lemons, ſweeten it with honey.

As the chief ingredient to be depended upon in the drink is the nitre, it may, perhaps, be as well given in water alone; but as a horſe's ſtomach is ſoon palled, and he requires palatable medicines, the other ingredients may in that reſpect have their uſe. Soleyſel for this purpoſe adviſes two ounces of ſalt of tartar, and one of ſal armoniac to be diſſolved in two quarts of water, and mixed with a pail of common water, adding a handful of bran or barley-flower to qualify the unpleaſant taſte: this may be given every day, and is an uſeful medicine.

The following alſo may be given for this purpoſe:

> Take Ruſſia pearl aſhes one ounce, diſtilled vinegar one pint, ſpring water two pints, honey four ounces; give a pint three or four times a day.

This neutral mixture, and the nitre drink above, may be taken alternately; they are both efficacious remedies, and in ſome caſes may properly enough be joined with the camphor drink.

His diet ſhould be ſcalded bran, given in ſmall quantities; which, if he refuſes, let him have dry bran ſprinkled with water: put a handful of picked hay into the rack, which a horſe will often eat, when he will touch nothing elſe: his water need not be much warmed, but ſhould be given often, and in ſmall quantities: his cloathing ſhould be moderate, too much heat and weight on a horſe being improper in a fever; which ſcarce ever goes off in critical ſweats (as thoſe in the human body terminate) but by ſtrong perſpiration.

If, in a day or two he begins to eat his bran, and pick a little hay, this method with good nurſing will anſwer; but if he refuſes to feed, more blood ſhould be taken away, and the drinks continued: to which may be be added two or three drams of faffron, avoiding at this time all hotter medicines: the following clyfter fhould be given, which may be repeated every day, efpecially if his dung is knotty and dry.

> Take two handfuls of marfhmallows, and one of chamomile flowers; fennel feed an ounce; boil in three quarts of water to two, ftrain off, and add four ounces of treacle, and a pint of linfeed oil, or any common oil.

Two quarts of water-gruel, fath broth, or pot-liquor, with the treacle and oil, will anfwer this purpofe; to which may be added a handful of falt. Thefe fort of clyfters are properer than thofe with purging ingredients.

The following opening drink is very effectual in thefe fevers, and may be given every other day, when the clyfters fhould be omitted; but the nitre-balls or drink may be continued, except on thofe days thefe are taken.

> Take of cream of tartar and Glauber's falts, each four ounces; diffolve in barley-water, or any other liquor: an ounce or two of lenitive electuary may be added, or a dram or two of powder of jallap, to quicken the operation in fome horfes.

Four ounces of Glauber falts or cream of tartar, with the fame quantity of lenitive electuary, may be given for the fame purpofe, if the former fhould not open the body fufficiently.

In four or five days the horfe generally begins to pick his hay, and has a feeming relifh to food: though his flanks will heave pretty much for a fortnight; yet the temper of his body, and return of appetite, fhew that nothing more is requifite to complete his recovery, than walking him abroad in the air, and allowing plenty of clean litter to reft him in the ftable.

This method of treating a fever is fimple, according to the laws of nature; and is confirmed by long experience, to be infinitely preferable to the hot method.

The intention here is to leffen the quantity of blood, promote the fecretions of urine and perfpiration, and cool and dilute the fluids in general.

How far vinous cordials, ftrong beer drinks loaded with fiery powders, and fuch methods are likely to anfwer thefe purpofes, is fubmitted to the judicious obferver; as alfo, whether adopting the cool one in its ftead is not as real an improvement in farriery as phyfic.

There is another fort of fever that horfes are fubject to, of a more complicate and irregular nature than the former; which, if not properly treated, often proves fatal.

The figns are a flow fever with languifhing, and great depreffions; the horfe is fometimes inwardly hot, and outwardly cold; at other times hot all over, but not to any extreme; his eyes look moift and languid; he has a continual moifture in his mouth, which is the reafon he feldom cares to drink, and when he does, it is but little at a time. He feeds but little, and leaves off as foon as he has eat a mouthful or two; he moves his jaws in a feeble loofe manner, with an unpleafant grating of his teeth; his body is commonly open; his dung foft and moift, but feldom greafy; his ftaling is often irregular, fometimes little, at other times profufe, feldom high-coloured, but rather pale, with little or no fediment.

When a horfe's appetite declines daily, till he refufes all meat, it is a bad fign. When the fever doth not diminifh, or keep at a ftand, but increafes, the cafe is then dangerous. But when it fenfibly abates, and his mouth grows drier, the grating of his teeth ceafes, his appetite mends, and he takes to lay down (which perhaps he has not done for a fortnight) thefe are promifing figns. A horfe in thefe fevers always runs at the nofe, but not the kindly white difcharge, as in the breaking of a cold, but of a reddifh or greenifh dufky colour, and of a confiftence like glue, and fticks like turpentine to the hair on the infide of his noftrils. If this turns to a gleet of clear thin water, the horfe's hide keeps open, and he mends in his appetite; thefe are certain figns of recovery.

The various and irregular fymptoms that attend this flow fever, require great fkill to direct the cure, and more knowledge of the fymptoms of horfes difeafes, than the nenerality of gentlemen are acquainted with. The experienced farrier fhould therefore be confulted and attended to, in regard to the fymptoms; but very feldom as to the application of the remedy, which is generally above their comprehenfion; though it may be readily felected, by duly attending to the obfervations here inculcated.

Firft then, a moderate quantity of blood, not exceeding three pints, may be taken away, and repeated in proportion to his ftrength, fullnefs, inward forenefs, cough, or any tendency to inflammation. After this, the fever drink may be given, with the addition of an ounce of fnake-root, and three drams of faffron and camphor, diffolved firft in a little fpirit of wine; the quantity of the nitre may be leffened, and thefe increafed, as the fymptoms indicate.

The diet fhould be regular; no oats given, but fcalded, or raw bran fprinkled; the beft flavoured hay fhould be given by handfuls, and often by hand, as the horfe fometimes cannot lift up his head to the rack.

As drinking is fo abfolutely neceffary to dilute the blood, if the horfe refufes to drink freely of warm water or gruel, he muft be indulged with having the chill only taken off, by ftanding in the ftable; nor will any inconvenience enfue, but oftener an advantage; for the naufeous warmth of water, forced on horfes for a time, palls their ftomachs, and takes away their appetites, which the cold water generally reftores.

Should the fever after this treatment increafe, the horfe feed little, ftale often, his urine being thin and pale, and his dung fometimes loofe, and at other times hard, fhould the moifture in his mouth continue, his fkin being fometimes dry, and at others moift, with his coat looking ftaring, and furfeited. Upon thefe irregular fymptoms, which denote great danger, give the following balls, or drink; for in thefe cafes there is no time to be loft.

> Take of contrayerva-root, myrrh, and fnake-root powdered, each two drams, faffron one dram, mithridate or Venice treacle half an ounce, make into a ball with honey, which fhould be given twice or thrice a day, with two or three horns of an infufion of fnake-root, fweetened with honey; to a pint and a half of which may be added, half a pint of treacle-water, or vinegar, which latter is a medicine of excellent ufe, in all kinds of inflammatory and putrid diforders, either external or internal.

Should thefe balls not prove fuccefsful, add to each a dram of camphor, and where it can be afforded, to a horfe of value, the fame quantity of caftor. Or the following drink may be fubftituted in their ftead for fome days.

> Take of contrayerva and fnake-root, of each two ounces, liquorice-root fliced one ounce, faffron two drams; infufe in two quarts of boiling water clofe covered for two hours, ftrain off, and add half a pint of diftilled vinegar, four ounces of fpirit of wine, wherein half an ounce of camphor is diffolved, and two ounces of mithridate or Venice treacle; give a pint of this drink every four, fix, or eight hours.

A more fimple drink, and perhaps full as efficacious may be thus prepared:

> Take camphor one dram diffolved in rectified fpirit of wine one ounce, then gradually pour on a pint of diftilled vinegar warmed, and give for two dofes. The quantity of camphor may be increafed.

Should the horfe be coftive, recourfe muft be had to clyfters, or the opening drink: fhould he purge, take care not to fupprefs it, if moderate; but if, by continuance, the horfe grows feeble, add diafcordium to his drinks, inftead of the mithridate; if it increafes give more potent remedies.

Let it be remembered, that camphor is a very powerful and effectual medicine, in thefe kinds of putrid fevers; being both active and attenuating, and particularly calculated to promote the fecretions of urine and perfpiration. It has been long celebrated in malignant fevers, as it gives motion to ftagnant humours, in the moft diftant parts, and promotes their expulfion by the common outlets; nitre may

may be advantageously joined with it in many cases. These are the medicines that are chiefly to be depended on in putrid epidemic fevers, where the circulation is slow and languid, the blood and juices tending to coagulate, putrify, and run into grumes.

A horse should drink plentifully to promote the operation of these medicines; but instead of them, to a horse of small value, give an ounce of diapente, and half an ounce of mithridate, and one dram of camphor, with a strong infusion of rue, scordium, and snake-root, in the manner as above directed.

Regard should also be had to his staling; which, if in too great quantities, so as manifestly to depress his spirits, should be controuled by proper restringents, or by preparing his drinks with lime-water. If, on the contrary, it happens that he is too remiss this way, and stales so little as to occasion a fullness, and swelling of his body and legs, recourse may be had to the following drink:

> Take of salt-prunella, or nitre, one ounce; juniper-berries, and Venice turpentine, of each half an ounce; make into a ball with oil of amber.

Give him two or three of these balls, at proper intervals, with a decoction of marshmallows, sweetened with honey.

But if, notwithstanding the method we have laid down, a greenish or reddish gleet is discharged from his nostrils, with a frequent sneezing; if he continues to lose his flesh, and becomes hide-bound; if he altogether forsakes his meat, and daily grows weaker; if he swells about the joints, and his eyes look fixed and dead; if the kernels under his jaws swell, and feel loose; if his tail is raised and quivers; if his breath smells strong, and a purging ensues, with a discharge of fœtid, dark coloured matter, his case may then be looked on as desperate, and all future attempts to save him will be fruitless.

The signs of a horse's recovery are known by his hide's keeping open, and his skin feeling kindly; his ears and feet will be of a moderate warmth, and his eyes brisk and lively; his nose grows clean and dry; his appetite mends; he lays down well, and both stales and dungs regularly.

Be careful not to overfeed him on his recovery; let his diet be light, feeds small, and increased by degrees as he gets strength: for by overfeeding, horses have frequent relapses, or great surfeits, which are always difficult of cure.

This is the most successful method of treating these irregular, malignant fevers; where it is evident, by the various efforts nature makes to relieve herself, she wants assistance, and a spur to quicken her motions. For by the use of these warm medicines, a crisis, or termination of the disease is quickened and promoted, as appears by the alteration made both in the urine and skin; the former of which, by its thickness, shews signs of concoction, as it is called, or of a separation of the feverish matter from the blood; and the latter by its smoothness and glossiness proves that a regular and free perspiration is obtained: these two secretions are of such importance to the welfare of every animal, that the necessity of rectifying them, when disordered, is obvious from the consequences.

If this fever should be brought to intermit, or prove of the intermitting kind, immediately after the fit is over, give an ounce of jesuits-bark, and repeat it every six hours, till the horse has taken four or six ounces; should eruptions or swellings appear, they ought to be encouraged, for they are good symptoms at the decline of a fever, denote a termination of the distemper, and that no further medicines are wanted.

The true reasons perhaps why so many horses miscarry in fevers, are, that their masters, or doctors, will not wait with patience, and let nature have fair play: that they generally neglect bleeding sufficiently at first; and are constantly forcing down sugar-sops, or other food in a horn, as if a horse must be starved in a few days, if he did not eat: then they ply him twice or thrice a day with hot medicines and spirituous drinks, which (excepting a very few cases) must be extrmely pernicious to a horse, whose diet is naturally simple, and whose stomach and blood, unaccustomed to such heating medicines, must be greatly injured, and without doubt are often inflamed by such treatment.

From the experience we lately had of the epidemic cold and fever among our horses, and from the observations of others in the years 1732 and 1734, it evidently appeared that the simplest method of treatment succeeded best. Thus it is proper to bleed largely at first, to the quantity of three quarts, if the horse is full and strong: and if it appears that his lungs are not relieved by it, but continue stuffed and loaded, the bleeding should be repeated; and a rowel may be put in his chest or belly.

Dilute the blood with plenty of water, or white drink; let his diet be warm bran mashes, and his hay sprinkled. Should the fever rise, which will be known by the symptoms above described, give him an ounce of nitre thrice a day in his water, or made up in a ball with honey. Let his body be kept cool and open, with the opening drink, given twice or thrice a week; or an ounce of salt of tartar may be given every day, dissolved in his water, for that purpose, omitting then the nitre. After a week's treatment in this manner, the cordial ball may be given once or twice a day, with an infusion of liquorice-root sweetened with honey; to which may be added, when the phlegm is tough, or cough dry and husky, a quarter of a pint of linseed, or sallad-oil, and the same quantity of oxymel squills.

As the kernels about the throat are greatly swelled in these cases, I need not mention the necessity of keeping the head and throat warmer than ordinary, to promote a freer perspiration, and forward the running at the nose, which in a horse answers the end of spitting, or expectoration in us: but the nose should never be syringed, as is sometimes done, to promote this discharge, which it often checks, and occasions bad swellings in the neighbouring parts and glands; for let it be remembered these are critical runnings of nature's own appointment, which by art may soon be frustrated. The following cooling purge is very proper to give at the decline of the distemper, and may be repeated three or four times.

> Take two ounces of senna; anniseed and fennel bruised, each half an ounce; salt of tartar three drams; let them infuse two hours in a pint of boiling water; strain off, and dissolve in it three ounces of Glauber salt, and two of cream of tartar: give for a dose in the morning.

This purge generally works before night very gently; and in fevers, and all inflammatory disorders, is infinitely preferable to any other physic.

Before we close this account of fevers, it may be no improper hint to the curious, to take notice that a horse's pulse should more particularly be attended to than is customary, as a proper estimate may thereby be made both of the degree and violence of the fever present, by observing the rapidity of the blood's motion, and the force that the heart and arteries labour with, to propel it round. The nighest calculation that has been made of the quickness of the pulse in a healthy horse, is, that it beats about forty strokes in a minute; so that in proportion to the increase above this number, the fever is rising, and if farther increased to above fifty, the fever is very high.

How often the pulse beats in a minute may easily be discovered by measuring the time with a stop-watch, or minute sand-glass, while your hand is laid on the horse's near side, or your fingers on any artery; those which run upon each side of the neck are generally to be seen beating, as well as felt a little above the chest. *Bartlet's Farriery, page* 31.

FEWEL, combustible matter; as fire, wood, coal, &c.

FIELD, a piece of ground enclosed, whether for tillage, or pasture.

FIELD *scabious*, a perennial weed common among the corn. It is all over rough and hairy. The stalk is upright, and often a foot or a foot and a half high, spotted, and branching. The lower leaves are oval, and indented about the edges. Those which grow on the stalk are divided, and of that sort which botanists called pinnatifid. The flowers are blue, and of the compound kind, consisting of a considerable number of small flowers, each divided into four parts, and having one seed under them. The taste of the plant is a disagreeable bitter.

FIG-TREE, the name of a fruit-tree common in the warmer climates, and which ripens its fruit very well in our gardens.

Method of cultivating FIG-TREES.

These trees are always planted as standards, in all warm countries; but in England they are generally planted against walls, there being but few standard fig-trees, at present, in the English gardens: however, since the fruit is found to ripen well upon the standards, and the crop of figs is often greater upon them, than upon those trees against walls, it may in time become the general practice to plant them either in standards or espaliers: the latter, I think, will succeed best in England, if they were managed as in Germany; where they untie the fig-trees from the espalier, and lay them down, covering them from the frost with straw or litter, which prevents their shoots being injured by the frost; and this covering is taken away gradually in the spring, and not wholly removed until all the danger of the frost is over; by which management they generally have a very great crop of figs: whereas, in England, where the trees grow against warm walls, if the spring proves warm, the young figs are pushed out early; and the cold, which frequently returns in April and May, causes the greatest part of the fruit to drop off, so that our crop of figs is generally more uncertain than most other sort of fruit; and it frequently happens, that trees which are planted against north and east aspected walls, produce a greater quantity of fruit in England, than those which are planted against south and south-east aspects, which must happen from the latter putting out their fruit so much earlier in the spring than the former: and, if there happen cold frosty nights, after the figs are come out, which is frequently the case in this country, the forwardest of the figs are generally so injured as to drop off from the trees soon after. In Italy, and the other warm countries, this first crop of figs is little regarded, being few in number; for it is the second crop of figs which are produced from the shoots of the same year, which is their principal crop; but these rarely ripen in England; nor are there above three or four sorts which ever ripen their second crop, let the summer prove ever so good; therefore it is the first crop which we must attend to in England: so that when these trees are growing against the best aspected walls, it will be a good method to loosen them from the wall in the autumn; and, after having divested the branches of all the latter fruit, to lay the branches down from the wall, fastening them together in small bundles, so that they may be tied to stakes, to keep them from lying upon the ground; the damp whereof, when covered in frosty weather, might cause them to grow mouldy; and hereby they will be secured from being broken by the wind. When they are thus managed in the autumn, if the winter should prove very severe, the branches may be easily covered with pease-haulm, straw, or any other light covering, which will guard the tender fruit-bearing branches from the injury of frost: and when the weather is mild, the covering must be removed, otherwise the figs will come out too early; for the intention of this management is to keep them as backward as possible: then in the spring, when the figs are beginning to push out, the trees may be fastened up to the wall again. By this management I have seen very good crops of figs produced in two or three places.

I have also seen great crops of figs in some particular gardens, after very sharp winters, when they have, in general, failed in other places, by covering up the trees with reeds made into panels, and fixed up against the walls.

In the pruning of fig-trees, the branches must never be shortened; because the fruit are all produced at the upper part of the shoots; so, if these are cut off, there can be no fruit expected; besides, the branches are very apt to die after the knife; so that, when the branches are too close together, the best way is to cut off all the naked branches quite to the bottom, leaving those which are best furnished with lateral branches at a proper distance from each other, which should not be nearer than a foot; and, when they are well furnished with lateral branches, if they are laid four or five inches farther asunder, it will be better.

The best season for pruning of fig-trees is in autumn, because, at that time, the branches are not so full of sap; so they will not bleed so much as when they are pruned in the spring; and, at this season, the branches should be divested of all the autumnal figs; and the sooner this is done, when the leaves begin to fall off, the better will the young shoots resist the cold of the winter. There are some seasons so cold and moist that the young shoots of the fig trees will not harden, but are soft and full of juice: when this happens, there is little hope of a crop of figs the succeeding year; for the first frost in the autumn will kill the upper part of these shoots, for a considerable length downwards: whenever this happens, it is the best way to cut off all the decayed parts of the shoots, which will prevent the infection from destroying all the lower part of the branches; and by this method I have seen a moderate crop of figs put out from the lower part of the shoots, where, if the shoots had not been injured, there would have been no fruit produced; because it is chiefly from the four or five uppermost joints of the shoots that the fruit comes out: and it is for this reason, that as many of the short lateral branches should be preserved as possible, those being the most productive of fruit; for, where the long strait shoots are fastened up, there will be no fruit, but at their extremities; so that all the lower part of the trees will be naked, if there be not a particular regard had to supply young shoots in every part of the trees. *Miller's Gard. Dict.*

FIG, the name given by farriers to a sort of wart on the frush, and sometimes all over the body of a horse. The figs that appear on the frush or sole, discharge a malignant stinking humour, which is very difficult to cure.

FIG-WORT, *pile-wort*, or *lesser centaury*, a perennial weed common in pasture-grounds. The roots consist of oblong knobs. The leaves are heart-shaped, cornered, and placed on foot-stalks. The flowers in general resemble those of the crowsfoot, but differ somewhat from them in having the cup divided into three parts only, the petals being about eight in number, and narrower. This low plant runs very much by the roots, and choaks all others which are near it.

FILBERT, or *filberd*, a species of the hazel propagated in gardens.

Filbert-trees may be raised by planting their nuts in February; till which time they should be kept in sand in a moist cellar, where no vermin can get at them: but the most expeditious way, and at the same time the surest of obtaining the sorts desired, is to raise them from layers.

FILLER, or *thiller* horse, that fastened immediately to the cart, and which supports the shafts.

FILLY, a female or mare colt.

FIMBLE-*hemp*, early ripe hemp.

FINE-BENT, the name of a very excellent species of grass found in great plenty on the best sheep-pastures. We have given a figure of this grass on Plate XV. Fig. 4. *see the article* GRASS.

FIRE-BLAST, an accident to which hops are very liable. *See the article* HOPS.

FIRE-BOTE, a quantity of fuel.

FIRING, an operation often performed on different parts of a horse. It is done in the following manner: when the firing-iron is red hot, the farrier applies the thinnest part to the horse's skin, in one or more places, according to the nature of the disease.

Firing, or cauterizing, is often necessary after strains and other accidents, which may occasion a long continued weakness, or where there is a fullness, and the part is grown hard and callous, especially about the joints, sinews, and nervous parts, those parts being composed of an infinite number of fibres and nervous threads, which lie so close together, that nothing but what is of the most powerful nature is sufficient to relieve them when obstructed. This is performed in the most effectual manner, by burning the outside, and giving vent to the inclosed matter to discharge itself; and sometimes proves beneficial, when all other helps have been found ineffectual.

In firing about the sinews and nervous parts, great care is to be taken not to go too deep at first, but by gentle repeated

repeated razes on lines, till they come to a pale red colour; for if the fire once touches the finew, it will make the horfe go lame as long as he lives: the fame ought to be drawn pretty clofe together on each fide the joints or finews, following the courfe of the hair, without making of crofs lines, which are of no ufe in thefe parts, and are only apt to disfigure the horfe afterward.

When the more flefhy parts, or an obftinate humour, that cannot be brought to fuppuration, requires firing, the fkin ought to be pierced deeper, in order to draw away a fufficient quantity of matter from the part; the fame ought to be performed upwards, to prevent any ulcerous difpofition attending it: and in fuch cafes little foft dofils of tow, dipped in warm bafilicon, and fpirit of wine, may be thruft gently up into the orifices.

The firing inftrument, or knife, ought to be fomewhat rounded on the edge, and gradually thicker to the back, fufficient to keep the heat of the fire for fome time; the fame fhould be rubbed clean, that no dirt or afhes may ftick to it, and not ufed until the flaming rednefs is in part gone off. All the feared parts ought immediately to be bathed with fpirits of wine, and where nothing elfe is requifite to complete the cure, the place is only to be anointed with oil and bees-wax melted together. *Gibfon's Farriery, vol.* I. *page* 251.

FIRING-IRON, a piece of iron about a foot long, one end of which is made flat, and forged like a knife, the back of it being half an inch thick, and the edge about the eighth of an inch.

FIR, a timber tree very common on mountainous and barren places, efpecially in the colder climates. It differs from the pine, in having fingle leaves, which are, for the moft part, produced on every fide of the branches; whereas the pine has two or more leaves produced out of the fheath or cover.

Fir trees are raifed from feeds taken out of their polyfpermous cones. The way to get out the feeds is, either by expofing the cones to a gentle fire, or by foaking them all night in water, which will caufe their fquamous cells to open, and readily emit their feeds. The former method is the beft, provided they are not expofed to too great heat. But this ought not to be done until you are ready to fow them, which is beft performed in the beginning of March.

Thefe plants fhould be all raifed in a nurfery, where they may be protected from the birds, otherwife they will be in danger of being deftroyed, when they firft come up: for as they bring up the hufk of the feed on the top of the plant, the birds in picking off the hufk will break off the plant, whereby a whole bed may be loft in a few hours, if they are not carefully guarded from them.

The beft time of fowing thefe feeds is about the latter end of March, or the beginning of April, on a bed of light earth, covering the feeds about half an inch deep with the fame fort of earth. In this bed the plants fhould remain until the following fpring, when there fhould be a number of beds prepared in the nurfery to receive thefe feedling plants; and the beginning of April they fhould be tranfplanted into the beds, at the diftance of fix inches row from row, and at three inches afunder in the rows. If the feafon fhould prove dry, it will be proper to water the plants every week once or twice, according to the warmth of the weather; and the beds fhould be covered with mats, to fcreen the plants from the fun, and drying winds, until they have taken good root; after which time they will require no farther care, but to keep them clear from weeds. In thefe beds the plants may remain two years; at the end of which they fhould be tranfplanted into an open fpot of ground; for their roots will in that time meet quite over the beds.

The diftance which thefe plants fhould be placed in this nurfery, fhould be four feet row from row, and two feet afunder in the rows.

When the plants are planted, if the feafon fhould prove dry, they fhould be watered, to fettle the earth to their roots; and if this is repeated three or four times, if the feafon fhould continue dry, it will greatly promote their taking new root, and fecure them from the injuries of the drying winds. In this nurfery the plants may remain two or three years, according to the growth they fhall have made; and, during this time, the ground between the plants fhould be conftantly keept clean from weeds, and dug between the rows every fpring; in doing of which, care muft be taken not to cut or i jure the roots of the plants: this is all the culture they will require during their continuance in the nurfery: and, when they are tranfplanted into the places where they are to remain, the neceffary care to be taken is, in taking them up, not to injure or cut off their roots, and let them be as little time out of the ground as poffible; and, when they are out, to guard their roots from the drying winds. The fureft time for removing of thefe trees is about the beginning of April; though they may, and often are removed with fuccefs at Michaelmas, yet the fpring is the more fure feafon, efpecially in moift land.

Moft of the kinds of firs may be removed at the height of fix or feven feet; but thofe of two feet high are much better, and will in a few years get the better of thofe taller trees. *Miller's Gard. Dict.*

FISH-PONDS, refervoirs of waters, applied to the breeding or feeding of fifh.

Fifh-ponds are no fmall improvement of watery and boggy lands, many of which are fit for no other ufe. In making of a pond, its head fhould be at the loweft part of the ground, that the trench of the flood-gate, or fluice, having a good fall, may not be too long in emptying. The beft method of making the head fecure, is to drive in two or three rows of ftakes above fix feet long, at about four feet diftance from each other, the whole length of the pond head, whereof the firft row fhould be rammed at leaft about four feet deep. If the bottom is falfe, the foundation may be laid with quick-lime, which flacking, will make it as hard as a ftone. Some lay a layer of lime, and another of earth dug out of the pond, among the piles and ftakes; and when thefe are well covered, drive in others, as they fee occafion, ramming in the earth as before, till the pond-head be of the height defigned.

The dam fhould be made floping on each fide, leaving a wafte to carry off the over-abundance of water in times of floods or rains; and as to the depth of the pond, the deepeft part need not exceed fix feet, rifing gradually in fhoals towards the fides, for the fifh to fun themfelves, and lay their fpawn. Gravelly and fandy bottoms, efpecially the latter, are beft for breeding; and a rich foil with a white fat water, as the wafhing of hills, commons, ftreets, finks, &c. is beft for fattening all forts of fifh. For ftoring a pond, carp is to be preferred for its goodnefs, quick growth, and great increafe, as breeding five or fix times a year. A pond of an acre, if it be a feeding and not breeding one, will every year feed two hundred carps of three years old, three hundred of two years old, and four hundred of a year old. Carps delight in ponds that have marl or clay bottoms, with plenty of weeds and grafs, whereon they feed in hot months.

Your pond fhould be drained every three or four years, and your fifh forted. If it is a breeding one, the fmaller ones are to be taken out to ftore other ponds with, leaving a good ftock of females, at leaft eight or nine years old, as they never breed before that age. In feeding ponds, it is beft to keep them pretty near of a fize. *Mortimer's Hufbandry, vol.* I. *page* 290.

FISTULA, a deep, narrow, and callous ulcer, generally arifing from abfceffes. *See* ULCER.

FISTULAR, FISTULOUS, an epithet applied by farriers to wounds and ulcers, which degenerate into fiftulas.

Fiftular, or *fiftulous*, is alfo an epithet applied by botanifts to leaves and flowers which are tubular, or that refemble a hollow pipe.

FLAGS, the turf, or furface of the ground, which they pare off for burning. *See* BURN-BAKING.

FLAIL, a well known implement of hufbandry, ufed in threfhing all forts of corn. *See the article* THRESHING.

FLAX, the name of a plant cultivated both for the fake of its ftalk and feed, the former being ufed in making linen, and the latter for oil.

The ftem of this plant, which is round and hollow, grows to the height of about two feet, and then divides into feveral branches: thefe are terminated by blue flowers, confifting of five petals, and are fucceeded by capfules divided within into ten cells, in each of which is enclosed a bright, slippery, elongated seed. Its leaves are long, narrow, sharp-pointed, and placed alternately along the stem and branches.

The soil for flax should be a stiff loam, rendered fine by tilth, and situated in a valley bordering upon water; or such a soil as is thrown up by rivers. If there be water at a small depth below the surface of the ground, it is thought still better, as is the case in Zealand, which is remarkable for the fineness of its flax, and where the soil is deep and stiff, with water almost every where, at the depth of a foot and a half, or two feet underneath it. It is said to be owing to the want of this advantage, that the other provinces of Holland do not succeed equally well in the culture of this useful plant; not but that fine flax is also raised on high lands, if they have been well tilled and manured, and if the seasons are not very dry.

It is justly remarked in the letters which the Dublin Society have published on the culture of flax, that moist stiff soils yield much larger quantities of flax, and far better seed, than can be obtained from light lands: nay, that the seed procured from the former may, with proper care, be rendered full as good as any that is imported from Riga or Zealand: but, as M. Du Hamel rightly observes, strong land can hardly yield such fine flax as that which grows on lighter ground.

In the southern countries, the husbandmen who raise flax, sow part of their seed in September and October; so that the plants which spring from thence, remain of course in the ground all the winter; and this is a judicious practice in those places, because plants which have not covered the earth well before the summer heats come on, are apt to be parched by the heat and drouth which usually prevail in that season. They sow linseed again in the spring; but the latter do not yield so large a crop: the flax, however, which it produces is more esteemed, because it is finer than that sown in autumn. M. Du Hamel seems, indeed to think, that the autumnal sowing yields the best seed; but however that be, in places where the winter is apt to be severe, and where the flax, which is but a tender plant, would in course be in danger of being destroyed during that season, almost all the flax is sown about the end of March, or in the beginning of April. This spring flax is what we shall principally consider in this article.

It may be laid down as a general rule, that the land which is intended for flax should be brought to exceeding fine tilth by repeated ploughings, and that it should be enriched by a manure suited to the quality of the soil. Thus, when a pasture is broken up in order to its being sowed with flax, it must be well ploughed during eighteen months, or two years, before it will be fit for producing a crop of flax. To defray the expence of this culture, some other crops may be got off the land in the mean time, especially of such plants as do not occupy it long, and particularly of those which are remarkably benefited by frequent stirring of the earth whilst they grow; such as beans, pease, turnips, &c. because these repeated stirrings render the mould fine and loose, and help to kill the weeds, which would otherwise do great damage to the flax. The Memoirs published by the Society of Britanny inform us, that the Livonians, when they clear woodland, burn the wood upon it, then plough it, and in this state prefer it to any other kind of soil for flax.

If the land which is intended for flax be stiff, great care should be taken not to till it when it is wet, for fear of kneading it.

If the ground on which flax is to be raised has been long in tillage, it should be ploughed deep before winter, and laid up in very high ridges, in order that the winter's frosts may the more effectually moulder or loosen it.

In the month of February, if the land be not too wet, some very rotten dung should be laid in the furrows, and immediately covered over. In March, for southern countries, or in the beginning of April, where the climate is colder, another ploughing should be given to lay the land smooth, the clods should be broken by hand, or with the spiky-roller, and the seed should then be sown and harrowed in with a light or bush-harrow, so as not to bury it above an inch deep. If the soil be moist and cold a little pigeon's dung may be sown with the seed, for it agrees admirably well with the flax: but this must not be done if the ground is very light and too dry. It will also be right to lay wet land out in beds thirty or forty feet wide, separated by deep trenches, to drain off the water, and convey it into the surrounding ditches.

Most of our linseed is brought from the North, namely, from Riga and Zealand: but we may ourselves raise it very good, by conforming to the directions here given.

Linseed is reckoned good when it is large, oily, heavy, and of a bright brown colour. To know whether it be oily, a few grains of it are thrown into a red-hot fire-shovel, and they in that case crackle almost instantly and blaze briskly. If it is sufficiently heavy, it will sink to the bottom of water; and to judge whether it be new, a number of seeds exactly counted should be sown on the end of a hot-bed, and notice taken whether they all grow.

When the goodness of the seed is known, more or less of it is to be sown according as the husbandman intends either to raise a quantity of linseed for sowing, or to have very fine and soft flax. In this last case, the seed should be sown pretty thick, in order that the plants may rise the closer together, and by that means grow slender and tall, which adds much to the fineness of the fibres of the flax. If the linseed is sown with an intention to let the flax remain for seed, a much less quantity of it should be used, that so the plants may come up thin, and thereby have room to grow to their full vigour and extent. As strong soils should be chosen for this purpose, it may perhaps be most advisable to follow the example of the judicious M. de Chateauvieux, in sowing it in drills, and horse-hoeing the intermediate spaces. He observed in his experiments, that the plants of flax thus raised yielded great plenty of excellent seed.

Some sow, with their linseed, either annual or perennial grass-seeds, when they intend to lay the land down for pasture after the flax is taken off. The plants grow but weakly under the flax, which, however, they do not hurt; but as soon as the flax has been pulled, they increase apace, to the great benefit of their owner.

Flax is sometimes damaged by insects when it is about three or four inches high. It is said that they may be destroyed by a slight strewing of soot, ashes, &c. At all events, it is certain that this dressing will give vigour to the flax, though it should not kill the insects.

If any weeds appear among the flax, as is almost always the case, they must be thoroughly rooted out; and that the flax may be as little damaged as possible in the doing of this, the weeders should work bare-footed: they may indeed sit down upon the flax, for sitting upon it is found not to hurt it; but it would be greatly injured, if not killed, by being trod upon with the heels of shoes.

The finest flax is most liable to be laid, particularly in countries subject to storms. To guard against this accident, some people run across their flax field slender poles fixed to stakes: but a better method, and which is practised by the ingenious gentleman who directs the cambrick manufactory at Winchelsea, is, to run small ropes across the field, both lengthwise and breadthwise; for these, being fastened where they interfect one another, and supported by stakes at due distances, form a kind of netting, which is proof against almost every accident that can happen from tempestuous weather.

Opinions are divided in regard to the degree of ripeness at which it is best to pull flax. Some think it should be pulled whilst it is green, in order that its fibres may be the softer and finer. Others, with the same view, pull it up before its seeds are quite formed; and others again think, that it should not be pulled till some of the capsules, which contain the seeds, have begun to open, being of opinion, that the fibres of green flax are too tender, and that they fall into tow. On the other hand, it is certain, that the fibres of flax which has stood till it is very ripe, are always stiff and harsh, that they are not easily separated from the reed, and that they do not bleach well. Here, therefore, as in most other cases, both extremes should be avoided; and it consequently seems most reasonable to think, that the properest time for pulling flax, is when its stalks begin to turn yellow, when its leaves begin to fall, and when its seeds begin to be brown.

As

As soon as the flax is thought to have attained a due maturity, it is pulled generally by handfuls: but as it is seldom all of an equal degree of ripeness, or of an equal degree of strength, it would certainly be advisable to pull first the ripest and strongest plants, and then the weaker and less ripe; for by this means they would at once be separated, which is of essential importance in the watering, because the weak and green flax requires much less steeping than the stronger and more ripe. All weeds, and the earth which adheres to the roots of the plants, should be carefully taken away, and then the handfuls of flax should be laid regularly on the ground.

The author of the judicious letters concerning flax, in the Dublin Society's Weekly Observations, seems to direct a too great degree of ripeness of the flax when it is pulled, and assigns as a reason, that it does not otherwise stand the force of the mill for scutching it. But as it has been found by experience, that the force of that mill is too great, and as a better method of performing this operation, in which the force can be suited to the strength of the flax, will soon be published, this great degree of ripeness will become the less necessary.

As the flax is pulled, it is laid together by handfuls, with the seed ends turned to the south. These handfuls should neither lie quite in a line with each other, nor directly across, but a little slanting upwards, so that the air may easily pass through them. Some, instead of this method, tie the handfuls of flax loosely at the top, then spread out their roots, and thus set several of them together upright upon their roots. In either of these ways, the flax is generally left twelve or fourteen days in the field to dry it. This drying is certainly not necessary for the rippling, because the ripple will separate the capsules from the flax as effectually before it has been dried, as it will afterwards; and if it be done with a view to ripen the seed, it should be considered, that the flax will be more hurt by the longer time of steeping, which will become necessary in consequence of this drying, than the seed can be benefited; because the more the membrane which connects the fibres to the reed is dried, the greater must be the degree of putrefaction necessary to loosen and destroy the cohesion of this connecting membrane: the finer parts of the flax itself must necessarily be destroyed by this degree of putrefaction; and if the putrefaction does not arise to such a degree as to destroy the cohesion of this membrane, the fibres of the flax will adhere so strongly to the reed, that the force necessary in scutching will prove equally detrimental to the flax. The practice in some parts of Brittany, as we are informed by the Memoirs of the Society of that province, seems therefore much more rational; and this is, to ripple the flax after it has lain in the air two or three days: but even one day will be sufficient if the weather is dry.

If any flax is raised on purpose for seed, or if, through the dryness of the season, or the badness of the seed that was sown, the flax is come up very thin, so as manifestly to shew, that the seed which it may produce will be more valuable than the rest of the crop; in either of these cases, the flax should be let stand till its seed is perfectly ripe; thus sacrificing the flax itself to the then greater advantage of having good seed.

In order to ripple the flax, which is the next operation, a large cloth should be spread on a convenient spot of ground, with the ripple placed in the middle of it. The manner of performing this work is so well known, that there can be no need to describe it here. Its purpose is to obtain the linseed, which is always of considerable value, even though the flax has been pulled before its perfect maturity.

After the flax has been rippled, the seeds thereby obtained should be spread in the sun, to dry. Those which separate from the pods of their own accord are the fullest and ripest, and should therefore be set apart for sowing, in case the precaution of raising some flax purposely for seed has not been attended to. The pods, or capsules, are then broken, either by treading, or by threshing, in order to get out the remaining seeds, the whole of which, as well as the former, should be carefully sifted, winnowed, and cleaned. When the seed is laid up, it must be frequently stirred, or ventilated, to prevent its heating. Even this second seed affords a considerable profit, by the oil which it yields, and also by being used, when broken, for fattening of cattle. The cakes of linseed, after the oil has been pressed out of them, are likewise found to be useful for this last purpose, though they are thought to render the fat of cattle yellow; for which reason it is advised not to give them till within a few weeks before the beasts are to be killed. Their utility as a manure has been already mentioned.

As soon as the flax has been rippled, it should be carried with all convenient speed to the watering place. If care has not been taken before to separate the different kinds of flax, that separation must now be made; because, otherwise, some of the flax will be rotted in the water, before the rest will be sufficiently steeped.

The choice of the water for steeping it in is thus very properly pointed out in the Directions for raising Flax, published by order of the Commissioners and Trustees for Fisheries, Manufactures, and Improvements, in Scotland.

"All flax ought to be watered in canals, which should be dug in clay ground if possible, because that soil best retains the water: but if a firm retentive soil cannot be got, the bottom or sides of the canal, or rather both the bottom and sides, may be lined with clay; or, instead of lining the sides with clay, which might fall down, a ditch may be dug without the canal, and filled with clay, which will prevent both extraneous water from entering, and the water within from running off.

"A canal of forty feet long, six broad, and four deep, will generally water the produce of at least an acre of flax.

"It should be filled with fresh soft water from a river or brook, if possible, two or three weeks before the flax is put in, and exposed all that time to the heat of the sun. The greater way the river or brook has run, the softer, and therefore the better, will the water be. Springs, or short runs from hills, are too cold, unless the water is allowed to stand long in the canal. Water from coal or iron is very bad for flax. A little of the powder of galls thrown into a glass of the water, will immediatly discover if it comes from minerals of that kind, by turning it into a dark colour, more or less tinged in proportion to the quantity of vitriol contained in it.

"The canal ought not to be under any shade, because this, besides keeping the sun from softening the water, might render some parts of the canal cooler than other parts, and thereby make it water the flax unequally.

"The flax raiser will observe, that, when the water has been brought to a proper degree of heat by the sun, small plants will rise quickly in it, numbers of small insects and reptiles will generate there, and bubbles of air will rise up to its surface. If no such signs appear, he may conclude, that the water is not warm enough, or that it is otherwise unfit for flax."

Running water is not proper for steeping flax, because it prevents that degree of putrefactive fermentation which is necessary to separate the fibres from the reed; and besides this, in such streams, the flax is apt to be carried away by sudden floods, or to be filled with the mud and slime which those floods bring with them: but to have a small rill of water pass through the steeping place is very advisable, because it will supply the loss of that which is evaporated. Stagnant water, which is naturally of a bad colour, should likewise be avoided, because this communicates to the flax a colour which is not afterwards easily got rid of.

The flax, after it has been rippled and sorted, as before mentioned, should be tied very slack, with a band made of a few stalks, in bundles not larger than a man can easily grasp with both his hands, in order that the water may the more easily and more equally penetrate through them; and in this condition they should be put into the canal, somewhat sloping, or even half-standing upon one end, which, say the Edinburgh directions, should be the seed end, and consequently the root end uppermost; because, add they, (though I do not find it at all noticed by any other writers on this subject) when the seed ends are uppermost, there frequently breeds a great deal of vermin, destructive of the flax, and this, they assure us, is effectually prevented by putting the seed end downmost. However this may be, the flax, when put into the water, should be covered with straw, or fern, upon which a wicker hurdle and some stones may be laid, to keep it down, but without preſſing too hard againſt the bottom. It is a common opinion, that if the flax is not thus covered, the ſun will diſcolour it, even though it be quite covered with water.

More or leſs time is requiſite for the ſteeping of the flax, according to the nature of the water, the heat of the air, and the greater or leſs degree of woodineſs of the flax. It is ſteeped ſooner with a ſouth than a north wind; and that which has been pulled green is alſo much ſooner ſteeped than that which has been pulled when very ripe: conſequently it is not poſſible to fix any preciſe length of time during which it ſhould remain in the water. The way to know whether it has been ſteeped enough, is to draw a few ſtalks from out of the middle of the heap, and then try it: if the reed ſnaps ſhort, without bending, and if the bark parts eaſily from the reed, towards its point, the hemp has been ſufficiently ſteeped, and it muſt, in this caſe, be ſpeedily taken out of the water, for otherwiſe it will ſoon become too tender, and begin to rot.

In ſome countries, the flax is ſteeped but four days, at the end of which it is taken out of the water, and the little bundles, or handfuls, into which it was before made up, are laid regularly ſide by ſide, till they have formed a pretty thick bed, upon which are then put planks loaded with ſtones. The flax is left in this condition four or five days, or more, according to the heat of the air; and its lying thus in a heap anſwers the intent of farther ſteeping in water: but as a great degree of putrefaction may ariſe in this operation, ſo much judgment and care are neceſſary, that I cannot think it an adviſable method.

The Memoirs of the Society, which the States of Brittany have inſtituted, upon a truly judicious plan, for the improvement of agriculture, arts, and commerce, inform us, in conſequence of an account which the duke of Choiſeuil, miniſter of ſtate in France for foreign affairs, received from the French ambaſſador at the court of Ruſſia, to whom he had written on this ſubject, at the requeſt of the ſociety, that the the Livonians uſe two ſorts of places for ſteeping their hemp and flax; that the moſt ſimple of theſe are only holes dug near the ſide of rivers, and that the flax, or hemp, watered in them (which is very like the method practiſed in France) generally ſells for from twenty-five to thirty per cent. leſs than that which has been ſteeped in the following manner.

When they would have flax or hemp of ſuperior quality, they chooſe a ſpot where there is a fall of clear water, and there make, one under another, five, and ſometimes ſix, baſons or reſervoirs, each of which is at leaſt one foot, and at moſt two feet deep. The water can either be let run from one baſon to another, or be ſtopped at pleaſure. The baſons are ſeparated by ſlight banks of clay; and in each bank is a little opening, which may be cloſed whenever it is thought proper. To prevent the ſtream from overflowing the firſt baſon, and afterwards ſucceſſively the others, it is itſelf turned a little aſide by a ſmall bank of clay, and this bank is broken down whenever the water is to be renewed in the baſons.

The Livonians put their hemp and flax firſt into the uppermoſt baſon only. At the end of two, three, or four days, they remove it into the ſecond baſon, from thence into the third, and ſo on, till they have brought the ſeveral bundles of theſe plants down into the loweſt. At each of theſe ſhiftings, the firſt baſon is filled with freſh flax, and the water is renewed in all the baſons. By this means, the ſteeping is not completed till the flax or hemp has paſſed through all the baſons, and has remained a proper time in the lowermoſt, which is the laſt. Neither the Engliſh nor the Dutch import any hemp from Riga, but what has been ſteeped in this laſt mentioned manner; whereas a great part of that which the French receive from thence, is ſuch as has been ſteeped in ſtagnant waters, in holes dug on the ſide of rivers.

When the flax is taken either out of the water in which it has been ſteeped, or from the heap above-mentioned, the bundles of it are ſpread out, like a fan, at the root end, and laid on a dry new-mown meadow, that it may dry, bleach, and become ſupple. It is there turned from time to time, and as ſoon as it is quite dry it is carried off: for otherwiſe the moiſture of the dews and graſs will have nearly the ſame effect upon it, as if it had remained longer in the water. This is evinced by the practice of thoſe, who, in ſome places, inſtead of putting their flax into water, only ſpread it on a damp meadow where the graſs is ſomewhat long, leave it there all night, and in the morning, before the ſun has dried it, gather it up in large heaps, and remove it into the ſhade, in order to ſpread it out again upon the graſs the next evening; and this is repeated till the flax is found to be ſufficiently watered. In other places, it is watered by hand during the day, and ſo let it remain conſtantly on the graſs. It is then let dry, and is afterwards houſed. But, as M. Du Hamel rightly obſerves, this method is ſo tedious and troubleſome, that, even if it ſhould, as ſome ſay it does, give a little additional whiteneſs to the flax; yet the advantage in that reſpect is ſo ſmall, as by no means to compenſate for the inconveniencies of the practice, which he therefore thinks is not adviſable in any caſe, unleſs it be when the flax, after being taken out of the water, is found not to have been ſufficiently ſteeped.

The diſadvantage of laying the flax upon long graſs, after it has been ſteeped, in order to dry it, is very juſtly pointed out in the Directions for raiſing Flax, publiſhed by order of the commiſſioners and truſtees for fiſheries, manufactures, and improvements in Scotland, when they adviſe the huſbandman by no means to follow this method, becauſe the graſs, growing through the flax, frequently ſpots, or rots it. Theſe judicious gentlemen therefore recommend ſhort heath, as the moſt preferable place for ſpreading flax upon, after it has been taken out of the water; and this the rather, becauſe, when the flax is wet, it faſtens to the heath, and is thereby prevented from being blown away by the wind, whilſt at the ſame time the heath keeps it a little above the earth, and ſo expoſes it the more equally to the weather: but grounds expoſed to violent winds ſhould alſo be avoided.

" The flax, continue they, when taken out of water, muſt be ſpread very thin upon the ground; and as it is then very tender, it muſt be gently handled. The thinner it is ſpread, the better, as it is then moſt equally expoſed to the weather: but it ought never to be ſpread during a heavy ſhower, becauſe that would waſh and waſte too much the bark, which is then exceſſively tender; though it ſoon after becomes firm enough to bear the rains, which, with the open air and ſunſhine clean, ſoften, and purify it to the degree deſired, and fit it admirably for parting from the reed: in ſhort, after the flax has acquired a little firmneſs by being a few hours ſpread in dry weather, the more rain and ſunſhine it gets, the whiter and better it will be.

" The ſkilful huſbandman, who follows this method, ſpreads his firſt row of flax at the end of the field from whence the moſt violent wind commonly comes, placing the root-ends foremoſt: he makes the root-ends of every other row overlap the ſeed-ends of the former row three or four inches, and binds down the laſt row with a rope; by which means the wind does not eaſily get below the flax, to blow it way: and as the ſeed-ends are ſeldom ſo fully watered as the root-ends, this over-laying has an effect like giving the ſeed-ends more watering.

" The flax is judged to have been ſufficiently graſſed, when it is of a clearer colour than before, when its bark is bliſtered up, when that bark parts eaſily from the reed, and when the reed is become very brittle: but no written deſcription can poſſibly here convey a knowledge of this point, at all equal to that which is acquired by experience.

" The whole of the flax ſhould be ſufficiently graſſed before any of it is lifted; for if a part be lifted ſooner than the reſt, that which remains will be in great danger from the winds.

" A dry day ſhould be choſen for taking up the flax; and if there is no appearance of high wind, it ſhould be looſed from the heath or graſs, and left looſe for ſome hours, to make it thoroughly dry.

" As a great quantity of flax can ſcarcely be all equally watered and graſſed, and as its different qualities will beſt appear at lifting it off the graſs, each different kind ſhould then be collected together, and kept by itſelf, that is to ſay, all of the ſame colour, length, and quality.

" The ſmaller the bundles are into which the flax is made up, the better they will be for drying, houſing, &c. and

and in making up these bundles, as in every other operation upon flax, it is of great consequence that all the stems be laid together as they grew, that is to say, root-ends to root-ends, and seed-ends to seed-ends.

The Livonians, say the before quoted Memoirs of the Society of Brittany, cut off the roots of their hemp, but not of their flax, when it is taking out of the steeping basons above described. They then tie the flax or hemp up in bundles about as thick as the lower part of a man's thigh. These bundles are placed upright, and supported by a stake, around which a few of the tops of their stalks are twisted, the better to secure their standing. They are left in this situation one day, to drain; then they are spread upon the grass for one or two days, and after this they are laid in heaps, and covered over with haulm, stubble, straw, or some other such like covering, to make them sweat. When the hemp or flax has sweated enough, it is laid in heaps in the shade, and there dried: but these heaps must not be so thick, but that the air may penetrate a little into them. It is on this last operation that the good or bad quality of the hemp or flax thus managed chiefly depends. Both of them may be kept two or three years, and even longer, upon their reeds, after they have been prepared in the manner above directed; and when it is intended to break them, after this keeping, they are put into an oven properly heated.

In the common way, after the flax has been grassed, it must be dried by heat, to make its reed break readily, and separate the more easily from the bark. To guard against the danger of fire, this business is frequently performed in a place distant from any other building. The caverns, or hollows under hills, or rocks, before described for drying hemp, are also very proper for this purpose.

There are two general ways of drying flax. Some place against a wall, upon uprights and cross pieces, a hurdle of which the bars are small, and about two inches asunder, and upon this the flax is spread four, five, or six inches thick: a small fire, made of broken reeds of flax, is cautiously kindled under it, and care is taken to turn the hemp from time to time, that it may dry equally in every part: the flax-dresser takes off only that part of it which is at the side of the hurdle next the wall, then pushes the rest forward into its place, and fills with fresh flax the vacancy thereby made at the fore-part of the hurdle. This operation should not be entrusted to any but a very attentive person, because if the flame should be suffered to rise too high, it would set fire to the flax. It is true, indeed, that this seldom happens; and when it does, the loss is not great, because but a small quantity of flax is laid together on the hurdle. Some say, that the smoke of the fire thus made of the broken reeds hurts the colour of the flax, and that this lessens its price when it is sold; but that the quality of the linen made of it is not at all the worse, this discolouring being easily removed by bleaching.

The other method of drying flax is by putting it into a hot oven. The Livonians make their ovens, for this purpose, either of clay, brick, or hewn-stone. Those which are built with clay, are sometimes large enough to contain eight hundred bundles at a time: but it is more common to make them for only two, three, or four hundred. They are shaped like the ovens for an army, that is to say, they are very high arched. They require no greater degree of heat, which is given with dead wood, furze, broom, &c. than is just sufficient to render the reed of the flax brittle; and the same of hemp, for the Livonians use them for both these plants, the bundles of which they set upright in them, and as soon as they take them out of the oven, they carry them to a kind of a mill, to be broken.

The Dutch build their ovens for drying flax within a large capacious chimney at the end of the building where the breakers and scutchers work. The usual dimensions of this building, which is well lighted, are, in the clear, thirty feet by fourteen; but it is sometimes larger where great business is carried on, though seldom, if ever, less. The dimensions of the oven here generally are fifteen feet in depth, ten in breadth, and five feet in height: its roof is arched, its entrance, which is just large enough to admit a man with tolerable ease, is made to shut close with a wooden door. This oven is not heated with wood, excepting at the very first; for after the workmen have begun to dress the flax, the broken reeds, and other refuse parts which are beaten off it, and swept up, suffice to continue the heat, so that each parcel affords firing for the next, till the whole is dried. The Dutch kindle the fire in the oven some hours before the day's work is over. The sweepings of the flax light easily, and the oven heats and cools again sufficiently before the breaking, and scrutching is finished. They fill it when they leave off work; and the next day when they return to it they find the flax dry and fit for breaking. The flax breaks best and most easily when it is a little warm and crisp: and consequently the working it then is cheapest and most advantageous; and accordingly the Dutch never draw two bundles together from the oven, but take them one by one as they want them. It will, perhaps, be needless to observe, that when the oven is heated, it must be well cleaned before the flax is put in; for the least spark will set the flax on fire, and this would be a considerable loss, as the ovens hold a large quantity.

An ingenious correspondent of the editors of the Museum Rusticum has given us the following directions for raising flax, as practised by the flax-raisers in Scotland.

Of the Choice of the Soil, and preparing of the Ground for Flax.

A skilful flax-raiser always prefers a free, open, deep, loam, and all grounds that produced the preceding year a good crop of turnips, cabbages, potatoes, barley, or broad clover, or had been formerly laid down rich, and kept for some years in pasture.

A clay soil, the second or third crop after being limed, will answer well for flax; provided, if the ground be still stiff, that it be brought to a proper mould, by tilling after harvest, to expose it to the winter frosts; and that a little sharp dung, such as pigeons, sheep, or horse-dung, or ashes, be spread upon the ground immediately before sowing.

All new grounds produce a strong crop of flax, and pretty free of weeds. When a great many mould heaps appear upon new ground, it answers the better for flax after one tilling.

Flax-seed ought never to be sown on grounds that are either too wet or dry, but on such as retain a natural moisture: and such grounds as are inclined to weeds ought to be avoided, unless prepared by a careful summer fallow.

Before sowing, the bulky clods should be broken, or carried off the ground; and stones, quickenings, and every other thing that may hinder the growth of the flax, should be removed.

Of the Choice of Linseed.

The brighter in colour, and heavier the seed is, so much the better: that which, when bruised, appears of a light or yellowish green, and fresh in the heart, oily and not dry, and smells and tastes sweet, and not fusty, may be depended upon.

Dutch seed of the preceding year's growth, for the most part, answers best; but it seldom succeeds if kept another year. It ripens sooner than any other foreign seed. Philadelphia seed produces fine lint and few bolls, and answers best in wet cold soils. Riga seeds produces coarser lint, and the greatest quantity of seed. Scots seed, when well winned and kept, and changed from one kind of soil to another, sometimes answers pretty well; but should be sown thick, as many of its grains are bad, and fail: it springs well, and its flax is sooner ripe than any other; but its produce afterwards is generally inferior to that from foreign seed.

Of Sowing Linseed.

The quantity of linseed sown should be proportioned to the condition of the soil; for if the ground be in good heart, and the seed sown thick, the crop will be in danger of falling before it is ready for pulling. From eleven to twelve pecks, Linlithgow measure, of Dutch or Riga seed, is generally sufficient for one Scots acre; and about ten pecks of Philadelphia seed, which, being the smallest grained, goes farthest.

The

The time for fowing linfeed is from the middle of March to the end of April, as the ground and feafon anfwer.

It ought always to be fown on a dry bed.

Of Weeding Flax.

It ought to be weeded when the crop is about four inches long. If longer deferred, the weeders will fo much break and crook the ftalks, that they will never, perhaps, recover their ftraightnefs again; and when the flax grows crooked, it is more liable to be hurt in the rippling and fwingling.

Quickening grafs fhould not be taken up; for, being ftrongly rooted, the pulling of it always loofens a deal of the lint.

If there is an appearance of a fettled drought, it is better to defer the weeding than by that operation to expofe the tender roots of the flax to the drought.

How foon the weeds are got out, they ought to be carried off the field, inftead of being laid in the furrows, where they often take root again, and at any rate obftruct the growth of the flax in the furrows.

Of Pulling Flax.

When the crop grows fo fhort and branchy, as to appear more valuable for feed than flax, it ought not to be pulled before it be thoroughly ripe; but if it grows long and not branchy, the feed fhould be difregarded, and all the attention given to the flax. In the laft cafe it ought to be pulled after the bloom has fallen, when the ftalk begins to turn yellow, and before the leaves fall, and the bolls turn hard and fharp pointed.

When the ftalk is fmall, and carries few bolls, the flax is fine; but the ftalk of coarfe flax is grofs, rank, branchy, and carries many bolls.

When flax has fallen and lies, fuch as lies ought to be immediately pulled, whether it has grown enough or not, as otherwife it will rot all together.

When parts of the fame field grow unequally, fo that fome parts are ready for pulling before other parts, only what is ready fhould be pulled, and the reft fhould be fuffered to ftand till ready.

The flax-raifer ought to beat the pains to pull, and keep by itfelf, each different kind of lint which he finds in his field; what is both long and fine, by itfelf; what is both long and coarfe, by itfelf; what is both fhort and fine, by itfelf; what is both fhort and coarfe, by itfelf; and, in like manner, every other kind by itfelf, that is of the fame fize and quality. If the different kinds be not thus kept feparate, the flax muft be much damaged in the watering, and the other fucceeding operations.

What is commonly called under-growth, may be neglected as ufelefs.

Few perfons that have feen flax pulled are ignorant of the method of laying it in handfuls acrofs other, which gives the flax fufficient air, and keeps the handfuls feparate and ready for the rippler.

Of Stacking up Flax during the Winter, and Winning the Seed.

If the flax be more valuable than the feed, it ought by no means to be ftacked up, for its own natural juice affifts it greatly in the watering; whereas, if kept long unwatered, it lofes that juice, and the harle adheres fo much to the boon, that it requires longer time to water, and even the quality of the flax becomes thereby harfher, and coarfer. Befides, the flax ftacked up over year, is in great danger from vermin and other accidents; the water in fpring is not fo foft and warm as in harveft; and near a year is thereby loft of the ufe of the lint: but if the flax be fo fhort and branchy as to appear moft valuable for feed, it ought, after pulling, to be ftacked and dried upon the field, as is done with corn, then ftacked up for winter, rippled in fpring, and, after fheeling, the feed fhould be well cleaned from bad feeds, &c.

Of Rippling Flax.

After pulling, if the flax is to be regarded more than the feed, it fhould be allowed to lie fome hours upon the ground to dry a little, and fo gain fome firmnefs, to prevent the fkin or harle, which is the flax, from rubbing off in the rippling; an operation which ought by no means to be neglected, as the bolls, if put into the water along with the flax, breed vermin there, and otherwife fpoil the water. The bolls alfo prove very inconvenient in the graffing and breaking.

The handfuls for rippling fhould not be great, as that endangers the lint in the rippling-comb.

After rippling, the flax-raifer will perceive, that he is able to affort each fize and quality of the flax by itfelf more exactly than he could before.

Of watering Flax.

A running ftream waftes the lint, makes it white, and frequently carries it away. Lochs, by the great quantity and motion of the water, alfo wafte and whiten the flax, though not fo much as running ftreams. Both rivers and lochs water the flax quicker than canals.

The flax-raifer will obferve, when the water is brought to a proper heat, that fmall plants will be raifing quickly in it, numbers of fmall infects and reptiles will be generating there, and bubbles of air rifing on the furface. If no fuch figns appear, the water muft not be warm enough, or is otherwife unfit for flax.

Mofs-holes, when neither too deep nor too fhallow, frequently anfwer well for watering the flax, when the water is proper, as before defcribed.

The proper feafon for watering flax is from the end of July to the end of Auguft.

The advantage of watering flax as foon as poffible after pulling has been already mentioned.

The flax being forted after rippling, as before mentioned, fhould next be put up in beets, never larger than a man can eafily grafp with both his hands, and tied very flack, with a band of a few ftalks.

The beets fhould be put into the canal flope-ways, or half ftanding upon end, the root-end uppermoft. Upon the crop ends, when uppermoft, there frequently breeds a deal of vermin, deftructive of the flax, which is effectually prevented, by putting the crop-end downmoft.

The whole flax in the canal ought to be carefully covered from the fun with divots; the graffy fide of which fhould be next the flax, to keep it clean. If it is not thus covered, the fun will difcolour the flax, though quite covered with water. If the divots are not weighty enough to keep the flax entirely under water, a few ftones may be laid above them; but the flax fhould not be preffed to the bottom.

When the flax is fufficiently watered, it feels foft to the grip, and the harle parts eafily with the boon or fhow, which laft is then become brittle, and looks whitifh. When thefe figns are found, the flax fhould be taken out of the water, beet after beet; each gently rinfed in the water, to cleanfe it of the naftinefs which has gathered about in the water; and as the lint is then very tender, and the beet flackly tied, it muft be carefully and gently handled.

Great care ought to be taken that no part is overdone; and as the coarfeft waters fooneft, if different kinds be mixed together, a part will be rotted when the reft is not fufficiently watered.

When lint taken out of the canal is found not fufficiently watered, it may be laid in a heap for twelve, eighteen, or twenty-four hours, which will have an effect like more watering; but this operation is nice, and may prove dangerous in unfkilful hands.

After the flax is taken out of the canal, frefh lint fhould not be put a fecond time into it, until the former water be run off, and the canal cleaned, and fupplied with frefh water.

Of Graffing Flax.

Short heath is the beft field for graffing flax, as, when wet, it faftens to the heath, and is thereby prevented from being blown away by the wind. The heath alfo keeps it a little a little above the earth, and so exposes it the more equally to the weather. When such heath is not to be got, links, or clean old ley ground is the next best. Long grass grounds should be avoided, as the grass growing through the lint frequently spots, tenders, or rots it; and grounds exposed to violent winds should also be avoided.

The flax, when taken out of the water, must be spread very thin upon the ground; and being then very tender, it must be gently handled. The thinner it is spread, the better, as it is then the more equally exposed to the weather: but it ought never to be spread during a heavy shower, as that would wash and waste the harle too much, which is then excessively tender, but soon after becomes firm enough to bear the rains, which, with the open air and sun-shine, clean, soften, and purify the harle to the degree wanted, and make it blister from the boon. In short, after the flax has got a little firmness, by being a few hours spread in dry weather, the more rain and sun-shine it gets, the better.

The skilful flax-raiser spreads his first row of flax at the end of the field opposite to the point from whence the most violent wind commonly comes, placing the root-ends foremost: he makes the root-ends of every other row over-lap the crop-ends of the former row three or four inches, and binds down the last row with a rope; by which means the wind does not easily get below the lint to blow it away: and as the crop-ends are seldom so fully watered as the root-ends, the aforesaid over-lapping has an effect like giving the crop-ends more watering. Experience only can fully teach a person the signs of flax being sufficiently grassed; then it is of a clearer colour than formerly; the harle is blistered up, and easily parts with the boon, which is then become very brittle. The whole should be sufficiently grassed before any of it is lifted; for if a part be lifted sooner than the rest, that which remains is in great danger from the winds.

A dry day ought to be chosen for taking up the flax; and if there is no appearance of high wind, it should be loosed from the heath or grass, and left loose for some hours, to make it thoroughly dry.

As a great quantity of flax can scarcely be all equally watered and grassed, and as the different qualities will best appear at lifting the flax off the grass, therefore at that time each different kind should be gathered together, and kept by itself, that is, all of the same colour, length, and quality.

The smaller beets the lint is made up in, the better for drying, and the more convenient for stacking, housing, &c. and in making up these beets, as in every other operation upon flax, it is of great consequence, that the lint be laid together as it grew, the root ends together, and the crop ends together.

Of keeping Flax after it is grassed.

Nothing needs be said here, but that if the flax is to be stacked, it should be set in an airy place, upon a dry foundation, such as pob-middings, or the like, and well covered from the weather; and if housed, the floor must be dry, and the house well aired and water-tight.

General Remarks.

Persons unskilful in flax-raising frequently neglect altogether the sorting of the flax, which ought carefully to be done at the three following different times, to wit, when pulling, after rippling, and when lifting it off the grass; the consequence of which neglect is, that very different kinds being mixed together, it can neither be watered, grassed, nor scutched equally. They neither prepare proper canals nor water. They make the beets for watering a great deal too large, bind them very hard, and compress all their lint so close together in the water, trampling it down to the bottom, and putting large stones, feals, or logs above it, that the hearts of the beets cannot be half watered, or not at all, when some of it is perhaps too much done. They frequently take it out of the water after it has been there a certain time, without examining whether it be underdone, or overdone. They lay it too thick upon the grass, and upon long grassy meadows, by which means some of it is tendered and rotted. In taking it off the field, they lay root-ends and crop-ends together, or, as is commonly called, head and thraws. Lint so managed must come out very ill in the dressing; and the fault is generally, but very unjustly, laid to the lint-mill, which must destroy what is well watered before it can clean the ill-watered part of the same handful. And thus it happens, that the ends are frequently beat away in the scutching, when the middle is not well cleaned, the ends of a beet being well watered, perhaps too much so, when the heart of the beet has scarce felt the water. Such inequality in the watering of the lint appears very remarkable as it lies upon the field, the middle of the rows then generally appearing of an higher colour than either of the ends. *Museum Rusticum, vol.* IV. *page* 453.

The famous M. Tschiffeli, of Berne, in Switzerland, has obliged the public with a Memoir on the Culture of Flax, the substance of which we shall lay before our readers.

In his directions for the choice of seed, he says, it should be of a bright shining brown colour, not flat, but thick and plump; should crackle much when cast on live coals, and should sink to the bottom almost as soon as thrown into water.

With respect to soils, this writer observes, that any may do for flax, provided it is not too wet, or too stoney, and has not too much sand or gravel mixed with it: some, however, are to be preferred, particularly black earth, neither too strong nor too light; and, in general, strong land is to be preferred to light.

To prepare grass-grounds and pastures for sowing flax, M. Tschiffeli lays down the following rules:

The land should, by the end of July at latest, be turned up in small furrows, about two inches deep. Early in the month of September, a heavy harrow should, in dry weather, be drawn over the field, in order to pulverize the soil; and the month following, if the land is not in great heart, it should have a good dressing of dung, which being first regularly spread, should, in dry weather, be ploughed in to the depth of six inches at least, with narrow furrows, leaving the field rough all the winter.

In the following spring this gentleman observes, that as soon as the ground is dry, the land should have a good harrowing; and about the middle of April, which is in Switzerland the season for sowing, it should, in dry weather, have its third ploughing, somewhat deeper than the second; and if the weather should not immediately afterwards be favourable for sowing, the land should the same day be harrowed down smooth.

When flax is to be sown on a fallow, the three usual ploughings are to be given, observing only, that every ploughing is deeper than the last; and the dung should be buried by the last, leaving it rough during the winter, and managing it as above in the spring.

When flax is sown the second year after a fallow, the land being dunged the preceding year, and in good heart, no manure will be necessary; but immediately after harvest it must be ploughed about two inches deep, to prevent the weeds from growing and impoverishing the soil. As soon as any weeds afterwards make their appearance, it must be well harrowed with heavy harrows, and about Michaelmas should be ploughed in narrow furrows, about six inches deep, lying rough during the winter season. The following spring the ridges should be harrowed down, and afterwards laid smooth with smaller harrows, being in April ploughed for the last time.

Flax, M. Tschiffeli remarks, thrives best upon land that has the preceding year borne a crop which shaded the ground, and prevented the weeds from growing; therefore good flax is seldom got after rye.

This writer very justly observes, that the quantity of seed to be sown should be proportioned to the nature and condition of the land, never less than two, nor more than three, bushels to the acre. Light land should be sown earliest, but always after the dread of white frosts is over, and never in rainy weather, or when the ground is wet: a mild day is best for this purpose, when the wind is not in the north-east, and dew may be expected in the evening.

It is best, our sensible husbandman says, to begin to plough for sowing after noon, the harrow following close at the heel of the plough. A little before sun-set, the seed is to be spread, best at three casts, and the work left in this ſtate till the next morning, when, without fail, the ſeed muſt be covered with light harrows, or ſtrong rakes. If the ſoil is rather light, and the ſpring likely to be dry, it will be beſt to roll the land; and if it was not manured before the winter, ſome very rotten dung may be ſpread after the ſeed is harrowed in, and before the field is rolled.

It is better to uſe no dung at all than that which is not well rotted: ſoot and aſhes, hogs or cows urine, are good manures for flax, or in fact almoſt any thing that will not carry weeds on to the land.

When flax is grown to the height of about four inches, it may ſafely be weeded; but the precautions taken in Switzerland on this occaſion are worth notice. There the work is carefully executed, but with as much expedition as poſſible, the weeders going bare-footed into the field, and working as much as they can, either ſitting or lying down, heaping the weeds, and carrying them away every time they leave off working. The weeders ſhould alſo, if poſſible, always face the wind, by beginning at the corner of the field to which the wind blows, as in this method the flax will riſe the ſooner; and the work ſhould never be done in rainy weather, or when the ground is wet.

If the flax is to be propped, the beſt time to do it is at the time of weeding. To prop flax is to fix ſupporters, about the ſize of a man's finger, branched a little at the top, and about three or four feet long, at the diſtance of every three feet.

Flax ſhould be pulled in dry weather, in general, when the foot of the ſtalk begins to turn yellow, though the ſeed ſhould not be quite ripe. If the crop is not all of equal ripeneſs, the ripeſt ſhould be ſeparated, as, if all were to be graſſed together, the unripe part would be rotten before the other was ſufficiently graſſed: it is alſo beſt to pull, though at one time, the longeſt ſeparate from the ſhorteſt. When it is all pulled, it muſt be ſpread on graſs-ground, or on a ſtubble, the crop-end of the ſtalk being laid to the ſouth, that the ſeed may ripen the better.

M. Tſchiffeli is of opinion, that when the quantity is large, it is beſt to ſeparate the ſeed by threſhing as ſoon as it is got in, in the following manner. The beds muſt be made pretty thick, the crop-ends of the ſtalk touching the wall of the barn; and over the feet of the ſtalks a heavy plank is to be laid, to prevent the flax from being ſcattered about in threſhing. The wall, by confining the workmen, will prevent them from ſtriking too hard, and thereby damaging the flax.

If the quantity of flax is ſmall, it may be rippled in the ordinary way, obſerving only that the handfuls be not too large. When the ſeed is ſeparated, it muſt be laid on a cloth, expoſed to the ſun for ſeveral days; and afterwards it ſhould be kept in a very airy place; but muſt be ſtirred every two or three days for three weeks. It may be kept in this condition two or three years, without the leaſt damage; but when once this ſeed is deprived of its capſule, it will ſcarcely ever keep above a year.

When the flax has been rippled, it muſt again be laid, but thinner than the firſt time, on a graſs-field that has been about a fortnight before mown, being ſpread, if poſſible, in dry years on damp ground, and in rainy years on dry land, but never on wet meadows. It muſt at this period be carefully turned every other day, if the weather is wet, or the dews heavy.

The time the flax is in graſſing, depends on the coarſeneſs or fineneſs of the ſtaple, the heat and the cold, dryneſs and wetneſs of he weather; but if, in bruiſing betwixt your fingers, the top of the ſtalk when it is dry, the harle or bark ſeparates eaſily from the woody part or boon, and this laſt is not tough, but brittle, the flax ſhould be taken from the ground, in order to be carried under cover as ſoon as it is dry.

The beſt method of drying flax for braking, this accurate writer ſays, is to dig a hollow place in the earth, two feet deep, three wide, and from twelve to fifteen feet long, lining it with ſtone, over which, at the height of about four feet, is fixed a griddle, or grating, conſiſting of ſmall poles, ſecurely made faſt to four or ſix piles, or ſtakes, driven into the ground.

The moſt proper fuel, we are told, for drying the flax, is either charcoal, or well-dried turf, as well becauſe they give an equal degree of heat, as on account of their not producing much of either flame or ſmoak.

When the workmen begin to brake the flax, they muſt go on briſkly; for it ſhould be done whilſt it is hot from the grating, and ſhould be effected by an equable motion, beginning at the crop-end.

In this manner does the ſenſible and patriotic Monſ. Tſchiffeli ſay that flax ſhould in this country be cultivated and managed; and, if we are not greatly miſtaken, the method might, with very little variation, be to advantage adopted in the Britiſh iſlands.

As different countries have different methods in cultivating the various productions of the earth in general; ſo thoſe relating to flax, in particular, are greatly deverſified. We have, therefore, given under this article every thing we thought worthy the reader's attention. The following is the method practiſed in the Mahera, a diſtrict of the county of Roſcommon in Ireland; and was wrote by Mr. John Irwin, a gentleman, who has long cultivated flax there with ſucceſs.

Of the Cultivation and Management of Flax in the Mahera.

The poorer ſort of people in the diſtrict I live in, are ſo indigent, that they are almoſt in a ſtate of ſlavery. Indeed, within theſe laſt forty years, they have much recovered from their bare and naked condition, owing in a great meaſure to the conſiderable extenſion of the linen manufacture.

Their chief riches conſiſt in their annual crops of flax, corn, and potatoes, in order to pay their rents, which they help off with day-labour; a moſt galling article to them; for, as to cattle, few of them have any, or but a milch-cow or two at moſt, which are appropriated for nouriſhing generally a numerous iſſue. The calves, which induſtry ought to be let remain with them to increaſe their funds, or to clothe their families, a rapacious landlord ſeldom wants a pretence of appropriating to himſelf. Theſe people then, from neceſſity, it is evident, muſt be perfectly verſed in the cultivation of flax and potatoes; and they would ſucceed very well as to corn, had they ſurmounted a few old prejudices reſpecting the form or make of their implements, and the methods of uſing them. It is, however, from ocular knowledge of their proceedings, in my work and their own, that what I now communicate to you is founded.

The ſoil about Oran, being ſtrong, deep, and moiſt, with a clayey loam moſtly at bottom, yields excellent flax. It is here ſcarcely ever produced immediately from the ley. The general practice is as follows: a parcel of ley land in good heart, that is, which has not been ploughed for many years, is proclaimed to be ſet to graſs potatoes (otherwiſe ſpaddane, a very miſtaken practice, eſpecially if a deep ſoil, if not to be ſanded, or if a light, if not marled, or limed, or otherwiſe manured:) for this land the poor are charged from three pounds to five pounds per acre, ſanding not always included: a moſt unconſcionable price!

They generally bargain for two ſucceſſive crops; and it is for their benefit, as alſo for that of the land, to have it ſanded, becauſe it ſtrengthens it the better to ſtand a continuation of tillage, and to come the ſooner to turf, and yield a good coat of graſs, when let back into the ley; but the ſky-farmers (thoſe who hold at rack-rents) are moſtly ſo greedy for grain, that it is with reluctance they agree to ſanding, as it abates fourteen ſhillings per acre of their price. When land that requires it is not ſanded previous to this kind of tillage, it is doing it great prejudice; but farmers are not always ſollicitous about this matter, eſpecially on ſhort leaſes.

Land properly ſet in this way ought to be ſanded at leaſt a year before ſetting, that it might have proper time to penetrate into the earth, and impregnate it with its ſalts; but they are ſuch bad farmers about me, that they ſet, ſand, and plant their potatoes almoſt at the ſame time. Even in this bad way the land ſhould be ſet and ſanded (or otherwiſe manured) at leaſt in November, and the potatoes planted the March following at fartheſt: but I have ſeen land not ſanded till March or April, and not ſowed till towards the end of May, (a palpable blunder;) yet this land has yielded a tolerable crop, owing to its great natural fertility; for the ſand becomes of little uſe, if the land is turned up ſoon after it is freſh laid on. This does much hurt in the country; for ſuch land, after it is let out from a long ſeries of tillage, (ſuppoſe fifteen years) is a long time recovering itſelf, and that which is ſpaddanized out of the ley, and not gravelled at all, unleſs of a moſt ſuperior rich kind, is doubly injured.

The potatoes ſhould be dug towards the end of October, or beginning of November at fartheſt, (froſty weather excepted) to make room for a crop of bere, or a crop of flax, the ſpring following; if for flax, the land ſhould get a deep ploughing before Chriſtmas, to benefit of the winter manure, ſuch as froſt, ſnow, air, &c. and a croſs ploughing the beginning of February; and towards the end of March, it ought to get another ploughing in the track of the firſt; then the ridges to be harrowed down as fine and as flat as poſſible, and the ſeed ſown in, and lightly covered with another gentle harrowing; for the ſeed is not apt, from any cauſe that I have obſerved, to be diſturbed in the ground.

In this ſituation it ſhould be left till June, then weeded. Some weed it when four or five inches high; but treading it ſo young hurts it; and this weeding is of no uſe, for it muſt be weeded again before pulling, eſpecially in deep chiltern countries, where weeds get a-head much more than in light gravelly ſoils. In theſe the flax is always ſhorter and finer, and the ſeed in leſs quantity; but the Iriſh ſeed, though it is often impoſed for foreign, is never ſo good: for example, the firſt year's return of foreign ſeed will produce a middling good ſort of flax, whereas the ſecond return will not. To ſow the ſeed even ſhould be moſt carefully attended to: a commonly ſkilful hand will with eaſe caſt it properly, the method being ſo well known. Sixteen pecks of ſeed, at twelve quarts to each peck, is a proper quantity for an acre of good light ſoil. In my deep grounds I have known fourteen pecks to be ſufficient.

The ſeed now much uſed in Ireland is the Plantation, but the better ſort of the Baltic or Riga ſeed I would prefer. The Dutch agrees worſt of all with our climate. The choice of it is eaſily known. The women are ſurpriſingly ſkilful in every thing that regards this plant: one of them will ſhut her eyes, put her hand into ſeveral hogſheads of flax-ſeed, and fix upon that which is beſt; but they have marks from preſſing it to oil between their fingers, ſo as to obſerve the edges, and from taſte, ſmell, and view, without requiring to make the other common experiments; whence they are ſeldom deceived; not but the merchants play them a thouſand tricks in this article, which is become very lucrative of late years, from the vaſt demands there are for it.

The heavy, pale reddiſh, or rather clear brown looking ſeed, being thick and ſhort, and oily in the feel, is the beſt. Sometimes, among ſome parcels of the ſeed, there are certain mixtures, by which predications the women immediately eſtimate the quality of it. The old Iriſh ſeed, of which quantities are ſtill ſown, is the worſt of all; the returns are extremely bad, and the flax but indifferent for uſe.

Two crops ſucceſſively are common in deep rich lands; but as flax is a great drawer, they are not the better for it, as it greatly retards their coming to graſs.

We always ſow flax after potatoes or corn, (bere) and, if proper care be taken in the preparation of the land, find it to anſwer well. How far better it may be immediately out of freſh land manured, I will not take upon me to ſay: ſome writers recommend this method; but it would never anſwer with our poor people. I have ſeldom known flax to be raiſed immediately from manured grounds: mine being rich, deep, and moiſt, and properly wrought to return a firſt crop of ſome other article, yields afterwards admirable flax. Where different ſoils can be had in the ſame diſtrict, it is needleſs to obſerve, that the richeſt and ſtrongeſt, with a clayey loam at bottom, is beſt: the nature of this plant requires ſuch, being a great drawer of the nutritive parts of the earth; but, on the other hand, there is a medium to be followed in this, as in moſt other things: land may be made too rich for flax, which will undoubtedly lodge it, that is, occaſion its prematurely lying flat to the ground: this prevents its ripening, conſequently occaſions great waſte of it, total loſs of ſeed, and what is recovered of it manufactures but indifferently, and ſtands the teſts of uſe worſe: however, there is much of this ſort ſpun into yarn by the poor, and impoſed for good on the eagle-ſighted yarn-buyer, notwithſtanding his great vigilance.

If middling good land, whether in the ley or not, be fallowed early in the ſummer, and gets the proper tilth till the March following, when it is to be ſown, there is no doubt but it will yield an excellent and abundant crop of flax. Land cannot be ploughed too often, or made too fine, for this purpoſe. Flax ought to be ſown and pulled in dry weather.

It is ripe in my neighbourhood, generally ſpeaking, not till the beginning or middle of Auguſt, and ſometimes later, when late ſown: the better ſort of huſbandmen think it is not neceſſary to ſow it earlier than Good-Friday: about that time moſt people begin.

The poor people have ſeveral marks by which they know when it is fit for pulling: the degree of brownneſs of the colour is the chief, and is a ſufficient guide to any perſon. The men and women, promiſcuouſly ranged in a row abreaſt, pull it expeditiouſly enough, eſpecially if they are a little refreſhed with ſome of the good things of this life, and lay it on the ſwarth. If there be danger of rain, they bind it the ſame evening into ſheaves, and ſtook it, putting commonly eight ſheaves in every ſtook. Here it is ſuffered to remain for ſome days, till it is ſufficiently dry to remove.

The poor, from neceſſity, proceed to manufacture it immediately, by rippling of the rows, and watering it, &c. But my method is as follows. After I let my flax ſufficiently ſeaſon in the field, ſo as to prevent the danger of heating, which deſtroys it, I draw it into my haggard, ſtack it, and thatch it well. Thus I let it remain till the next ſowing time, (March) when I ripple it and water it, and, if I have leiſure, proceed to dreſs it; if not, make it back into a ſtack, and let it lie ſo, without any hazard of danger, as long as convenient: or, (another way) ſoon after pulling, it may be rippled, watered, and ſtacked, ſo as to be ready for dreſſing the ſpring following. But I chuſe the former method, becauſe I thereby preſerve the ſeed, and ſell it, if I take a little care, equal to the foreign, which will go a good way in reimburſing me my expence: it is true, the quantity of flax will be ſomewhat diminiſhed for remaining ſo long unwatered; but then it makes ample amends in meliorating it; for I have obſerved, that the flax thus managed dreſſes and manufactures much better, and when in linen, it wears beſt. But the impatience of our Iriſh ladies, who are the conductors of this branch, from the time the flax is over ground, till made into linen, is ſuch, that they do not reliſh delays of this ſort, though infinitely the beſt method of proceeding.

For watering flax, clear ſtagnated pools or canals, or ponds, are beſt, provided there are no fiſh, as it kills them: ſprings and running waters muſt be avoided. To ſink it under water is proper, and let it lie about three weeks, more or leſs, according to the quality of the flax, and the condition of it at putting in.

About me the poor people ſtill perverſely will water it in bog holes, becauſe they think the water cannot be too ſoft, and that the banks, being unincumbered with long graſs, facilitate the drying of it.

When it is brought home (as they have no ovens) they fix a large hurdle horizontally by a ditch ſide, about four or five feet from the ground: on this they lay a parcel of flax, and underneath make a large turf fire, and keep conſtantly turning it.

They judge it fit for the brake, by rubbing a parcel between their hands, and finding the prickles to detach themſelves eaſily from the flax.

The braking is a very laborious part: it is pity that about where I live there are no engines contrived for this purpoſe, as it would ſave great expence in labour. This part of the proceſs ought, properly ſpeaking, to fall ſolely to the ſhare of the men; but the women as commonly do it, which I think very unſeemly, and ſtill more ſo to ſee a man ſcutching and hackling flax, which is equally as common with us: but the women always ſcutch mine, and I find do it beſt, as I order them refreſhment, it being merry making time, (though but ſhort) like vintage, or ſheep-ſhearing time.

The conſtruction of the brakers I need not explain; they are ſimple engines, and known to every body. The broad ſcutch is beſt, as it hurts the flax leſs; it ought to be made of well-ſeaſoned oak, to be light, that the women, who are dexterous at it, may manage it the more eaſily.

A great deal depends on the ſkill of the hackler, who ought

ought to be very expert and knowing in dividing it properly, and in arranging the sorts according to their different fineness. I have had some hacklers manage this matter so well, that out of the very tow they produced I had good linen for common use. I had other hacklers, who, instead of preparing my flax to spin to eight or ten dozen of yarn to the pound, of which it was capable, prepared it so badly, as to produce me only from four to six dozen yarn.

To the spinners we keep in our houses we generally give from thirty-five to forty shillings a year: these spin from four to eight dozen yarn; but if they spin finer, they are entitled to get a gratuity in addition, or higher wages. There are girls in plenty in the north of Ireland (where the manufacture most flourishes) who spin surprisingly fine, and many of them with both hands at once, at wheels adapted for the purpose; but scarcely any of these ever come into the parts where I live.

As to the rest, from the time the yarn is sent to the weaver, till it is brought home from the bleach fit for use, it forms a particular process in itself, and shall be communicated to the public, when more ample leisure will permit. However, before I dismiss this subject, it may not be improper to make a few detached observations to illustrate still more what I have already said.

There are various ways to know good seed, which is one of our most essential objects. First, To discover its thickness, by taking some grains, and squeezing them between the fingers, until the white edges of the inside pulp or grain are forced to appear. To estimate its goodness by its weight may be easily done, by throwing a handful into water, and if good it will sink quickly. To prove if it be oily, throw a handful on the fire, and if, as soon as it touches the coals, it burns up and crackles, its goodness may be depended on. But no seed of Irish growth, as I said before, will thrive well a second year in any of the soils in my neighbourhood; nor will the same soil answer for more than two successive seasons, without the intermediate occupation of other crops procured from manures.

As the culture of flax lays down land very smoothly and well, if you chuse to have your land let out, you may sow grass-seeds with a light roller, or busk, in some little time after your flax is in the ground: they will not hurt it; and by this means you will have a full coat of grass the same season, which otherwise perhaps would not be the case for two or three seasons, flax being a great impoverisher.

When the flax is a clear yellow, or a clear brown, something resembling a lemon colour, and begins to drop its leaves, it should be pulled; but never when it is green, though often done, which is a very destructive method, for in this case it loses considerably in quantity and quality, both with respect to flax and seed. Those who imagine pulling it green will make it yield the finer linen are mistaken: they need only consult the method of the Flemings, who suffer it to remain the longer in ground, the finer they want it to prove for their laces, cambricks, &c. Care, however, should be taken not to let it remain too long in ground, as this makes it work badly, yield bad yarn, and not bleach so well.

I have kept my flax in stack in my haggard some two or three seasons, and never found it was damaged by vermin, though I know there are preventatives laid down by some writers for this purpose.

If the season be moist, there is no stacking it with safety, till it remains unheaped a considerable time in the barn, as the least heating is certain destruction to it.

No land can be too good for flax, if the seed be duly proportioned to it. If the crop fails on a rich and strong soil, it has too much seed; for it should not be so thick, but that every stem may have the benefit of the sun and air to fortify it. *Museum Rusticum, vol.* I. *page* 5.

A short Account of the Advantages of the new Machinery for breaking, scutching, and beating Flax and Hemp, invented by Robert Mac Pherson, Assistant-Secretary to the Commissioners and Trustees for Improvements in Scotland.

The breaking of flax by the Dutch hand-brake (which is the best old method of breaking) the scutching with stock and hand, and beating with hand-mallets, being laborious, tedious, expensive, and requiring many hands, it was thought a valuable improvement, when, some years ago, a water-mill was invented, by which these operations are performed with more ease and expedition. But in some parts of the country, a sufficiency of water and water-fall is not to be met with; in other parts where these are to be had, lint-mills are not erected, on account of their heavy expence; and where-ever erected, they are found liable to the following inconveniencies. First, The expence of fitting up the mill, making dams, the aqueduct, &c. and keeping these in repair, is great; and much damage happens by fire, and by water-floods. Secondly, In Scotland, it has hitherto been found, that on account of the scarcity of hands, and difficulty of dressing in the old hand-methods, flax never was raised in considerable quantities, until the country people found the conveniency of a mill in their neighbourhood; and therefore the first fitter up of a mill in a part of the country where there was none before, could not for years expect business adequate to his out-lay of money. This circumstance obliged the linen board in Scotland to defray part of the expence of fitting up many of these mills. Thirdly, This mill is extremely dangerous to the workmen; many have lost arms by it, some their lives, and the nature of the work there is otherwise remarkably unhealthy. Fourthly, This mill is so constructed, that the stroke of its scutchers is ineffectual, unless they are moved with a degree of violence, that nothing less than the utmost dexterity and closest care can prevent from destroying a very considerable part of the flax; and as that skill and unremitted attention cannot be expected among a number of common day-labourers, the great waste of flax always attending these mills is easily accounted for, especially as unskilful hands are often employed; for being called to this work only in winter, the lint-miller must content himself with labourers that, at the beginning of the season, are not otherwise engaged. Fifthly, The carriage of the rough flax to mills at a distance, the delay there, sometimes for months, till others be served, during which time the flax must lie without doors: damage, embezzlement, &c. these are much complained of; and, with the waste before-mentioned, have in general ruined the character of these mills. Sixthly, The expence of flax-dressing is still kept high, because the proprietor of the mill must have a large rent, especially as his outlay upon it is extensive; the miller must have a living; and the workmen extraordinary wages for such dangerous and unhealthy work. In short, it has become very doubtful, whether, upon the whole, these mills have not been more hurtful than beneficial to the manufacture.

The new water-mill for dressing flax and hemp, invented by Robert Macpherson, removes part of these inconveniencies. For, 1. It is much less wasteful of the flax; as much so, it is presumed, as water machinery can possibly be. It not only yields more flax from the scutch, but the flax dressed by it yields still more from the heckle. 2. It is fitter for dressing long hemp. 3. It is no way dangerous nor unhealthy to the workmen. 3. It requires a less expensive mill-house, and less annual repair. 5. It requires much less water. 6. For one, two, or a few workmen, the parts of its machinery which dress the flax or hemp, may be joined to the movement of a corn-mill, or any other mill, by a small iron-axle, or by rope and pully, through any wall or partition, at a side, above, or below.

Where much business in the beating way is to be done, the new machinery with water or a horse, gives entire satisfaction. But scutching proves an operation that requires more judicious management than can be expected at a public water-mill. A lint-miller, who dresses flax for others, finds his profit in the dispatch made by the great velocity which can be given to the scutchers by a power of water; but the proprietor of the flax loses more by the waste occasioned by that velocity than the miller gains by the greater dispatch. In short, the dressing of flax by any expensive public water-mill remains still liable to many of the inconveniencies mentioned in the first part of this paper.

The foot-machines (likewise invented by Robert Macpherson) it is presumed, obviate all these inconveniencies, and go far towards towards bringing flax-dressing to perfection. For, 1. They waste the flax or hemp as little as the

the hand methods of dressing. 2. They are much more expeditious, and as much so as dare be attempted without destroying a considerable part of the flax or hemp, which above every thing else ought to be avoided. 3. The working with them is not so laborious as the hand methods. 4. They are not dangerous to the workmen. 5. They are not too bulky for general use: they are portable upon a cart, are of small expence, simple construction, can be made by any good carpenter and smith, and each machine is wrought by a single person.

With these foot-machines any person may have his flax or hemp dressed under his own eye, by his own servants, and at times when otherwise they would be idle, in the dark afternoons of winter, when the lanthorns used by hecklers will prevent accidents by fire, and in the day-time when bad weather hinders working in the fields. Thus the dressing of flax and hemp becoming easy, the raising of these crops, of all the most profitable to the farmer, and to the country, will become more general; many will have their flax or hemp dressed by their own servants, without expence; and when others are hired to that work, the expence must be much less than by the hand methods, as the machines are greatly more expeditious. The water-mills are not taken into this comparison, because their waste of the flax or hemp overbalances the profit of their greater dispatch.

The importance of this new machinery to Britain, Ireland, and the colonies, must appear very great, when the following particulars are considered.

	l.
The value of the flax and hemp raised in England yearly cannot be reckoned less than -	250,000
It appears from the Customhouse accounts, that there was imported into England, from Christmas 1762, to Christmas 1763, 100,997 bushels of linseed. In the fens about Lincoln-Wash, thirty towns and villages have yearly about 6000 acres of flax and hemp. There are likewise some thousand acres of these crops yearly in the marsh-lands on the borders of York and Lincolnshires. The town of Snaith in Yorkshire has the greatest flax-market of any place in Britain.	
The value of the flax and hemp raised in Scotland yearly is calculated about - - - -	190,000
There is imported into Scotland about 60,000 bushels of linseed yearly.	
The value of the flax and hemp raised in Ireland yearly may be reckoned about - - - -	500,000
The linen manufacture there is about double that in Scotland, and mostly made of their own flax.	
Sum of these - - -	940,000

The expence of breaking and scutching that 940,000 pounds worth of flax and hemp may be reckoned 150,000 pounds; one half of which, or 75,000 pounds per annum, must come in time to be saved by the use of the new machines; for the new scutcher does more than double the work of the old hand-scutch in the same time. The new brake is not so advantageous in that respect; yet the inventor thinks he errs on the safe side, when he states the new brake and scutcher both together, as doing only double work.

The colonies in America are now encouraged to raise flax and hemp, by a parliamentary bounty in Britain.

The great advantages of raising our own seed, flax, and hemp, instead of providing them from foreign countries, need not be here represented. What is at present imported appears from the Customhouse accounts as follows: and it cannot be doubted but the aforesaid new machinery will be the means of increasing our own growth, and consequently decreasing the foreign importation.

	l.
The linseed imported into England is annually about 100,000 bushels, reckoned in value about - - - - - - - - - -	40,000
Into Scotland, about 60,000 bushels - - -	25,000
Into Ireland, about 80,000 - - - - -	34,000
Flax and hemp into England, about - - -	700,000
Into Scotland, about - - - - - - -	120,000
Into Ireland, about - - - - - - -	
Sum of these, exclusive of the blank for Ireland	919,000

And that there can be no want of market for an extension of our linen and hempen manufactures (which the new flax-machinery must greatly promote) appears evident from the extensive importation of these manufactures from foreign countries; for, according to the Customhouse accounts, there is annually imported into England, from the continent of Europe.

	l.
Linen-yarn, of value about - - - - -	200,000
Linen-cloth, of value about - - - - -	1,500,000
And thread, lace, sail-cloth, cordage, sacking, &c. the amount of which must also be considerable.	

Explanation of Plate XVI. *representing the* Foot-Machines *for* Breaking *and* Beating Flax *and* Hemp.

Of the Foot-Brake.

A The three under-brake teeth, or swords, seventeen inches long, three inches deep, one and a quarter inch thick at back or bottom, a quarter of an
B inch at edge, the edges two and three quarters inches asunder at the end next the guide B, and two inches asunder at the other end.

C The two upper teeth, about one inch shorter than the under teeth.

D The brake-mallet, about thirty-three pounds English weight.

E, e, A compound foot-treadle. E is eight feet four
F inches between the fulcrums, raised at F eight inches above the ground (or rather five inches higher than the stance of the workman.) e is two feet four inches between the fulcrums, and is raised
G at G eighteen inches above the ground; that is, fifteen inches higher than the stance of the workman.

H The sword or upright timber-rod which turns the wheel by the treadle-crank.

I The treadle crank, of seven and a half inches radius.

K The fly-wheel, four and a half feet diameter, above sixty pounds English weight. As here represented it is beat or cast-iron, but it is also made of timber.

L Brass cods or bushes.

M, m The lifting crank. m is fixed firm upon the axle of the fly, while the crank M, about eight inches radius, plays freely round the axle. In position first, m begins to take round the crank (which by the lever R pulls up the mallet:) when it comes to position second, the mallet is again at liberty, and by its weight pulls up the crank (faster than the fixed pieces moves) into position third.

N. B. The treadle-crank is advanced about one eighth part of the circle before the lifting crank.

a A small pulley, which turns easily round on the end of the crank, and to which a rope is fixed.

O A piece of timber which prevents the rope from falling in upon the axle, but which should not rub against the rope in its coming down.

P Here the rope passes between two friction-rollers, which are so placed that the rope comes down there four inches, or half the radius of the lifting crank, to the side of a plummet-line crossing the centre of the wheel; that is, to the side on which the crank turns when it pulls down the rope.

Q A pillar, which serves only to support the guard for the rope O, and the friction-rollers at P.

R The lever.

S The lever-pillar.

T Part of the mallet-frame.

U Two pillars which guide the brake-mallet.

V An iron spring which receives the leap of the mallet, and throws it the quicker down.

W The pillars which support the fly.

X, U The pillars which bear the brake-teeth and mallet.

Y Spur and cross, supports of the pillars.

Z The bottom frame-piece.

a A broad stool upon which the workman stands, three inches above the ground.

The brake-teeth are made of good beech or planetree, the brake-mallet of planetree, ash, elm, birch, or oak; the

FLA

the fword, or upright timber-rod between the treadle and the treadle crank, of beech, planetree, or birch; and the lever of beech, afh, or oak. The fly-wheel, if timber, fhould be made of oak, afh, beech, elm, or planetree. All the other parts of timber worth mentioning may be made of fir.

Of the Foot-Beaters.

The before-mentioned brake may at any time be converted to a beater of flax and hemp, by removing the brake-teeth, and putting in their place flat boards. In the upper of thefe boards may be driven thirty-two nails, the head about three quarters of an inch long, and the point of the head about a quarter of an inch diameter; the points of the nail-heads may be placed one inch clear afunder, and in the order marked B, at equal diftances, as in this way any of the nails may moft eafily be drawn out in repairing the mallet. An iron hoop about the mallet will prevent its burfting with the indriving of the nails.

For the fole purpofe of beating flax and hemp, the narrow end of the mallet is placed toward the workman; and where there is much work in that way, the mallet and fly may be made heavier, and then two or more workmen can work together upon the foot-treadles, which may alfo be made equally long.

Plate XVII. Fig. 1. reprefents the fcutching machine, where *b* BG is the foot-board; D, D, fcutchers; Q, the center of the iron wheel C, C, Q; S, the upright piece, or fcutching ftack; A the piece on which the hand refts in order to fcrutch the flax. The machine is put in motion by the nunch at M, which is moved by the foot-board.

We have been the more particular in our account of the various methods ufed in cultivating and dreffing flax, becaufe it is an article, which, with proper encouragment, may become of the utmoft importance to thefe kingdoms; and, therefore, we were perfuaded that we could not do a more acceptable piece of fervice to the hufbandman, than by giving the various methods at full length, though we are confcious that in doing this the reader will meet with fome repetitions, which could not be avoided without curtailing the whole, and confequently rendering it lefs valuable. It is for the fame reafon, that we think the following account of the progrefs of the flax-hufbandry in Scotland, will be confidered as a very ufeful and entertaining addition to this article.

Progrefs of Flax-Husbandry *in* Scotland.

[Written by lord Kames; and publifhed, about the middle of January, 1766, by the Truftees for Improvements.]

As the power of a ftate confifts chiefly in the number and induftry of its people, every thing muft be of importance that contributes to thefe ends. This obfervation puts the linen manufacture in a confpicuous light; for it employs many hands, and requires the moft painful induftry. In Scotland, this manufacture, which, within the memory of man, fcarce deferved the name, has of late years made a progrefs fo rapid, as to become our chief manufacture, circulating more money than all our other manufactures in conjunction. Nor is there any fymptom of its being ftationary: on the contrary, it is every year boldly advancing with wider and wider fteps.

This profpect muft be agreeable to every well-hearted Briton; and to gratify the laudable curiofity of fuch perfons, the following brief account of the progrefs of the manufacture is prefented. The board of Truftees was eftablifhed anno 1727: the value of the linen ftamped from the 1ft of November 1727 to the 1ft of November 1765, not including what was made for private ufe, was as follows. [xii. 351.]

Anno		L.	Anno		L.
1728	———	103,312	1737	———	183,620
1729	———	114,383	1738	———	185,026

1755	———	345,349	1765	———	579,227

Though the progrefs of the linen manufacture in general is not the profeffed purpofe of this paper, yet I fhall endeavour to account for it, as a proper introduction to an hiftorical narrative of the meafures taken by the truftees for promoting our flax-hufbandry.

The union of the two crowns of England and Scotland was a fatal event for the latter. The great increafe of power which our kings thereby acquired, reduced the Scotch nobility to a ftate of humble dependence. From being petty monarchs, they became flaves to the crown, and had nothing left to fupport their accuftomed dignity, but, under protection of the crown, to enflave their inferiors. The national fpirit, bold and brave, fubfided by degrees; and a general torpor fucceeded, the never-failing effect of flavery. Though reftored to liberty and independence, by the union of the two nations, yet mutual jealoufy and enmity obftructed long the advantages of our new fituation. At length the bleffings of liberty and independence became confpicuous, and invigorated multitudes to exert themfelves in laudable undertakings. And hence that fpirit for improvement in Scotland, difplayed upon hufbandry, upon manufactures, upon commerce, and upon literature.

The eftablifhing a board of truftees for directing this national fpirit, upon fifheries, and upon the manufactures of linen and woollen, was a meafure wife and political, zealoufly promoted by a worthy patriot, who was rewarded, by the opportunity he long had of ferving his country, as an eminent member of that board. His ftatue was erected in the fenate-houfe, by thofe of his own profeffion, in token of their veneration for him, as a judge above all corruption. From his fellow-citizens in general a ftatue was not lefs due, as a token of their gratitude for his patriotifm.

But whatever was his zeal for the public good, and whatever zeal he infpired into others, yet the operations of that board were not at firft attended with great fuccefs. The indolence and ignorance of the low people, and their want of honefty, could not be cured but by perfeverance and artful management. But unluckily we were at that time ill provided with political phyficians fkilled in the cure; which is always the cafe in a country where induftry is dead, and no perfon thinks of it. The truftees were forced for fome time to grope in the twilight of knowledge: they frequently miftook their road, and adopted meafures that were not always adequate to the ends propofed. But as the intendment of this paper is neither to make a fatire nor encomium upon the truftees, it fhall only be obferved in paffing, that the ignorance of this nation with refpect to manufactures, and with refpect to the means of promoting them, may well excufe the few errors committed by the truftees at the commencement of their management; and that thefe errors ought not to derogate from their merit, in ferving their country without the flighteft motive of private intereft.

The truftees, having with great affiduity furmounted endlefs difficulties and obftructions, were encouraged to redouble their diligence. The people are in a meafure reclaimed from idlenefs and difhonefty: induftry is gaining ground, and is fpreading even to diftant corners: fpinners and weavers greatly multiplied, are daily acquiring more and more fkill: many bleachfields are perfected, and the colour of our linens is much improved. Nor have water-mills been neglected for dreffing flax of our own growth; though thefe, after much expence beftowed, do not now give general fatisfaction.

Thefe expenfive articles drew great fums from the truftees; fo great, that little was left for promoting other branches. But thefe articles being now far advanced, fo as not to require much further fupport, it is the intention of the truftees, to promote the growth of our own flax with their utmoft affiduity. This appears the proper time for encouraging that capital article, becaufe a market is now provided for it, viz. a home market, which of all is the beft; and no perfon can doubt of this market, when he is informed, that foreign flax, to the amount of 110,000 l. is yearly imported into Scotland.

The faving this annual fum to the nation is not the only, nor indeed the greateft benefit that will accrue by promoting flax-hufbandry. A manufacture cannot but be upon a precarious footing, when recourfe muft be had to a foreign market for the crude materials; and a nation muft be upon a precarious footing, when it is in the power of foreigners, with a fingle fiat, to ftarve a great proportion of its people, by withdrawing from them the means of labour. This obfervation is in part unhappily verified by the prefent ftate of our flax-commerce; for foreign flax has, within thefe feven years, been gradually fo much raifed upon us, that we pay now for it fifty per cent. more than formerly. Secondly, For a further encouragement to raife flax, the farmer may be affured, that our own flax, when fkilfully managed, and the ground well prepared, is tough, compact, and fmooth; and confequently, for thread, lace, gauze, cambrick, and lawn, is better fitted than that of Holland, which generally is fpungy and cottony. Scotch flax, when brought to its utmoft perfection, may probably rival even that of Flanders. It is too good for Ofnaburgs, which require coarfe Ruffian flax. The Dutch flax is only preferable for thick hollands. Thirdly, All the labour beftowed upon foreign flax purchafed by us, in preparing the ground, in fowing and pulling, in watering, grafing, and dreffing for the heckle, is paid for by us. What a benefit to this nation muft it be, to give bread to numbers of our own people, by employing them in that work? Fourthly, As a confiderable proportion of the flax we ufe is of foreign growth, and as the heckler and the fpinner muft pay money for it, the one is difpofed to over-heckle it, and the other to draw it out into too fine yarn, in order to make the moft of their money. This evil would be in a good meafure prevented by having flax in plenty of our own growth; for the heckler and fpinner would in that cafe ufe it freely, without labouring to draw it beyond its grift.

The truftees, for thefe reafons, cannot direct their management to a more important object than to that of flax-raifing. This indeed they had early in view, though they did not always hit upon the moft effectual means. They brought flax-raifers and flax-dreffers from Holland, Flanders, and England: they publifhed directions for raifing flax: they laid out money for breeding apprentices to flax-raifing and flax-dreffing: they encouraged the erection of lint-mills; gave falaries to ftationed raifers and dreffers of flax, and diftributed heckles. The article laft mentioned did good, and continues to do good; but moft of the other articles were lefs fuccefsful than was expected, becaufe the truftees, inflamed with the fpirit of patriotifm, made a more rapid progrefs than was confiftent with the circumftances of the country. For one inftance, it feldom happens that the beft artifts are moved by the hope of greater gain to defert their native country; and therefore to fend fome hopeful young men abroad to be thoroughly perfected in the art, is a meafure more flow indeed, but always more fuccefsful. And had this method been followed, the fuperior fkill of the men thus educated, would have procured them good bread, without burdening the public fund with falaries. By neglecting this fafe meafure, there were few or no fkilful perfons that could be employed as ftationary raifers and dreffers of flax; and the truftees were forced to take up with fuch perfons as could procure the beft recommendations, which generally proceeded from interefted motives. The negligence, accordingly, and unfkilfulnefs of thefe perfons, ruined all.

One of the encouragements for flax-raifing, was a premium of fifteen fhillings upon every acre prepared for flax-feed, according to a method prefcribed. This premium was in effect putting the plough before the horfes. It indeed excited many to fow linfeed; but it was foon difcovered, and might have been forefeen, that it was no fufficient encouragement, without providing a market for the flax, when feparated from the ground. The premium was not the half of the price of the feed: the product lay upon the farmer's hand, who had neither fkill nor people for dreffing it with ftock and hand, lint-mills being at that time extremely rare; and, by thefe means, he was upon the whole a great lofer by this premium.

Lint-boors came next in play, by a hint taken from Holland and Flanders. The lint-boors there purchafed all the green lint in the neighbourhood, water and grafe it, and, in a word, prepare it for the heckle. This meafure had a fair appearance; the truftees were fond of it, and gave great encouragement for carrying it into execution. But this meafure proved abortive; and it could not happen otherwife. It was not adverted to, that the culture of flax had fubfifted in Holland and Flanders for centuries; and that confiderable ftocks were acquired by dealing in the different branches of the manufacture, part of which could not be better employed than in the lucrative trade of a lint-boor, furrounded with lint fields, that fave the expence of carriage. In Scotland every article was oppofite: the manufacture was ftill in its infancy: no provifion of fkilful hands; lint-fields were thinly fcattered; and it was a great burden upon the lint-boor to carry fo weighty a crop from a great diftance: no perfon had a ftock for building houfes, preparing canals, &c. and had there been fuch perfons, they would not have ftooped to an inferior branch, while the higher branches lay open to employ their money upon.

The water-mills, mentioned above, having a fpecious appearance, met with vigorous encouragement, and exhaufted a great deal of public money. They were favourites of the country-people, by faving labour in dreffing the flax; of which thofe were the moft fenfible who were acquainted with the flownefs and fatigue of the ftock and hand. It was not doubted but that thefe mills would incline every farmer to raife flax; and the truftees were intent to accelerate that effect. A premium was notified of eighteen-pence per ftone for dreffed flax of our own growth; which was confined to the three great linen counties of Perth, Fife, and Angus, becaufe the public fund was not adequate to a more general premium. The fuccefs of this meafure has been confiderable; and would have been ftill more confiderable, had a fufficient number of fkilful flax-raifers been provided to inftruct the country people. The demand for foreign flax has greatly fubfided in thefe counties; and in a few years will probably vanifh altogether. This premium is now transferred to the counties of Lanark, Air, Renfrew, Dumbarton, and Stirling, where it will certainly produce the fame beneficial effects; and the intention is, to carry it progreffively through the kingdom.

For the fame purpofe of promoting flax-raifing, quantities of linfeed have been diftributed, moftly in the highlands, at firft gratis, and afterward under prime coft. This meafure had a good effect; but not equivalent to the fums beftowed upon it. For the farmers were not fufficiently fkilled in preparing the ground: and they were not fufficiently anxious to be inftructed, becaufe they put little value upon feed which they got for nothing, or at a low price.

To remedy this evil, and to excite a fpirit of cultivation, large premiums were given for the greateft quantities of flax produced upon an acre. This inflamed the induftry of the farmer, and had the effect of procuring very rich crops. Some farmers became expert in high dreffing for flax-feed, and every one was fond to receive inftruction; which was the great object of the premium. And yet the truftees were forced to drop this premium, though with great reluctance, before the effect was completed. Induftry was not fo far advanced as to have reclaimed entirely the labouring poor from trick and deceit. The premiums were confiderable; and if, upon the one hand, they promoted good hufbandry, they, on the other, were a temptation to practife fraudulent methods for obtaining falfe reports of the quantities of flax produced. Such frauds are infectious; and the truftees faw no other means to prevent the infection, but to withdraw the bounty altogether. There is no reafon, however, to repent of having fet this meafure on foot; for tho' it may not have had the complete effect intended, it has undoubtedly promoted fkill in flax-hufbandry, and has alfo given fufficient evidence to the flax-farmer, that plentiful crops can be produced by high cultivation.

To proceed in the hiftory of water-mills, experience difcovered that they were attended with many inconveniencies. The labour of carrying rough lint to thefe mills from a diftance, came to be felt; as alfo the delay of getting the lint dreffed, when the mill happens to be much employed. At the fame time, the ordinary yield of this mill in dreffed flax, is fo much inferior in quantity to that of ftock and hand, as to over-balance fully what is faved upon labour; not to mention the hurt that is done to the flax by the violent and ill directed action of the mill. But the worft of all is, that the lint-miller, being under no check nor controul, is tempted to defraud his cuftomers of part of their dreffed flax: and there are inftances where the whole has been with-held from poor people, who it was thought would not have courage to bring a law-fuit. In many places there is not fufficient houfe-room provided for the flax that is brought to the mill: which, in a bufy time, is often expofed to the air for months together before the miller can reach it. By thefe means, many lint-millers, I am far from faying the whole, are fo funk in their credit, that the farmers in their neighbourhood, rather than fubmit to the foregoing hardfhips, chufe to abandon flax-raifing altogether.

It is peculiarly lucky for Scotland, that, during this diftreffing fituation, a flax-machine has been invented, that promifes not only to remedy the faid inconveniencies, but alfo to advance flax-dreffing to its perfection, with no lefs frugality than expedition. It is wrought by a fingle hand, takes up little room, is portable in a cart, and fo little expenfive, that three or four neighbouring farmers may have one in common for a meer trifle contributed by each. Its motion, at the fame time, is fo eafy, and fo much under command, that it is equal to ftock and hand with refpect to the yield of dreffed flax, and alfo with refpect to the gentlenefs of its motions. And taking into the account the expedition of this machine, which performs at leaft thrice the work of ftock and hand, it muft be pronounced a happy invention.

But we have not exhaufted all that can be faid in its favour, nor indeed the greater part. It is a capital advantage, that by it the farmer can fuperintend the dreffing his flax without hazard of being cheated; and, what is ftill more, to get his flax dreffed without a farthing of charge; which may be done by the following method. The flax is generally watered and grafed before the corn-harveft, or at leaft before the bufy time of it; and therefore may be done by the farm-fervants, without interrupting other work. The flax may be houfed at the end of a barn, or other convenient place, till winter, when the farm-fervants, for want of light, are laid idle for fome hours in the afternoon. During this time, the farmer and his fervants cannot be more profitably employed than in dreffing their flax; and the long nights afford more than fufficient time for dreffing all that will be raifed by a knot of neighbouring farmers. And even fuppofing the fwifteft progrefs of lint-hufbandry, every farmer may afford to purchafe a machine for his own ufe folely, which may be employed, not only during the dark hours of the afternoon, but frequently in day-light, when bad weather forbids all field-operations.

It is difficult, I am fenfible, to entice people to employ in labour their accuftomed idle hours; but addrefs and perfeverance will conquer many difficulties. And to operate this converfion of idlenefs into labour, there is one means among many that cannot fail of fuccefs. An article is commonly ftipulated by farm-fervants as part of their wages, which is, to have ground allotted them for fowing fome lint-feed. They are generally put off with the worft foil, ill prepared: their crops are fcanty: the expence of dreffing unconfcionable: and ftating every article by a juft calculation, lint purchafed at a market would come cheaper to them than what they thus procure. To engage them to work at the machine, no more is neceffary but that the farmer take them in as partners. He has, for example, one hogfhead of linfeed; they another among them. Let it be all fown promifcuoufly in the fame field; upon which, for his own fake, the farmer will beftow the higheft dreffing. It is watered in common, grafed in common, and dreffed in common. When a divifion is made in proportion to the quantities fown, the poor labourers will rejoice in a double increafe, purchafed with a little additional labour, without any expence. Far from grudging this labour, their convening together in one place, with a fire for drying the flax, will afford them high amufement. Their labour will be eafy, being divided among many hands, and it is fit that the farmer encourage them by taking part in the labour. A little care, at the fame time, with proper lanterns, fuch as are ufed in heckling, will remove all hazard of fire; efpecially if the farmer himfelf take a narrow furvey every evening when the fervants leave off work.

Though the dreffing of flax by this machine requires not more fkill than by ftock and hand, yet to fhow the management of it, particularly the dexterous handling of the flax, and to inftruct the country people in the preceding articles of chufing and preparing ground, weeding, pulling, watering, and grafing, it muft be of confequence that the truftees educate and employ in different parts a number of itinerants. This method of having the flax dreffed by the country fervants in their otherwife idle hours, is far fuperior to that of lint-boors, even fuppofing we were ripe for thefe artifts; becaufe by no other means it is poffible to get flax dreffed without expence, and indeed without any labour that can be reckoned upon. The expence of dreffing has hitherto been a bulky article; and confidering the wafte occafioned by water-mills, is perhaps not under forty per cent. of the flax; all of which may be faved by the machine under confideration.

Though few of the meafures laid down by the truftees for promoting flax-hufbandry, have correfponded to the fanguine hopes at firft conceived of them; yet thefe meafures, imperfect as they were, contributed confiderably to the improvement of flax-hufbandry, which is farther advanced than is commonly thought. The value of flax annually produced in Scotland, after it is heckled, and ready for the fpinner, may be pretty nearly afcertained as follows: The value of linen cloth now made in a year, amounts to about 700,000 l. the value of the thread manufactured in a year cannot be lefs than 100,000 l. we are more uncertain about the quantity of the linen yarn exported; but we cannot be far wrong in ftating it at another 100,000 l. and thefe articles amount in whole to 900,000 l. The next point is to afcertain the value of heckled flax ufed in thefe different articles. Taking all the different kinds of linen cloth at an average, the value of the heckled flax may be about a third; and the proportion is rather more in thread. Of the yarn exported, the value of the flax cannot be much below the half. Joining thefe particulars together, the value of the heckled flax annually manufactured in Scotland amounts to 316,666 l. Subtract the value of the flax imported, and the price of heckling it, which is performed at home, computed to 125,000 l. the remainder, 191,666 l. or 190,000 l. in round numbers, is the value of the heckled flax from our own growth.

The purpofe of this paper is, to encourage landholders and farmers to apply vigoroufly to flax-raifing, which, from what is faid above, will appear equally beneficial to themfelves and to their country. The truftees ftruggled at firft with many difficulties; the ignorance, the idlenefs, the indocility of the people. But happily thefe difficulties are in a meafure furmounted. There are not wanting hands expert in raifing and dreffing flax; and the truftees are bent upon increafing their number. To deal in this article, the encouragement muft be great, when there is a market at home; and there muft always be fuch a market while importation continues. The late premiums for the greateft quantity of flax upon an acre, have fpread the art of preparing land for flax-feed; and reiterated experiments of the great produce of flax from high dreffing, muft roufe every farmer. The bounty of eighteen-pence per ftone for dreffed flax, though limited to a few counties, will in time make its progrefs through every county; and farmers, if they regard their intereft, will early prepare for receiving the benefit of this bounty when it reaches them. But of all encouragements for flax-raifing, that of the new machine is in reality the greateft; by preventing a great wafte of flax, by refcuing farmers out of the fraudulent hands of lint-millers, and by faving an endlefs expence formerly laid out for bringing lint to the heckle. In ufing this machine, a farmer fuperintends the dreffing his own flax; it is done by his own fervants when they cannot be otherwife otherwiſe employed; and it is done without expence. A crop of flax, of all the moſt lucrative, will by theſe means pay a conſiderable part of the rent, and make quicker returns of money than moſt other crops. Nor ought it to be overlooked, that the finding employment for ſervants when they would otherwiſe be idle, comes to the ſame with leſſening their wages. The truſtees will diſperſe a few of theſe machines *gratis* in different quarters to ſerve as models. The machine is of eaſy conſtruction, and can be correctly copied by any good workman.

It is zealouſly to be wiſhed, and may reaſonably be expected, that the flax-raiſing will be greatly promoted by this machine, and will creep into every corner. But there is ſomething ſtill wanting to complete the encouragement; and that is, a ready market for the flax when it is prepared for the heckle. To that end the truſtees will conſider whether it may not be proper to appoint lint-markets in certain counties, where buyers and ſellers may reſort: and to proclaim premiums for the greateſt quantities of flax brought by individuals to theſe markets: and we cannot copy a better model than the premiums given for improving the ſtaple of our wool; a regulation that has a fine effect. It is ſubmitted, whether it may not be proper to begin with appointing three or four markets within the five weſtern counties which at preſent enjoy the bounty of eighteen-pence per ſtone for home flax; becauſe frauds that may be committed in claiming the propoſed premiums, will be eaſily checked by the itinerant raiſers and dreſſers of flax appointed for inſtructing the people in theſe counties. The truſtees will alſo conſider, whether it may not be uſeful to proclaim at the ſame time flax-fairs in central places of other counties, aſſuring the inhabitants of the premium in their courſe.

Having diſcuſſed flax-raiſing, we ſhall ſubjoin an appendix regarding the linen manufacture in general. As this manufacture is now advanced much beyond what is neceſſary for our own conſumption, it is the duty of the truſtees to attend to the commerce of that commodity, and to uſe their endeavours to put it upon the beſt footing. To form a ſolid judgment upon this important ſubject, one muſt be previouſly acquainted with the manner in which that commerce is carried on at preſent; a brief view of which is as follows: London is our capital market: our linens are conſigned to factors who ſell upon time; to them it is of little conſequence what the price be, or whether punctual payment be made, becauſe they remit only what money they receive: commiſſion and other charges are ſubtracted; which, with ſlow payments, is a grievous burden upon the dealers in this country. Of a commerce carried on in this manner, the natural and neceſſary effect with reſpect to the dealers here, is to confine it to thoſe who have large ſtocks, and can afford to lie out of their money. This ſtate of our linen-commerce muſt cramp the manufacture exceedingly: it is in effect a monopoly, and a monopoly of the very ſtricteſt kind, confining manufacturers to the wholeſale-dealer who lives among them, or in their neighbourhood; for to try all the dealers where a ſingle web only is to be ſold, would be a great waſte of time, with little proſpect of a better price. There are, it is true, ſome petty dealers engaged in this commerce, known by the name of hawkers, who afford to the weaver ſome ſlight relief againſt this ſlaviſh dependence. Theſe men lay out their ſmall ſtocks in picking up linen cloth as it comes from the loom; which they alſo muſt ſell to the wholeſale-man, for they cannot afford to deal directly with London. But being better able than a weaver with a ſingle web, to cope with the wholeſale-dealers, and having more knowledge of the trade, they generally obtain a more equal price, becauſe they can change about if they be ill treated. Hence it is, that theſe hawkers are no favourites of the wholeſale-men; which remarkably appeared in an application to the board of truſtees, inveighing bitterly againſt hawkers, and calling forth the vengeance of the board upon them as deſtructive to the manufacture. It was poſſibly imagined, that the truſtees might have overlooked a maxim of which none are ignorant, viz. That the more numerous purchaſers are, the better for the manufacture. But this incident may juſtly give reaſon to apprehend a combination among the wholeſale-dealers to deſtroy hawkers: an agreement not to purchaſe from them, or to keep down the price, will produce that effect; and, by this ſimple means, the whole trade may be monopolized by the great dealers without a competitor.

The plan that bids the faireſt for putting this commerce upon its moſt advantageous footing, is, that there be four linen fairs held annually at Edinburgh, as the moſt central place, each of them to continue four or five days; which will naturally produce a conſiderable circulation of ready money, and conſequently afford the poor manufacturer ſome inſtant relieve for carrying on his buſineſs. We indeed can ſcarce hope for commiſſions from wholeſale-merchants in London, who have linen-drapers at hand to furniſh them goods for completing their aſſortments. But an inſtance ſomewhat ſimilar, gives encouragement to hope that other Engliſh dealers may reſort to our fairs. When the commerce of black cattle was laid open by the union, our people carried their droves to England: but expence of travelling, and fluctuation of markets, made this a precarious and hazardous commerce, and reduced to bankruptcy many of our drovers. At length the proſpect of choice and cheapneſs at a public market, drew down to this country the Engliſh dealers; and now the greater part of our cattle are ſold at home for ready money. What reaſon have we to doubt, but that the Engliſh dealers will reſort to our fairs for linen, as they do for cattle? There is no reaſon to doubt, provided we perform our part; which is, to be induſtrious in advancing our linens to their perfection. Our ſituation for ſuch fairs is undoubtedly better than that of Ireland: for, ſuppoſing other articles equal, an Engliſh dealer, unaccuſtomed and averſe to ſea-voyages, will never prefer a perilous navigation before a ſafe and ſnug journey upon *terra firma*.

The trouble and expence of carrying home goods that remain unſold at a fair, have ſuggeſted a linen-hall, as a repoſitory for ſuch goods, where dealers may be provided during the interval between two fairs. But as it is difficult to foreſee the fate of any new project, the truſtees, ſenſible of former diſappointments, will probably be diſinclined to adopt any expenſive plan for a linen-hall. It is the ſafeſt courſe to be frugal in making the experiment: ſucceſs may encourage them hereafter to be more bold.

One capital view of the plan propoſed, which can ſcarce fail of ſucceſs is, to reſcue the poor weavers from the oppreſſion of the wholeſale-dealer, by affording them a choice of markets. If the price offered by their neighbour, the wholeſale-man, be not thought ſufficient, a number of them clubbing together may ſend their goods to an Edinburgh fair, under the care of one of themſelves, or of any truſty perſon. This plan will be a ſignal bleſſing to the hawkers in particular: it will enlarge their field of action; it will make them independent; and it will augment their number: than which nothing can be more beneficial to the manufacturer. Every web is picked up as it comes from the loom, with a view to ſome little profit at an approaching fair; and in ſo ſwift a circulation, a very ſlender profit will content a hawker. This plan will be equally convenient for pedlers, who, inſtead of painful journies through the country to make up their aſſortments, find at hand, in a fair, every ſort they have occaſion for. Nor need we be diffident of commiſſions from Glaſgow, Liverpool, and other trading towns on the weſt coaſt; becauſe the dealers in theſe towns will find themſelves cheaper ſerved here than at London.

Theſe effects of the plan are obvious at firſt view. But there appear other good effects, ſome more, ſome leſs extenſive, that caſt up upon further conſideration. In the firſt place, frugal perſons, who purchaſe for their own uſe, will undoubtedly reſort to the public market, becauſe ready money will afford them both choice and cheapneſs. Secondly, Buyers and ſellers coming to be mutually acquainted, the reputation of the beſt artiſts will procure them private commiſſions for all the linen they make. Thirdly, Theſe fairs will be a great means for improving the fabrick of our linens. At preſent there is little opportunity for a comparative trial; but here manufacturers will ſoon be made ſenſible that they have little chance to vend their goods if the fabrick be in any degree imperfect. Laſtly, The quick circulation of money produced by theſe fairs, will enable the manufacturer to vend his goods at the loweſt price; and the current price for ready money being

being thus fixed, muſt have the effect to regulate in ſome meaſure the bargains that are made upon time.

Every one who gives attention to what is paſſing in the world, muſt perceive the importance of the linen manufacture to Scotland. Like a ſtone rolled halfway uphill, it muſt be puſhed to the ſummit, or it will fall to the bottom, and involve all in ruin. Honeſt labour and unrelenting induſtry will puſh this manufacture to the ſummit, and produce a moderate degree of opulence, with its never-failing attendants, plenty and population. Opulence ſo acquired, being diſtributed through every vein of the politic body, ſerves to animate every member. May heaven avert from our thoughts the ambition of acquiring wealth independent of labour and induſtry; for profuſe wealth, being always unequally diſtributed, never fails to ſap the foundations of virtue, to erect a throne for luxury, and for depraved ſelfiſhneſs, which reduce a nation to an abject ſtate of degeneracy, and terminate in a total corruption of manners.

FLAYL. *See* FLAIL.

FLEABANE, or *Fleawort*, the name of a pirennial weed common in paſtures, the ſtalk of which is round, bending, ſolid, and hearty. The leaves are oblong, ſharp-pointed, wrinkled, downy, and embrace the ſtalk on which they grow very thick without any regularity. The flowers are yellow, radiated, and incloſed in a flower-cup, made of narrow ſcales like briſtles.

FLEAK, a gate ſet up in a gap.

FLEAWORT. *See* FLEABANE.

FLET-MILK, milk that has been ſkimmed, or had the cream taken off.

FLOATING *of Meadows*. *See the article* MEADOW.

FLOTE-FESCUE graſs, an excellent graſs for cattle, growing in watery places.

The flote-feſcue affords excellent feed for horſes. Mr. Stillingfleet, quoting a piece publiſhed in the Amæn. Acad. Vol. III. entitled *Plantæ Eſculentæ*, takes notice, that the author of it ſays, article 90, " That the ſeeds of this graſs are gathered yearly in Poland, and from thence carried into Germany, and ſometimes into Sweden, and ſold under the name of manna-ſeeds. Theſe are much uſed at the tables of the great, on account of their nouriſhing quality and agreeable taſte."

Our ingenious countryman, in his addition to this paſſage, has the following words: " Mr. Dean, a very ſenſible farmer at Ruſcomb, Berkſhire, aſſured me, that a field, always lying under water, of about four acres, that was occupied by his father when he was a boy, was covered by a kind of graſs that maintained five farm-horſes in good heart, from April to the end of harveſt, without giving them any other kind of food, and that it yielded more than they could eat. He, at my deſire, brought me ſome of the graſs, which proved to be the flote-feſcue, with a mixture of the marſh-bent. Whether this laſt contributes much towards furniſhing ſo good a paſture, I cannot ſay. They both throw out roots at the joints of the ſtalks, and therefore likely to grow to a great length. In the index of dubious plants, at the end of Ray's Synopſis, there is mention made of a graſs, under the name of *gramen caninum ſupinum longiſſimum*, growing not far from Saliſbury, twenty-four feet long. This muſt, by its length, be a graſs with a creeping ſtalk; and that there is a graſs in Wiltſhire, growing in watery meadows, ſo valuable, that an acre of it lets from ten to twelve pounds, I have been informed by ſeveral perſons. Theſe circumſtances incline me to think it muſt be the flote-feſcue; but whatever graſs it be, it certainly muſt deſerve to be enquired after.

" There is a clammineſs on the ear of the flote-feſcue when the ſeeds are ripe, that taſtes like honey, as I have often found; and for this reaſon, perhaps, they are called manna-ſeeds.

" Linnæus Flor. Suec. article 95, ſays, that the bran of this graſs will cure horſes troubled with bots, if kept from drinking for ſome hours." So far the very ingenious Mr. Stillingfleet.

From what has been ſaid above, we may conclude, that the flote-feſcue is one of the beſt graſſes that we can cultivate for the uſe of our horſes, and the more eſpecially, as it appears to thrive beſt in wet, low meadows, where many other graſſes would not grow.

There are at Clacton-Lodge, in the county of Eſſex, not far from Thorp, ſome low meadows, which are every year flooded for months together during the winter ſeaſon: theſe meadows are covered with a graſs of a remarkable fattening quality; for when old cows have been turned into them, though they were ever ſo poor and low in fleſh, they have in a very ſhort ſpace of time grown as remarkably fat; and when killed, their meat would appear as fine, and taſte as well, as that of any ſteer or ox; therefore it is reaſonably to be ſuppoſed, that the graſs growing in theſe meadows is no other than that of the flote-feſcue.

FLY, in turnips. *See* TURNIPS.

FLY, in ſheep, a ſpecies of maggot very troubleſome to that animal. The reader will find an infallible method to deſtroy theſe troubleſome inſects under the article SCAB *in Sheep*.

FOAL-TEETH. *See the article* AGE *of a Horſe*.

FODDER, hay, ſtraw, haulm, &c. given to cattle.

In the foddering-yards of backſides, or other outhouſes, to have ſeveral diviſions, over and above what is conſtantly uſed, has great conveniencies in it; one of which is, that in them you may diſpoſe of a two-yearling cow, or another cow, at the time of bulling; not only to keep them from a bull, but from the other beaſts alſo, that would be leaping ſuch a cow, whereby they may hurt each other, &c. eſpecially cows forward with calf will be apt to warp by leaping a bulling-cow.

The open winters make hay the deareſt, if a hard froſt and ſnow come at the fore-hand of them; for if once cattle come to fodder, they muſt be held to it, or they will receive great damage. In waſhy weather all the hay that can be given to cattle will not make them thrive, but in dry froſty weather they will thrive with their meat very well.

Mr. Liſle ſays, that he let his cows go at large from their foddering-yard, during the winter, and ſo continued till April, when they fed on ſome graſs; and thoſe that had calved, he foddered with hay: the conſequence of which was, that by the middle of April his cows would not ſtand to eat any ſtraw at all, but were, during the months of March and April, ſo weaned from ſtraw, by baits of graſs and hay, that they fell off from the ſtraw quite, and grew much leaner, and worſe in fleſh than they had been, and apparently worſe than the farmers cows, which were, after the winter months, wholly pent up to their ſtraw, and to the pond.

All ſorts of cattle that chew the cud, as ſheep, cows, &c. care not to graze after each other, nor to eat one another's leavings in the foddering-yards; but cattle that do not chew the cud will eat after thoſe that do, and *vice verſa*.

Pliny tells us, where hay was ſcarce, it was uſual to feed their cattle with chaff and barley-ſtraw. Of chaff, ſays he, that is the beſt ſort, which is the thinneſt and ſmalleſt, and neareſt to duſt; the beſt therefore is from millet, the next from barley, and the worſt from wheat, except it be for hard-labouring beaſts.

On ſound experience I am convinced, ſays Mr. Liſle, that in our hilly-country we ought not to have any dependence on ſending our cattle out of the foddering-yard to graſs before the middle of May, and therefore we ought to be provided with winter fodder for cows accordingly.

At the beginning of winter, ſuppoſe the latter end of October, and a great part of November, while cattle ſtill continue out in the field at graſs, it is very neceſſary to fodder them early in the morning, while the hoar-froſt hangs on the graſs, which they will not eat kindly off till the ſun has warmed it.

The ſtraddling racks are beſt for foddering, if made ſtrong enough, that is, ſo as not to be over-turned; for theſe racks may be lifted up as the dung mixen riſes, which thoſe fixed in the ground cannot be.

It is a practice in many places, to tie their cows up to a rack to fodder; but if a perſon would rightly conſider the places where it is done, we ſhould find it only uſed where the fodder is good, being either hay, or very good ſtraw; but in the hill-country of Hampſhire, where the cattle have ſtraw fodder only, and that not ſo good as the ſtraw in the valleys, the cuſtom is to fodder their cows in racks, or cribs, in the open yard, which they think better than tying their cattle up to racks in houſes;

houſes; for though in cold and rainy weather the houſes may keep their loins dry, yet in countries where the fodder is coarſe, eſpecially after wet and backward harveſts, when the ſpirit of the ſtraw is waſhed out by the rain, the giving cattle ſtraw from racks, from whence they cannot pick and chooſe, as from cribs they may, is judged to tend to the impoveriſhing the cattle, whereas in cribs they can pick the ſweet from the coarſe.

There is a very remarkable difference in cattle eating their fodder, when freſh threſhed, and when it has been threſhed two or three days, eſpecially if the ſtraw be but indifferent fodder. *Liſle's Huſbandry, vol.* I. *page* 392.

FOGGE, long graſs remaining in paſtures till winter.

FOISSEN, the natural juice or moiſture of the graſs or other herbs.

FOLD, the moveable incloſure wherein ſheep are confined during the night.

It appears that the ſheep-folds of the eaſtern nations were not ſuch as ours, but houſes erected for that purpoſe.

Mr. Garret, who has lived four years in Spain, ſays the ingenious Mr. Liſle, aſſures me, that in thoſe parts where he was, they fold their ſheep as we do ours, only their fold is made netwiſe with ſtrong cords, and about ſix feet high, with the bottom ſtaked down to the ground, and two cur-dogs, of a breed between a maſtiff and a greyhound, lie within the fold to guard the ſheep from the wolf.

" In favour rather of keeping a weather-flock than an ewe-flock on the hill country, beſides other conveniencies, you may have the benefit of the fold for barley at the principal time when it does moſt good, viz. on the fallows between the latter end of February and the middle of April, when the ewes cannot be folded.

" The limitation of an ewe-flock for folding and keeping on throughout the winter, or be it a weather-flock, ought to depend on theſe rules; Firſt, Not to keep more at winter than you can winter either by meads, or ſowed graſſes and hay. Secondly, Not to be ſatisfied that you can provide hay for them by ſowed graſſes, as broad clover, &c. in caſe ſuch lands as are fitteſt to carry ſuch graſſes, lie at a diſtance for mowing, whereby you muſt maintain them with dung, where, by reaſon of carriage, it will be chargeable, unleſs your fold can maintain more ground than your out-lying lands to your farm, which, in the hill country, is not likely: and to carry but ſeven or eight pots of dung in a day, by reaſon of the diſtance, and mowing, is not reaping a profit, but bare exchanging: but if you have much land round about, and near your houſe, whereto you can carry thirty or forty load of dung a day, and which will bear broad clover hay, then you may increaſe your flock proportionably.

" As to fatting your ewes and lambs out of your flock, if you have lands diſpoſed for fatting, you ought to conſider, if you break your flock by drawing out ewes with their lambs for that purpoſe, what flock you will have left to fold on your wheat fallows, and how far your wheat land ſtands in need of a fold; for if you leave yourſelf not ſufficient, it will be indiſcretion to weaken your fold; beſides, it will hurt your breed; for you will draw off many forward lambs, which might, perhaps, have carried on the breed otherwiſe, and when a hill country farmer is ſettled in a flock, it is not good to be buying yearly, to keep up his complement, on account of many dangers which may from thence enſue: it is better, therefore, in ſuch caſe to buy ewes with their forward lambs to put into your fatting grounds; but in caſe you ſow wheat land good enough without the fold, or have another way of manuring it, by liming, &c. then it may be very well to fat off certain numbers of your flock.

" Though, ſays a very good farmer of my acquaintance, I have but a mean opinion of winter-folding, or to fold on barley ſown, and may in time fallow on graſs-ground inſtead of barley-land, yet I would fold on barley-land fallowed or ſtirred, from the time my lambs were ſtiff enough after lambing to go on ſuch fallows; for, ſays he, the benefit of an acre ſo folded, is three times as good as one winter-folded for barley.

" Farmer Glyde, of the Iſle of Wight, with whom I was talking of huſbandry affairs, told me, there was one thing he believed I knew not of, which he would tell me; he would, he ſaid, adviſe me to fold my ewes and lambs on the barley-land in the ſpring, and divide my flocks in folding; for, ſaid he, two hundred ewes and their lambs will do as much, if not more good, by folding on an acre of land, as four hundred weathers: I have, ſaid he, folded a part of the ſame land at the ſame time two hundred ewes and their lambs, and in another fold of equal dimenſion five hundred weathers, and I have always found, that the folding of the ewes did me the beſt ſervice, and brought me the beſt corn.

" My ſhepherd is of opinion, that ewes ought not to be folded on the barley fallows, or any other fallows in lambing-time, but weathers only; for the lambs, being wet when lambed, would be dirted with the fallows, and the ewes would preſently forſake them; therefore the ewes ought in lambing-time to be folded in the meadows, where it is clean, and the folds removed as often as the cold wind ſhould change from corner to corner. And afterwards, he ſaid, they ought to fold weathers on the barley till a fortnight after May, but the ewes never after Candlemaſs.

" It is plain, that the early folding an ewe-flock, and lambs in April, on wheat fallows, pinches the lambs, and ſo does folding them at that time on the barley grounds, both which are too cold for them, eſpecially in our hill country; care ought therefore to be taken, that thoſe lands do not of neceſſity want folding on in thoſe months, but that they may be otherwiſe provided for, and that during that time the ewe-fold may be on graſs-grounds, or lay-grounds deſigned for fallows.

" We muſt be more cautious in April and May of folding an ewe-fold on the barley-land, they being wettiſh, than of folding them on the wheat ſown in Auguſt or September; becauſe the lambs in April and May make the ewes riſe often and move, whereby the ground becomes much more trodden at that time of the year by the ewe-fold, than it would be by a weather-fold, or an hog-fold, as may apparently be ſeen, if the folds be divided.

" Telling Mr. Gerriſh the grazier, and farmer Iſles, how dear Mr. Eyres our miniſter ſold fat lambs to the number of fifteen, May eighteenth, viz. for ten ſhillings and ſixpence each, and that they had been folded all along to the very day he ſold them. They replied, that folding the lambs did very little hurt them with reſpect to their fat, provided they were drove pretty late to fold, and let out early in the morning.

" Walking with Mr. Raymond into his arable common fields, October twenty-fifth (anno 1708) we met his ſhepherd pitching the fold on the new ſowed wheat. I aſked him, whether he did not find that pitching the fold on the wheat at this time of the year, and a fortnight later, turned to a much better account than folding for the barley crop for the year following. Mr. Raymond and his ſhepherd readily replied, undoubtedly it turned to the beſt account to fold after this time on wheat. I ſaid, for my part, I had obſerved the fold carried on the land deſigned for barley ſo early in the winter had little effect, its ſtrength being ſpent and waſhed away by ſpring, ſo that it will make but little ſhew in the crop of barley next ſummer, and that therefore I choſe to preſerve four, five, or ſix acres of wheat-fallow that lies warm, and will bear ſowing late, to carry my fold over to the latter end of October, rather than finiſh my wheat fold by the end of September, and then carry it on my barley; for though the latter part of October might, in our cold country, be too late to ſow wheat, yet it was better than to be ſo ſoon folding barley, which would be no better for it. To which they replied, I was much in the right. And as I have before obſerved how inſignificant the fold is in the winter, eſpecally in hard froſts, I imparted it to Mr. Raymond, who concurred with me, and ſaid, he had folded on arable land in ſnow, and found not the leaſt benefit: whereupon he reſolved in ſuch caſes to fold on meadow and paſture, in mighty expectations of graſs; but it made no return; wherefore in ſnows he now lets his ſheep ramble.

" Whereas I have ſaid, that in cold clay ground, and in a cold hill country, a winter-fold does little good; yet I have by experience found the contrary in ſuch parts of the hill country, where the land is dry and light, and that it does great ſervice to the barley crop. This difference may be reconciled thus, i. e. where the land, though called hill country land, does not lie very high, for the height much tends to the chilling of the ground. Again, the explanatory reason of this difference, though hardly accountable for, yet seems to me chiefly to lie in the chilling quality of the ground which at first receives the dung and piss, and that deadens the ferment; whereas in warmer ground its progression toward that end is supported by a sufficient benign warmth, since in both sorts of earth, the urine does undeniably sink into the earth, and mix with it.

" My ground being cold and feeding, I should in the spring of the year, when I come either to pitch my fold on the barley fallows, or on the sown barley, set it very wide, in order to avoid the usual inconveniencies of penning at that time, viz. the rankness and lodging of the barley, and the consequences, thinness and coarseness.

" It was the tenth of October (anno 1720) when my fold was going to be set on the wheat-fallows of a field, which was heavy land, and the fallows, where the fold was to go, were to be ploughed up the next day; I was afraid the land would be too wet to fold on after the wheat was sown, and spoke to the shepherd about it. He said, he believed I might be in the right, especially since the rams had been some days put to ramming the ewes, because the rams would keep moving and stirring the ewes all night in the fold, whereby the ground would be battered and trod, and so squatted, that the wheat might not get through.

" That the Greeks did pen up their sheep, that they might piss through hurdles, as in Herefordshire, you may see in Palladius's calendar, November, to avoid dirtying and damaging their fleeces.

" Farmer Miles, whom I have often mentioned with approbation, advised me, if I would turn arable into meadow, and lay it up to grass, to fling straw upon it that is less than half rotten, and then fold upon it the same night, and it will bring the ground on very fast.

" Pursuant to what has been before said, that folding in winter for barley is not profitable, because, by waiting for the fold's running over the land, we lose the principal season of fallowing; yet however it may be proper to fold till Christmas, and then go on the wheat-lay; because we can lose no fallowing season by that; we cannot well have finished our fallowing any year before Christmas.

" I find by Mr. Antill and Mr. Clerk, and others, that in Leicestershire they have no winter-folding for barley; they leave off by Michaelmas at farthest, and sometimes cannot fold again till May; the reason is, their lands are so wet they would be always in a poach, and the coldness of the lands would kill the sheep: to help which defect, they muck their barley-lands, and from thence begin their husbandry, and sow wheat the year after, often under furrow, on their barley-stubble, for they say, if they should dung their wheat-ground it would rot their wheat, and they sow pease or beans after the wheat, and then lay the ground to summer-fallow again, to be mucked in May for barley, or to fold for wheat; so that they carry out their dung before it is half rotten, or the seeds of the weeds killed: but in their inclosures they sow four crops of corn all on one earth, without dung, for the most part beginning with oats, and laying down to grass with wheat.

" I am told, that in Dorsetshire the aim of the farmers is, to fold on their sheep-leases in the middle of July, and so till Michaelmas, that in the winter there may be a good head of grass for the milch-ewes.

" It seems to be inconvenient to grasp at so large a wheat or barley-crop, as hardly to be able to compass it without folding late on the wheat after it is sowed, or on the barley-land after it is sowed; for by being under the above necessity, in order to compass what one has engrossed, one may often be obliged to fold unseasonably on each sort of corn, nor will the fold in that case make good the damage done to the flock by the lateness of the season: and an ewe-fold is often damaged by folding on the cold land at the latter end of October; whereas it is better to come early with your fold off of the wheat-lands on to the barley lay-grounds, and from the sowed barley on to the wheat-fallows; for thereby you will fold the same quantity of ground of the respective grains without the respective inconveniencies.

" Between washing and shearing-time sheep ought not to be folded, because of dirtying their wool, nor from the cutting of the lambs till a fortnight after, nor in sheap-leases or arable in wet weather, for it will tread the grass into dung.

" A servant of mine, a man of very good understanding, tells me, he has been many years a shepherd, but could never observe that the fold ever did any good in frosty weather: particularly he remembers a very sharp frosty winter, in which a whole flock used daily to gather to a hay-reek, in a ground where they were foddered, yet he could not observe there was any better corn there than elsewhere. I asked him the reason of it; he said, the frost wasted and preyed on the dung; and I the rather approve this observation of his, because of the great prejudice strong beer and spirits receive by being frozen, even so as to become mere *caput mortuum*.

" If frost has the same effect on dung, by impoverishing it, that it is said to have on the sheep-fold, and on strong beer: quere, whether it be proper or not, to leave horse or cow-dung spread on land without ploughing it in?

" Mr. Raymond is also of opinion, that the winter-frosts do very much deaden the folding of the sheep, and rob it of its virtue.

" Farmer Elton said, the method he best approved of in folding, was always to fold that land first that was first designed to be ploughed, such as white or whitish land, they not being apt to bear weeds, nor will the fold be apt to cause weeds to come, and such land he would sow first, viz. at St. James's-tide. I said, I should think, though such land should be sowed ever so wet, yet, if the month of August should prove dry and scorching, it would burn, and suffer by such early sowing. He replied, if sowed wet, yet so as it came up, he never knew the drought to hurt it.

" It was a very dry season from the first of March to the sixth of May (anno 1701) during which time I set my fold on my barley. Several of the farmers in my neighbourhood said, it would be apt to do the barley more harm than good, for the sheep would scratch up the seed; whereas, if rain had come, so that the ground had not been in a dust, their scratching would have done no harm. But I rolled before I set my fold, and so I presume the ground was so fast as to receive the less damage, it being also stony, and therefore the sheep could not search it so much as otherwise perhaps they might have done: the event was, the fold did no harm, but good.

" Mr. Gilbert of Madington was telling me, the way of husbandry about him, near Salisbury, was, to fold on their wheat after it was sowed till St. Luke's-tide, which is in the middle of October; then to draw off their flock for a month to fold their sheep-leases, and then on the barley-fallows. I asked some North-Wiltshire farmers, if about them they ever folded on the wheat-land after it was sowed; they said no, they never knew it to be done in any parts thereabouts, yet folding after the corn was sown did it more good than before; but the reason why they did not do it about Holt, &c. they believed was, because they were forced to lay up the wheat-lands in high ridges by reason of the deepness of the earth, and its wetness, and the sheep if folded on such land, would do nothing but lie between the furrows, which would do the land but little service: besides, they said, in the hill-country the land was rather of the lightest, and the treading of the sheep, after it was sowed, pressed it closer than it was before, and so did it service.

" Mr. Raymond assured me, that sheep folded on sandy lands would thereby be sensibly more impoverished than those folded on clay lands, and this, said he, the shepherds agree to, who live where there are such different sorts of land. The reason seems to be, because the sandy lands draw forth and drink up the moisture of the sheep, to fill up which emptiness of the outward vessels, a fresh juice must succeed, and so on; or else that the sandy lands being hot, make the sheep perspire more than clay lands do, whereas the cold clay rather repels perspiration.

" If sandy or light ground, as has been before hinted, draws the fat and moisture of the sheep-fold off, so as to impoverish a flock more than if they had been folded on

cold

cold clay lands, it muſt be allowed, on the other hand, that light ground may be better enriched by a fold than heavy land, becauſe the light ground imbibes more of the moiſture and fat of the flock; and this gives ſome account why it is ſaid, poor lands often pay better for their folding than ſtrong lands: for the ſame reaſon winter folding, when the ground is wet and cold, holds no proportion to ſummer folding.

" Diſcourſing with farmer Biggs on huſbandry, he ſaid, he folded on the fallows all winter long, though never ſo wet; yet, ſaid he again, ſometimes the fold does harm: let it be never ſo wet, ſaid he, early in the year, folding on the fallows does no harm; for, in the firſt, there is heat enough in the ground at the firſt hand of the year to keep off the chill, and then the ground is not ſo ſettled, but that the rain ſoon runs through it, but at the latter end of the year the ground is ſettled; then treading it with the fold in wet weather makes it hold water, by which it may be chilled, and kneads the very wet into it, whereby there will be the leſs corn.

" Before I came from Crux-Eaſton in February (anno 1698) in order to go into the Iſle of Wight, I had a diſcourſe with an old experienced ſhepherd about folding the flock on fallows: he ſaid, as to wheat, it was excellently good, but they rarely folded on barley-land after it was ſowed, for if it was a whitiſh land, and a hot ſummer came, it would be burnt up: beſides, the ſheep would be ſcraping at that time of the year on barley-land, and would take the corn out of the ground; but the wheat, ſaid he, lay too deep for them to do ſo. But when I came into the Iſle of Wight, farmer Collins was of a different opinion, and ſaid, he had always folded with good ſucceſs on hot, dry, ſandy ground after it was ſown with barley, and was earneſt with me to try it; for, ſaid he, you will quickly ſee the benefit, and though the ſheep ſhould ſcrape, you will find the barley come thickeſt there. There is land, however, about Huſborne and Stoke in Hants, that will burn by folding on in the ſpring, and get more harm than good, if hot weather come, it being a hungry ſharp gravel.

" As it ſeems to me, the double folding on the early wheat-fallows, to be ſown on one earth, cannot occaſion the roots of the graſs ploughed-in to ſhoot up afreſh, but rather prevents it, by treading the earth down into a hard plaiſter, ſo that they cannot riſe; it is true, it may bring up a freſh new graſs, which, having weak roots, will eaſily be torn up by the draggs.

" Columella, ſpeaking of feeding ſheep, ſays, there is no ſort of land, or food, but what (by the continual uſe of that only) ſheep will be tired of, unleſs you give them ſome ſalt now and then to lick, from whence they may procure a new appetite to their meat and water. All the ſummer time during the hot ſeaſon they muſt be let out to feed as early as may be, while the dew is on the graſs; and when the ſun is about four hours high, they muſt be led to water and under ſhade, and again to feed towards ſun-ſet. In the dog-days the flock ſhould be ſo led as to feed with their heads towards the weſt in the forenoon, and towards the eaſt in the afternoon; for it is of great conſequence, ſays he, that the ſheep's heads ſhould be turned from the ſun, which would be hurtful to them. And Varro gives the ſame directions, becauſe, ſays he, the ſheeps heads are extremely ſoft. Perhaps this may be the chief reaſon of the rams and ewes in companies turning face to face, in hot ſun-ſhiny days. During the winter, and early in the ſpring, they ſhould be kept in their fold, till the ſun has melted the hoar-froſt from the graſs, which would occaſion rheums in their heads, and would alſo ſcour them: for this reaſon in the cold wet ſeaſons of the year they ſhould be watered but once a day. They let their ewes, as Varro aſſures us, go out to feed with the reſt of the flock, but kept back the lambs, which were ſuckled by the ewes at their return, and then again ſeparated from them. They alſo tethered their lambs at ten days old, leſt they ſhould diſlocate or hurt their tender limbs by playing together." *Liſle's Huſbandry*, *vol.* II. *page* 178.

FOLE-FOOT, the ſame with colt's-foot. *See* Colt's-Foot.

FOOD, a general name for whatever aliments are taken into the body to nouriſh it.

Food *of plants*, the particles they extract from the ſoil, air, &c. in order to their nouriſhment.

Philoſophical inquiries into the principles of vegetation, and the manner in which it is performed, are an object well worthy the attention of gentlemen whoſe ſituation allows them to purſue that truly uſeful and entertaining ſtudy. But as the induſtrious huſbandman, for whoſe benefit this work is chiefly intended, as a compendium of the beſt practice in agriculture, founded on the reſult of experience, cannot afford time for matters of ſpeculation; nor would they, in point of prudence, conſiſt with his neceſſary occupations, even if his education fitted him for ſuch reſearches; it may be ſufficient for him to form a general, but juſt, idea of the means by which plants are moſt ſucceſsfully raiſed. A proper notion of this will help to guide him in the management of his lands, and ſhew him in what ſtate the earth ſhould be, to enable the plants which he cultivates moſt eaſily and readily to find their neceſſary food. This general knowledge of the baſis of agriculture is even requiſite in every one who would be ſatisfied of the reaſonableneſs of his methods of proceeding.

Whether any one active principle does univerſally nouriſh all plants, or whether ſome particular ſalts or juices feed one plant, and others another, is a queſtion that has been warmly debated by philoſophers.

The ancients generally entitled the earth to the production of the animals, vegetables, and other bodies, upon and about it; but ſeveral of the moderns, and among them ſome of very great name, both here and abroad, have declared in favour of water, as the efficient cauſe of vegetation. Lord Bacon was of opinion, that, " for the nouriſhment of vegetables, water is almoſt all in all; and that the earth doth but keep the plant upright, and ſave it from over-heat and over-cold." Others carry this hypotheſis ſtill farther, aſſerting water to be the only principle or ingredient of all natural things. They ſuppoſe that, by I know not what proceſs of nature, water is tranſmuted into ſtones, into plants, and, in ſhort, all other ſubſtances whatever. Van Helmont, and his followers, to whoſe opinion even the illuſtrious Mr. Boyle has ſhewn a ſtrong propenſity, are very poſitive in this, and alledge, as proofs, the conſiderable growth of mint, and ſeveral other plants, in water, and his well-known experiment on a willow-tree. Van Helmont planted this tree, which weighed five pounds, in two hundred pounds of earth dried in an oven, and watered it with rain, or diſtilled water, after carefully covering the caſe in which it ſtood with a perforated tin cover, to prevent the admittance of any other earth. Five years after, weighing the tree, with all the leaves it had produced in that time, he found its weight amount to one hundred and ſixty-nine pounds three ounces; while the weight of the earth was only diminiſhed about two ounces.

Mr. Evelyn thought, with the learned Dr. Sharrock, whom he quotes, that water is, of its own conſtitution alone, a ſoil to vegetables, not only as the moſt genuine vehicle of the riches which it imparts to plants, through the ſeveral ſtrainers, and by means of which all change and melioration is effected; but becauſe it is, of all other ſubſtances, beſt diſpoſed for ingreſſion, to inſinuate into, and fertilize the earth; which is the reaſon why floated grounds are ſo remarkably fertile after the flood has ſubſided. " It is, ſays he, the neareſt of kin to the whole vegetable race; for to aſſert, with any confidence, what part of the mere earth paſſes into their compoſition; or whether the earth ſerves only for ſtability, or as a womb and receptacle to their ſeeds, I ſhall not undertake to diſcuſs; though I do not yet conceive the earth to be altogether ſo dull and inactive, as to afford no other aid to the generation of what ſhe bears; the diverſity of ſoils being infinitely various, and the difference of inviſible infuſions far beyond our arithmetic. But neither do I here by any means exclude the air, nor deny its perpetual commerce and benign influencies, charged as it comes with thoſe pregnant and ſubtile particles, which pervading and inſinuating into the earth's more ſteady and leſs volatile ſalts, that inteſtine fermentation is begun and promoted, which gives life, growth, and motion, to all that ſhe produces. Dr. Mayow has proved, that the moſt exhauſted and worn-out mould, if repaired by a bare expoſure to the air alone, without which it produces nothing. Nor can plants, totally excluded from the air, live, or so much as erect themselves to any thriving purpose, as being deprived of that breath and vital balm, which no less contributes to their growth and nourishment than does the earth itself, with all our assistance. Besides, we find that the air is near of kin and affinity to water, and indeed seems as if it were but a thinner water; for how else are vines, and other trees of prodigious growth, maintained among barren rocks, and thirsty pumices, where rains but seldom fall, if not from the benign influencies of the air?"

To this aerial food and moisture it is that most of the sedum kind owe their growth. Succulent groundsel, and the fragrant wall-flower, draw their nourishment from the same source. An ash now growing out of a wall of the abbey-church at St. Alban's, affords a remarkable instance how much even trees are nourished by the air.

As all kinds of water, as well as air, contain many other substances besides the pure elements of water and air, it is difficult to ascertain whether these extraneous substances, or some of them, are not the food of plants. Dr. Woodward's experiments, as related in the Philosophical Transactions, seem to confirm the opinion that they are: for he observes, that a great part of what he calls terrestrial matter, mixed with the water in his experiments, ascended up into the plant, as well as the water; and that the plants were more or less nourished in proportion as the water in which they stood contained a greater or smaller quantity of that matter. With regard to Van Helmont's tree, and the growth of plants in water, he very justly observes, that nothing like what the advocates for water would infer from thence, can possibly be concluded from any such experiments, unless the water used in them be absolutely pure, homogeneous, and not charged with any sort of terrestrial mixture, to which the plant may owe its growth and increase: for that all water, even the clearest and most transparent, does abound with such matter, will appear to any one who shall put some of the very purest into a clean glass phial, and stop it with the greatest care. Though perfectly transparent at first, it will grow cloudy, if suffered to stand some time without being stirred, and at length deposite an opaque sediment. Filtring and distilling will indeed intercept some of the earthy particles with which it is naturally charged; but neither of these operations, nor any other that we know of, though ever so often repeated, will free it entirely from all extraneous matter, some of which will always remain in it, very fine and light, fit to attend every motion of the water, whose extreme tenuity, and exactly spherical globules, enable it to pervade smaller ducts than even imagination can conceive. We hardly know any fluid in all nature, except fire, whose constituent parts are so extremely subtile as those of water. They will pass through pores and interstices, impervious to air, or any other fluid. This enables them to enter the finest tubes and vessels of plants, and to introduce the nutritive matter lodged in the earth, conveying it to all parts of them; whilst each, by means of organs it is endowed with for the purpose, intercepts and assumes into itself such particles as are suitable to its own nature; letting the rest pass on through the common ducts.

The judicious Mr. Worlidge, uninfluenced by the new and prevailing mode of thinking in his time, according to which all vegetables were supposed to be fed by water only, declares positively, that he cannot but explode this opinion as destitute of foundation; for that, although several plants set in water only, do emit fibrous roots, and flourish therein for a time; yet, at best, this nourishment is but weak, because water does not contain a sufficient quantity of the true nutritive particles, as the willow, poplar, and other aquatic plants raised therein, demonstrate, and as is still farther evident from their better thriving if the water be often changed. "Experiments, says he, have been made of gourds and cucumbers, planted in baked earth, and watered with water only; and after they have grown to such a bulk as the experimenter thinks proper, they are weighed, and also the earth, which last is probably but little diminished, or perhaps not at all; from whence they conclude, that the substance of those vegetables proceeded from the water. Thus have men made experiments speak as they would have them, to favour the new opinions they would impose on the credulous."

Spring and rain-water contain pretty near an equal charge of vegetable matter; river-water more than either of them. Nor can any doubt be made, but that the water which falls in rain at some times, is more charged with particles fit for the vegetation of plants, than that which falls at others. A more powerful degree of heat must draw up a larger quantity of that matter, with the humid vapours which form rain, than a more feeble warmth possibly can. The water of one spring may also flow with a higher charge of this matter than that of another: this depending partly upon the quickness of the ebullition of the water, and partly upon the quantity of that matter latent in the earth, through which the fluid passes, and the greater or less laxity of that earth. For the same reason, the water of one river may abound with it more than that of another; and the same river, when much agitated, may bear up more of it than when it moves with less rapidity.

Though water be not itself the food of plants, it is an absolutely necessary agent, by which the matter proper for their nourishment, which remains inactive till it be diluted by, and incorporated with this fluid, is conveyed to them, and introduced and distributed into their several parts, both from the earth and the air. But still it is not capable of performing even this office, without the concurrent assistance of heat, which gives it the necessary action, exalts and digests the nutritive juices, dilates the pores of the plant, and raises the sap into the stem, branches, and fruit, where the sun perfects the work, by ripening it.

The necessity of heat in vegetation is apparent from our fields and forests, our gardens and our orchards. We see, that in autumn, as the power of the sun decreases, so its effects on plants diminish, and their vegetation slackens by degrees. Its failure is first discernible in trees, which, being raised high above the earth, require the most heat to elevate the water, charged with their nourishment, to their tops and extremities; so that for want of fresh support and nutriment, they shed their leaves, unless secured by a very firm and hardy constitution, like that of our ever-greens. Next, the shrubs part with theirs; and then the herbs and lower tribes; the heat being, at length, not sufficient to supply even these, though so near the earth, the fund of their nourishment. As the heat returns with the ensuing spring, they all recruit again, and are furnished with fresh supplies of verdure: First, Those which are lowest and nearest the earth, because they require the least degree of heat to raise into them the water with its nutritive charge; next, the shrubs and higher vegetables, in their turns; and, lastly, the trees. As the heat increases, it grows too powerful, and hurries the sap with too great rapidity through the finer and more tender plants. These, therefore, go off and decay; and others, which are more hardy and vigorous, and require a greater degree of warmth, succeed in their order.

Mr. Tull is the only person who makes earth the food of plants. The experience of all ages contradicts this opinion; for the necessity of inducing something into poor soils, to enable them to produce crops, is universally acknowledged; whereas, if earth alone was the food of plants, it would in all cases produce the same effect.

As to the grand question, whether plants of different kinds are nourished by one universal food, or whether each particular species imbibes only its peculiar aliment; the supporters of this last opinion, among whom are the great lord Verulam and Dr. Woodward, say, it is not possible to conceive that one uniform homogeneous matter should constitute bodies so unlike in all respects as the various tribes of vegetables; nay, even as the different parts of the same plant. But a moment's reflection will shew, that the latter part of this objection confutes the former; for if the plant has the power of altering the original juices taken in by the roots into so many various forms as experience proves it has, each plant may be indued with the faculty of assimilating to itself the juices it meets with in the earth; as we find the same food not only nourish different animals, but produce in each its peculiar character.

We have ocular demonstration, that the willow and alder thrive best on a moist soil, and that the elm, pine, fir, and cypress, prefer a drier earth. Yet these, and many

many more of the wideſt difference, are ſometimes ſeen to draw their whole ſuſtenance, bulk, and ornaments, whether annual or perennial, from the juices they find in the ſame piece of ground, and from the ambient air and dews; though our ſtricteſt diligence cannot diſtinguiſh the particular aliments which approach their ſeveral roots. Changing the earth about the roots of theſe, or any other trees, whoſe bark, ſap, fruit, and ſeed, are of very different kinds and qualities, will only make each tree proſper the better. "Hence, ſays Dr. Beal, we may juſtly ſuſpect, that the very contextures of their bodies, from the firſt ſpirting of their ſeed, and as they are formed gradually from the inviſible principles or ſpirit and vigour of their ſeeds, however ſmall and imperceptible, are the natural alembics, where the common rain-water and air are digeſted into very much differing leaves, fruit, ſeed, reſins, gums, &c. perhaps as the cow's belly converts the common juices of all ſorts of graſs into milk, or as the bee collects honey and wax from all ſorts of flowers."

The ſame ſoil that has once been proper for the production of ſome ſorts of vegetables (continue thoſe who think that each particular ſpecies of plants has its particular food) does not always continue to be ſo; but in time loſes its property. If wheat, for example, be ſown upon land proper for that grain, the firſt crop will ſucceed very well, and perhaps the ſecond, or as long as the ground is in heart; but in a few years it will produce no more, if ſown with that corn. Some other it may, as barley, rye, or buck-wheat.

That this is owing to an improper culture of the land, more than to any defect in the ſoil itſelf, will evidently appear to thoſe who ſhall candidly weigh the principles of the New Huſbandry, when that ſubject comes to be treated of.

Mr. Du Hamel makes no doubt, but that the particles which plants appropriate to themſelves, take different forms in each plant, and even in the ſeveral parts of the ſame plant; but, as he juſtly obſerves, it does not at all follow from thence, that they were not originally the ſame. What would induce one to think them the ſame, is, that plants of different kinds rob one another of the nouriſhment which is in the earth: for, if a lettice, for example, drew from the earth a food different from that of endive, a lettice planted among endive would not only thrive better than if planted among other lettice, but as well as if no other plant was near it. But we know, by experience, that this lettice would grow very poorly, and conſequently that plants, though of different ſpecies, do hurt and rob one another. If each plant drew from the earth only the particular juices proper for itſelf, poppies, thiſtles, &c. which kill wheat, would not in that caſe do it any hurt, farther than by ſhading it with their ſtalks. But that the injury they do the corn is chiefly occaſioned by their roots, which conſume the neceſſary nutritive juices, is evident from this, that if dry branches were ſet in ſuch numbers as to make even a greater ſhade than thoſe weeds, they would not equally prejudice the growth of the wheat.

After ſome other arguments of equal force, Mr. Du Hamel concludes, that plants of different ſpecies feed on the ſame, or nearly the ſame ſubſtance; that there is no plant which does not rob thoſe that are within its reach of ſome part of their food; and that the ſoil which once is good for any one kind of plant, will always be able to ſupply it with food, provided it be properly cultivated.

To prove that the ſame juice takes different qualities in the veſſels of the ſame plant, he inſtances an experiment which he made, by grafting a young lemon, of the ſize of a pea, by the ſtalk, upon a branch of an orange tree. It grew there, ripened, and retained its quality of lemon, without partaking in any ſhape of that of the orange. The juices of the orange tree muſt therefore have changed their nature at once, on their paſſing into the lemon.

It is an old opinion, generally received by the ancients under the name of occult qualities, or ſympathy and antipathy, that ſome plants delight in being near each other, while others will not live together. Several of the moderns have likewiſe embraced this ſentiment, and urged in ſupport of it, the fig-tree and rhue, garlick and the roſe, which, ſay they, agree remarkably well together, becauſe the juices ſuited to the one are avoided by the other. Lavender, laurel, thyme, marjoram, and other aromatic plants, cannot, on the contrary, according to them, flouriſh together, becauſe they feed on ſimilar juices, of which they rob one another. Mr. Evelyn ſeems to be nearer the truth, when, ſpeaking of this ſubject, he aſſigns as a reaſon why ſome plants will not thrive near others, certain effluvia or ſteams emitted by the one, which may be noxious to the other. Plants will not thrive under the walnut-tree, the oak, and others of the ſame kind, becauſe their numerous and wide-extended roots exhauſt the earth around them, and the drippings from their leaves are impregnated with an acrid matter, which is an enemy to vegetation.

Though there are evident inſtances of an election of food in ſome plants of very different kinds, ſuch as the aquatic race, and thoſe which delight in a dry ſituation; yet, ſo far as relates to the farmer, they may be ſaid to be nouriſhed with one and the ſame ſubſtance; but at the ſame time it is neceſſary, that both the earth and that ſubſtance be fitted for receiving and nouriſhing them: for be the earth ever ſo good, rich, and proper for the production of vegetables, little will come of it, unleſs its parts have that juſt degree of ſtrength, or coheſion, which ſhall give ſtability to the plant, and at the ſame time afford an eaſy admittance to the fibres of its roots, to ſpread and extend themſelves in ſearch of that food.

FOOT, the part that ſupports an animal.

A horſe may have a very well made foot, and well proportioned, and yet if it chance to be thin and weak, the buyer will be diſappointed of his expectation; for ſuch a foot is liable to be ſpoiled in ſhoeing, by travelling on hard ſtony grounds, by too much drought in hot ſeaſons, or by too much moiſture in winter. A thin foot is that where the cruſt or horn is thin. This may be eaſily ſeen when the ſhoe is taken off, becauſe the verge all round the ſole will appear thin; and where it is ſo, a horſe will winch with the leaſt touch of the pincers; but as this trial will ſeldom be allowed in buying of a horſe, the beſt way to thoſe who would be acquainted with ſuch things, is to obſerve the bottom of the cruſt, which is generally ragged, and where the ſhoe-nails are clenched and rivetted: if theſe be high, it is a token the foot is thin, and that there has not been ſufficient hold for the nails, without driving them a good way upwards in the cruſt. In a thin foot, the heel and frog are alſo apt to be ſoft and tender to the touch, and by reaſon of the weakneſs natural to ſuch kind of foot, it ſometimes turns away, and one point of the heel will ſtand higher than the other, though this may be alſo owing to the crookedneſs of the paſtern joints, and will ſometimes happen where the foot is tolerably ſtrong; but is moſt common to ſuch as have weak feet; and where it is ſo, the horſe wears his ſhoes more on one ſide than the other, and often cauſes him to cut, and go lame in a journey.

As a thin weak foot is juſtly reckoned a very great defect in a horſe, ſo a very ſtrong foot is not always the moſt eligible, but is liable to ſeveral accidents. A ſtrong foot has the fibres of the hoof very diſtinct, and for the moſt part run in a ſtraight line from the coronet to the toe, like the grain of oak, lignum vitæ, or any other hard wood that eaſily ſplits; and though ſome ſuch feet will laſt very well, and keep free from accidents, where ſufficient care is taken to keep them moiſt and pliable; yet when they happen to be neglected upon a long journey, or much hard riding, eſpecially on dry ſtony grounds, or when they ſtand long in a hot dry ſtable, they will go lame and tender, at the ſame time that no defect is to be ſeen on the foot; for when the ſoft parts within are bruiſed by the hardneſs of the hoof, or by the thickneſs and hardneſs of the ſole, which in all ſuch feet is like a plate of iron; and when this happens, a horſe will be in pain, and the true cauſe ſometimes not found out for a long time, which I have known in ſeveral inſtances; nor is it eaſy to reſtore ſuch feet to a due temperament, as will be ſhown hereafter.

When a horſe that has a very ſtrong foot takes up a channel nail, or happens to be cut into the quick with a ſharp bone, a ſharp flint, or piece of glaſs, and a flow of humours follows upon ſuch a wound or puncture, the confinement theſe meet with from the ſtrength of the foot create much anguiſh, and, for want of vent below, frequently cauſes an eruption round the coronet, which proves

for

for the moſt part troubleſome, and makes the cure tedious and uncertain, eſpecially when ſuch caſes happen to fall into bad hands.

I have known ſome inſtances where the hoof and the ſole have been quite looſened from all their attachments to the foot, the filaments and fibres that unite the horny part to the fleſh being all torn and pulled aſunder by the thickneſs and ſtrength of the horn; and where this happens in any degree, it is apt to leave a tenderneſs behind it, unleſs an uncommon care be taken to prevent it.

But the greateſt inconveniency in a very hard ſtrong foot, is its being ſubject to reſts and fiſſures, which cleave the hoof quite through, ſometimes from the coronet down to the bottom; and this kind of foot is the more eaſily expoſed to ſuch accidents, that the horny fibres have a more viſible ſtraight direction than where the feet is more ſoft and pliable; theſe clefts, being for the moſt part in the quarter, ſeldom admit of any other remedy than extirpating the whole piece that lies next the heel, which defect is from thence called a falſe quarter, wherein the cure is ſeldom ſo perfect, eſpecially in the fore feet, as to leave no infirmity or blemiſh behind it. When the fiſſure or cleft does not penetrate through the horn, but makes a line on the ſurface, it is called a ſand crack, being very common in ſome ſandy countries, where the horſe's hoofs turns dry and crack with the heat of the ſand. Theſe are but little regarded where the lines are ſuperficial, and not deep in the horn, and are often cured by raſping the foot, and keeping it cool and moiſt. However, it is a defect that muſt leſſen the value of a horſe, in proportion to the degree of goodneſs or badneſs of his foot; for when the foot happens to be otherwiſe bad, theſe blemiſhes often degenerate, and are of ill conſequence.

The next defect I ſhall take notice of in the feet, is of thoſe horſes that have narrow heels. Some horſes feet are tolerably good, even where the heels are narrow; but when the foot is hot and inclined to rottenneſs, and the quarters loſe the round turn that they ought to have as they approach the heel, and look as if they were bent and pinched together, inſomuch that the heels of ſome ſuch horſes are not above two fingers in breadth, then the foot is bad; and the way that many take to mend theſe kind of feet, by hollowing on each ſide the frog, and thinning the quarters to cauſe them to ſtretch to a wider ſhoe makes them worſe; for the ſtretching out the quarters contracts the hoof on the inſtep, and almoſt always turns ſuch horſes hoof-bound, and wire-heeled.

But horſes often grow hoof-bound from other cauſes, and in ſome it proceeds from the ſhape of the coffin-bone, when it happens to be flat or hollow, where it ought to be riſing and round, when the coffin drops by thinning the ſole too much, and not taking care to ſtay it up with ſtuffing and ſplinters, and from diſeaſes in the feet that leave a weakneſs and deformity in them. But when a horſe that has a very ſtrong flinty foot happens to be hoof-bound, the caſe generally turns out bad. For the harder the hoof, the more it preſſes round the inſtep and heel. This preſſure makes the parts all round the coronet to grow fleſhy and project over the inſtep, ſo as to be conſtantly bruiſed by the upper part of the hoof, eſpecially when a horſe carries any great weight upon him, and by this means in the end ingenders a quitter, which creeps ſo under the hoof that it can ſeldom be removed without the loſs of a quarter, the ſame as when there is a fiſſure and cleft, or rather worſe, becauſe of the depreſſion and binding all round the upper part of the foot with the diſtemperature of the coronet, which often renders ſuch cures both very tedious and imperfect. Therefore this ought to be well looked into, eſpecially in chooſing a ſaddle horſe, that his feet be tolerably ſhaped, ſmooth, and cool, not narrow heeled, nor hoof-bound, neither weak-footed, nor too remarkably ſtrong; for moſt horſes of this latter kind are alſo coarſe, and chiefly fit for labour.

Another thing that ought carefully to be looked into, is that both his fore-feet be of equal ſize; for wherever this defect is the leaſt apparent, though it may proceed from a horſe's uſing one leg more than the other, as it happens to working men who uſe the right-hand and arm more than the left; yet when one foot is ſmaller than the other, it is a blemiſh, and carries ſome doubt that ſuch a foot may in time fail and periſh, even as theſe do that have been hurt by accidents, or after old lameneſſes in the ſhoulders, legs, and muſcular parts, where the foot at laſt periſhes in proportion as the muſcular and nervous parts ſhrink and diminiſh.

Another defect in horſes feet, is when they are flat and without depth. If ſuch a foot happens to be ſtrong, and the hoof ſmooth; if the ſole be alſo firm, and the frog no ways rotten or fleſhy, ſuch a horſe will endure the roads tolerably well. But when a flat foot is ſhaped like an oyſter, has many rings or wrinkles, if the ſole be ſoft, and the frog fleſhy and ſpongy, it is a very great defect. Some horſes are ſo remarkably faulty in this reſpect, that the frog bunches out beyond the bottom cruſt of the hoof, that their ſhoes muſt be made hollow, and the plates ſo broad as almoſt to cover the whole bottoms of their feet, to keep them from the ground. But indeed ſuch horſes are only fit for a draught, and not for the ſaddle.

Some horſes have tolerably good feet, only that their heels are low. Horſes that have long yielding paſterns are the moſt ſubject to this defect, and alſo thoſe that have their paſterns very ſmall, ſhort, and ſtanding almoſt quite upright; theſe have generally long heels and flat feet, and their fore-legs coming ſtraight down from the ſhoulder to the foot, without any bending of the paſterns, and for this reaſon are frequently called goat-legged. Many of the horſes bred in the fens are of this kind, have but an awkward uſe of their limbs, and make very bad travellers, and thoſe low heeled horſes which have very long yielding paſterns, are apt to have their heels wear quite to nothing upon a journey, and all the care imaginable in ſhoeing cannot prevent it.

A very high heel is another extreme, which greatly leſſens the value of a horſe; for even where ſuch a foot happens to be ſtrong and ſmooth, it is nevertheleſs the cauſe of unſteadineſs in a horſe's going, expoſes him often to trip and ſtumble, to ſprains in the coffin and paſtern-joints, &c.

There is one kind of horſe, eſpecially among the coach and cart breed, very remarkable for a large deep foot; the horn extremely thick and ſcaly, the heels broad and mouldering, and are apt to grow ſo very faſt, that the farriers when they go about to ſhoe ſuch horſes, thinking to eaſe them of their great load, and to bring their feet into a better ſize, pare and raſp them to ſuch a degree, that they leave their feet much larger about the coronet and inſtep than at the bottom; ſo that they always look as if they went upon pattens, which is not only very ugly, but ſuch horſes are ſeldom good for much.

A very large foot of any kind is to be avoided in a horſe, even ſuppoſing it to be in itſelf firm and good. But when I ſpeak of a large foot, I mean only when it is diſproportioned to his other parts, for a large horſe muſt of courſe have a larger foot than a ſmall one. But when we ſee the foot large, and the limb ſmall, in all ſuch it muſt be obſerved by thoſe who have experience, that the bones and ſinews are alſo ſlender, which not only denotes weakneſs, but heavineſs and inaptitude to any briſk and vigorous action; and therefore unfit for the coach or ſaddle, but to draw in a cart or waggon, or to carry a burden.

Some object greatly againſt white feet, as being generally worſe than thoſe of any other colour. Indeed when a horſe has too many of his feet white, they do not always prove the beſt, yet I have ſeen white-footed horſes have their feet ſuch as the ableſt judges could not find fault with. When a foot is ſmooth and tough, of a middle ſize, without wrinkles, neither too hard and brittle, nor too ſoft, and when the heel is firm, open, and no ways ſpongy or rotten, and the frog horny and dry, and the ſole ſomewhat hollow, like the inſide of a diſh or bowl, whatever be the colour, ſuch a foot will for the moſt part turn out good, though the dark or black hoof, where it reſembles that of deer, is generally the beſt; and for this reaſon thoſe who are the moſt curious about a horſe's feet, do not chooſe ſuch as have much white upon their legs and paſterns, to avoid their having too many white feet. *Gibſon's Farriery, vol.* I. *page* 19.

FORK, an inſtrument divided at the end into two or more points, or prongs.

FORKEN ROBIN, an earwig; ſo called from its forked tail.

FOSSE, a ditch or moat.

FOSTAL,

FOSTAL, a way leading from the main road to a large houſe.

FOUL FEEDING, a voracious appetite to which ſome horſes are ſubject, and, though not properly a diſeaſe, is often the cauſe of various maladies. It is generally the effect of ſome latent diſtemper, as vermin, which have a quite different effect on ſome horſes to what they have on others; for as horſes of a lax habit of body often loſe their appetites by worms, and are frequently griped and ſickly in their bowels; ſo horſes of ſtrong rigid conſtitutions, that can bear the irritation thoſe animals make in their inteſtines, are often voracious in their appetites, and continually craving after food.

Foul-feeders, however, differ in ſome things from thoſe that have voracious appetites: for as the latter crave only after their common food, and can hardly ever be ſatisfied; ſo the latter will leave their hay to eat their litter, and ſeem to like it the better when it is well ſauced with their own dung and urine; and, therefore, they may be properly ſaid to have a vitiated or depraved appetite. Though this does not always proceed from a voracious appetite, yet the firſt is often productive of the latter, and may probably be occaſioned by enlarging the capacity of the ſtomach and inteſtines to ſuch a degree, that nothing will ſatisfy their cravings, but what has weight and ſolidity; for the ſame kind of horſes will eat mould and wet clay, or any kind of foul naſty weeds out of the ditches, and in the ſtable will eat ſtinking muſty hay, which the generality of horſes will refuſe.

There are others of depraved appetites, that are neither foul nor voracious feeders, ſuch as we often obſerve eat dry loam or mud out of the walls, which perhaps denotes ſome vitiated juices in their ſtomach; and this alſo is frequently owing to vermin, or at leaſt to a bad digeſtion, though perhaps not to any imbecility in their conſtitutions; for though thoſe horſes have a longing after thoſe extraneous things, yet their appetites at the ſame time ſeldom fail: but as this is often owing to full feeding, with the want of ſufficient exerciſe, ſo we often ſee them recover and quite loſe that vitiated taſte, when they come to ride a journey, or go upon any other conſtant exerciſe.

The beſt method in all theſe caſes of a vitiated or depraved appetite, is to begin with purging, and to diſſolve chalk in their water, and afterwards to give them good exerciſe. The ſame method may be complied with to thoſe that feed voraciouſly. To theſe the following draught may alſo be given, to blunt their appetites:

> Take a large handful of the roots of marſhmallows, cummin-ſeeds, and fenugreek-ſeeds, of each an ounce: liquorice roots ſliced, half an ounce; boil in three pints of water till the roots are ſoft and ſlimy, then pour off the decoction, and diſſolve in it an ounce of gum-arabic, and add four ounces of linſeed-oil.

Let the horſe have four handfuls of this every morning faſting, till his appetite abates. If the horſe be lean, which many voracious feeders are, he will gather more fleſh under this management, and as his fleſh increaſes his appetite will abate.

As to foul feeders, many of theſe begin with voraciouſneſs, and when they come to be ſtinted, take to eating of their litter to fill their ſtomachs, and in time take a great liking to it; and it is obſervable, that many of the horſes that go broken winded, have this evil faculty; and therefore I ſhould adviſe any one who has a foul-feeding horſe, to keep his ſtall as clean as poſſible, to let no wet, dirty litter, lie under him, nor to put his litter under the manger, but to beſtow it on ſome other horſe, otherwiſe they will paw it out, and feed upon it greedily; but clean ſtraw that has not been ſoaked with horſe-piſs and filth, will never hurt any horſe; for though there is no harm in the urine, yet when the ſtraw has been ſoaked in it with the dung, it often turns into a wad, or like a ſponge in their bowels, and cauſes great diſorders. But when their wet litter is taken away every morning, it may be the means to make them leave off that ill habit. *Gibſon's Farriery, vol.* II. *page* 96.

FOWL, a general name for all ſorts of birds; but uſed in a particular ſenſe to ſignify ſuch as are bred in the farmer's yard for profit.

The countryman's farm or habitation cannot be ſaid to be completely ſtored or ſtocked without fowl as well as beaſt, which yield a conſiderable advantage by their eggs, brood, bodies, and feathers. Any poor cottager that lives by the highway-ſide may keep them, they being able to ſhift for themſelves the greateſt part of the year, by their feeding on inſects, corn, or any thing almoſt that is eatable by any other ſort of animal: and therefore they are kept to great advantage at barn-doors, and other places, where corn or ſtraw is ſcattered.

As for cocks and hens, we ſhall not enter into a deſcription of the ſeveral ſorts of them, only obſerve that thoſe that are the beſt breeders, and the beſt layers, are to be choſen, the oldeſt being always the beſt ſitters, and the youngeſt the beſt layers; but no ſort will be good for either, if they are kept too fat. The beſt age to ſet a hen for chickens, is from two years old to five; and the beſt month to ſet them in, is February, though any month between that and Michaelmas is good. A hen ſits twenty days; wheras geeſe, ducks, and turkeys, ſit thirty. Obſerve to let them have conſtantly meat and drink near them while they ſit, that they may not ſtraggle from their eggs, and chill them. One cock will ſerve ten hens.

If fowls are fed with buck or French wheat, or with hemp, canary, or millet-ſeed, which is commonly ſown in March, it is ſaid they will lay more eggs than ordinary; and buck-wheat, either whole or ground, and made into paſte, which is the beſt way, is a grain that will fat fowls or hogs very ſpeedily; but the common food to fat them with is barley-meal wet with milk or water; but wheat-flour is better: but if you deſign to bring up chickens, give a barley-corn or two to each of them, as you take them out of the neſt, and ſo continue to feed them till they are fit for fatting.

For the beſt methods of breeding ducks, geeſe, turkeys, pigeons, ſwans, peacocks, &c. *ſee each under its proper article* DUCKS, GEESE, TURKEYS, &c.

FOWL'*s Dung*. *See the article* DUNG.

FOX, a well known animal of the canine kind, with ſharp ears, and a buſhy tail.

The fox is very prejudicial to the huſbandman, by taking away, and deſtroying of his lambs, poultry, geeſe, &c. eſpecially in places that are near foreſt-woods, and covert places. The beſt way of deſtroying them is with guns or traps, after this manner: if you deſign to ſhoot them, procure a ſheep's paunch, and tying of it to a long ſtick, rub your ſhoes well upon it, that the fox may have no ſcent of your feet, and draw the paunch after you, with which make a trail a mile or two in length; and order it ſo as to bring it near ſome thick-headed tree. At which place, when you have made your trail, leave your paunch, and with your gun get up into the tree; and as ſoon as it begins to be dark, you will ſee him come by you upon the ſcent of the trail, where you may ſhoot him. Obſerve that you draw the trail to windward of the tree, if you can.

But if you have a mind to catch them with a ſteel-trap, which is the ſureſt way, chooſe a place to ſet it in a plain part of a large field; let it be out of the way of all paths, but not near either a hedge or any ſhelter. Open your trap, and lay it upon the ground, and cut out in the turf juſt the form thereof, and take out ſo much earth as may make room to lay it, covering of it again very neatly with the turf you cut out; and becauſe the joints of the turf will not cloſe exactly, get ſome of the fine mould that is to be found in a new caſt up mole-hill, and fill the joints with it, taking ſome graſs, and ſticking of it in the mould, as if it grew there. Make all ſo fine and plain, as that it may deceive your own eye to look upon it. About eight or ten yards from the trap, three ſeveral ways, ſcatter ſome of the fine mould that you had out of the mole-hill, very thin, upon a place about fourteen or fifteen inches ſquare; and upon theſe places, and where the trap is, lay two or three ſmall bits of cheeſe, and with a ſheep's paunch, as is before directed, draw a trail of about a mile long to each of the three places, that are at a diſtance from the trap, and from thence to the trap, that ſo the fox may come upon one of thoſe places firſt, which will make him

him approach the trap with more boldneſs, where you will ſeldom fail of him; only you muſt obſerve not to faſten your trap, but to leave it looſe, that he may draw it to the hedge-ſide, or to ſome cover, or elſe he will bite off his leg, and be gone.

Some bend down a ſtick in the wood, and ſet a trap for them in their paths, like that which is ſet for woodcocks, which hangs them up, or any other ſort of vermin. *Mortimer's Huſbandry, vol.* I. *page* 312.

FOX-TAIL GRASS, the ſame with cow-wheat. *See the article* COW-WHEAT.

FRAGRANT, odorous, ſweet of ſmell.

FREE-MARTIN, a barren heifer.

FRENCH BARLEY, a ſpecies of barley called by botaniſts *tritico ſpeltum*. Some call it wheat-barley. It is naked, and the grain like wheat, but the ear ſhaped like that of the common barley. This ſpecies is often ſown about Rowley, Hamſtal, and Redmore, in Staffordſhire. It yields a large increaſe, and makes good bread and good malt. *See the article* BARLEY.

FRENCH-BEANS. *See the article* BEANS.

FRITH, an arm of the ſea running into the land.

FROST, the laſt effect of cold; the power or act of congelation.

Froſt is a great fertilizer of land, and therefore when the ſoil be a harſh, churliſh, or obſtinate clay, it ſhould be turned up in ridges at the beginnning of winter, which will greatly tend to remove its bad qualities, and ſeparate its particles.

Hard winters are generally of ſervice to corn in many reſpects; eſpecially if the land has been thoroughly drained, and is well covered with ſnow. This laſt mellows the ground, and keeps it warm; while froſt, neither the rigour nor duration of which need be feared if it comes on gradually, and the land is dry, not only kills great numbers of vermin and inſects, but, by leaving the earth in a looſe ſtate, fits it for roots to extend themſelves therein as the warmth of the ſpring approaches, and thereby enables them to produce ſtrong plants; whereas frequent rains in winter, without froſt, ſodden the earth, which afterwards produces nothing but blades, ſoon to be deſtroyed by the hoar froſts of the ſpring, by inſects, and by weeds; or which would yield at moſt only ſtraw without grain. The winter's froſts may indeed nip off the blades; but then the roots being unhurt, new ones will ſhoot up in the ſpring. This was the caſe in the remarkably ſevere winter of 1608, of which Mezeray ſpeaks, and which, notwithſtanding its extreme ſeverity, was followed by a plentiful harveſt; and ſuch alſo, or nearly ſuch, was the long winter of 1729.

The great danger from froſts is, when the earth is wet, and not covered with ſnow. For example, if a ſtrong froſt returns after a ſudden thaw, the fibres of the roots are broken by the expanſion of the ſurrounding water when frozen, and the too great abundance of moiſture in the plants themſelves, when frozen, tears their fibres to pieces by the ſame expanſion. This was what happened in 1684.
