B. ischiadica m. glutei maximi.—A small inconstant bursa between the tuber ischii and the gluteus maximus muscle. **B. trochanterica m. glutei maximi.**—A large bursa constantly present between the fascial tendon of the gluteus maximus and the posterior lateral surface of the great trochanter and the origin of the vastus lateralis muscle. **B. gluteofemorales.**—Two or three small bursæ on each side of the tendon of attachment of the gluteus maximus to the femur. **B. trochanterica m. glutei medii anterior.**—A small bursa constantly present between the tendon of the gluteus medius muscle and the lateral surface of the great trochanter. **B. trochanterica m. glutei medii posterior.**—A small bursa frequently present between the tendons of the piriformis and the gluteus medius. **B. trochanterica m. glutei minimi.**—A fairly large bursa generally present between the margin of the great trochanter and the tendon of this muscle. **B. m. piriformis.**—A small bursa frequently present between the tendons of the piriformis and superior gemellus muscles and the femur.

2. Ischio-pubo-femoral Musculature of the Hip

The muscles belonging to this group, the obturator internus, the two gemelli, the quadratus femoris and the obturator externus, extend from the pubis and ischium across the back of the hip-joint to the great trochanter and the neighboring part of the shaft of the femur. They are powerful lateral rotators of the thigh. The **obturator internus** (fig. 473), a large, flat, triangular muscle, arises from the pelvic surface of the innominate bone and from the obturator membrane. At the lesser sciatic notch its tendon is joined by the two **gemelli** (fig. 472), one of which arises on each side from the bony projections which make the notch, and the combined tendon is inserted into the trochanteric (digital) fossa. The **quadratus femoris** (fig. 472) passes from the tuber of the ischium to the femur behind and below the great trochanter. These muscles are supplied by special nerves which arise from the front of the sacral plexus and enter the deep surfaces of the muscles. A fifth muscle, attached to the greater trochanter and associated with this group, the **obturator externus,** is differentiated near the adductor muscles of the thigh and is supplied by a branch from the obturator nerve. It arises from the outer surface of the bones bounding the ventral two-thirds of the obturator foramen and is inserted by a tendon into the trochanteric (digital) fossa.

These muscles seem to have no certain representatives in the arm, where the shoulder-joint is entirely ensheathed by the dorsal musculature. It is possible that the pectoral group has a corresponding embryonic origin. The group is represented, with marked variations, in the lower extremities of amphibia and all higher vertebrates.

FASCIÆ

Within the pelvis the obturator internus lies on the obturator membrane. It is covered by the **obturator fascia,** which is attached to the body of the pubis, to the iliac portion of the arcuate line, to the ventral margin of the great sciatic notch, to the ischial spine, to the sacrotuberous (great sacrosciatic) ligament, and with the falciform process of that ligament, to the ischial and pubic rami. Near the upper part of the obturator foramen the fascia instead of being attached to bone is reflected over the muscle and attached to the obturator membrane. It here helps to bound the canal for the obturator vessels and nerve. The upper part of the fascia lies beneath the pelvic peritoneum and the levator ani. The lower part forms the outer boundary of the ischiorectal fossa. The fascia is continued as a thin, adherent membrane over the obturator internus and the gemellus muscles to their attachment. The quadratus femoris is invested by a thin adherent fascial sheet.

MUSCLES

The obturator internus (fig. 473).—*Origin.*—From (1) the pelvic surface of the pubic rami near the obturator foramen; (2) the pelvic surface of the ischium between the foramen and the great sciatic notch; (3) the deep surface of the obturator internus fascia; (4) the **fibrous arch** which bounds the canal for the obturator vessels and nerve; and (5) the pelvic surface of the obturator membrane except in the lower part.

Structure and insertion.—From this extensive area of origin the fiber-bundles converge toward the lesser sciatic notch and become applied to the broad tendon of insertion. At the notch the muscle curves laterally and extends outward and upward to its insertion into the fore part of the trochanteric fossa of the femur. The tendon is formed of five or six bands which begin high in the muscle and converge into a common tendon situated on the deep surface of the muscles as the latter curves about the ischium. The tendon bands at first throw the tendon into folds which run in ridges in the fibrocartilage which lines the notch. The attachment of fiber-bundles continues upon the dorsal surface of the tendon to half way between the lesser sciatic notch and the great trochanter.

Nerve-supply.—A special nerve to the obturator internus arises from the front of the sacral plexus, usually from the lumbosacral cord and the first and second sacral nerves. This nerve passes lateral to the sacrospinous (lesser sciatic) ligament, then re-enters the pelvis through the lesser sciatic notch and sends out branches of distribution on the pelvic surface of the obturator internus.

Action.—This muscle with its two companions, the gemelli, is a powerful lateral rotator of the thigh. It is also an extensor and abductor when the thigh is bent at a right angle

Relations.—The chief pelvic relations have been described in connections with the obturator fascia which completely covers the medial surface of the muscle. The muscle passes out between the two sacroischial (sacrosciatic) ligaments. Outside the pelvis the gemellus muscles run on each side of the tendon, which is here closely applied to the capsule of the joint. Dorsal to it lie the gluteus maximus, the sacrotuberous (great sacrosciatic) ligament, the inferior gluteal (sciatic) vessels, and the sciatic and posterior cutaneous nerves. The nerve of the quadratus femoris runs beneath the obturator internus and gemellus muscles.

Variations.—It varies in the extent of its insertions. It may be divided into two parts, a pubic and an ischial. Fasciculi may be sent to the posteroinferior part of the iliopectineal eminence, the tendon of the psoas minor, the tuber ischii, the sacrotuberous (great sacrosciatic) ligament, the ischial spine, etc.

The gemellus superior (gemellus spinalis NK) (fig. 472).—*Origin.*—From the outer surface of the ischial spine and the neighboring edge of the lesser sciatic notch.

Structure and insertion.—The fiber-bundles encircle the upper border and ventral aspect of the tendon of the obturator internus. They are inserted into the upper border of this tendon, and sometimes also into the trochanteric fossa.

Nerve-supply.—From a small nerve which arises either directly from the plexus or as a branch of the nerve to the obturator internus or of that to the quadratus femoris. This nerve usually enters the deep surface of the muscle near the junction of its ischial and middle thirds.

Action.—It is essentially a part of the obturator internus.

Relations.—It lies between the piriformis and the tendon of the obturator internus. Proximally it adjoins its fellow beneath this tendon; distally, the two gemelli enclose the tendon in a musculotendinous sheath.

Variations.—It may be wanting or may have a more extensive origin than usual. It may be joined to the piriformis or to the gluteus minimus or be joined more closely than usual to the obturator tendon.

The gemellus inferior (gemellus tuberalis NK).—*Origin.*—From the upper part of the inner border of the tuberosity of the ischium, the sacrotuberous (great sacrosciatic) ligament and from the neighboring edge of the lesser sciatic notch.

Structure and insertion.—The fiber-bundles converge upon the inferior border of the tendon of the obturator internus, and are inserted by tendon-fibers into this or into the great trochanter below the obturator internus tendon.

Nerve-supply.—From a branch of the nerve to the quadratus femoris. This branch enters the deep surface of the muscle near the junction of the ischial with the middle third.

Action.—It is essentially a part of the obturator internus.

Relations.—It lies between the quadratus femoris and the tendon of the obturator internus.

Variations.—It is rarely absent. It may be joined to the quadratus femoris. It is frequently closely bound up with the obturator internus. It may be doubled.

The quadratus femoris (fig. 472).—*Origin.*—From the upper part of the outer border of the tuber of the ischium.

Structure and insertion.—The fiber-bundles take a nearly parallel course and are inserted into the vertical ridge which terminates above on the inferior dorsal angle of the great trochanter.

Nerve supply.—From a nerve which arises usually from the lumbosacral cord and the first sacral nerve and passes under the gemelli and the tendon of the obturator internus. The nerve enters the deep surface of the muscle near the junction of the ischial and middle thirds.

Action.—It is a powerful lateral rotator and a weak adductor of the thigh.

Relations.—It is covered by the gluteus maximus. Between this muscle and the quadratus femoris runs the sciatic nerve. The obturator externus muscle lies in front. The inferior gemellus extends along its superior border. The adductor minimus adjoins it distally.

Variations.—It is absent in from 1 to 2 per cent. of instances. (Schwalbe and Pfitzner.) It may be double near its femoral insertion. It may be fused with the inferior gemellus or the adductor magnus. It may send a fasciculus to the semimembranosus.

The **obturator externus** (figs. 471, 473, 476).—*Origin.*—From the lateral surface of the pubic and ischial rami, where they bound the obturator foramen, and from the surface of the obturator membrane.

Structure and insertion.—Often the muscle is distally divided into three fasciculi, a superior from the superior pubic ramus, a middle from the inferior pubic ramus and the obturator membrane, and an inferior from the ischium. The fiber-bundles converge upon a tendon which is at first deeply buried, then appears on the lateral surface of the muscle and is continued as a rounded tendon over the capsule of the joint to its insertion into the dorsal part of the trochanteric fossa.

Nerve-supply.—The obturator nerve gives rise, usually in the obturator canal, to a branch which bifurcates to enter the superior border and ventral surface of the muscle in its middle third.

Action.—It is a powerful lateral rotator of the thigh and is also a weak adductor.

Relations.—It is covered by the pectineus, the iliopsoas, and the adductor magnus muscles in front, and by the quadratus femoris behind near its insertion. It covers over the obturator membrane. The obturator nerve passes either above the muscle or through its upper portion.

Variations.—The reported variations are few. It may be joined by a slip from the adductor brevis.

Bursæ

B. m. obturatoris interni.—A fairly large bursa constantly present between the tendon of the obturator internus muscle and the lesser sciatic notch. It may extend on each side beneath the gemellus muscles. **B. m. quadrati femoris.**—A small bursa frequently found between this muscle and the small trochanter. **B. m. obturatoris externi.**—A bursa is sometimes found between the tendon of this muscle and the capsule of the joint.

B. MUSCLES OF THE THIGH

In the thigh three groups of muscles may be recognized, an anterior or extensor (figs. 475, 476), a medial or adductor (figs. 473, 475, 476), and a posterior, flexor or hamstring group (figs. 462, 477).

In the proximal part of the thigh the anterior group of muscles is separated from the medial group by the iliopsoas muscle (fig. 475) and by the femoral blood-vessels and nerve, and from the posterior group by the gluteus maximus (fig. 477). More distally it is separated from the medial group by the medial

intermuscular septum and from the posterior by the lateral intermuscular septum (see below). The medial and posterior groups are closely associated. The adductor magnus belongs ontogenetically to both.

The three groups of muscles, with numerous modifications, are represented in the thighs of amphibia and all higher vertebrates. In the human arm they are likewise represented, the adductor group in a much reduced form by the coracobrachialis. The quadriceps is represented by the triceps in the arm, the long head of the triceps corresponding with the rectus femoris. The hamstring muscles are represented by the biceps and the brachialis.

FASCIÆ

The **fasciæ** and the relations of the musculature of the thigh may be followed in the cross-sections, figs. 471, 474, 478.

The **tela subcutanea** of the thigh varies considerably in thickness in different regions, but is well developed throughout and contains a considerable amount of fat. Over the front of the thigh, especially in the upper medial region, one or more deeper membranous layers may usually be separated from the superficial adipose layer. Between the former and the latter are situated the inguinal lymphatic nodes and the saphenous vein. The deepest layer near the inguinal (Poupart's) ligament is fused with the fascia lata (see below). Medially it is attached to the pubic arch. Thus fluids beneath the tela subcutanea of the abdomen and perineum do not readily pass into the region of the thigh.

Over the lower half of the patella a subcutaneous bursa (**b. præpatellaris subcutanea**) is found. Another is usually found over the upper end of the patellar ligament (**b. infrapatellaris subcutanea**).

The muscles of the thigh are enclosed in a dense fascial sheet, the **fascia lata** (figs. 451, 474). The gluteal portion of this and the iliotibial band have already been described (p. 525). The ventral portion of the fascia, composed chiefly of transverse fibers, is a dense, fibrous membrane. Above it is attached to the inguinal ligament from the anterior superior spine to the pubic tubercle. Below it extends over the knee, where it is united to the capsule of the joint and is strengthened by expansions from the vastus lateralis and medialis. Between the front of the patella and the fascia is a bursa (**b. prepatellaris subfascialis**). Above the knee the fascia is strengthened by an *arciform process* which extends obliquely distally across the fascia from the iliotibial band to the capsule of the knee. This gives rise to a fold in the skin when the leg is extended and the muscles are not tense. Over the medial and posterior regions of the thigh the fascia is less dense. It extends from the body and inferior ramus of the pubis, the inferior ramus and tuber of the ischium, and the sacrotuberous ligament into the fascia of the back of the leg. Above the popliteal space it is strengthened by a transverse band of fibers. Near the knee the tendons of the quadriceps, sartorius, gracilis, and semitendinosus become bound to the fascia by membranous laminæ. The density of the fascia lata is of clinical importance in causing pus to burrow, especially downward, and in rendering difficult the diagnosis of swellings beneath the fascia.

The relations of the fascia lata to the inguinal ligament and the iliac fascia are somewhat complex. The fascia of the iliopsoas muscle extends over the muscle to its femoral insertion. Above the inguinal ligament this fascia is called the **fascia iliaca**; below the ligament, the **fascia iliopectinea.** This fascia is firmly united to the lateral extremity of the inguinal ligament. The pectineus muscle is likewise invested with a fascial membrane which extends over the muscle from the pubis to the femur and is fused laterally with that of the iliopsoas. This combined fascia is firmly bound between the muscles to the iliopectineal eminence. The iliopectineal fascia divides the space beneath the inguinal ligament into a lateral **lacuna musculorum,** which contains the iliopsoas muscle and the femoral (anterior crural) nerve, and a medial **lacuna vasorum,** which contains the femoral artery and vein. Medial to the vein is the **femoral ring,** bounded medially by the **lacunar (Gimbernat's) ligament.** This is closed off from the abdominal cavity by a septum derived from the transversalis fascia, the **femoral septum,** but offers passage for lymph-vessels.

Beyond the inguinal ligament the fasciæ of the iliopsoas and pectineal muscles line **Scarpa's triangle** [trigonum femorale], a space bounded by the inguinal (Poupart's) ligament superiorly, the sartorius laterally and long adductor muscles medially. Within this triangle is a depression, the **iliopectineal fossa,** through which run the femoral vessels (fig. 471). The sartorius muscle partly overlies the distal lateral margin of this fossa. The fascia lata is here reflected from the surface of the sartorius to the iliopsoas fascia, and becomes fused with it. From the medial margin of the sartorius a process of the fascia is continued over the lateral and upper part of the fossa, and is attached to the inguinal and lacunar (Gimbernat's) ligaments (fig. 453). Over the lower extremity of the fossa a process is continued medially into the pectineal fascia. On the medial margin of the fossa the fascia lata is continued directly into the pectineal fascia. The lateral concave margin of the fascia overlying the fossa is called the **falciform margin;** the upper extremity of this, the **superior cornu;** the distal extremity, the **inferior cornu.** The oval space bounded by the margo falciformis is called the **fossa ovalis** (saphenous opening) This is covered by the **fascia cribrosa,** which some consider a deep layer of the tela subcutanea and others a portion of the fascia lata. This fascia cribrosa contains many openings for the passage of blood-vessels and lymphatics. The space which lies medial to the femoral vessels between the femoral ring and the fossa ovalis is called the **femoral canal** (crural canal), through which femoral hernia descends.

From the fascia intermuscular septa descend in between the underlying muscles. Of these, the medial and lateral intermuscular septa are the best marked (fig. 474).

The **lateral intermuscular septum** separates the extensor muscles from the hamstring group. It extends from the tendon of the gluteus maximus to the lateral epicondyle. It is

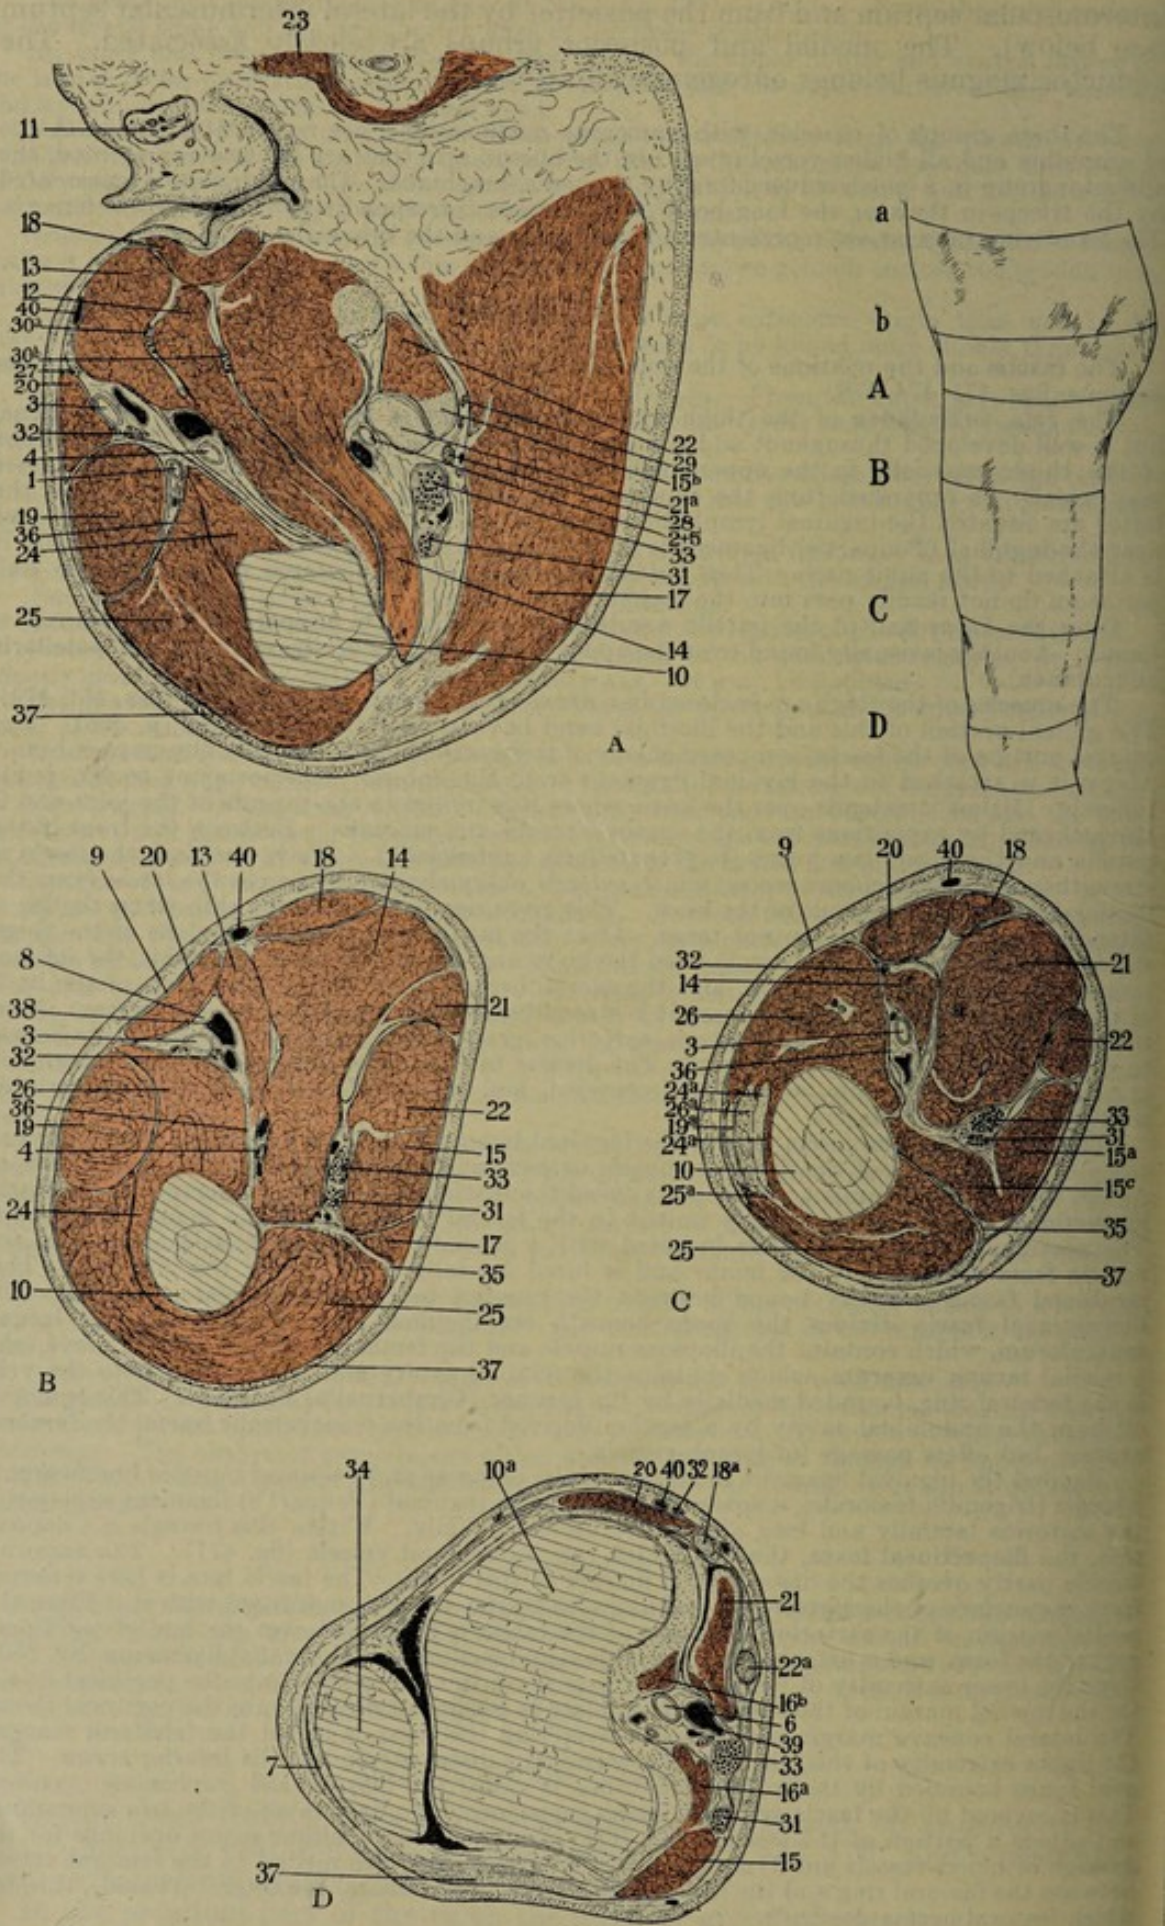

FIG. 474, A–D.—TRANSVERSE SECTIONS THROUGH THE LEFT THIGH IN THE REGIONS INDICATED IN THE DIAGRAM.

a and *b* in the diagram indicate the regions through which pass sections A and B, fig. 471.

composed chiefly of longitudinal fibers and is thickest distally. The vastus lateralis is united to its ventrolateral surface; the short head of the biceps, to its dorsomedial surface.

It will be noted that this septum serves to divide primarily ventral from primarily dorsal musculature, with the exception of the short head of the biceps, which, though primarily dorsal, occupies a position, perhaps secondarily acquired, with the primarily ventral muscles.

The **medial intermuscular septum** serves to divide the anterior extensor from the medial adductor musculature. It is perhaps simplest in the region immediately distal to the iliopectineal fossa (fig. 474B). Here a well-marked septum may be seen extending to the femur between the sartorius and quadriceps on the one side, and the adductor longus and brevis on the other. The septum here, next the muscles, has on each side a membranous lamina. Between the two laminæ there is a looser tissue in which run blood-vessels and nerves. A fibrous membrane extends between the rectus and sartorius to the septum.

More distally the sartorius comes to overlie the septum (fig. 474C). The sheath of the sartorius on the lateral margin becomes fused with the fascia of the vastus medialis, and on the medial margin to a membrane that covers the ventral surfaces of the adductor longus and magnus. Beneath the sartorius and between the adductor longus and the vastus medialis is a three-sided space bounded by the sheaths of these muscles, and filled with a loose areolar tissue in which run the femoral vessels and the saphenous nerve. This space, first described by John Hunter, is known as **Hunter's canal,** or the **adductor canal.** Still more distally the vessels with their surrouding fibrous tissue pass through the hiatus tendineus, between the long tendon of the adductor magnus and the femur, to the back of the thigh. The septum here passes behind the posterior surface of the vastus medialis to the femur. Hunter's canal therefore extends from the apex of the femoral triangle to the upper end of the popliteal space.

1. The Anterior Group

(Figs. 475, 476)

This group, which forms a semiconical mass pointed upward, is composed of the quadriceps femoris and the sartorius muscles, innervated by the femoral nerve.

The **sartorius** is a long, ribbon-like muscle which arises from the anterior superior spine of the ilium and extends along the medial margin of the quadriceps, passing obliquely across the upper part of the thigh, and then descending to the dorsomedial side of the knee, whence its tendon curves forward to be inserted into the ventromedial surface of the superior extremity of the tibia.

The **quadriceps femoris** is composed of four muscles differentiated from a common embryonic origin. Of these, the **rectus femoris,** which arises from the ventrolateral margin of the ilium by two tendons, is the most superficial and the most completely differentiated. The **vastus lateralis,** which arises from the superior extremity of the ventral surface of the shaft of the femur and from the lateral lip of the linea aspera; the **vastus medialis,** which arises from the medial lip of the linea aspera and from the intertrochanteric line; and the **vastus intermedius** (crureus), which arises between these two and beneath the rectus from the surface of the femur, are less distinctly differentiated from one another. The vastus intermedius and vastus lateralis are partly fused at the insertion, the intermedius and medialis at their origins. From the four muscles arises a tendon which is inserted into the tuberosity of the tibia. In this tendon, which is closely applied to the capsule of the knee-joint, lies a sesamoid bone, the patella.

The sartorius flexes, abducts, and rotates the thigh lateralward; it extends and medially rotates the leg. The quadriceps extends the leg; the rectus portion in addition flexes the thigh.

In the embryo the sartorius has an origin distinct from that of the quadriceps. In the anthropoid apes it is much more developed than in man.

1. Arteria circumflexa femoris lateralis. 2. A. circumflexa femoris medialis. 3. A. femoralis. 4. A. femoralis profunda. 5. A. glutea inferior (sciatic). 6. A. poplitea. 7. Bursa præpatellaris subfascialis. 8. Adductor (Hunter's) canal. 9. Fascia lata. 10. Femur—a, distal extremity. 11. Funiculus spermaticus (spermatic cord). 12. Musculus adductor brevis. 13. M. adductor longus. 14. M. adductor magnus. 15. M. biceps femoris—a, long head; b, tendon of origin; c, short head. 16. M. gastrocnemius—a, lateral head; b, medial head. 17. M. gluteus maximus. 18. M. gracilis—a, tendon. 19. M. rectus femoris—a, tendon. 20. M. sartorius. 21. M. semimembranosus—a, tendon. 22. M. semitendinosus—a, tendon. 23. M. sphincter ani. 24. M. vastus intermedius (crureus)—a, tendon. 25. M. vastus lateralis—a, tendon. 26. M. vastus medialis—a, tendon. 27. Nervus cutaneous femoris anterior. 28. N. cutaneous femoris posterior (small sciatic). 29. N. gluteus inferior. 30. N. obturatorius—a, superficial branch; b, deep branch. 31. N. peroneus communis (external popliteal). 32. N. saphenus (great saphenous). 33. N. tibialis (internal popliteal). 34. Patella. 35. Septum intermusculare laterale. 36. Septum intermuscular mediale. 37. Tractus iliotibialis (iliotibial band). 38. Vena femoralis. 39. Vena poplitea. 40. V. saphena magna (great saphenous vein).

In addition to supplying the muscles of this group, the femoral nerve also gives branche to the iliacus muscle (p. 522) and the pectineus muscle (p. 538).

The sartorius (fig. 475).—*Origin.*—From the anterior superior spine of the ilium and th area immediately below this.

Insertion.—Into the medial surface of the tibia near the tuberosity and into the neighborin ascia of the leg.

Structure.—The muscle arises by short tendinous strands. The fiber-bundles take a nearly parallel course. The component muscle-fibers are said to be the longest in the body. Near th

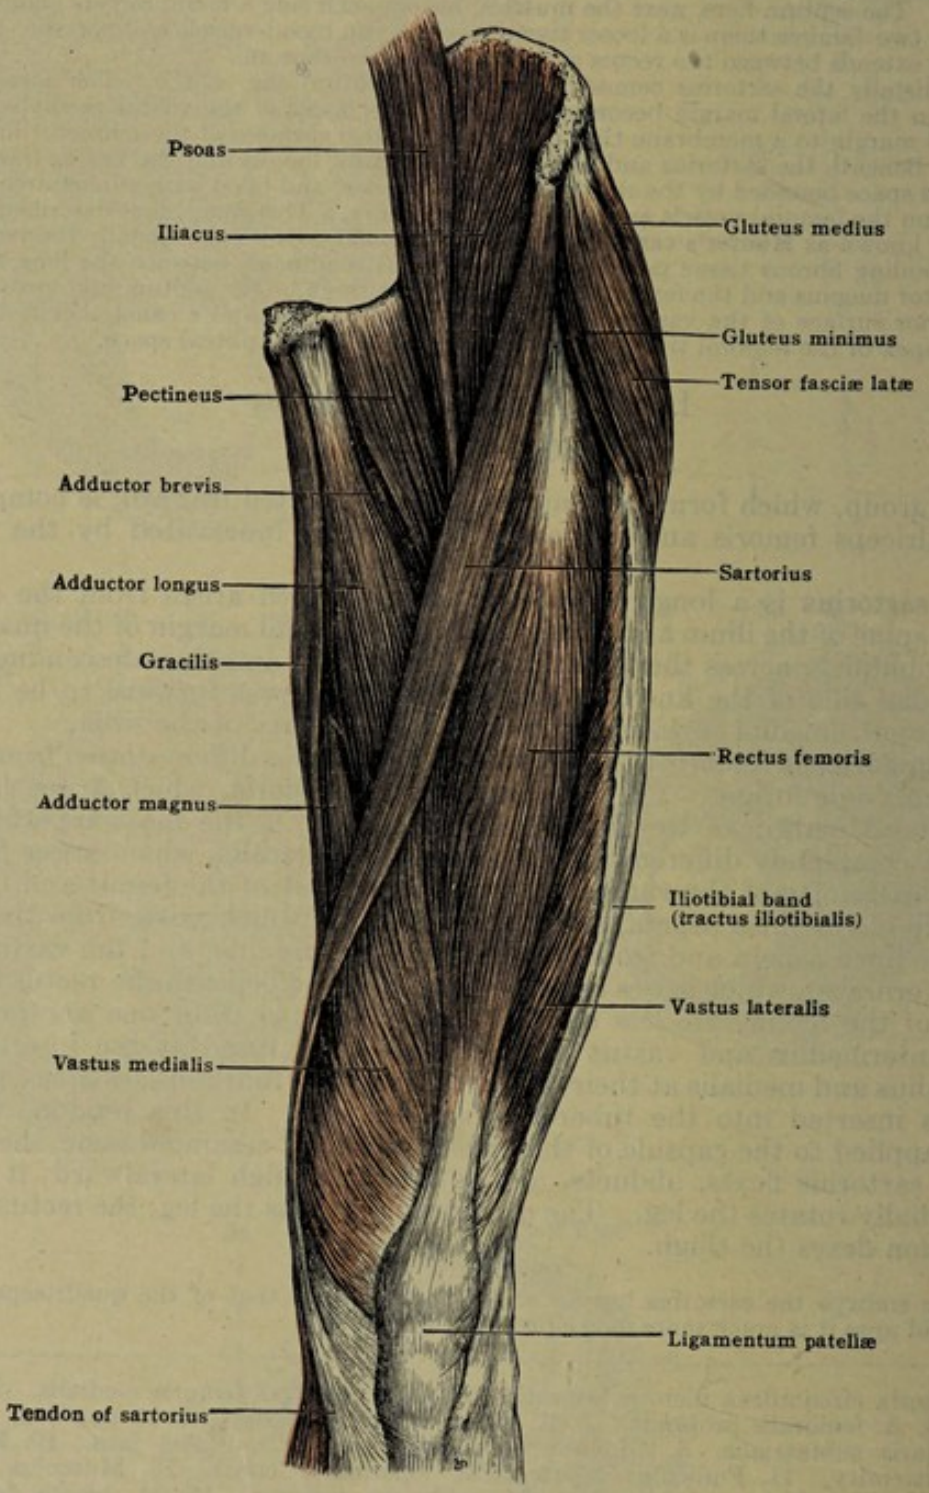

FIG. 475.—MUSCLES ON THE FRONT OF THE THIGH.

medial epicondyle of the femur the tendon of insertion makes its appearance on the deep aspect of the muscle. On the superficial surface of the tendon the muscle-fibers are inserted as far as the distal margin of the knee-joint. From there the tendon turns forward to its insertion.

Nerve-supply.—Usually two branches enter the deep surface of the proximal third of the sartorius. One or both of them may be bound up with an anterior cutaneous nerve passing through the muscle. The first of the branches is distributed chiefly to the lateral and proximal, the second to the medial and distal, portions of the muscle. Within the muscle is a complex plexus.

Action.—(1) To flex the thigh at the hip, abduct and rotate it lateralward; (2) to flex the leg and rotate it slightly medialward; (3) to make tense the medial part of the fascia lata.

Relations.—The sartorius lies in a fascial canal bounded by the fascia lata and by intermuscular septa which descend from this. It crosses the rectus femoris, iliopsoas, the adductor longus and magnus, and the vastus medialis muscles, the femoral vessels and nerve, and the knee-joint. At its insertion its tendon covers the gracilis and semitendinosus.

Variations.—It may arise from the inguinal ligament or be inserted into the fascia lata, the medial epicondyle, or the capsule of the knee-joint. It may be longitudinally divided into two parts. The tendon of the secondary slip is in such instances usually attached to the capsule of the knee-joint, but sometimes is attached to the fascia over the vastus medialis or to the anterior wall of the adductor canal. More frequently the muscle is partly divided proximally or distally. The secondary tendon of origin may arise from the anterior inferior spine, the iliopectineal eminence, etc. The muscle is very rarely absent. It may be crossed by a tendinous inscription, or more rarely it is rendered digastric by an intervening tendon.

The quadriceps femoris (figs. 475, 476).—This, as pointed out above, is composed of the rectus femoris and the vastus lateralis, intermedius, and medialis.

The rectus femoris (fig. 475).—*Origin.*—By two tendons. The anterior 'straight' tendon is attached to the anterior inferior spine of the ilium; the posterior 'reflected' tendon to the posterosuperior surface of the rim of the acetabulum. The two tendons unite so as to form a small arch above the capsule of the joint.

Structure and insertion.—From this arch an aponeurotic expansion descends upon the front of the muscle nearly to the middle of the thigh. This expansion is broad above, becomes narrower as it descends, and is continued a short distance as a narrow intramuscular tendon after it disappears from the surface. The tendon of insertion begins on the back of the muscle above the middle of the thigh, expands into a broad aponeurosis, and finally becomes a strong band which is attached to the proximal border of the patella, with ultimate insertion into the tuberosity of the tibia, as explained later; through the patellar ligament. The fiber-bundles pass in a bipenniform manner from the back and sides of the tendon of origin to the front and sides of the tendon of insertion.

Nerve-supply.—As a rule, two branches enter the muscle. One of these enters the deep surface of the muscle in its upper fourth, and is distributed mainly to the proximal part of the lateral half. The other enters the medial margin of the muscle near the junction of the proximal and middle thirds, and is distributed chiefly to the medial half and distal portion of the muscle.

The vastus lateralis (vastus externus) (fig. 476).—*Origin.*—From—(1) the shaft of the femur along the anteroinferior margin of the great trochanter and in front of the gluteal tuberosity; and (2) the lateral intermuscular septum along the upper half of the linea aspera.

Insertion.—By a flat tendon into—(1) the proximolateral border of the patella; and (2) the front of the lateral condyle of the tibia and the fascia of the leg. See also patellar ligament.

Structure.—The fiber-bundles arise partly from the bone, partly from an aponeurosis which covers the proximal two-thirds of the muscle, and from the lateral intermuscular septum. They take a parallel course distally in a ventromedial direction, and are inserted into an aponeurosis which lies on the deep surface of the muscle and receives fibers until within a few centimeters of the patella. Ventrally this aponeurosis fuses with the rectus tendon, medially with that of the vastus medialis, and dorsally it receives some of the fiber-bundles of the vastus intermedius. Commonly the muscle is distinctly divisible for the greater part of its course into two sheets, a superficial and a deep. The deep sheet is often subdivided into two laminæ.

Nerve-supply.—Usually there are three nerves, one of which, accompanied by blood-vessels, runs on the inner surface of the superficial sheet midway between the tendons of origin and insertion, the second between the two laminæ of the deep layer, and the third passes through the innermost lamina to be distributed in part to the vastus intermedius (crureus) muscle.

The vastus medialis (vastus internus) (fig. 476).—*Origin.*—From the whole extent of the medial lip of the linea aspera and from the distal half of the intertrochanteric line. The origin takes place by means of an aponeurosis which is adherent to the tendons of insertion of the adductor muscles.

Structure and insertion.—The fiber-bundles arise from the deep surface of this aponeurosis and are inserted on the medial surface and margin of a tendon which begins on the deep surface of the muscle about its middle near the lateral margin. On the distal lateral border of the muscle it is inserted into the medial half of the proximal margin of the patella and into the medial condyle of the tibia and the fascia of the leg. For some distance near the knee the lateral margin of the tendon is united to the tendons of the vastus intermedius (crureus), lateralis (externus) and the rectus. For the ultimate insertion, see patellar ligament.

Nerve-supply.—The nerve to this muscle descends on its medial surface, often bound up with the saphenous nerve for a part of its course. It gives off successive branches and finally sinks into the muscle substance. These branches enter about midway between the origin and insertion of the fiber-bundles of the muscle.

The vastus intermedius (medius NK) (crureus) (figs. 474, 476).—*Origin.*—From (1) the distal half of the lateral margin of the linea aspera and its lateral bifurcation; (2) the anterolateral surface of the shaft of the femur. Between the origin of the vastus intermedius (crureus) and that of the vastus medialis the shaft of the femur is free from muscle attachment.

Structure and insertion.—On the ventral surface of the muscle lies an aponeurosis which extends from its proximal fourth to the proximal margin of the patella. The fiber-bundles of the muscle are inserted into the deep surface of this and into the deep surface of the aponeurosis of insertion of the vastus lateralis. The proximal fiber-bundles descend vertically, the medial and lateral, especially the latter, obliquely to their insertion. Medially the tendon is more or less fused with that of the vastus medialis, and laterally with that of the vastus lateralis. The muscle is composed of muscle lamellæ superimposed concentrically about the shaft of the femur. The deepest, most distal of these is called the **articularis genus** (subcrureus). The fiber-bundles

of this layer are inserted into the capsule of the joint or into the superior margin of the patella and ultimately, through the ligamentum patellae, into the tuberosity of the tibia.

Nerve-supply.—Several branches are usually distributed to this muscle. To the lateral region a branch from the nerve to the vastus lateralis is usually given; to the middle of the muscle another branch descends from the femoral (anterior crural) nerve; to the medial portion there extend several twigs from the nerve to the vastus medialis.

Tendon of the quadriceps.—The quadriceps tendon may be more or less distinctly divided into layers, of which the superficial layer belongs to the rectus, the deep to the vastus

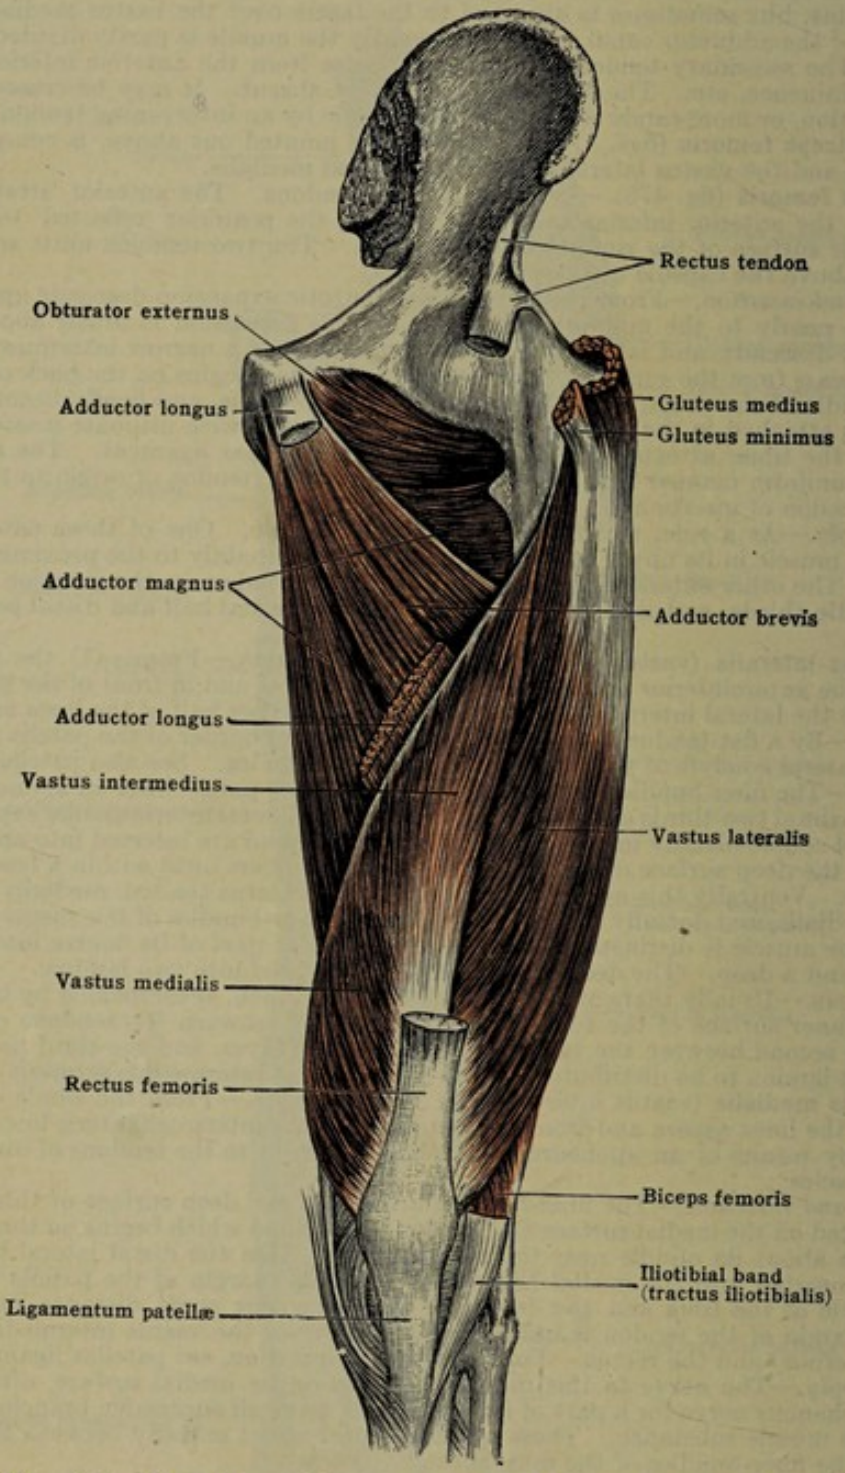

FIG. 476.—THE DEEP MUSCLES OF THE FRONT OF THE THIGH.

intermedius, and the intermediate to the vastus lateralis and medialis. Some of the more superficial fibers of the tendons of the two vasti, however, cross in front of the rectus tendon. The combined tendon of the quadriceps is in part attached to the superior and lateral margins of the patella, and in part extends over the patella into the patellar ligament. A part of the tendon fibers of the vastus lateralis and medialis run on each side of the patella to the ventral surface of the condyles of the tibia. These form the **retinacula patellæ mediale and laterale.** The medial is the broader and better developed. With the retinacula are included bundles of fibers which run from the epicondyles to the patella and into which some muscle fiber-bundles are inserted. From the apex of the patella to the tuberosity of the tibia the quadriceps tendon is continued as the **patellar ligament** (fig. 479).

Nerve-supply.—The relations of the branches of distribution to the various parts of the muscle have been pointed out above in connection with each head. The general relations of these branches of the femoral nerve are as follows:—From the femoral nerve near the proximal end of the vastus medialis the branches for the vastus lateralis, vastus intermedius (crureus), and rectus pass distally and laterally between the rectus and vastus intermedius (crureus) to be distributed to the muscles named, while the chief nerve for the vastus medialis descends on the medial side of this muscle in company with the saphenous nerve. The branches to the vastus lateralis and intermedius are commonly bound up in a single nerve-trunk for some distance. The branches to the rectus are usually bound up with this trunk for a shorter distance. The nerve to the vastus medialis may be united to this trunk for a slight distance, but more frequently it is more or less bound up with the saphenous nerve.

Action.—The quadriceps is the extensor of the leg. The rectus femoris also flexes the thigh at the hip and is a weak abductor of the thigh. The articularis genu makes tense the capsule of the knee-joint.

Relations.—The quadriceps is covered ventrally immediately by the fascia lata. The sartorius runs along its medial margin; the tensor fasciæ latæ lies over the proximal quarter of its lateral surface. Dorsal to the vastus lateralis lie the gluteus maximus and biceps; dorsomedial to the vastus medialis, the three adductor muscles and the semimembranous. Next to vastus medialis lies the adductor canal with the femoral vessels and the saphenous nerve.

Variations.—The variations of this muscle, aside from a greater or less fusion of its parts, are not marked. The attachment of the rectus femoris to the anterior inferior spine, which takes place in the embryo later than its insertion above the acetabulum, may be wanting. On the other hand, this tendon may extend to the anterior superior spine. Occasionally the deep reflected tendon may be wanting. The **rectus accessorius** is a fasciculus rarely found, which arises by a tendon from the rim of the acetabulum and is inserted into the ventral edge of the vastus lateralis. It is innervated by a twig from the branch to the rectus.

Bursæ

B. m. recti femoris (superior).—A small bursa between the deep tendon of the rectus femoris and the edge of the acetabulum. Rare. **B. m. recti femoris (inferior).**—Between the tendon of the rectus and combined tendon of the vastus lateralis and medialis. Occasional. **B. præpatellaris subtendinea.**—A bursa between the tendon of the quadriceps and the periosteum of the patella. Of the three præpatellar bursæ—the subcutaneous, subfascial, and subtendinous—as a rule only one occurs. When two or three exist, they usually communicate freely with one another. **B. suprapatellaris.**—A bursa between the anterior surface of the lower end of the femur and the tendon of the quadriceps. It usually communicates with the joint cavity. **B. infrapatellaris profunda.**—A bursa between the patellar ligament and the tibia. It seldom communicates with the joint cavity. **B. m. sartorii propria.**—A bursa, fairly large, between the tendon of the sartorius and the tendons of the semitendinosus and gracilis muscles. This usually communicates with the bursa anserina (see p. 539).

2. The Medial (Adductor) Group

(Figs. 473, 475, 476)

To this group of muscles belong the gracilis, the pectineus, the adductors brevis, longus, and magnus, and the obturator externus. The most superficial of the group is the **gracilis** (figs. 472, 475). This ribbon-shaped muscle arises from the inferior pubic and ischial rami, extends along the medial side of the thigh, and gives rise to a tendon which curves forward from behind the medial condyle of the femur to be inserted under the tendon of the sartorius into the medial side of the upper extremity of the tibia. The quadrilateral **pectineus** arises from the body and superior ramus of the pubis; the triangular **adductor longus** from the superior ramus medial to this (fig. 475). The pectineus is inserted into the pectineal line of the femur; the adductor longus into the middle third of the linea aspera. The triangular **adductor brevis** (fig. 476) arises from the inferior pubic ramus below the adductor longus. It is inserted into the pectineal line and the upper third of the linea aspera. The large, triangular **adductor magnus** (figs. 473, 476) arises from the inferior ramus and the tuber of the ischium and is inserted behind the short and long adductors into the whole length of the linea aspera, and by a special tendon into the adductor tubercle of the femur. The deepest muscle of the group, the **obturator externus,** which arises from the outer surface of the bones bounding the ventral two-thirds of the obturator foramen, and is inserted by a tendon into the trochanteric (digital) fossa, has been described in connection with the ischio-pubo-femoral muscles of the hip.

All the muscles of this group adduct the thigh. The gracilis, obturator externus, adductor brevis and the lower part of the adductor magnus (when the thigh is extended) rotate it lateralward. The pectineus, adductor longus, and the adductor magnus rotate it medialward. Those attached to the pubis flex the thigh. The gracilis flexes the leg and rotates it medialward. The inferior part of the adductor magnus extends the thigh.

The muscles of this group are supplied by the obturator nerve, except the pectineus, which usually gets its whole supply from the femoral (anterior crural). nerve, and the adductor magnus, which gets a part of its supply from the sciatic nerve.

In embryonic development the pectineus arises in close conjunction with the obturator group, and in the adult it may get the whole or a part of its nerve-supply from the obturator nerve or from the accessory obturator nerve. In the lower mammals the nerve-supply may come from the femoral (anterior crural) or the obturator nerve or from both. It is not certain whether the innervation from the femoral nerve indicates that the muscle belongs phylogenetically, if not ontogenetically, with the primitive dorsal musculature of the limb. By some it is considered to be derived in part from the primitive dorsal, in part from the primitive ventral, musculature. The adductor magnus arises in the embryo as two distinct portions, one connected with the flexor group of muscles, the other with the adductor group. These two portions later become fused. Primitively the sciatic portion of the adductor magnus and the semimembranosus constitute a single medial flexor muscle.

The gracilis (figs. 472, 475).—*Origin.*—By a flat tendon from the medial margin of the inferior ramus of the pubis and the pubic extremity of the inferior ramus of the ischium.

Structure and insertion.—The nearly parallel fiber-bundles which arise between two laminæ of the tendon form a thin band of muscle which is narrower and thicker distally than proximally. They are inserted on a tendon which begins as an aponeurosis on the posterior border and medial surface of the muscle in the distal third of the thigh, becomes free as a rounded cord a little proximal to the medial condyle of the femur, runs behind the condyle, and then turns forward to be inserted by an expanded process into the tibia below the medial condyle.

Nerve-supply.—The nerve enters the deep surface of the muscle near the junction of the superior and middle thirds.

Action.—To adduct, flex and (slightly) rotate the thigh lateralward, and flex the leg. With the knee flexed, it acts as a medial rotator of the leg.

Relations.—It occupies a position beneath the fascia lata and superficial to the adductor brevis, longus, and magnus muscles. Distally the sartorius lies in front, the semimembranosus behind. Its tendon crosses the tibial collateral ligament of the knee-joint and the tendons of the semitendinosus and the semimembranosus, and is overlapped by that of the sartorius.

Variations.—The pubic origin of the muscle may be much reduced or may be double. Its tendon of insertion may give rise to an accessory fasciculus which extends distally in the leg. In some of the apes the tendon descends normally much farther down the leg than in man.

The pectineus (fig. 475).—*Origin.*—(1) From the pecten (crest) of the os pubis, the bone in front of this, and the pectineal fascia near this origin; and (2) from the anterior margin of the obturator sulcus and from the pubocapsular ligament. Laterally the two areas of origin are usually separated by most of the superior surface of the body of the pubis. Medially they come together.

Structure and insertion.—From each area of origin a separate lamina arises. The fiber-bundles of each layer take a nearly parallel course and terminate between two tendinous lamellæ which fuse to be inserted into the upper half of the pectineal line behind the small trochanter. The fiber-bundles of the superficial layer cross those of the deep slightly obliquely. The muscle faces ventrally at its origin, laterally at its insertion.

Nerve-supply.—From a branch of the femoral (anterior crural) nerve, which passes behind the femoral artery and vein and through the pectineal fascia to enter the ventral surface of the muscle. It may also be supplied by the accessory obturator nerve, when present, or by a branch from the obturator. When both the femoral (anterior crural) and obturator nerves supply this muscle, the femoral supplies the superficial, the obturator, the deep lamina (Paterson).

Action.—To flex and adduct the thigh (as in crossing the legs).

Relations.—It is covered by the pectineal fascia, lies between the iliopsoas and the adductor longus muscles, and crosses the obturator externus and adductor brevis muscles. The medial circumflex artery runs between it and the iliopsoas, the deep femoral artery between it and the adductor longus.

Variations.—The extent of the division of the pectineus into superficial and deep portions varies considerably. It may also be divided into a lateral and a medial division. Often the pectineus is fused with the adductor longus. It may receive an accessory fasciculus from the capsule of the hip-joint, the iliacus muscle, the obturator externus, or the adductor brevis muscles, or the small trochanter. It may send a fasciculus to the sartorius.

The adductor longus (fig. 475).—*Origin.*—From the medial corner of the superior ramus of the pubis by a strong tendon which extends for some distance on the medial border of the muscle.

Structure and insertion.—From this tendon the fiber-bundles diverge toward their insertion. This takes place between two lamellæ of a short tendon attached to the middle third of the linea aspera. The tendon is usually fused to the medial intermuscular septum and sends an expansion to the long tendon of the adductor magnus.

Nerve-supply.—A branch from the anterior division of the main obturator trunk gives off several twigs which enter the middle third of the deep surface of the muscle. Occasionally a small branch from the femoral (anterior crural) nerve enters the muscle. This is probably sensory in nature.

Action.—To adduct and flex the thigh, and rotate it medialward.

Relations.—The sartorius, the vastus medialis, and the femoral vessels lie anterolateral to it. Behind it lie the adductor brevis and adductor magnus muscles. Between these and the longus run the profunda vessels. Its lateral border touches the pectineus above, but is separated from it toward the insertion.

Variations.—It may be fused with the other adductors, including the pectineus. It may be doubled. The femoral insertion may extend to the medial epicondyle.

The adductor brevis (fig. 476).—*Origin.*—From the medial part of the outer surface of the inferior ramus of the pubis directly, and by means of short tendinous processes or a short flat tendon.

Structure and insertion.—From their origin the fiber-bundles diverge into a sheet which is inserted by short tendinous bands into the distal two-thirds of the pectineal line and the upper third of the linea aspera. The muscle is more or less completely divided into two fasciculi near its insertion. The place of division is near where the intertrochanteric line curves away from the linea aspera.

Nerve-supply.—Usually from the anterior but also sometimes from the posterior branch of the main obturator trunk. The rami enter the middle third of the muscle near the proximal border.

Action.—It is chiefly an adductor and to a less extent a flexor and a lateral rotator of the thigh.

Relations.—In front lie the pectineus and adductor longus; behind, the obturator externus quadratus femoris and adductor magnus. It is crossed by the profunda artery. The first perforating artery passes usually between the two fasciculi of the insertion.

Variations.—It may be fused with other members of the group. It may be divided completely into two fasciculi, rarely into three.

The **adductor magnus** (figs. 473, 476).—The *origin* of this muscle begins on the inferior ramus of the pubis posterior to the origins of the adductor brevis and gracilis muscles. From here it extends backward along the inferior margin of the ventrolateral surface of the ischium to the tuberosity. The muscle in passing from this curved origin to its extensive femoral insertion presents posteriorly a longitudinal groove in which rest the hamstring muscles. The adductor magnus is composed of three superimposed fasciculi, of which the first is frequently fairly distinct and is called the **adductor minimus,** while the other two are normally fused, but are occasionally distinct.

The **superior fasciculus (adductor minimis)** *arises* directly from the inferior rami of the pubis and ischium. From here the fibers diverge to form a thin sheet *inserted* by tendinous bands to the medial side of the gluteal ridge and the superior part of the linea aspera. The **middle fasciculus** *arises* directly from the inferior margin of the ventrolateral surface of the inferior ramus and the tuber of the ischium, and from a tendon which descends along the dorsomedial margin of the muscle from the tuber ischii. The fiber-bundles diverge to be *inserted* between the lamellæ of a narrow flat tendon attached to the distal three-fourths of the linea aspera. This tendon is pierced by the perforating vessels. The **inferior fasciculus** *arises* dorsal to and in common with the middle fasciculus. The fiber-bundles converge toward a strong tendon which begins in the distal third of the thigh and is *inserted* into a tubercle at the distal end of the medial supracondylar ridge.

Nerve-supply.—The chief nerve-supply is from the posterior ramus of the obturator. This enters by one or more branches the proximal portion of the ventral surface of the muscle about midway between its pubic and femoral attachments. It also receives a branch from the sciatic which enters the dorsal surface of the muscle in the middle third of the thigh. To the adductor minimus a branch may be sent from the nerve to the quadratus femoris.

Action.—It is the strongest of the adductors. The superior and middle fasciculi rotate the thigh medialward and flex it; the inferior rotate it lateralward when the thigh is extended, but medialward when the thigh is flexed. The latter also extend the thigh.

Relations.—In front are the pectineus, the short and long adductor and the vastus medialis muscles, and the profunda artery. Behind lie the hamstring muscles and the gluteus maximus. Medially lies the gracilis muscle. The femoral and perforating arteries pass through its attachment to the shaft of the femur.

Variations.—The divisions of the muscle may be more or less distinct. It may be partly fused or exchange fasciculi with neighboring muscles—the semimembranosus, quadratus femoris, adductor brevis, and adductor longus.

Bursæ

B. m. pectinei.—A small bursa frequently present between this muscle and the iliopsoas and small trochanter. **B. anserina.**—A fairly large bursa which lies between the tendons of the sartorius, gracilis, and semitendinosus muscles and the tibial collateral ligament of the knee-joint. (See also B. M. Sartorii Propria, p. 537.)

3. The Posterior (Hamstring) Group

(Figs. 472, 477)

The muscles of this group are the semitendinosus, semimembranosus, and biceps. They flex the leg and extend and adduct the thigh. The semitendinosus and semimembranosus rotate the thigh and the leg medialward; the biceps, lateralward. The semitendinosus and the long head of the biceps constitute a superficial layer; the semimembranosus and the short head of the biceps a deep layer. The **semitendinosus** and the **long head of the biceps** arise by a common tendon from the tuber of the ischium. The somewhat fusiform semitendinosus gives rise to a tendon in the lower half of the thigh. The tendon curves forward behind the knee to be inserted under that of the sartorius into the medial side of the tibia. The penniform **short head of the biceps** arises from the linea aspera in the lower part of the thigh, and is inserted, together with the fusiform long head, into a tendon that passes over the lateral side of the knee and is attached

to the head of the fibula. The **semimembranosus** arises from the tuber ischi through a long, flat, triangular tendon. The belly of the muscle increases in thickness toward the knee. It is inserted by a strong tendon on the back of the

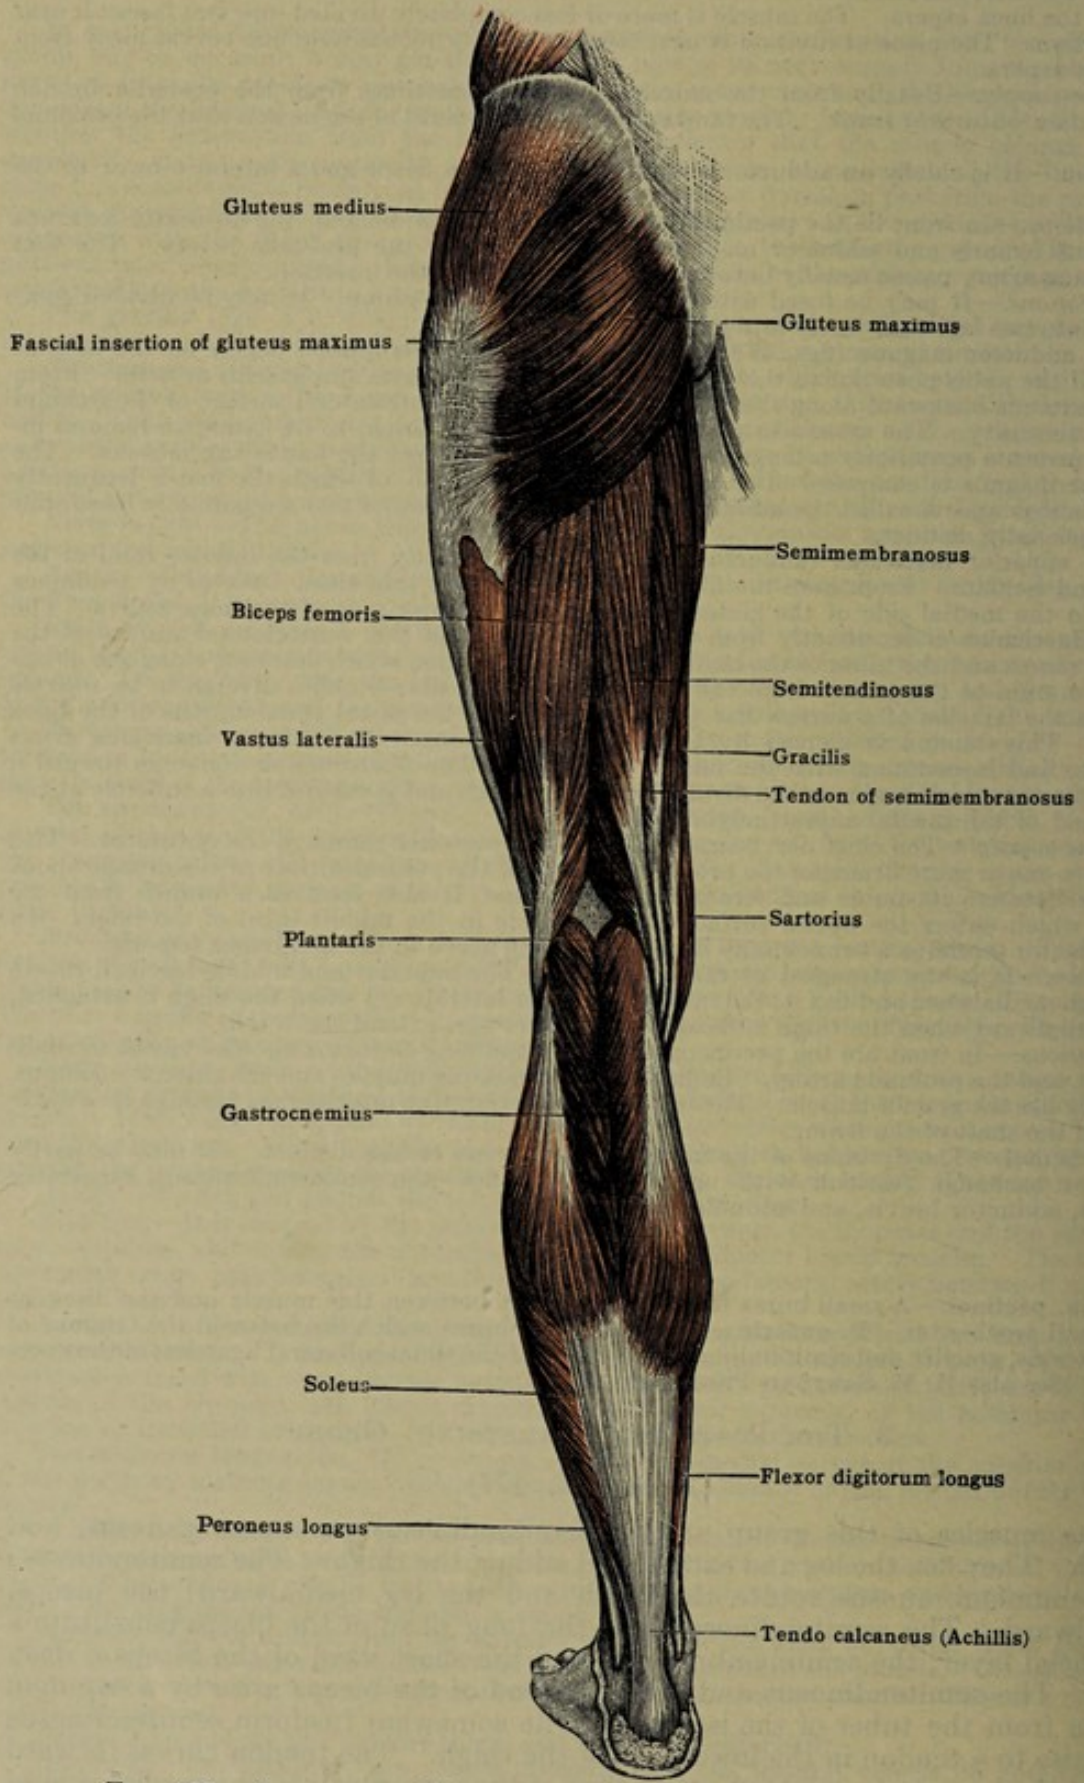

FIG. 477.—SUPERFICIAL MUSCLES OF THE BACK OF THE THIGH AND LEG.

medial condyle of the tibia. From the tendons of all the hamstring muscles expansions are sent into the crural fascia.

The muscles of this group are all supplied by the tibial portion of the sciatic, except the short head of the biceps, which is supplied from the peroneal portion.

The femoral head of the biceps is characteristic of the anthropoid apes and man. In many mammals its place is taken by a slender muscle, the **tenuissimus**, which extends from the caudal vertebræ, the sacrotuberous (great sacrosciatic) ligament, or the gluteal fascia to the fascia of the back of the leg. In some forms this muscle is broad instead of slender. According to Testut, the long head of the biceps may be looked upon as arising by two fasciculi, one primitively attached to the posterior part of the ilium, the other to the caudal vertebræ or coccyx. The sacrotuberous (great sacrosciatic) ligament represents the reduced upper portion of this muscle. In the fetus the origin of the muscle extends higher on the sacrotuberous ligament than in the adult. In many of the lower mammals the origins of the semimembranosus and semitendinosus take place in part from the sacrocaudal vertebræ.

In the mammals below man the insertion of the biceps, gracilis, and semitendinosus takes place chiefly into the fascia of the back of the leg, and extends more distally than in man. This insertion of these flexor muscle is associated with a permanent position of flexion of the leg at the knee. In the human embryo likewise these muscles are inserted more distally than in the adult. In the lower primates the semimembranosus is chiefly a medial rotator of the leg.

Biceps femoris (figs. 472, 477).—**Long head** [caput longum].—*Origin.*—From a tendon common to it and the semitendinosus. This tendon arises from the more medial of the two facets on the back of the tuber of the ischium and from the sacrotuberous (great sacrosciatic) ligament. It is continued for a third of the distance to the knee as a septum between the biceps and the semitendinosus, and for a short distance as an aponeurotic sheath on the deep surface of the biceps.

Structure and insertion.—The fiber-bundles begin to arise from the tendon some distance from the ischium. They form a thick fusiform belly which is inserted into the deep surface of a tendon that begins laterally on the back of the muscle about the middle of the thigh. The insertion of the fiber-bundles of the long head continues on the medial margin of the deep surface of the tendon nearly as far as the lateral condyle of the femur.

Short head [caput breve].—*Origin.*—By short tendinous fibers from the lateral lip of the linea aspera of the femur from the middle of the shaft to the bifurcation of this line, the proximal two-thirds of the supracondylar ridge, and the lateral intermuscular septum.

Structure and insertion.—The fiber-bundles take a nearly parallel course, to be inserted on the deep surface of the common tendon of insertion. The most distal fibers are inserted nearly to the skeletal attachment of the tendon. The tendon is inserted into the superior extremity of the head of the fibula, into the lateral condyle of the tibia, and into the fascia of the leg.

Nerve-supply.—Commonly two branches are given to the long head of the biceps. One of these branches is given off proximal to the ischium, and enters the proximal third of the deep surface of the muscle. The other is given off more distally and usually enters the middle third. Either or both branches may be doubled or the two may be combined for some distance in a common trunk. The nerve-fibers arise usually from the first, second, and third sacral nerves. The branch to the short head arises from the peroneal (external popliteal) portion of the sciatic nerve about the middle of the thigh. It enters the posterior surface near the lateral margin of origin and insertion. The nerve-fibers come chiefly from the fifth lumbar, first and second sacral nerves.

Action.—To extend and adduct the thigh and flex the leg. The short head acts only on the leg. The long head acts as a lateral rotator of the thigh, and of the leg when flexed.

Relations.—The upper extremity of the muscle is covered by the gluteus maximus. Below this the long head and tendon of insertion lie beneath the fascia lata and overlie the short head. Ventral to the muscle lie the tendon of origin of the semimembranosus, the adductor magnus and vastus lateralis muscles, and the lateral head of the gastrocnemius. The medial border is in contact with the semitendinosus and semimembranosus. Distally it forms the upper lateral border of the popliteal space. The sciatic nerve runs between it and the adductor magnus.

Variations.—The short head is rarely absent. It may be more isolated from the long head than usual, and at times has a separate tendon of insertion. It may itself be divided into two distinct laminæ. Its origin may take place higher up on the femur than usual or from the fascia lata. Variations of this sort suggest the tenuissimus muscle of some of the lower mammals (see above). The long head of the biceps may receive accessory fasciculi from the coccyx, sacrum, sacrotuberous (great sacrosciatic) ligament, tuber of the ischium, or the deep surface of the gluteus maximus. These fasciculi suggest the iliac and sacrococcygeal origin of the muscle found in lower vertebrates (see above). Inferiorly, a muscle fasciculus may take the place of the fibrous prolongations from the tendon of the biceps into the sural fascia (the **tensores fasciæ suralis**). This may extend to the tendon of Achilles. The long head may have a tendinous inscription similar to that of the semitendinosus.

The **semitendinosus** (figs. 472, 477).—*Origin.*—Partly from a mediodorsal facet on the distal margin of the tuber of the ischium by direct implantation of the fiber-bundles, and partly from the medial surface of the tendon common to it and the long head of the biceps.

Structure and insertion.—The fiber-bundles spread out to form a flat, fusiform belly which, about the middle of the thigh, again contracts toward the tendon of insertion. This begins on the medial margin and dorsal surface of the muscle, becomes free from the muscle slightly above the medial condyle of the femur, passes behind this and curves forward to be inserted by a triangular expansion into the proximal part of the medial surface of the tibia behind and distal to the insertion of the gracilis. An aponeurotic expansion is continued into the fascia of the leg. About the middle of the muscle a narrow irregular tendinous inscription more or less completely divides the belly into proximal and distal divisions.

Nerve-supply.—To the muscle two nerves are commonly given. One arises from the sciatic nerve or directly from the plexus, proximal to the tuber of the ischium, sometimes in com-

pany with a branch to the long head of the biceps. It enters the middle third of the deep surfac of the proximal portion of the muscle. The other branch arises from the sciatic nerve, usuall distal to the ischial tuber, sometimes in common with a nerve to the biceps or the semimem branosus. It enters about the middle of the deep surface of the distal half of the muscle Either or both branches may be represented by two nerves. The nerve fibers of the firs branch arise chiefly from the first and second sacral nerves, those of the second from the fift lumbar and first sacral nerves.

Action.—To extend and adduct the thigh and rotate it medialward and to flex the leg and with knee flexed, to rotate the leg medialward.

Relations.—It is covered by the gluteus maximus and fascia lata; on the lateral side lie the biceps; and in front, the semimembranosus and adductor magnus.

Variations.—It may be completely separated from the biceps at its origin. It may b fused with neighboring muscles. There may be two tendinous inscriptions. It may have femoral head (a condition characteristic of many birds). A muscle fasciculus may extend fron the body of the muscle to the fascia of the back of the leg.

The **semimembranosus** (figs. 472, 477).—*Origin.*—By a long, flat tendon which lies beneath the proximal half of the semitendinosus, and which arises from the more lateral of the two facet on the back of the tuber of the ischium, between the tendons of the biceps and the quadratu femoris. The tendon is at first adherent to the tendon of the adductor magnus in front an to that of the biceps and semitendinosus behind. It descends to the middle of the muscle.

Structure and insertion.—From both surfaces of the medial side and distal extremity o the tendon of origin fiber-bundles arise which take an oblique course to their insertion on th aponeurosis of the tendon of insertion. This appears on the deep surface and medial margi of the muscle opposite the end of the tendon of origin and descends on the medial side and deep surface of the muscle. Near the back of the medial condyle of the femur the insertion of muscle fibers ceases and the tendon is inserted directly on the back of the medial condyle of the tibia and by aponeurotic expansions into the capsule of the joint, into the lateral condyle of the femur into the tibial collateral ligament, and into the fascia of the popliteus muscle.

Nerve-supply.—By several branches from the sciatic nerve, which usually arise from a common trunk in company with the branches to the adductor magnus. These branches enter the deep surface of the muscle about midway between the origin and insertion of the constituent fiber-bundles.

Action.—To flex the leg and rotate it medialward and to extend and adduct the thigh and rotate it medialward.

Relations.—It is covered by the gluteus maximus, the long head of the biceps, the semitendinosus, and the fascia lata. It lies dorsal to the quadratus femoris, the adductor magnus, and the knee-joint.

Variations.—It may be fused with the semitendinosus or the adductor magnus. It may be doubled. Its tendons may have a more extensive attachment than usual. The extent of the belly of the muscle varies considerably. A muscle fasciculus may be sent into the popliteal space. An extra head may arise from the ischial spine.

Bursæ

B. m. bicipitis femoris superior.—A fair-sized bursa which frequently lies between the tendon of origin of the long head of the biceps and semitendinosus and the tendon of the semimembranosus and the ischial tuber. **B. m. bicipitis femoris inferior.**—A small bursa which separates the tendon of insertion from the fibular collateral ligament of the knee-joint. **B. m. bicipitis gastrocnemialis.**—A bursa infrequently found between the tendon of the biceps and the tendons of origin of the lateral head of the gastrocnemius and the plantaris muscles. **B. m. semimembranosi.**—This is a large double bursa constantly present. One part extends between the semimembranosus, the medial head of the gastrocnemius, and the knee-joint. With the cavity of the joint it frequently communicates. The other part extends between the tendon of the semimembranosus and the medial condyle of the tibia.

POPLITEAL SPACE

The diamond-shaped popliteal space or fossa behind the knee is shown in fig. 477. It is bounded above by the biceps laterally and the semitendinosus and semimembranosus medially; below by the two heads of the gastrocnemius. In flexion, the hollow of this space appears; in extension it is obliterated and its boundaries are ill-defined, the only ones now to be made out being the semitendinosus and the biceps. Its *roof* is formed by the popliteal fascia; its *floor* by the planum popliteum of the femur above, by the popliteus muscle (fascia) below, and between these by the oblique popliteal ligament of the knee-joint. Its chief *contents* are the popliteal vessels, the termination of the small saphenous vein, the tibial and common peroneal nerves, and a few popliteal lymph nodes,—all embedded in a mass of fatty tissue.

Landmarks.—When the knee is a little bent and the foot rests on the ground, the following can be made out:—on the *lateral aspect*, behind the iliotibial band, and descending to the prominence on the lateral side of the head of the fibula, is the tendon of the biceps. This prominence also gives attachment to the fibular collateral ligament, which splits the tendon into two parts. Behind is the apex (styloid process) from which the posterior part of the fibular collateral ligament arises. Parallel and close to the medial border of the tendon, the peroneal nerve descends, as a rounded cord, to cross the neck of the fibula and enter the peroneus longus. In tenotomy of the biceps an open incision should be employed to avoid injury to the nerve and insure the division of any contracted fascial bands. On the *medial side* the tendons are thus arranged: Nearest to the middle of the popliteal space is the long and more slender tendon of the semitendinosus; next, the thicker tendon of the semimembranosus; this and the gracilis, which comes next, appear as one tendon, but by a little manipulation the finger can be made to sink into the interval between the semimembranosus, with its thick rounded border laterally and the

gracilis medially. The sartorius can easily be thrown into relief on the medial side of the joint by telling the patient to raise the leg extended, the limb being rotated laterally and one leg crosses over the other.

C. MUSCULATURE OF THE LEG

(Figs. 477, 479, 480)

The musculature of the leg arises in part from the distal end of the femur, but in the main from the tibia and fibula. The muscle-bellies are best developed in the proximal half of the leg, where they give rise to the 'calf' behind and to less well-marked ventral and lateral protrusions. Toward the ankle the muscle-bellies give way to tendons which attach the muscles of the leg to the skeleton of the foot.

The musculature is divisible into **anterior, a lateral** and a **posterior group** of muscles. The anterior and lateral groups are separated from one another by an intermuscular septum. The anterolateral groups are separated from the posterior group by the tibia and fibula, the interosseous membrane, and by an intermuscular septum which extends from the lateral margin of the shaft of the fibula to the fascia enveloping the leg. Medially the separation is well marked by the broad medial surface of the tibia. Laterally the line of division is not so clearly marked externally. In the proximal part of the leg the dorsal musculature protrudes somewhat ventrally; in the distal part the lateral musculature passes dorsal to the lower end of the fibula. The posterior group is divided by a transverse septum into superficial and deep divisions.

The anterior group of muscles flexes the ankle dorsally, everts the foot and extends the toes. The lateral group extends the ankle (plantar flexion) and everts the foot. The posterior group flexes the knee, extends the ankle, inverts the foot and flexes the toes.

While in the forearm the extensor-supinator muscles extend proximally on the radial side of the arm to the humerus, and the flexor-pronator muscles on the ulnar side, in the leg both of the corresponding sets of muscles extend primitively on the fibular side of the leg to the femur. In the higher vertebrates the superficial layer of the flexor musculature of the leg takes origin from both sides of the distal extremity of the femur, and the origin of the extensor musculature ceases to extend to the femur. The crural musculature is primitively inserted into the bones of the leg, the tarsus, and the aponeuroses of the foot. On the extensor side of the leg the musculature ultimately becomes attached wholly to the foot by means of tendons differentiated, in part at least, from the dorsal aponeurosis. The lateral portion of the extensor musculature, which primitively extends from the femur to the fibula, in the higher vertebrates extends from the fibula to the tarsus and metatarsus (peroneal musculature). On the flexor side of the leg the more superficial musculature maintains a tarsal attachment through the tendon of Achilles. The deeper musculature in part extends from the femur to the tibia, and in part arises from the fibula and tibia, and is inserted into the metatarsus and the digits through tendons differentiated from the plantar aponeuroses. The musculature of the sole of the foot is highly developed in five-toed vertebrates, but in those which walk on the toes, and especially in hoofed animals, it is very greatly reduced.

FASCIÆ OF THE LEG

(Fig. 478)

The **tela subcutanea** of the leg contains a considerable amount of fat where it overlies the muscles, but less where it overlies the bones and joints. Subcutaneous bursæ are found over the tuberosity of the tibia (**b. subcutanea tuberositatis tibiæ**) and over each of the malleoli (**b. subcutanea malleoli medialis et lateralis**). Over the dorsum of the foot the tela contains comparatively little fat, but on the sole of the foot and plantar surface of the toes it contains much fat interposed between dense fibrous tissue. The **b. subcutanea calcanea** lies beneath the tuber calcanei.

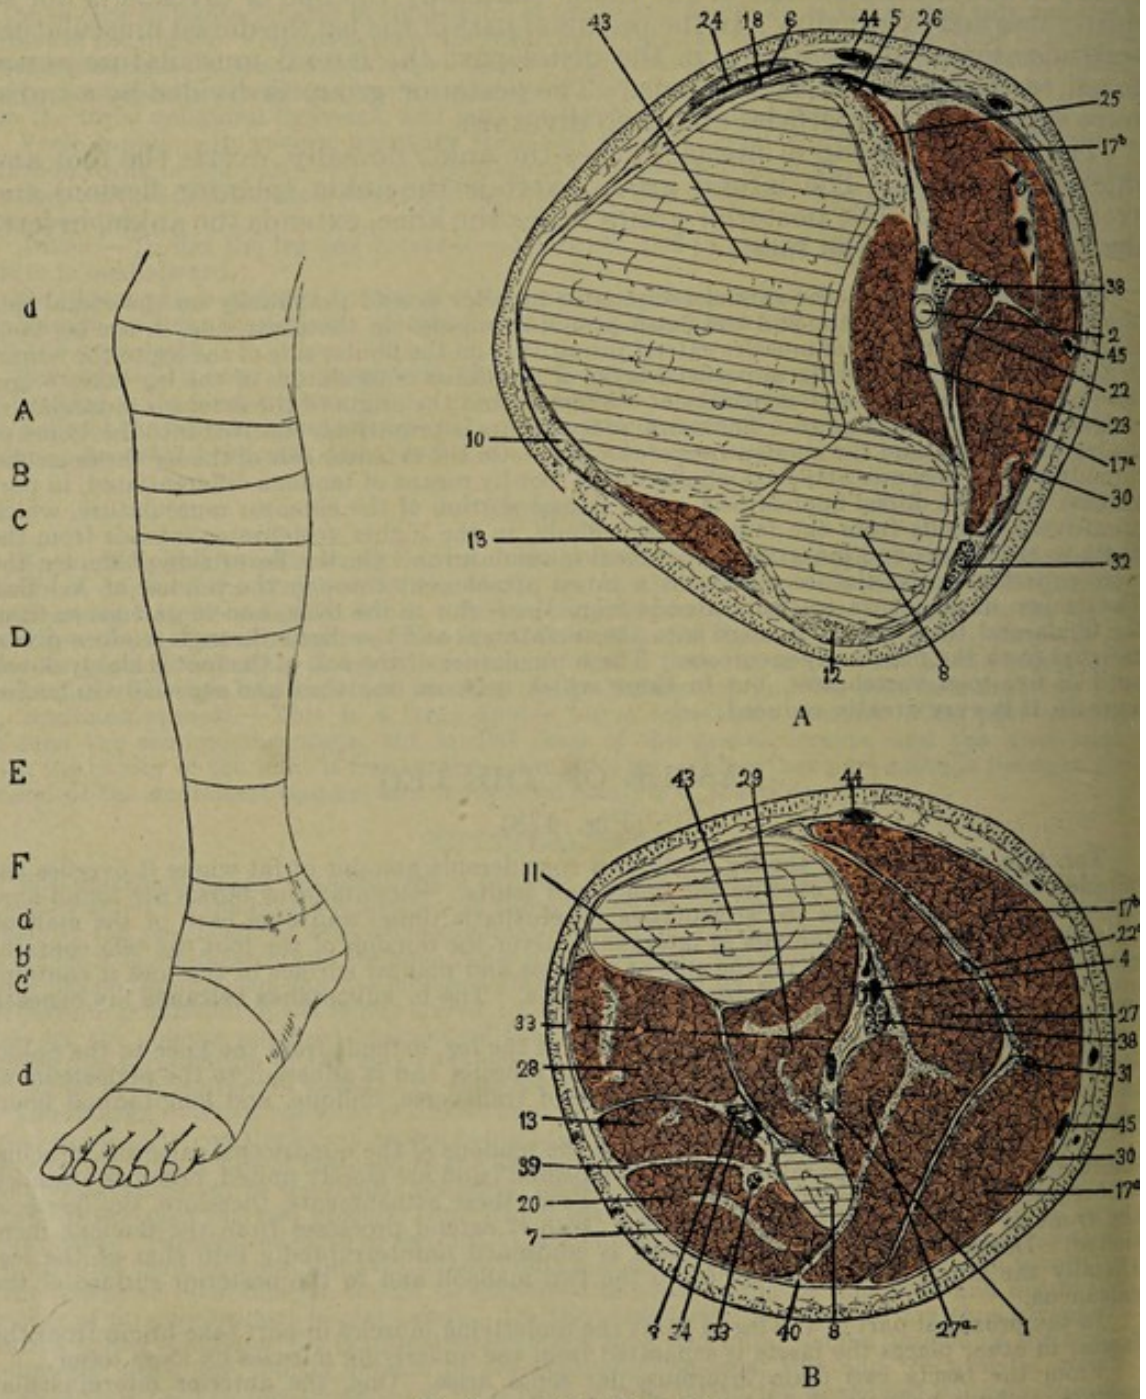
The **crural fascia,** or external layer of fascia of the leg, extends from the knee to the ankle. It forms an enveloping cone-like sheath for the muscles and is adherent to the periosteum of the medial surface of the tibia. It is formed of transverse, oblique, and longitudinal fibers and is thickest in front.

Ventrally the fascia of the thigh, to which the tendons of the quadriceps, sartorius, gracilis, semitendinosus, and biceps muscles and the iliotibial band are closely united, becomes attached with these tendons to the tibia and fibula. From these attachments, therefore, the fascia of the front of the leg may be said to arise. Into it extend processes from the tendons mentioned. Dorsally the fascia of the thigh is continued uninterruptedly into that of the leg. Distally the crural fascia is attached to the two malleoli and to the posterior surface of the calcaneus.

In the proximal part of the leg in front the underlying muscles in part take origin from the fascia; in other places the fascia is separated from the underlying muscles by loose tissue.

From the fascia two main intermuscular septa arise. One, the **anterior intermuscular septum,** extends between the extensor digitorum longus and peroneal muscles to the anterior

crest of the fibula; the other, the **posterior intermuscular septum**, between the peroneal muscles and the soleus to the lateral crest of the fibula. These septa separate compartments for the anterior, lateral, and posterior groups of muscles.



As the heads of the gastrocnemius pass over the back of the knee they are held in place by a special deep lamina of the fascia lata, which distally becomes fused with the crural fascia (fig. 478 A).

The semimembranosus has a special fascial investment which, on the back of the knee becomes bound on each side of the muscle and its tendon to the capsule of the joint. This fascia extends into a transverse septal membrane which is continued over the deep muscles of the back of the leg to the ankle. It is united on one side to the tibia, on the other to the fibula. Proximally the fibers are continued into it from the tendon of the semimembranosus. Over the back of the tibia the septum is interrupted by the attachment of the soleus to the popliteal line. Beyond the tibial origin of the soleus it is fused on the medial side of the flexor digitorum longus to the crural fascia.

In addition to the two intermuscular septa and the longitudinal transverse septum, other septa serve to separate the individual muscles of the different groups.

Above the ankle the fascia is reinforced by bands of tissue so that ligaments are formed which serve to retain in position the various tendons which pass from the leg into the foot.

The **transverse crural ligament** (upper part of anterior annular ligament) (fig. 479) lies on the front of the lower part of the leg above the ankle. It is composed of fascia strengthened by transverse bundles which pass from the medial side of the tibia to the ventral margin of the fibula. From its deep surface a strong, broad septum descends to the tibia and divides the underlying space into two osteofibrous canals, a medial for the tibialis anterior and a lateral

For Legend See Page 545.

for the long extensor muscles. The lateral compartment is further subdivided by a slightly marked septum into a medial division for the extensor hallucis longus and a lateral for the extensor digitorum longus and the peroneus tertius.

The **cruciate ligament** (lower part of anterior annular ligament) (figs. 479, 482, 483) holds the tendons of the anterior muscle group in place as they pass to the dorsum of the foot. In part it is formed by a dense fibrous band lying in the fascia over the ankle, in part of a ligament which passes from the bones of the ankle to the deep surface of this band. The superficial band is V-shaped. It arises from the lateral surface of the body of the calcaneus and passes

across the dorsum of the foot, one arm of the V going to the medial malleolus, the other to th side of the foot, where it terminates in the fascia over the first cuneiform bone. The apex o the V lies over the tendons of the extensor digitorum longus and peroneus tertius muscles The distal arm extends over the tendons of the extensor hallucis longus and tibialis anterio muscles. The proximal arm passes over the tendon of the extensor hallucis longus and the divides into two layers, between which the tendon of the tibialis anterior passes. The deepe ligament mentioned above arises from deep within the tarsal sinus, some of its fibers ever from the sustentaculum tali. It then passes forward and medially beneath the long extenso tendons, and divides into two parts, one of which curves about the medial margin of the ten don of the extensor digitorum longus, the other about the extensor hallucis longus tendon t the under surface of the proximal arm of the V-shaped band.

The **peroneal retinacula** are strengthened regions in the fascia which serve to hold the tendons of the peroneal muscles in place. The **superior** extends from the lateral malleolus int the fascia on the back of the leg, and to the lateral surface of the calcaneus. The **inferio** overlies the tendons on the lateral surface of the calcaneus, and is attached to this bone o each side of them. Between the tendons it sends a septum to the bone. It is connected wit the superficial layer of the cruciate ligament (figs. 482, 483).

The **laciniate ligament** (internal annular) (figs. 480, 482) is on the medial side of the ankle Here the fascia is strengthened by fiber-bands which form a well-marked ligament that holds in place the tendons of the deep dorsal cruropedal muscles. This ligament extends from the dorsal and distal margins of the medial malleolus to the calcaneus. It is closely bound to the tibia and the talotibial (tibioastragaloid) ligament until the tendon of the tibialis posterior is reached. It passes over this and becomes bound to the bony structures on the posterio margin of the tendon. From this attachment two layers, a deep and a superficial, extend backward. The superficial layer extends to the tuber calcanei, and is connected superiorly with the crural fascia. The deep layer, which represents a continuation distally of the trans- verse septum, extends over the tendons of the flexor digitorum longus and flexor hallucis longus to the medial surface of the calcaneus, and is closely united to the underlying bone on each side of these tendons, thus giving rise to osteofibrous canals.

MUSCLES

1. Muscles of the Front of the Leg

(Figs. 479, 486)

The anterior musculature of the leg consists of four muscles, the tibialis anterior, extensor digitorum longus, peroneus tertius, and extensor hallucis longus. The **tibialis anterior** has a quadrangular prismatic belly which arises from the lateral side of the tibia and adjacent interosseous membrane in the proximal half of the leg. The tendon passes over the front of the tibia to the first metatarsal. The **extensor digitorum longus** is a transversely flattened, fusiform muscle, which arises from the superior extremity of the tibia, the anterior crest of the fibula, and the adjacent interosseous membrane, and gives rise to a tendon which passes over the front of the distal extremity of the tibia and sends tendons to the terminal phalanges of the four more lateral toes. The **peroneus tertius** represents a more or less completely differentiated portion of the preceding muscle. Its tendon passes laterally through the same osteofibrous canal in the same synovial sheath and terminates on the fifth metatarsal. The **extensor hallucis longus** is a narrow muscle which arises from the distal half of the medial surface of the fibula and the interosseous membrane. Its tendon extends over the ankle to the great toe. The tendons of these muscles are held in place by the transverse and cruciate ligaments described above.

All the muscles of this group flex the foot. The extensors extend the toes; the peroneus tertius and the extensor digitorum longus evert the foot. The nerve supply is from the deep peroneal (anterior tibial) nerve.

The tibialis anterior is represented in the arm probably by the brachioradialis and the two radial extensors; the extensor digitorum longus by the extensor digitorum communis and extensor digiti quinti proprius; and the extensor hallucis longus by the extensor pollicis longus. Two abnormal muscles not infrequently found, the abductor hallucis longus and extensor primi internodii hallucis, represent probably the corresponding normal muscles of the hand.

The tibialis anterior (or dorsalis NK) (fig. 479). *Origin.*—From the distal surface of the lateral condyle of the tibia, and the lateral surface of the proximal half of the shaft of the tibia, the adjacent interosseous membrane, the overlying fascia near the condyle (tuberosity) of the tibia, and the intermuscular septum between it and the extensor digitorum longus.

Structure.—Bipenniform. The fiber-bundles converge upon a flat tendon which begins high in the muscle and emerges on the anterior margin of the muscle about the middle of the leg. On the deep surface the implantation of fiber-bundles continues to the transverse crural (anterior annular) ligament.

Insertion.—The tendon passes over the front of the tibia to the medial side of the foot, where it is inserted into the medial surface of the first cuneiform and the base of the first metatarsal.

Nerve-supply.—As a rule, a branch from the common peroneal (external popliteal) nerve enters the proximal portion of the muscle by several twigs, and another from the deep peroneal (anterior tibial) enters near the middle of the belly on the lateral edge.

Relations.—In the proximal half of the leg the extensor digitorum longus lies lateral to it; and between the two muscles, the anterior tibial artery and vein. It is covered by the crural fascia and rests on the interosseous membrane. Distally it lies over the extensor hallucis

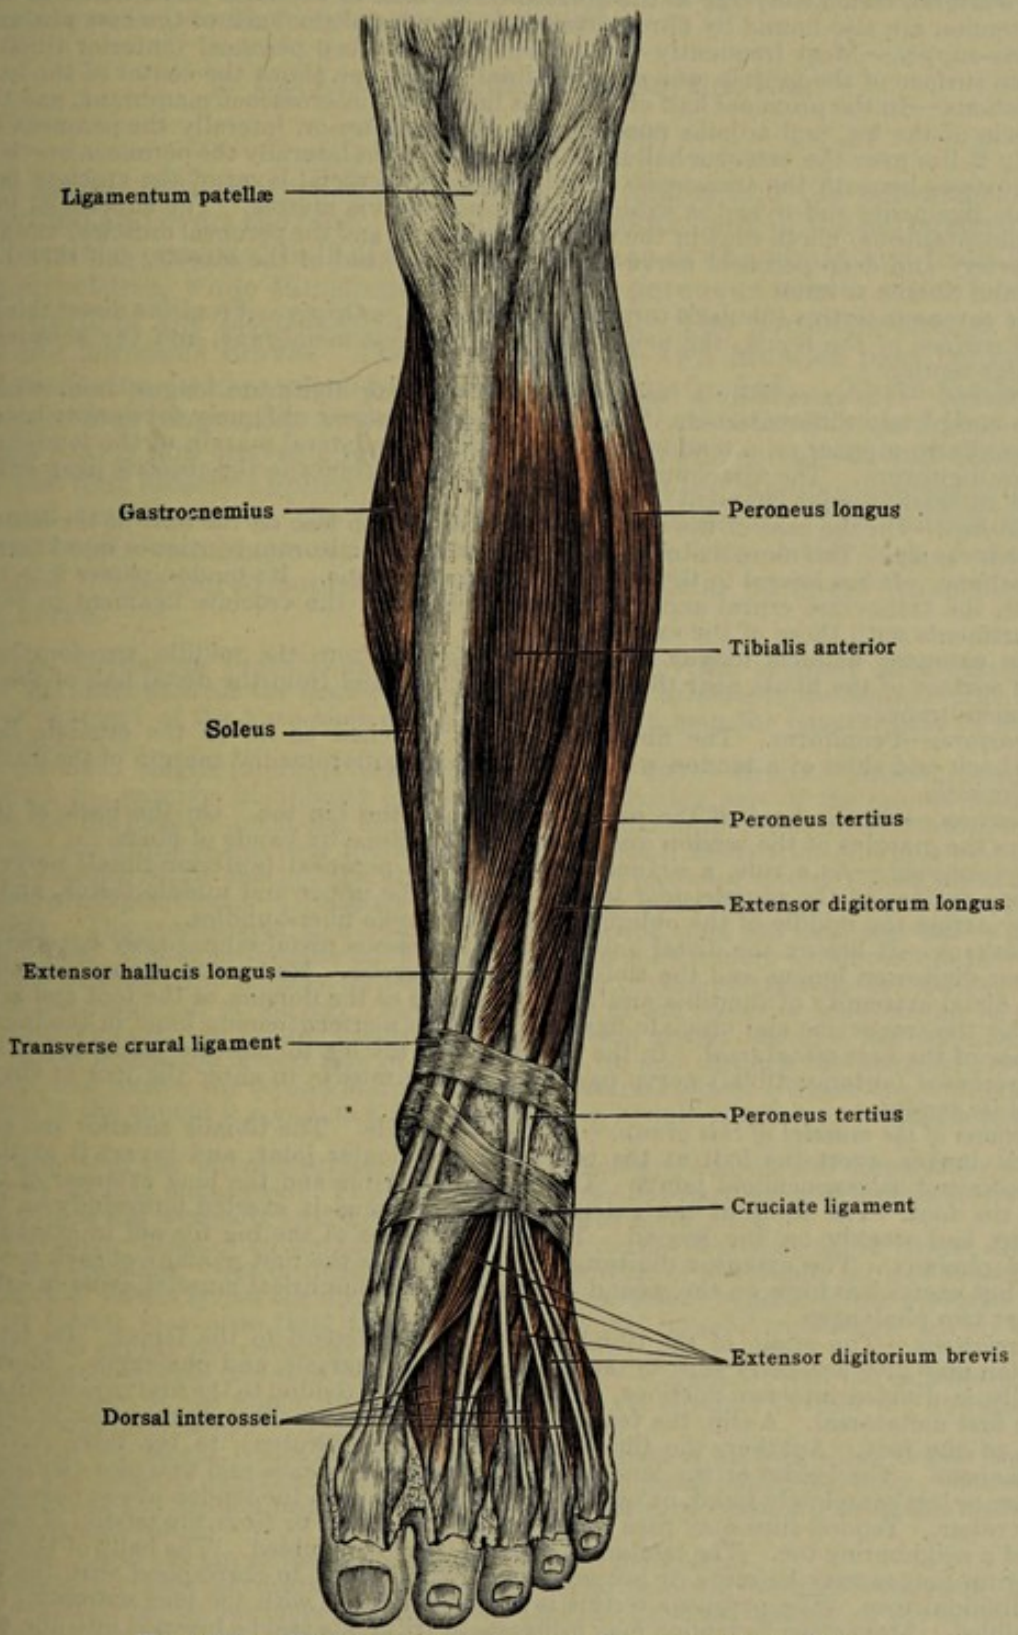

FIG. 479.—THE MUSCLES OF THE FRONT OF THE LEG.

longus. The tendon passes in special compartments beneath the transverse and the cruciate (anterior annular) ligaments.

The extensor digitorum longus (fig. 479).—*Origin.*—From the lateral condyle of the tibia, the anterior crest (surface) of the fibula, the intermuscular membrane between it and the tibialis anterior, the lateral margin of the interosseous membrane, the septum between it and the peroneus longus, and the fascia of the leg near the tibial origin.

Structure.—Penniform. The fiber-bundles converge upon the posterior surface of a tendon which begins at the middle of the leg. The implantation of fibers continues nearly to the

ankle. Usually at the distal margin of the transverse (anterior annular) ligament the tendon divides into two parts which pass between the two layers of the cruciate (lower part of anterior annular) ligament, and then each divides again into two parts, thus giving rise to four slips, one for each of the four lateral toes.

Insertion.—Each tendon on the dorsal surface of the toe to which it goes divides into three fasciculi: an intermediate, which is attached to the dorsum of the base of the second phalanx and two lateral, which converge to the dorsum of the base of the third phalanx. The margins of the tendon are also bound by fibrous tissue to the sides of the back of the first phalanx.

Nerve-supply.—Most frequently two branches of the deep peroneal (anterior tibial) enter the deep surface of the muscle, one near its tibial origin, one about the center of the belly.

Relations.—In the proximal half of the leg it lies on the interosseous membrane, and beneath the fascia of the leg, and adjoins medially the tibialis anterior, laterally the peroneus longus. Distally it lies over the extensor hallucis longus and adjoins laterally the peroneus brevis. The tendon passes beneath the transverse crural and the superficial layer of the cruciate (anterior annular) ligaments and over the extensor digitorum brevis muscle. The superficial peroneal (musculocutaneous) nerve runs in the septum between it and the peroneal muscles; the anterior tibial artery and deep peroneal nerve pass beneath the head of the muscle, and then between it and the tibialis anterior.

The peroneus tertius (fibularis tertius NK) (fig. 479).—*Origin.*—From the distal third of the medial surface of the fibula, the neighboring interosseous membrane, and the anterior intermuscular septum.

Structure.—It is essentially a fasciculus of the extensor digitorum longus, from which it is seldom completely differentiated. The fiber-bundles descend obliquely forward to be inserted in a penniform manner on a tendon which runs along the lateral margin of the tendons of the extensor digitorum. The attachment of fiber-bundles continues to the cruciate ligament (lower part of anterior annular ligament).

Insertion.—On the base of the fifth metatarsal and often also on the base of the fourth.

Nerve-supply.—The more distal nerve to the extensor digitorum continues into this muscle.

Relations.—It lies lateral to the extensor digitorum longus. Its tendon passes into the foot beneath the transverse crural and the superficial layer of the cruciate ligament in the same compartments with those of the extensor longus.

The extensor hallucis longus (fig. 479).—*Origin.*—From the middle two-fourths of the medial surface of the fibula near the interosseous crest, and from the distal half of the interosseous membrane.

Structure.—Penniform. The fiber-bundles are attached as far as the cruciate ligament to the back and sides of a tendon which begins on the anteromedial margin of the distal third of the muscle.

Insertion.—On the base of the second phalanx of the big toe. On the back of the first phalanx the margins of the tendon are attached to the bone by bands of fibers.

Nerve-supply.—As a rule, a branch from the deep peroneal (anterior tibial) nerve enters the deep surface of the muscle near the junction of the upper and middle thirds, and passes distally across the middle of the obliquely running muscle fiber-bundles.

Relations.—It lies on the distal half of the interosseous membrane, partly covered by the extensor digitorum longus and the tibialis anterior muscles. Its tendon passes over the front of the distal extremity of the tibia and the medial side of the dorsum of the foot and is held in place by the transverse and cruciate ligaments and by a strengthening band in the fascia over the base of the first metatarsal. In the distal part of the leg the anterior tibial artery and the deep peroneal (anterior tibial) nerve pass beneath the muscle to enter the foot at the lateral side of its tendon.

Actions of the muscles of this group.—All flex the ankle. The tibialis anterior and extensor hallucis longus evert the foot at the talocalcaneonavicular joint, and invert it at the talonavicular and calcaneocuboid joints. The peroneus tertius and the long extensor of the toes evert the foot. The force of the extensor hallucis longus is exerted powerfully on the first phalanx and weakly on the second. The short muscles of the big toe aid in extending the second phalanx. The extensor digitorum longus extends the first phalanx of each toe powerfully, but exerts less force on the second and third. The lumbrical muscles assist in extending the last two phalanges.

Variations.—The origin of the tibialis anterior may extend to the femur. Its tendon of insertion may give accessory slips to the cuneiforms, metatarsals, and phalanges. More rarely its belly is divided into two portions, one of which sends a tendon to the first cuneiform and one to the first metatarsal. A slip, the **tensor fasciæ dorsalis pedis** (Wood), may pass to the dorsal fascia of the foot. Another, the **tibioastragalus anticus** (Gruber), to the talus (astragalus) or calcaneus. The bellies or the tendons of the extensor hallucis and extensor digitorum may be more or less completely fused, or tendon slips may pass from the tendon of one muscle to that of the other. Tendon slips may pass to the metatarsal bones or from the tendon of one toe to that of a neighboring toe. The tendon to each toe may be doubled. The belly of the extensor digitorum longus may be more or less completely subdivided to correspond with the tendons to individual toes. The peroneus tertius is frequently fused with the long extensor. It may be doubled. More often its tendon may bifurcate or trifurcate and be inserted into the extensor tendons of the fifth toe or into the fourth or third metatarsal. It is absent in about 8.5 per cent. of bodies (Le Double).

Abnormal Muscles.—The **abductor hallucis longus** is rarely found as a completely independent muscle. It usually arises as a fasciculus of the extensor digitorum longus, extensor hallucis longus, or the tibialis anterior. It is inserted into the base of the first metatarsal. The **extensor primi internodii hallucis** (extensor hallucis brevis) has an origin similar to that of the long abductor above described. It is inserted into the dorsum of the base of the first phalanx of the big toe. It is not to be confounded with that portion of the extensor digitorum brevis connected with the great toe and also sometimes called the extensor hallucis brevis.

B. subtendinea m. tibialis anterioris.—A small bursa between the medial surface of the first cuneiform bone and the tendon of the tibialis anterior. **B. subtendinea m. extensoris hallucis longi.**—A small bursa beneath the tendon near the tarsometatarsal articulation. It may communicate with the synovial sheath of the tendon. **B. sinus tarsi.**—A large bursa in the sinus tarsi and on the lateral surface of the neck of the talus (astragalus) beneath the tendons of the extensor digitorum longus and the fibrous bands between the talocalcaneal and the cruciate ligaments. It extends back to the talocrural, forward to the talonavicular joint, and may communicate with the joint cavity of the latter.

2. Lateral Musculature of the Leg

(Figs. 479, 480, 490)

The lateral muscles consist of the peroneus longus and the peroneus brevis. They extend and evert the foot. The thick prismatic belly of the **peroneus longus** arises from the proximal half of the lateral surface of the fibula and from neighboring structures, while the smaller belly of the **peroneus brevis** arises from the middle third of the lateral surface of this bone. The peroneus longus partly covers the peroneus brevis. The tendons of the two muscles pass behind the lateral malleolus, held in place by special retinacula (p. 546). There the tendon of the peroneus longus lies at first lateral to and then crosses behind that of the peroneus brevis and curves about the lateral side of the calcaneus and across the sole of the foot closely applied to the cuboid and to the tarsometatarsal articulations, and terminates on the base of the first metatarsal. The tendon of the peroneus brevis terminates on the lateral side of the foot at the base of the fifth metatarsal. The nerve supply is from the superficial peroneal (musculocutaneous) nerve.

The two muscles are probably represented in the arm by the extensor carpi ulnaris. In some of the lower animals the head of the peroneus longus extends to the femur. The fibular collateral ligament of the knee-joint probably represents in man the femoral head of the peroneus longus.

The peroneus longus (fibularis longus NK) (figs. 480, 490).—*Origin.*—Anterior head: tendinous from the anterior tibiofibular ligament, the neighboring part of the lateral condyle of the tibia, and the head of the fibula; fleshy from the proximal third of the anterior intermuscular septum and the crural fascia near the tibia. Posterior head: fleshy from the proximal half of the lateral surface of the shaft of the fibula and from the posterior intermuscular septum.

Structure.—Bipenniform. The fiber-bundles converge upon a tendon which begins high in the muscle. The constituent fiber-bundles of the anterior head are long and take a nearly vertical course. The fiber-bundles of the posterior head take a more oblique course and their attachment extends more distally on the tendon. The tendon emerges on the surface of the muscle in the distal half of the leg. The fiber-bundles of the posterior head extend to within a few centimeters of the lateral malleolus. The tendon passes through the retromalleolar groove, passes across the lateral face of the calcaneus, to and through the peroneal groove of the cuboid, and crosses the second and third tarsometatarsal joints. Where the tendon enters the groove in the cuboid it contains a fibrocartilaginous nodule which may become a sesamoid bone.

Insertion.—On the inferior surface of the first cuneiform and on the inferolateral border and base of the first metatarsal. From the region of the fibrocartilaginous nodule above mentioned a fibrous slip is usually sent to the base of the fifth metatarsal.

Nerve-supply.—Most often the common peroneal (external popliteal) nerve before dividing gives off two branches. One of these enters the deep surface of the middle third of the anterior head, the other passes across the middle third of the constituent bundles of the posterior head. The latter branch may arise from the superficial peroneal (musculocutaneous) nerve, and it may extend to supply the peroneus brevis.

The peroneus brevis (fibularis brevis NK) (fig. 480).—*Origin.*—From the middle third of the lateral surface of the fibula; (2) from the septa which separate it from the anterior and posterior groups of muscles.

Structure.—Penniform. The fiber-bundles converge upon a tendon which begins high in the muscle and becomes visible on the lateral surface of the distal half of the belly. Behind the lateral malleolus the tendon becomes free, then passes forward below the malleolus and across the calcaneus and cuboid.

Insertion.—Into the tip of the tuberosity of the fifth metatarsal.

Nerve-supply.—The nerve arises from the superficial peroneal (musculocutaneous) nerve, or from a branch to the peroneus longus. It enters the proximal margin of the muscle and passes distally across its constituent fiber-bundles.

Relations.—The peroneal muscles in the leg are contained in a compartment bounded by the anterior and posterior intermuscular septa, by the fibula, and by the fascia of the leg. The peroneus longus to a considerable degree overlies the peroneus brevis. Beneath the upper part of the peroneus longus the peroneal (external popliteal) nerve bifurcates into its two chief branches. The deep peroneal (anterior tibial) nerve passes medially beneath the anterior head of the muscle. The superficial peroneal (musculocutaneous) nerve extends in the interval between the areas of the attachment of the two heads of the peroneus longus, and along the anterior margin of the peroneus brevis to the anterior intermuscular septum, through which it passes to its superficial distribution. The tendon of the peroneus longus at first lies lateral to

and slightly overlaps that of the peroneus brevis. Toward the tip of the malleolus it lies almos directly posterior to this tendon. On the lateral surface of the calcaneus the tendon of th brevis lies superior to that of the longus, from which it is separated by bony spine, the processu trochlearis of the calcaneus. The tendon of the longus is separated from the deep surface of th abductor of the little toe, and is held in place in the groove in the cuboid by the long planta ligament.

Action.—The peroneus brevis everts the foot. The peroneus longus extends, abducts, an everts the foot, and supports the arch of the foot. The peroneus brevis also extends the foo when this is flexed.

Variations.—The two peroneal muscles may be more or less fused. The origin of th peroneus longus may extend to the femur. The two heads of origin may be fused. Its tendo of insertion may send slips to the second, third, and rarely to the fourth and fifth metatarsals The tendon may be united to that of the tibialis posterior (12 out of 45 bodies—Picou). Sesa moid cartilages or bones are occasionally found in the retromalleolar and calcaneal portions o the tendon. The tendon of the peroneus brevis may send a slip to the second or third phalan or to the head of the metatarsal of the fifth toe, to its extensor tendon, or to the cuboid. It ma also send a fasciculus to the fourth metatarsal or the extensor tendon of the fourth toe.

Accessory peroneals.—Poirier considers these all varieties of a muscle which in its simples form arises from the distal fourth of the fibula and is inserted by a tendon into the fifth toe. corresponding muscle is normally found in many of the monkeys (**peroneus digiti quinti**). I man in one form or another it is a frequent anomaly. It may be so fused with the peroneu brevis that only its tendon of insertion is apparent. It may appear as a special muscle fasciculu of the peroneus longus or brevis. It may be merely a tendinous band, or it may be tendinou at origin and insertion, with an intermediate belly. Instead of being attached to the fifth toe it may be inserted into the fifth metatarsal, the cuboid, the tendon of the peroneus longus, th calcaneus, lateral malleolus, or posterior talofibular ligament.

3. Musculature of the Back of the Leg

a. Superficial Group (fig. 477)

To this group belong the gastrocnemius, soleus, and plantaris muscles. They extend the foot and flex the leg. The two ovoid heads of the **gastrocnemius** aris one on each side from above the condyles of the femur, extend about to the middl of the back of the leg, and are inserted into the posterior surface of the tendon o Achilles, and through this into the back of the calcaneus. The broad, flat, ovoi **soleus** arises beneath the gastrocnemius from the tibia and fibula, and is in serted into the deep surface of the tendon of Achilles as far as the ankle. The two heads of the gastrocnemius and the soleus constitute the **triceps suræ.** The **plantaris** is a slender muscle which passes along the medial margin of the latera head of the gastrocnemius and beneath the medial head, where it gives rise to a slender tendon that runs between the gastrocnemius and soleus and along the medial margin of the tendon of Achilles [tendo Achillis] to the fatty fibrous tissue of the heel. The nerve-supply is from the tibial nerve.

The muscles of this group have a common embryonic origin, and are first differentiated on the fibular side of the leg, whence they extend over the posterior tibial vessels and nerve t their medial attachments. The gastrocnemius corresponds with the flexor carpi radialis and ulnaris, the plantaris with the palmaris longus, the soleus with a portion of the flexor digitorum sublimis of the forearm. In many of the monkeys and in the prosimians the plantaris is much more developed than in man.

The gastrocnemius (fig. 477).—**Medial head.**—*Origin.*—From a facet on the back of the medial condyle of the femur above the articular surface, from an area on the back of the femur superior and lateral to this, and from the femoral margin of the capsule of the knee-joint **Lateral head.**—*Origin.*—From a facet on the proximal portion of the posterolateral surface of the lateral condyle of the femur and from a rough area situated more medially and at a greater distance from the joint.

Structure and insertion.—The heads of the gastrocnemius are similar in structure. From the condylar facets there descend aponeurotic bands, one on the medial margin and the medial side of the posterior surface of the medial head, the other on the lateral margin and the lateral side of the posterior surface of the lateral head. These bands descend about two-thirds of the way down the muscle. In the tendon of the lateral head a sesamoid bone is frequently found. The fiber-bundles of the muscle pass obliquely from the supracondylar areas of origin and from the deep surface of the aponeurosis on each side to the tendon of insertion. This tendon begins as a septum between the two heads, and as a lamina on the deep surface of each head. The septum and laminæ soon fuse with the broad aponeurosis which covers the dorsal surface of the soleus. The attachment of fiber-bundles continues to about the middle of the back of the leg. The attachment of the medial head extends more distally than that of the lateral head. As a rule, the medial head is also the broader and thicker of the two.

The soleus (fig. 477).—*Origin.*—(1) By a fibular head from the back of the head and the proximal third of the posterior surface of the shaft of the fibula, and from the intermuscular septum between it and the peroneus longus; and (2) by a tibial head from the transverse septum over the distal margin of the popliteus, from the popliteal line, and from the middle third of the medial border of the tibia.

Structure and insertion.—From the fibular and tibial origins arise broad aponeuroses which unite proximally on the deep surface of the muscle so as to form a fibrous arch over the pos-

terior tibial vessels and nerves. Distally they diverge and become more narrow, but the fibular aponeurosis is continued on the fibular side and the tibial aponeurosis on the tibial side of the muscles as far as the distal quarter of the leg. The main portion of the belly of the muscle is formed by fiber-bundles which arise from the posterior surface of these aponeuroses and pass obliquely to be inserted in a bipenniform manner on the deep surface of the tendon of Achilles. This tendon begins as a broad aponeurosis which covers the greater part of the posterior surface of the muscle, and gradually converges into a heavy fibrous band that is inserted into the calcaneus. The bundles of fibers of the tendon take a slightly spiral course. Those on the posterior surface run from the medial margin toward the lateral surface of the calcaneus; those on the anterior surface in a reverse direction. The attachment of the fiber-bundles continues to within a short distance of the heel. A few of the fiber-bundles arise directly from the fibula and the posterior intermuscular septum. On the deep surface of the belly of the muscle there is an **accessory fasciculus** which is formed by fiber-bundles that spring on each side from the anterior surface of the aponeuroses of origin of the muscle and have a bipenniform insertion on each side of a thin, oblique tendinous lamina which inferiorly becomes united to the deep surface of the tendon of Achilles.

The plantaris (fig. 477).—This muscle *arises* from the distal part of the lateral line of bifurcation of the linea aspera, in close association with the lateral head of the gastrocnemius. The fiber-bundles give rise to a flat, short, fusiform belly, and are united to a narrow tendon which extends along the medial edge of the tendon of Achilles to the dorsal surface of the calcaneus, where it *terminates* in the neighboring fibrous tissue.

Nerve-supply.—From the tibial (internal popliteal) part of the sciatic nerve in the popliteal space nerves arise for each head of the gastrocnemius. Each nerve enters the middle third of the deep surface of the head near the proximal margin. The nerve-supply for the soleus is from two sources. One nerve arises in the popliteal space, often in company with the nerve to the lateral head of the gastrocnemius. It enters the posterior surface of the muscle near the proximal border and divides into two branches, one for each head of the muscle. The tibial (posterior tibial) nerve gives rise to a branch which, about half-way down the leg, enters the deep surface of the muscle and furnishes branches for the deep portion of the muscle on each side The nerve-supply of the plantaris is by a branch from the tibial (internal popliteal) portion of the sciatic. This arses in the popliteal space and enters the deep surface of the muscle.

Relations.—The semimembranosus winds about the medial margin of the medial head of the gastrocnemius to its deep surface. The biceps passes to the lateral side of the lateral head of the gastrocnemius, and the plantaris along its medial margin. The semimembranosus and biceps above, the medial head of the gastrocnemius and the plantaris below, bound the popliteal space. The peroneal (external popliteal) nerve passes from the popliteal space obliquely across the plantaris and the lateral head of the gastrocnemius. The medial sural (short saphenous) nerve and the small saphenous vein pass between the heads of the gastrocnemius to the surface and thence to the lateral side of the ankle. From the peroneal (external popliteal) nerve in the popliteal space the lateral sural (communicans peronei) nerve extends distally over the calf. The (posterior) tibial nerve and posterior tibial artery and vein run between the two heads of the gastrocnemius, and then beneath the soleus to the medal side of the ankle. In the region of the tendon of Achilles a considerable space filled with fatty tissue intervenes between the tendon and the transverse septum.

Action.—The contraction of the triceps suræ produces extension, adduction, and inversion of the foot. The gastrocnemius is also a flexor of the leg. The plantaris is a weak flexor of the leg at the knee, and extensor of the foot at the ankle.

Variations.—There is considerable variation in the extent of the separation of the different parts of the triceps suræ. The tendons of the three heads may be separate nearly to the heel. Either or both heads of the gastrocnemius or the soleus may be doubled. A slip from the biceps or semimembranosus, from the linea aspera, or popliteal space may join the triceps and give rise to a quadriceps suræ. On the other hand, one of the heads of the gastrocnemius or the tibial head of the soleus may be missing. A supernumerary fasciculus may extend from the deep surface of the soleus to the calcaneus. The plantaris is exceedingly variable in origin, structure, and insertion. The origin may be from the capsule of the knee-joint, the fascia of the leg, or from the tibia. Its tendon may terminate at almost any part of its course in neighboring structures. It may be represented by a fibrous band. It is absent in about 7 per cent. of instances (Le Double).

Bursæ

B. m. gastrocnemii lateralis.—A bursa is often found between the tendon of the lateral head of the gastrocnemius and the capsule of the joint. It may communicate with the joint cavity. **B. m. gastrocnemii medialis.**—A bursa usually lies between the tendon of origin of the medial head of the gastrocnemius, the condyle of the femur, and the capsule of the joint. Another bursa (**b. m. semimembranosi**) extends between the semimembranosus and the medial head of the gastrocnemius muscle. The two bursæ frequently communicate with one another and with the joint. **B. tendinis calcanei.**—This lies between the tendon of Achilles and the upper part of the back of the calcaneus. Between the back of the tendon and the crural fascia another bursa is frequently present.

b. Deep Group

The deep posterior musculature is separated from the superficial by the transverse septum described above (p. 544). The muscles covered by this septal fascia are the **popliteus**, the **flexor digitorum longus**, the **flexor hallucis longus**, and the **tibialis posterior.** An intermuscular septum between the popliteus and the tibialis posterior, and the attachment of the soleus to the popliteal line on the

back of the tibia serve to separate the popliteus from the other deep posteric muscles which lie distal to this region and send tendons into the sole of the foo The deep posterior musculature may thus be considered as divided into a proxim femorotibial and a distal cruropedal group. Both sets of muscles are supplie by branches of the tibial nerve.

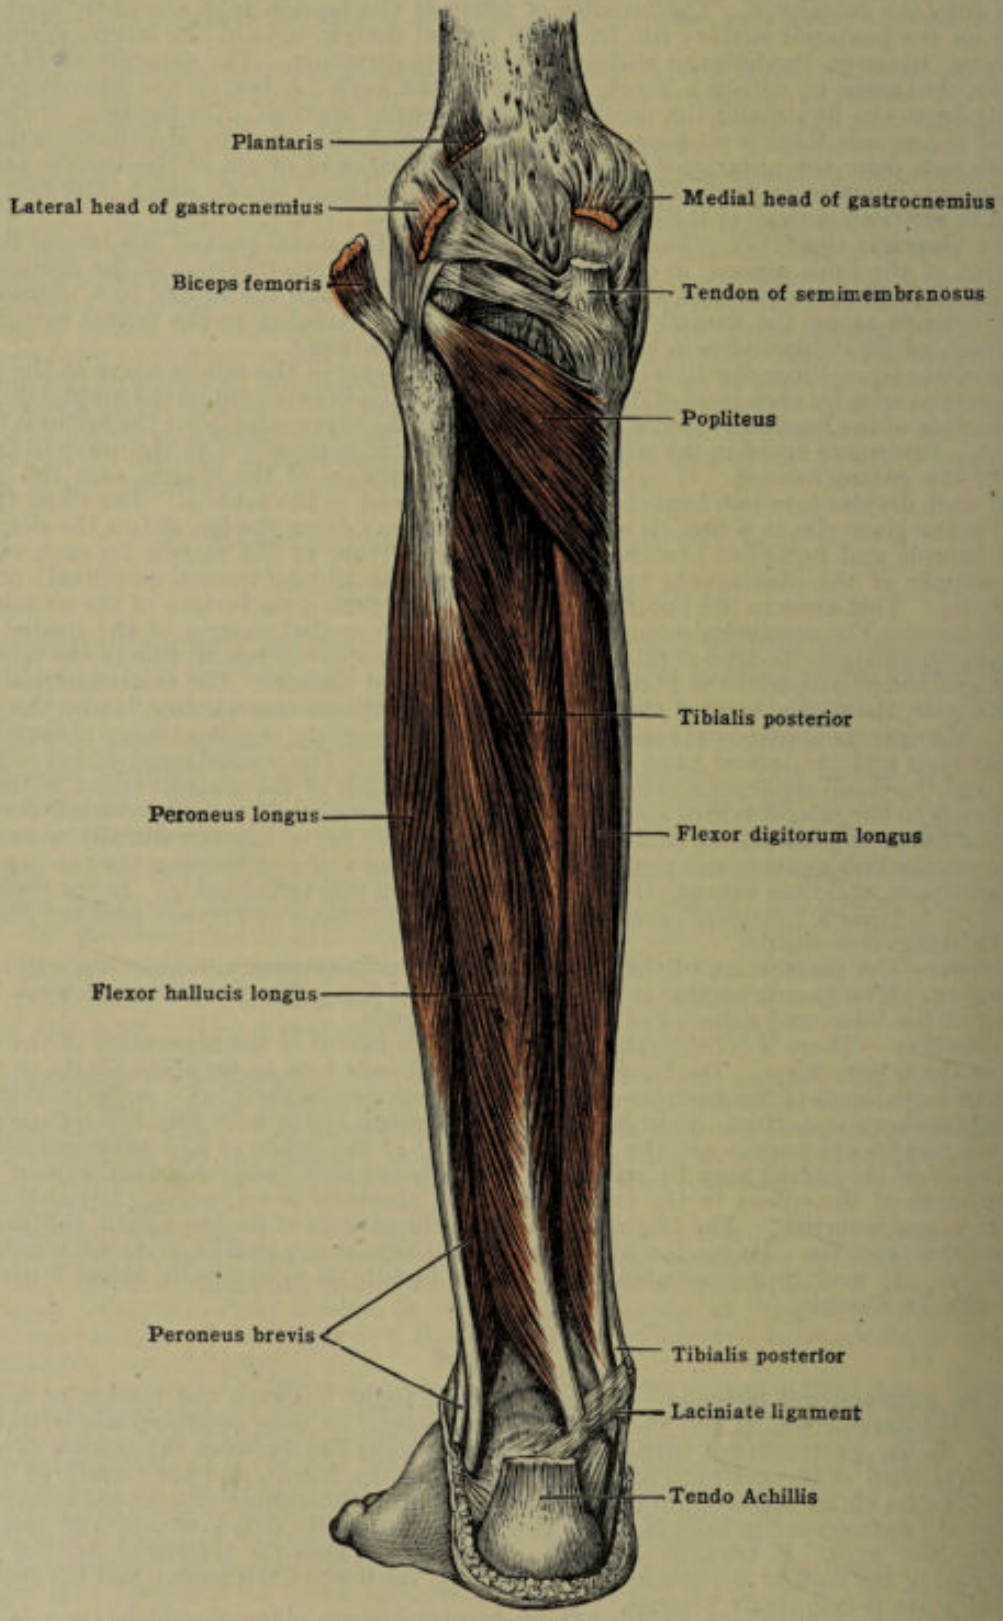

FIG. 480.—THE DEEP MUSCLES OF THE BACK OF THE LEG.

Femorotibial Muscle

The popliteus (fig. 480).—A triangular muscle which *arises* from an ovoid facet at the inferior extremity of the groove on the outer side of the lateral condyle of the femur and is *inserted* into the proximal lip of the popliteal line of the tibia and the surface of the shaft of the tibia proximal to this. It rotates the leg medialward and flexes it.

Structure.—From the origin a broad tendon glides over the condyle within the capsule of the joint, then over the lateral fibrocartilage and through a groove on the back of the tibiofibular articulation. From both surfaces of this tendon, fiber-bundles diverge toward the area of insertion. The tendon is more or less intimately united to several structures with which it comes in contact about the joint. Rarely it contains a sesamoid bone. The fibers of insertion terminate in part in the fascia covering the muscle. The popliteus is homologous with the pronator teres of the arm, or, according to some investigators, with the deep portion of that muscle.

Nerve-supply.—A nerve which arises either independently or in conjunction with that to the posterior tibial muscle enters the popliteus near the middle of its distal edge. Sometimes a branch from the chief nerve to the knee-joint enters the proximal edge of the muscle.

Action.—To flex and rotate the leg medially.

Relations.—The popliteus lies within a compartment bounded by the transverse septum, the capsules of the knee and superior tibiofibular joints, the back of the tibia, and a septum extending to the popliteal line (see above). On the transverse septum run the popliteal vessels and the tibial nerve. The proximal margin of the soleus overlaps the distal margin of the popliteus. The synovial membrane of the knee-joint sends a prolongation between its tendon and the back of the lateral condyle of the tibia.

Variations.—It is rarely absent. An accessory head may arise from the medial side of the lateral condyle or from some neighboring structure. The **fibulotibialis** (peroneotibialis) is a small muscle found by Gruber in one body in seven. It arises from the medial side of the head of the fibula and is inserted into the posterior surface of the tibia beneath the popliteus.

Cruropedal Muscles (figs. 480, 488)

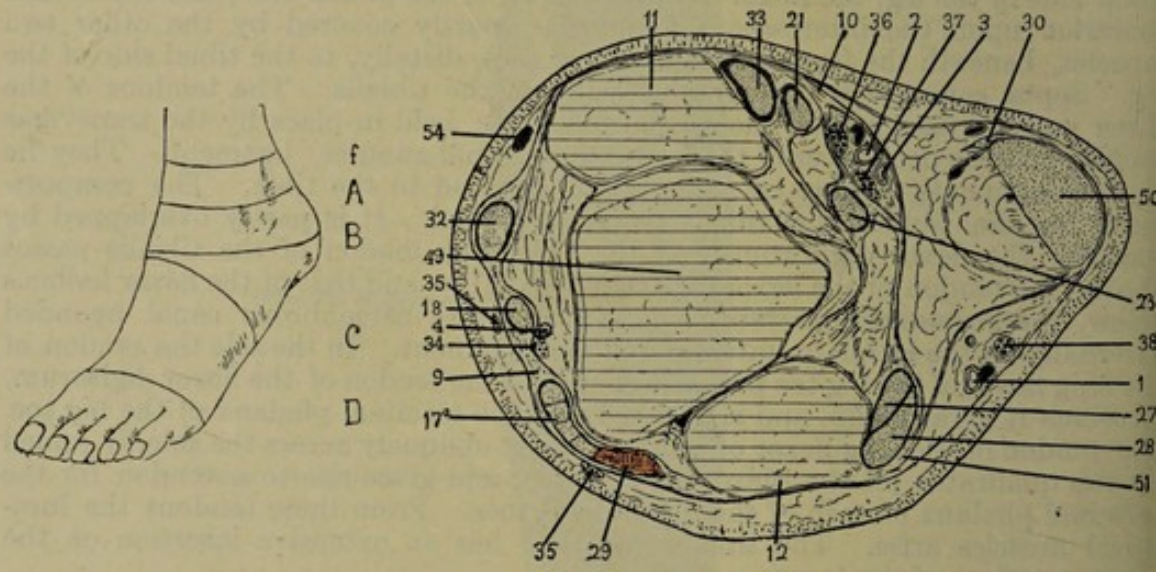
Of the three muscles of this group, the **flexor digitorum longus** lies on the tibial side of the leg, the **flexor hallucis longus** on the fibular side, and the **tibialis posterior** upon the interosseous membrane, partly covered by the other two muscles, beneath the former of which it crosses, distally, to the tibial side of the leg. Septa separate the flexor muscles from the tibialis. The tendons of the three muscles pass behind the medial malleolus, held in place by the transverse septum and the deep layer of the laciniate (internal annular) ligament. They lie in compartments divided by septa which descend to the tibia. The compartment for the tibialis posterior is the most medial. It is partly overlapped by that for the flexor digitorum. At the ankle the tendon of the tibialis passes above, the tendon of the flexor digitorum medial to, and that of the flexor hallucis below, the sustentaculum tali, each in a separate osteofibrous canal bounded externally by the laciniate (internal annular) ligament. In the sole the tendon of the long flexor of the big toe passes deeper than the tendon of the flexor digitorum, to which it gives a slip, and is inserted into the terminal phalanx of the big toe. The tendon of the long flexor of the toes passes obliquely across the sole, is joined by the quadratus plantæ (flexor accessorius), and gives rise to a tendon for the terminal phalanx of each of the four lateral toes. From these tendons the lumbrical muscles arise. The tibialis posterior has an extensive insertion on the plantar surface of the tarsus.

The long flexors act chiefly on the toes. Together with the tibialis posterior they invert and extend the foot.

The long flexors of the toes probably represent the flexor profundus and the flexor pollicis longus of the forearm. The tendons of the deep flexors of the forearm do not, however, cross like those of the long flexors of the toes. In the lower mammals there is much variation in the toes to which the tibial and fibular flexors are distributed. The tibialis posterior has no certain representative in the forearm. The rare ulnocarpeus may represent it.

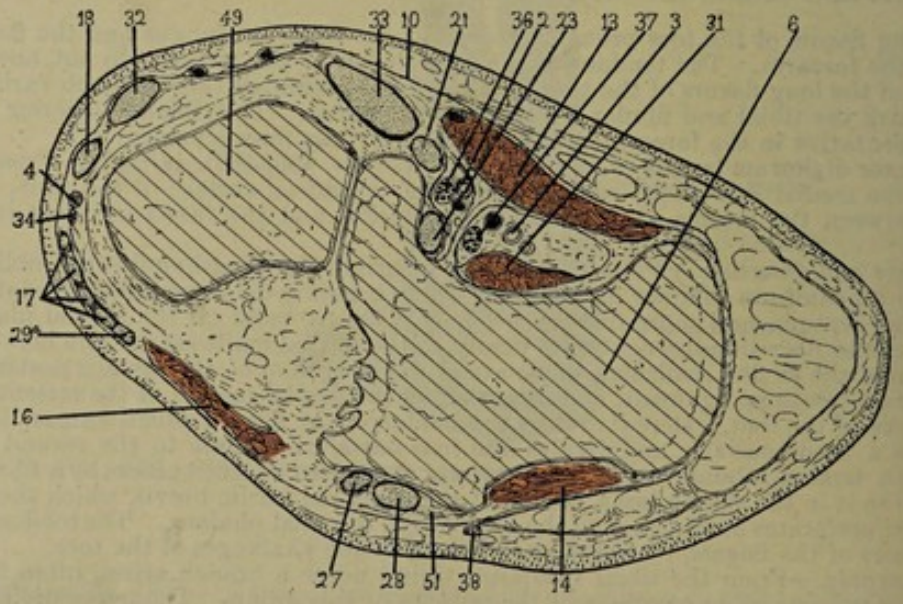
The flexor digitorum longus (fl. dig. tibialis NK) (figs. 480, 488).—*Origin.*—From the popliteal line, the medial side of the second quarter of the dorsal surface of the tibia, the fibrous septum between the muscle and the tibialis posterior, and the fascia covering its proximal extremity.

Structure and insertion.—From these areas of origin the fiber-bundles run obliquely to be inserted in a penniform manner on a tendon which begins in the proximal quarter of the muscle as a narrow septum, and more distally becomes a strong band on the medial margin. The insertion of the fiber-bundles continues nearly to the medial malleous. From here the tendon passes behind the medial malleolus, dorsolateral to the tendon of the tibialis posterior, crosses the posterior talotibial ligament, and passes along the medial margin of the sustentaculum tali into the sole of the foot. Here it crosses the tendon of the flexor hallucis longus, from which it receives a tendinous slip, and divides into four parts, which pass to the second to the fifth toes. Each tendon is bound to the phalanges of the toe to which it passes by a fibrous sheath. Superficial to it in the sheath lies a tendon of the flexor digitorum brevis, which the flexor longus tendon perforates as it passes to the base of the terminal phalanx. The tendon is connected, like those of the fingers, by vincula tendinum, to the phalanges of the toes.



Nerve-supply.—From the tibial (posterior tibial) nerve a branch arises, often in company with nerves to some other or others of the muscles of this group. The nerve divides into two branches, one of which passes to the lateral side of the muscle, where it extends along near the middle of the fiber-bundles of that side, while the other branch passes along near the middle of the fiber-bundles of the medial side of the muscle.

Relations.—In the proximal half of the leg it lies on the tibia, in the distal half on the po terior tibial muscle. Between it and the flexor hallucis lie the posterior tibial vessels an nerve. Near the ankle the plantar vessels and nerves cross the tendon of the muscle, separate from it by the deep layer of the laciniate (internal annular) ligament. In the upper two-thir of its extent it is covered by the triceps suræ. In the lower third of the leg it emerges medial the soleus and the tendon of Achilles. The relations of its tendon at the ankle have been d scribed above. The tendon lies beneath the origin of the abductor hallucis muscle and in th sole is covered by the flexor digitorum brevis, crosses the tendon of the long flexor and th oblique adductor of the big toe and the interosseous muscles, is joined by the quadratus plant (flexor accessorius), and gives origin to the lumbrical muscles.



The flexor hallucis longus (flexor digitorum fibularis NK) (figs. 480, 488).—*Origin.*—Fro the distal two-thirds of the posterior surface of the fibula, the septa between it and the tibial posterior and peroneal muscles, and the fascia above its proximal extremity.

Structure and insertion.—The fiber-bundles converge upon a tendon which begins in th second quarter of the muscle, within its substance, and emerges upon the posteromedial margi in its distal half. The insertion of the fiber-bundles continues to the end of the tibia. Fro here the tendon passes over the dorsal talotibial (tibioastragaloid) ligament, and through th groove on the posterior surface of the talus and the under surface of the sustentaculum tal where it lies on the fibular side of the tendon of the flexor digitorum longus. It then cross the deep surface of this tendon, to which it gives a slip, passes over the plantar surface of th medial head of the flexor hallucis brevis, and between the sesamoid bones of this muscle int the osteofibrous canal on the plantar surface of the big toe. It is inserted into the base the terminal phalanx of the big toe.

Nerve-supply.—The nerve arises from the tibial (posterior tibial) nerve, often in compan with the nerve to the flexor digitorum longus or the other muscles of the group. It runs alon

the deep surface of the muscle and sends twigs into the middle third of its constituent fiber-bundles. Sometimes two nerves are furnished to the muscle.

Relations.—It lies on the fibular side of the distal two-thirds of the leg. Proximally it diverges from the preceding muscle so as to disclose the tibialis posterior, which is more deeply situated. Between it and the tibialis posterior lie the peroneal vessels. Distally its tibial margin approaches the flexor digitorum longus, but between them lie the posterior tibial vessels and nerve. Lateral to it lie the peroneal muscles. It is covered in the leg by the soleus.

In the distal part of the leg its tendon lies medial to the tendon of Achilles. On entering the foo the tendon crosses beneath the abductor hallucis muscle and the lateral plantar vessels an nerve. The other relations of the tendon have been described above.

The tibialis posterior (or tibialis plantaris NK) (figs. 480, 490).—*Origin.*—From—(1) th lateral half of the distal margin of the popliteal line and the middle third of the posterior surfac of the tibia; (2) the medial side of the head and of that part of the body of the fibula next th interosseous membrane in the proximal two-thirds; (3) from the whole of the proximal and th lateral portion of the distal part of the posterior surface of the interosseous membrane; and (4 from the septa between its proximal portion and the long flexor muscles.

Structure.—From this extensive area of origin the fiber-bundles converge upon a tendon which is at first deep seated within the muscle-belly, but about the middle of the leg emerge on the medial margin of the muscle. The fibular portion of the muscle is much more extensiv than the tibial. The proximal fibers take a nearly perpendicular, the most distal (from th fibula) a nearly transverse, course. The insertion of fibers stops a little proximal to the media malleolus. The tendon then extends to the medial side of the tendon of the long flexor o the toes, passes through the groove on the back of the malleolus, across the medial talotibia (tibioastragaloid) ligament, and above the sustentaculum tali to the sole.

Insertion.—The tendon divides into two chief divisions, a deep and a superficial. (1) The deep portion becomes attached chiefly to the tubercle of the navicular bone, and usually in part also to the first cuneiform. (2) The superficial spreads out to be attached chiefly to th

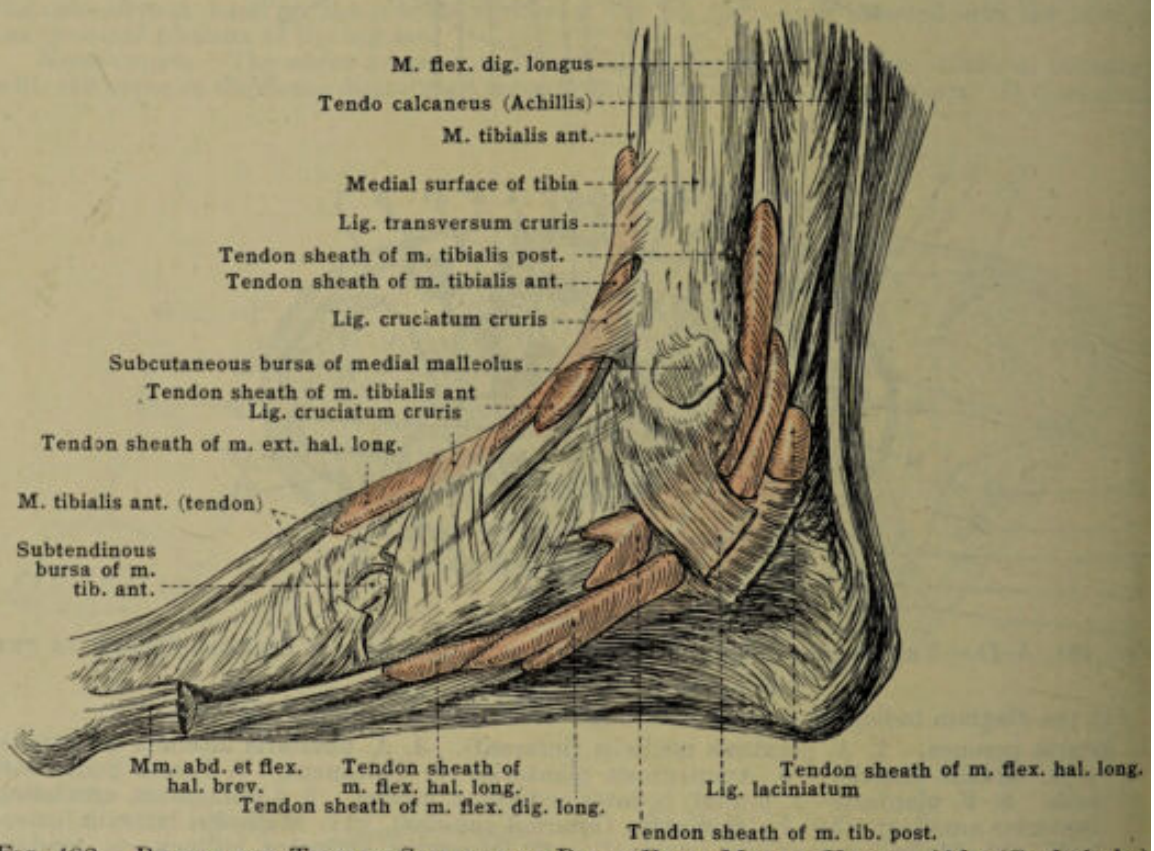

FIG. 482.—BURSÆ AND TENDON SHEATHS OF RIGHT FOOT, MEDIAL VIEW. (After Spalteholz.)

third cuneiform and the base of the fourth metatarsal, but also in part to the second cuneiform, to the capsule of the naviculocuneiform joint, to the sulcus of the cuboid, and usually also to the origin of the short flexor of the big toe and the base of the second metatarsal. Slips may, however, also be given to other structures. A sesamoid bone is usually found in the tendon either near the calcaneonavicular ligament or the navicular bone.

Nerve-supply.—The nerve arises from the tibial (posterior tibial) in company often with branches to the other muscles of the group. It enters the posterior surface of the muscle in its proximal third, and gives off one or two branches for the tibial fasciculus. The main trunk descends across the middle third of the fasciculi arising from the fibula.

Relations.—The muscle covers the posterior surface of the interosseous membrane, and extends distally over the posterior surface of the tibia beneath the flexor digitorum longus. It is covered proximally by the soleus, distally by the two long digital flexors. The posterior tibial and peroneal arteries and the tibial (posterior tibial) nerve run upon its posterior surface. The tendon in the sole is under cover of the origin of the plantar muscles of the big toe.

Action.—The tibialis posterior adducts the foot and slightly inverts it. The flexor digitorum longus flexes the terminal phalanx on the second and the second on the first, and at the height of its contraction the first on the metatarsals. It also rotates medially to some extent the ends of the fourth and fifth toes, and inverts the foot. The flexor hallucis longus flexes the second phalanx of the big toe on the first, and, less energetically, the first on the metatarsal. It also inverts the foot. All three muscles extend the foot. The flexor hallucis is the strongest of the three in this respect.

Variations.—The muscles of the group may be more or less fused with one another or be united by fasciculi. This is especially common between the two flexors of the toes. The

individual muscles vary in development. The flexor digitorum longus may be more or less divided into separate fasciculi for the individual toes. The slip from the flexor hallucis longus to the flexor digitorum longus varies greatly in extent, but usually passes mainly to the second and third toes, more rarely to the second, third, and fourth, and very rarely to the fifth. In most of the apes the tibial flexor (flexor digitorum) sends tendons to the second and fifth, the fibular flexor (flexor hallucis) to the first, third, and fourth toes. This condition is also sometimes found in man. A slip may pass from the tendon of the flexor digitorum to that of the flexor hallucis longus. There may be a sesamoid bone in the tendon of the flexor hallucis longus as it passes over the talus (astragalus) and calcaneus. The tibialis posterior may be doubled. Aberrant fasciculi may arise from various regions on the back of the leg and join any one of the three muscles of the group.

Abnormal muscles.—**The soleus accessorius.**—Arises by a tendon from the head of the fibula beneath the soleus. It is usually a slender muscle inserted into the medial surface of calcaneus. **The tibialis secundus** (tensor of capsule of ankle-joint).—A small muscle which arises from the tibia beneath the flexor digitorum and is inserted into the capsule of the ankle-joint. **The fibulocalcaneus medialis** (peroneocalcaneus internus of MacAlister, flexor accessorius long. dig. long., etc).—A fasciculus which arises from the lower third of the body of the fibula and gives rise to a tendon which passes beneath the laciniate ligament to the quadratus plantæ or to the tendon of the flexor digitorum longus.

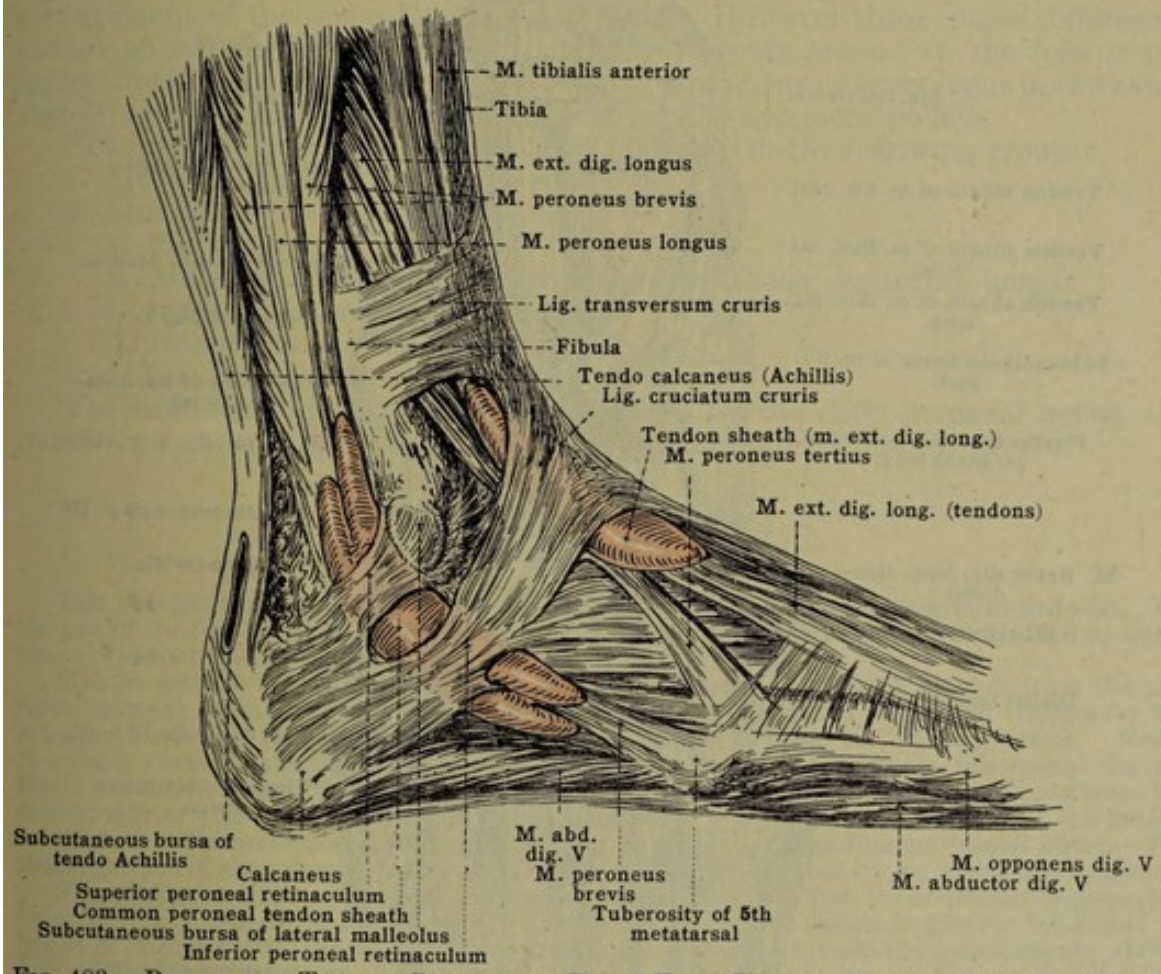

FIG. 483.—BURSÆ AND TENDON SHEATHS OF RIGHT FOOT, LATERAL VIEW. (After Spalteholz.)

BURSÆ

B. subtendinea m. tibialis posterioris.—A small bursa between the navicular fibrocartilage and the tendon.

SYNOVIAL TENDON-SHEATHS (FIGS. 482–484)

Vagina m. flexoris digitorum longi.—The tendon is surrounded by a synovial sheath from the back of the medial malleolus to where it crosses the tendon of the flexor hallucis longus below the navicular bone. It may communicate with the sheath of the tibialis anterior or with that of the flexor hallucis longus. **Vaginæ tendinum digitales.**—The tendons of the long flexor, together with those of the short flexor, are surrounded by synovial sheaths from the heads of the metatarsals to the insertions of the tendons. In structure these resemble those of the fingers. **Vagina m. flexoris hallucis longi.**—The tendon is surrounded by a sheath from the back of the medial malleolus to the crossing of the tendon of the flexor digitorum longus. Another sheath surrounds the tendon from the middle of the first metatarsal to its insertion. **Vagina m. tibialis posterioris.**—The tendon is surrounded by a synovial sheath extending from a region proximal to the medial malleolus to the insertion of the tendon.

Vagina tendinis m. tibialis anterioris.—This sheath surrounds the tendon from above the transverse crural ligament to the talonavicular joint. **Vagina tendinis m. extensoris**

hallucis longi.—The sheath begins above the proximal arm of the cruciate ligament, an ends near the tarsometatarsal joint beneath a band-like thickening of the dorsal fascia of th foot. **Vagina tendinum m. extensoris digitorum longi.**—This sheath surrounds the tendons o the long digital extensor and the peroneus tertius from above the cruciate ligament to th middle of the third cuneiform bone.

Vagina tendinum peroneorum communis.—There is a double sheath for the tendons o the peroneal muscles as they pass back of the lateral malleolus. From this region of union th sheath sends processes along each tendon proximally above the malleolus and distally over th lateral surface of the calcaneus. This process on the tendon of the peroneus longus ofte communicates with the following sheath. **Vagina tendinis m. peronæi longi plantaris.**— This sheath begins in the peroneal groove of the cuboid and ends near the medial border of th long plantar ligament.

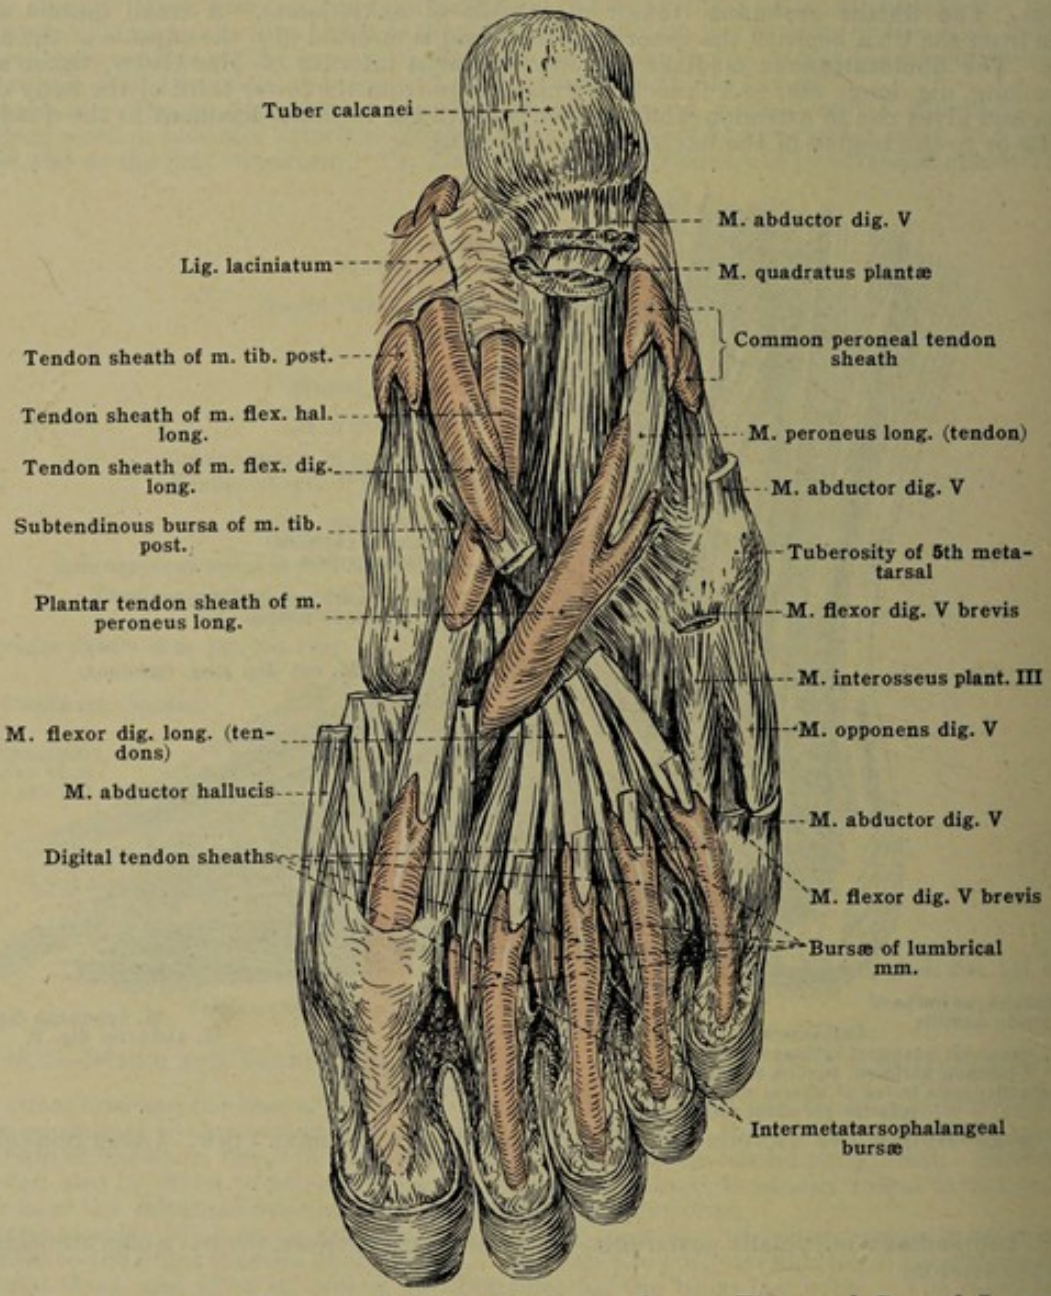

FIG. 484.—BURSÆ AND TENDON SHEATHS OF RIGHT SOLE. First and Second Layers o Muscles Removed. (After Spalteholz.)

Clinical aspects. Tenotomy and guides to the tendons.—The **tendo Achillis** should b divided about 3.7 cm. (1½ in.) above its insertion, its narrowest point, which is about on a leve with the medial malleolus. The knife should be introduced on the medial side and close to the tendon, so as to avoid the posterior tibial artery.

The **tibialis anterior** may be divided about 25 mm. (1 in.) above its insertion into the first cuneiform, a point which is below the level of its synovial sheath. The tendon has here the dorsalis pedis on its lateral side, but separated by the tendon of the extensor hallucis longus.

The **tibialis posterior.**—The usual rule for dividing this tendon is to take a point 5 cm. (2 in.) above the medial malleolus, and as accurately as possible midway between the anterior and medial borders of the leg. This point will give the medial margin of the tibia, in close apposition to which the tendon is lying, and is a point at which the tendon is rather farther from the artery than it is below, and is also above the commencement of its synovial sheath.

Owing to the risk of injury to the posterior tibial vessels, the difficulty of ensuring division of the tendons, the following open method is, nowadays, superior, being more certain, and admitting of division of ligaments, e. g., talonavicular and anterior part of deltoid (syndesmotomy of Parker), which are always contracted in advanced talipes equinovarus. A V-shaped flap with its apex over the first metatarsal bone and its two limbs starting, the lower below the margin of the plantar fascia on a line with the medial malleolus, the upper from a point over the head of the talus, is turned backward. The plantar fascia is divided, the tibialis anterior is found, near its insertion, under the upper lip of the wound, the tibialis posterior and the flexor digitorum longus in the lower, the former close to the navicular. If necessary, the calcaneo- and talonavicular and anterior part of the deltoid ligaments can be divided also.

Peronei.—The peronei longus and brevis may be divided 5 cm. (2 in.) above the lateral malleolus, so as to be above the level of their synovial sheath. The knife should be inserted very close to the bone, so as to pass between the fibula and the tendons. Division below the lateral malleolus by a small flap is easier.

D. MUSCULATURE OF THE FOOT

(Figs. 486–490)

The musculature of the foot in its general arrangement is similar to the arrangement of the musculature of the hand. However three major differences should be noted: (1) the extensor digitorum brevis present in the foot is not represented in the hand; (2) the quadratus plantae has no homologue in the hand; and (3) there is no homologue in the foot for the opponens pollicis.

The intrinsic muscles of the foot are taken up in the following groups:

1. Muscle of the dorsum of the foot.
2. Muscles of the sole of the foot.
   a. Flexor digitorum brevis
   b. Muscles attached to the tendons of the flexor digitorum longus
   c. Intrinsic muscles of the great toe
   d. Intrinsic muscles of the little toe
   e. The interosseus muscles

The extensor digitorum brevis is supplied by the deep peroneal nerve, the muscles on the sole of the foot by the medial and lateral plantar nerves.

FASCIÆ

(Fig. 481)

Tela subcutanea.—Over the dorsum of the foot the tela subcutanea contains little fat. On the sole of the foot and the plantar surface of the toes it contains much fat embedded in dense fibrous tissue.

Muscle fasciæ.—Over the **dorsum** of the foot a fascial membrane extends from the cruciate ligament mentioned above to the toes, where it is continued as fibrous sheaths for the extensor tendons. Laterally and medially it is continued into the plantar fascia. Where it overlies skeletal structures it becomes adherent to them. In the main this fascial sheet is thin. Over the base of the first metatarsal it is strengthened by a band which runs from the medial side of this bone over the extensor tendons of the big toe to the base of the second metatarsal. The extensor digitorum brevis is covered by an adherent fascial sheet. The dorsal surface of each dorsal interosseous muscle is likewise covered by an adherent membrane.

The **plantar surface** of the foot is invested by a fascia in which three distinct regions may be observed, a central, a lateral, and a medial. The central region is greatly thickened by bands of fibrous tissue, the **plantar aponeurosis,** which diverge toward the toes from the medial half of the tubercalcanei. These bands become distinct from one another as the toes are approached, and each finally terminates partly in the skin over the head of the corresponding metatarsal and in the digital sheath of the flexor tendons. Some of the fibers are continued into the transverse capitular ligaments, the others extend through near the metatarsophalangeal articulation to the dorsum of the foot. Broader, thicker bands go to the three middle toes than to the big and little toes. At the margins of this central area some fibers radiate into the fascia of the lateral and medial area, some extend laterally into the skin, and some sink into the intermuscular septa described below. Near the toes well-marked transverse bundles of fibers may be seen between the digital bands. The central area of the plantar fascia is not densely adherent to the skin.

The digital sheaths of the flexor tendons of the toes correspond essentially with those previously described (p. 469) for the fingers.

The **medial plantar fascia** is thin and adherent to the skin. It extends between the central plantar and the dorsal fascia over the intrinsic muscles of the big toe. The **lateral plantar fascia** is thick and well-developed near the heel, thin as the little toe is approached. A dense band, the **calcaneometatarsal ligament,** strengthens it between the calcaneus and the tuberosity of the fifth metatarsal.

At the junction of the medial with the central region of the plantar fascia the **medial intermuscular septum** sinks in to be attached to the first cuneiform, the navicular and the tendon of the posterior tibial. A similar **lateral intermuscular septum** sinks in between the lateral and central regions of the plantar fascia and is attached to the long plantar ligament, the tendon sheath of the peroneus longus and the base of the fifth metatarsal. The fascia of each of these

regions in considerable part extends into these septa instead of becoming continuous acros them.

The sole is thus divided into three great fascial compartments by these septa, a lateral, central, and a medial. In the lateral lie the intrinsic pedal muscles of the little toe; in th medial, the abductor and the flexor brevis of the big toe and the distal end of the tendon o the flexor hallucis longus. The central compartment is subdivided by transverse septa int several subcompartments. In the most superficial compartment lies the flexor digitorun brevis; in the second, the tendons of the flexor digitorum longus and its associated muscles the quadratus plantæ (flexor accessorius) and the lumbrical muscles; in the third, the adducto muscles of the big toe; and in the fourth, the interosseous muscles.

The first two subcompartments are most clearly marked in the region of the tarsus. Dis tally they become merged by the disappearance of the intervening transverse septum, an longtiudinally subdivided by fibrous septa which serve to make a complete sheath over eac digit for the flexor tendons. The sheath over the adductor muscle of the big toe is a thin mem brane continued laterally from the medial intermuscular septum. Where the two heads of th adductor muscle advance upon their tendon of insertion, the medial septum has no skeletal at tachment, so that the adductor subcompartment of the middle fascial compartment com municates freely with the medial compartment. Over the cuneiform bones the tendon o the flexor hallucis longus passes from the long flexor region of the middle compartment int the medial compartment. Here the medial intermuscular septum divides into two layers which form a sheath for the tendon as it passes to the plantar surface of the flexor halluci brevis.

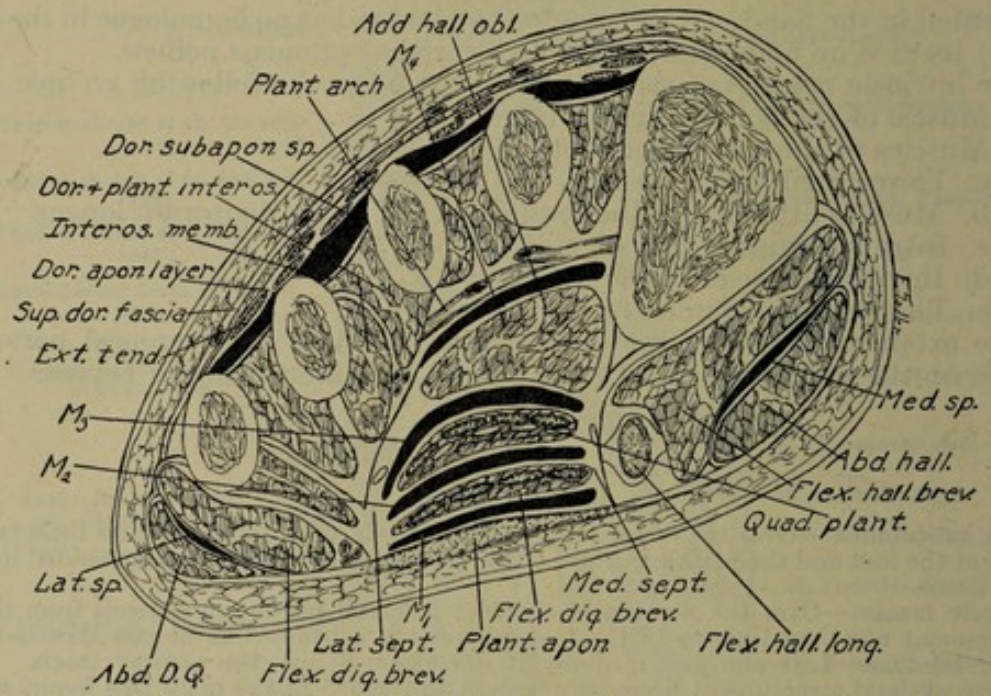

FIG. 485.—FASCIAL SPACES OF FOOT INJECTED. CROSS SECTION OF FOOT AT LEVEL OF THE MIDDLE OF THE FIFTH METATARSAL BONE (PROXIMAL SURFACE). (Dr. M. Grodinsky in Surgery, Gynecology & Obstetrics.)

FASCIAL SPACES OF THE FOOT

Areas between the various fascial layers in the foot represent potential spaces where pus may accumulate when the foot is infected. A study of these spaces and their relationship to the spread of infectious processes was recently completed by Grodinsky (fig. 485). Grodinsky describes four potential median spaces on the plantar side of the foot which he designates as M_1, M_2, M_3 and M_4. M_1 represents the space between the central part of the plantar aponeurosis superficially and the flexor digitorum brevis muscle deeply. M_2 is described as lying between the flexor digitorum brevis and the quadratus plantae. Below the quadratus plantae the third space M_3 is found whose floor consists of the tarsal bones and ligaments posteriorly and more anteriorly the tendon of the peroneus longus the fascial coverings of the adductor hallucis obliquus, and the plantar and dorsal interossei muscles. M_4 is the space deep to the oblique head of the adductor hallucis muscle. In addition a lateral space deep to the abductor digiti quinti, a medial space deep to the abductor hallucis and spaces along the lumbrical muscles are demonstrated by the author. On the dorsum of the foot two spaces are described, a subcutaneous space above the dorsal aponeurosis and a subaponeurotic space between the aponeurosis and the fascia covering the dorsal interosseous muscles. In the leg fascial spaces exist between the superficial and deep muscle layers of the calf, and deep to the fascial sheaths of the peroneal muscles.

MUSCLES

1. MUSCLE OF THE DORSUM OF THE FOOT

The **extensor digitorum brevis** (fig. 486) is broad and thin, lies beneath the tendons of the long extensor muscle on the tarsus, lateral to the navicular and

the head of the talus, and sends tendons to the four more medial toes. It arises from the calcaneus. Its nerve-supply is from the deep peroneal.

Origin.—From the lateral and superior surfaces of the body of the calcaneus and from the apex of the cruciate ligament.

Structure and insertion.—The fiber-bundles arise directly from the ligament, and by short tendinous bands from the bone. As they extend distally they become grouped into four bellies. Those of the most medial and largest belly, the **extensor hallucis brevis**, become inserted in a bipenniform manner on the lateral and medial margins of a tendon which begins opposite the cuboid. The insertion of fiber-bundles continues to the base of the first metatarsal. The insertion of the fiber-bundles of the other bellies, which are seldom so distinctly isolated as the first, takes place in a penniform manner into their respective tendons, but the exact mode of attachment is subject to great individual variations. The tendon of the first digit is inserted mainly into the middle of the back of the base of the first phalanx, but it is often also united to the tendon of the long extensor. The other three tendons are fused with the lateral margins

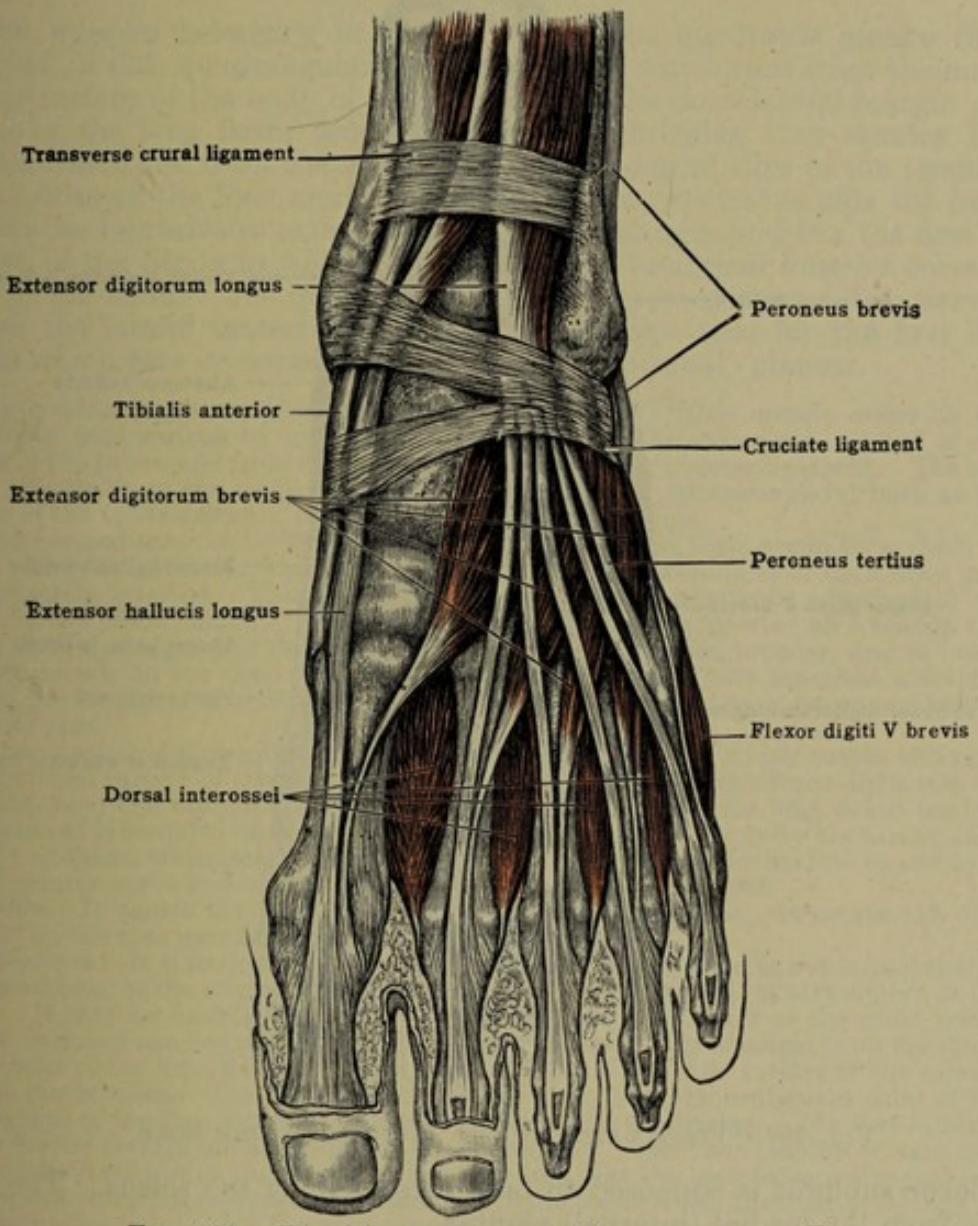

FIG. 486.—THE MUSCLES OF THE DORSUM OF THE FOOT.

of the corresponding tendons of the long extensor near the bases of the three middle digits. They also usually give slips to the bases of the first phalanges of the corresponding toes.

Nerve-supply.—The deep peroneal (anterior tibial) nerve, which, accompanied by the anterior tibial artery, passes beneath the medial belly of the muscle, gives off a branch which passes transversely across the middle of the deep surface of the muscle and sends twigs into it.

Relations.—It lies on the lateral side of the tarsus, beneath the long extensor tendons of the toes. The relations of its tendons have been described above.

Action.—It aids the long extensors in extending the first phalanx of each of the four medial digits. It has but a limited action on the second and third phalanges. It serves also to pull the ends of the toes to which its tendons go toward the little toe.

Variations.—The muscle shows great variation in development. Rarely the whole muscle, more frequently one or more of its digital divisions, may be missing. On the other hand, it may be more highly developed than usual. Accessory fasciculi vary greatly in origin and termina-

tion. Most frequently their tendons go to a metacarpophalangeal articulation or to the second or the fifth toe.

2. Muscles of the Sole of the Foot

a. Flexor Digitorum Brevis (fig. 487)

The **flexor digitorum brevis,** the most superficially placed of the plantar muscles, lies in the midplantar region beneath the plantar fascia and over the tendons of the long flexor of the toes and its associated muscles. It arises from the calcaneus, and has a flat, elongated belly, which toward the middle of the sole is prolonged into four processes, each of which has a special tendon that is inserted into the second phalanx of one of the four lateral toes. The tendons of the muscle correspond to those of the flexor sublimis in the palm. The belly

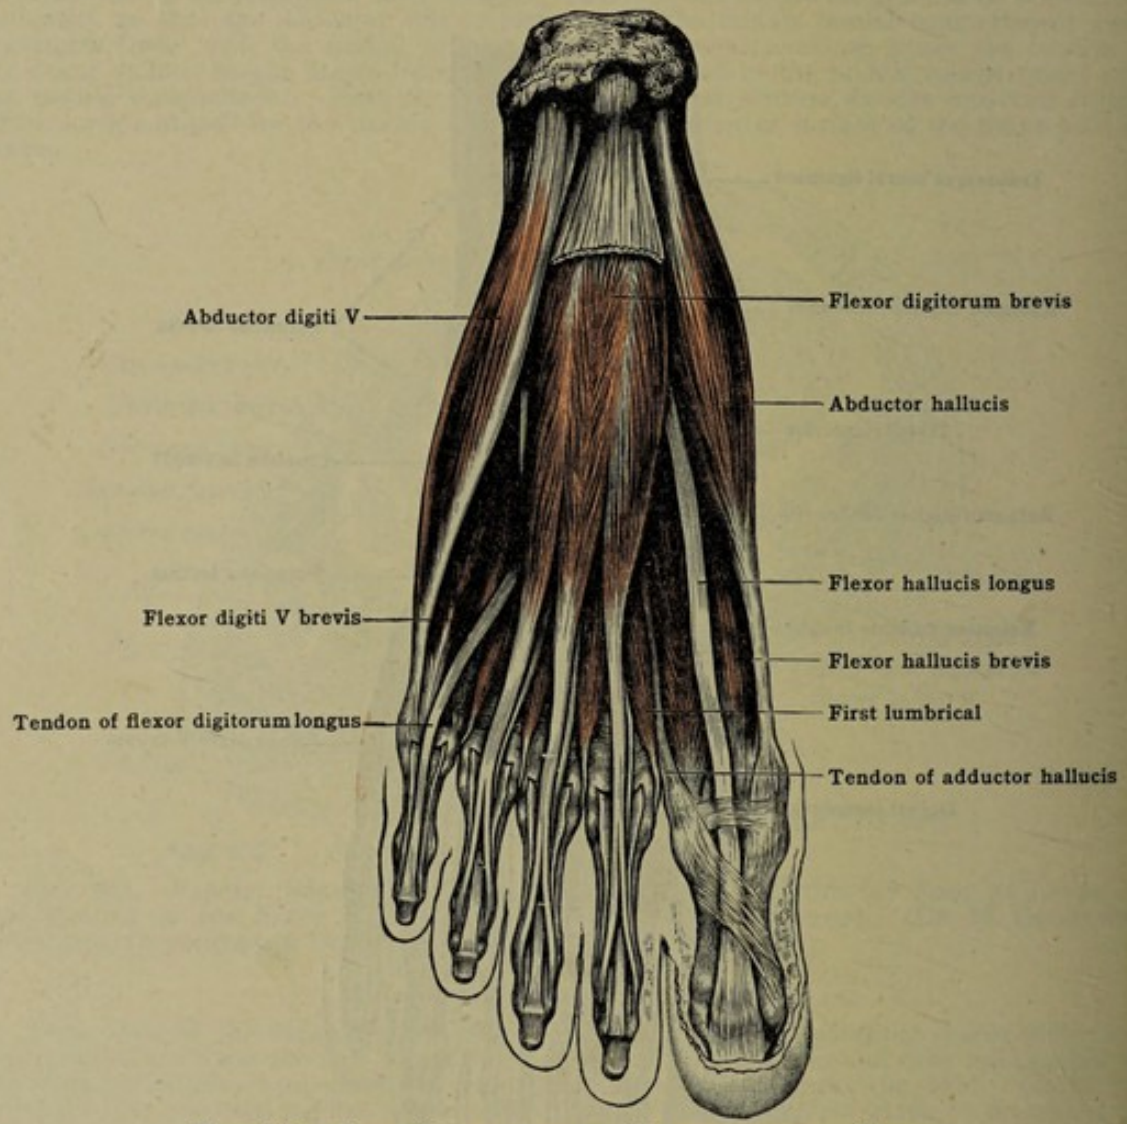

Fig. 487.—First Layer of the Muscles of the Sole.

of the flexor sublimis is supposed to be represented by the soleus. The nerve supply is from the medial (internal) plantar.

Origin.—From (1) the medial process of the tuber calcanei; (2) the posterior third of the plantar aponeurosis; and (3) the medial and lateral intermuscular septa.

Structure.—The constituent fiber-bundles pass distally in a compact mass. The tendons of insertion begin within the muscle substance, and as the fiber-bundles become inserted on them, the separate fasciculi become more and more distinct. The fasciculi for the second and third toes are larger and arise more superficially than those for the fourth and fifth toes. The fasciculus for the fifth toe is often very small, and its tendon takes an oblique course to the insertion.

Insertion.—The tendons of the short flexor pass superficial to those of the long flexor into the osteofibrous canals on the flexor surface of the digits. Upon the first phalanx of each toe the tendon of the short flexor divides and forms an opening (chiasma tendinis) through which the tendon of the long flexor passes, while the tendon of the short flexor becomes attached to the base of the second phalanx. The arrangement is essentially like that described at length for the flexors of the fingers (p. 466).

Nerve-supply.—From the medial plantar nerve by a branch which enters the middle third of the deep surface near the medial margin of the muscle.

Action.—It is a strong flexor of the second row of phalanges.

Relations.—The short flexor is separated from the abductors of the big toe and little toe by strong intermuscular septa (p. 559), and from the long flexor tendons and the quadratus plantæ (flexor accessorius) by a transverse septum in which the lateral plantar vessels and nerve cross the foot. In its distal two-thirds it is separated from the plantar fascia by loose tissue.

Variations.—The muscle shows a tendency toward reduction, one or more of its fasciculi being frequently absent, and occasionally the whole muscle. The fasciculus for the fifth toe is absent in about 20 per cent. of bodies (Le Double). When a fasciculus is absent, its tendon is usually replaced by an accessory tendon from the long flexor. The muscle or its tendons may be more or less fused to the tendons of the flexor digitorum longus.

b. Muscles Attached to the Tendons of the Flexor Digitorum Longus (fig. 488)

The muscles belonging in this group are the **quadratus plantæ** (flexor accessorius), a flat, quadrangular, bicipital muscle which runs from the medial and plantar surface of the body of the calcaneus to the dorsolateral margin and deep surface of the long flexor tendon; and the **lumbricales**, four slender bipinnate muscles which run from the medial sides of the digital slips of the tendon to the medial sides of the four more lateral toes. The quadratus aids the long flexor muscle; the lumbricales extend the last two phalanges and flex the first phalanx of each of the digits to which they pass. The lumbrical muscles correspond to those of the hand. The quadratus is not there represented. The nerve-supply is from the lateral (external) plantar nerve except that for the first lumbrical muscle which gets its supply from the medial (internal) plantar.

The quadratus plantæ (flexor accessorius) (fig. 488).—This muscle *arises* by two heads. The *lateral head* springs by an elongated tendon from the calcaneus in front of the lateral process of the tuber, and from the lateral margin of the long plantar ligament. The *medial head* arises directly from the medial surface of the body of the calcaneus as far back as the medial process of the tuber calcanei, and from neighboring ligaments.

Structure and insertion.—The two heads are separated at their origin by a short triangular space. They soon fuse to form a single belly, but the fiber-bundles of each head in the main are separately inserted. Those from the lateral head diverge to be attached to the lateral margin of the flexor tendon. Those from the medial head are inserted on a tendon that begins on the medial margin and deep surface of this head, becomes broader, and is inserted as a flat aponeurosis on the deep surface of the flexor tendon. There are great individual variations in the structure of this muscle. The fibers of either part may be inserted with those of the other part.

Nerve-supply.—From a branch of the lateral plantar nerve which passes obliquely across the superficial surface of the muscle parallel with the tendon of the flexor digitorum longus.

Relations.—The muscle lies in a fascial compartment with the long flexor tendons. This compartment is bounded on each side by intermuscular septa, deeply by the tarsus, and plantarward by a septum which intervenes between it and the flexor digitorum brevis, and in which the lateral plantar nerve and vessels cross to the lateral side of the foot.

Action.—It assists the long flexor tendon in flexing the toes. It makes the direction of traction on the toes parallel with the long axis of the foot.

Variations.—It is frequently reduced in size. The lateral head is not infrequently missing, the medial head or the whole muscle much more rarely. The mode of attachment to the tendon varies. It may be inserted in part or wholly into the long flexor of the great toe. It may receive, in about one body in twenty (Wood), an accessory slip of origin from the fibula, one of the muscles of the leg, the fascia of the leg or foot, or the medial surface of the calcaneus, etc.

The lumbricales.—The three lateral muscles *arise* from the contiguous sides of the digital tendon-slips of the flexor digitorum longus in the angles of division. The first lumbrical arises on the medial margin of the tendon to the second toe. The fiber-bundles of each muscle converge on both sides of a tendon which becomes free near the metatarsophalangeal joint and is *attached* to the medial side of the first phalanx of the toe to which the muscle belongs. A tendinous expansion is sent into the aponeurosis of the extensor muscle.

Nerve-supply.—The three lateral lumbrical muscles are most frequently supplied by branches of the deep ramus of the lateral plantar nerve, the medial by the first common plantar digital branch of the medial plantar nerve. The latter nerve may supply the two more medial muscles or the more medial muscles may receive a double supply. The branches of the lateral plantar nerve enter the deep surfaces of the muscles in the middle third. The branches of the medial plantar enter the medial borders of the muscles near the junction of the proximal and middle thirds.

Relations.—The lumbrical muscles lie in a plane with the long flexor tendons deeper than the flexor brevis tendons and superficial to the adductor hallucis. The deep branches of the lateral plantar nerve and vessels pass across their deep surface; superficial branches of both plantar nerves across the superficial surface.

Action.—To extend the last two phalanges of the toes and to flex the first.

Variations.—One or more of the muscles may be absent. Sometimes a muscle is doubled. This is more frequently the case with the third and fourth muscles. The first may arise wholly from the tendon of the posterior tibial muscle or from this and the long flexor of the big toe.

The third lumbrical may arise from the flexor digitorum brevis; an anomalous insertion is shown in fig. 488. The second and fourth lumbricals may be inserted into the tendons of the flexor digitorum brevis.

c. Intrinsic Muscles of the Great Toe (figs. 487–489)

These muscles are the abductor, flexor brevis, and adductor. Of the three muscles, the first two lie in the medial fascial compartment, while the last lies in the middle compartment covered by the flexor digitorum longus and its associated muscles.

The **abductor hallucis** (fig. 487), the largest and most superficial of these muscles, lies on the border of the sole medial to the short flexor muscle. It passes from the calcaneus across the tendons of the long flexor muscles, and is inserted

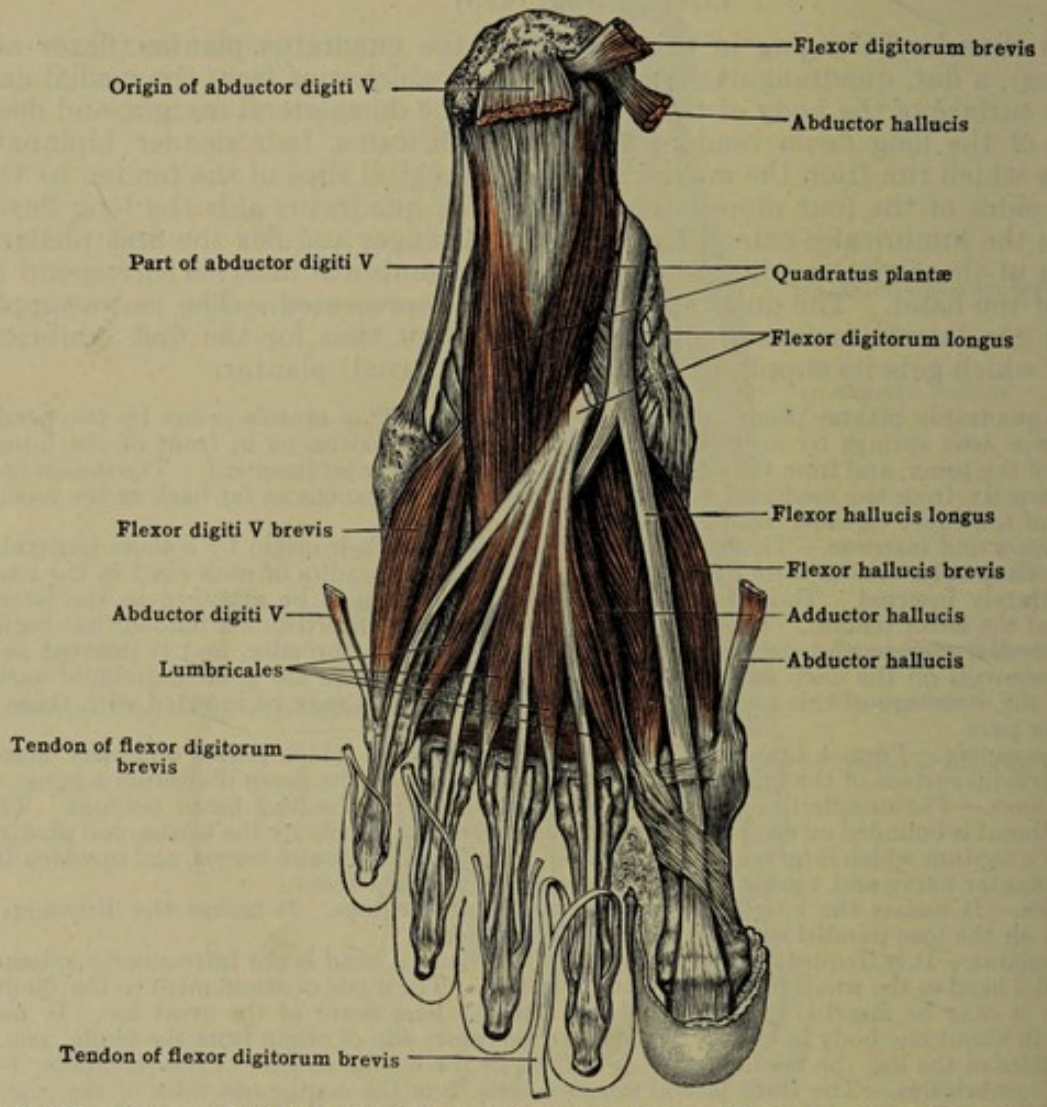

Fig. 488.—Second Layer of the Muscles of the Sole. (Shows an anomalous insertion of the third lumbrical.)

into the medial side of the base of the first phalanx of the great toe and into the medial side of the long extensor tendon. The **flexor hallucis brevis** (fig. 489) is a bicaudal muscle which arises in the region of the cuneiform bones and is inserted on each side of the base of the first phalanx. Its tendons are fused with those of the abductor and the oblique head of the adductor. The **adductor hallucis** (fig. 489) is composed of two distinct heads, an oblique and a transverse. The oblique head extends from the long plantar ligament to the lateral side of the base of the first phalanx of the great toe. Its tendon of insertion is joined by the transverse head, which arises from the capsules of the third to the fifth metatarsophalangeal joints.

These muscles perform not only the functions indicated by their names, but also extend the second phalanx. They correspond fairly well with those of the thumb. The opponens is not normally present in the foot. The nerve supply for

the adductor is from the lateral (external) plantar nerve; that for the other muscles is from the medial (internal) plantar.

The abductor hallucis (fig. 487).—*Origin.*—From (1) the medial process of the tuber calcanei; (2) the deep surface of the neighboring plantar fascia; (3) the laciniate (internal annular) ligament; (4) the septum between the muscle and the flexor digitorum brevis; and (5) a fibrous arch which extends on the deep surface of the muscle over the plantar vessels and nerves and the long flexor tendons from the calcaneus to the navicular bone.

Structure.—From the medial process of the tuber calcanei a tendinous band passes to the deep, lateral side of the muscle. Numerous tendinous bands arise from the other areas of origin. The fiber-bundles arise from these tendons and directly from the fibrous arch. They are attached in a penniform manner to numerous tendinous slips which extend far up in the muscle. These slips become gradually fused into a tendon which appears on the superficial plantar aspect of the muscle. Opposite the distal half of the first metatarsal bone the tendon leaves the belly of the muscle and becomes closely bound to the medial belly of the flexor hallucis brevis.

Insertion.—In conjunction with the tendon of the medial belly of the flexor brevis into the base of the first phalanx. It usually sends an expansion to the extensor tendon.

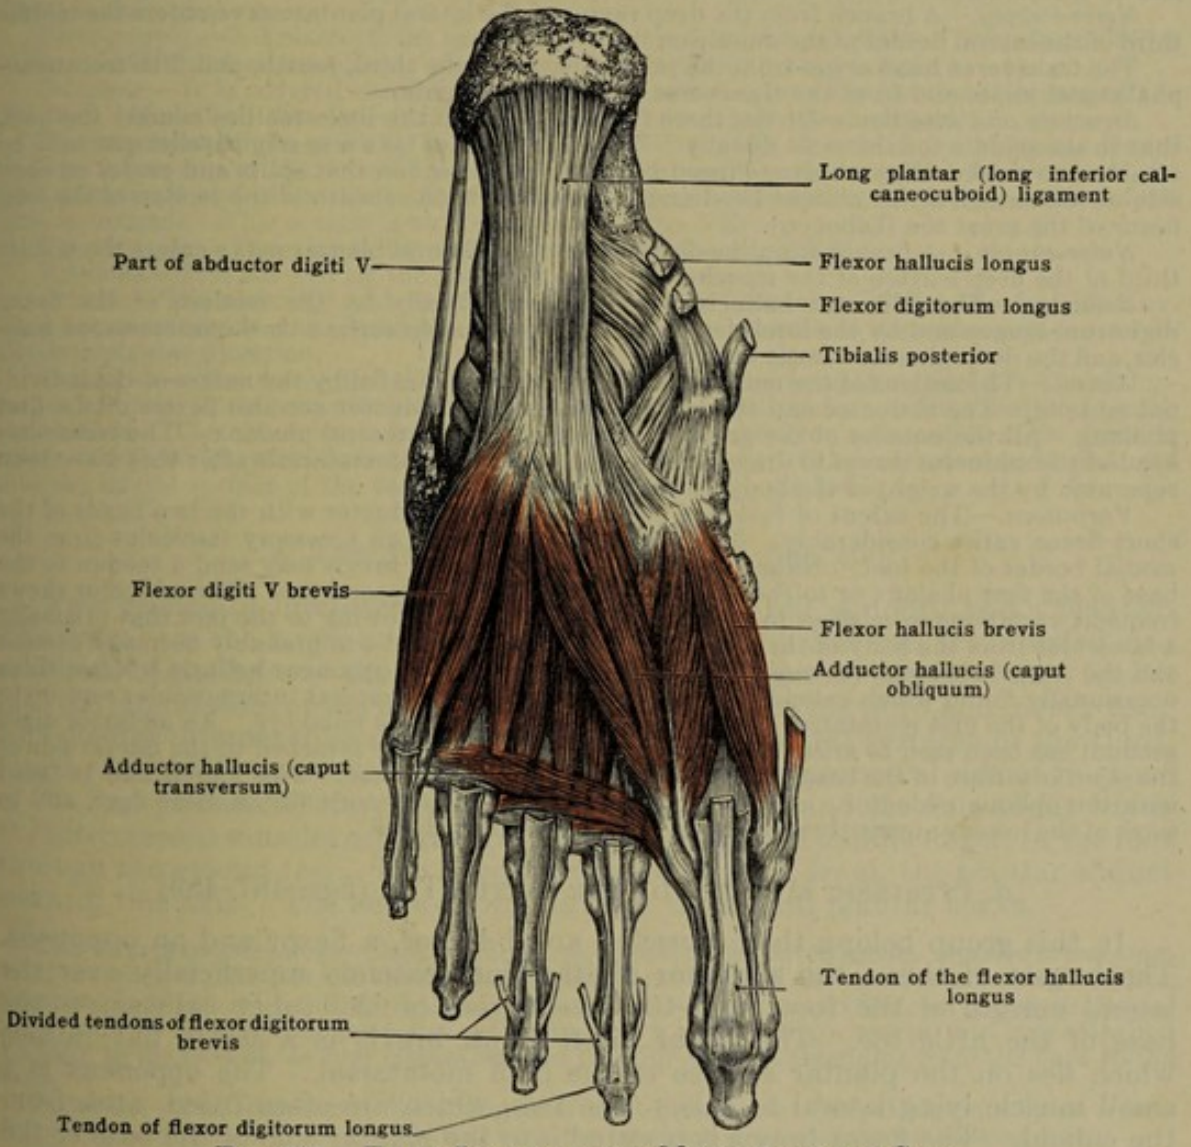

FIG. 489.—THIRD LAYER OF THE MUSCLES OF THE SOLE.

Nerve-supply.—A branch from the medial plantar nerve usually enters near the middle of the lateral border of the muscle.

Relations.—It is covered by the plantar fascia and is separated from the muscles of the medial compartment by the medial intermuscular septum. It crosses the tendons of the tibialis anterior, tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles and the plantar vessels and nerves.

The flexor hallucis brevis (fig. 489).—*Origin.*—From a tendon attached to the first (internal), second and third cuneiform bones. The more lateral of its fibers are continued into the plantar calcaneocuboid ligament and the more medial into the expansion of the tendon of the posterior tibial muscle.

Structure and insertion.—The fiber-bundles give rise to two bellies, a medial and a lateral. Those of the medial belly pass obliquely medially to be inserted into the tendon of the abductor hallucis, and by a short tendon fused with this into the medial side of the plantar surface of the base of the first phalanx. This tendon contains a sesamoid bone. Those of the lateral converge upon the tendon of the oblique head of the adductor, and the two muscles are inserted by a

common tendon, which contains a sesamoid bone, into the lateral side of the plantar surface of the base of the first phalanx.

Nerve-supply.—A branch from the medial plantar (or first plantar digital) nerve divides over the plantar surface of the muscle and gives a twig to each belly near the middle third. Rarely the lateral belly may receive a branch from the lateral plantar nerve.

Relations.—The abductor hallucis covers it medially; the tendon of the flexor hallucis longus passes between its two heads. Branches of the medial plantar vessels and nerve lie on its superficial surface.

The adductor hallucis (fig. 489).—**The oblique head.**—*Origin.*—From (1) the tuberosity of the cuboid and the sheath over the tendon of the peroneus longus muscle; (2) the plantar calcaneocuboid ligament; (3) the third cuneiform; (4) the bases of the second and third metatarsals and (5) a fibrous arch which extends from the plantar calcaneocuboid ligament to the interosseous fascia.

Structure and insertion.—From short tendon-slips the fiber-bundles pass forward to form a thick, fusiform belly which is attached in a bipenniform manner to a flat tendon. The tendon begins about the middle of the plantar surface of the muscle and is inserted in common with that of the flexor brevis into the lateral side of the plantar surface of the base of the first phalanx, and by a slip into the aponeurosis of the long extensor muscle on the back of the big toe.

Nerve-supply.—A branch from the deep ramus of the lateral plantar nerve enters the middle third of the lateral border of the muscle on its deep surface.

The **transverse head** *arises* from the joint-capsules of the third, fourth, and fifth metatarsophalangeal joints and from the transverse capitular ligaments.

Structure and insertion.—Of the three fasciculi, that to the little toe lies nearest the heel, that to the middle toe the most distally. The fiber-bundles take a nearly parallel course to be attached to tendon-slips which are fused into a common tendon that splits and passes on each side of the tendon of the oblique head and is inserted into the sheath of the tendon of the long flexor of the great toe (Leboucq).

Nerve-supply.—A branch from the deep ramus of the lateral plantar nerve enters the middle third of the deep surface of the muscle.

Relations.—The adductor hallucis is crossed superficially by the tendons of the flexor digitorum longus and by the lumbrical muscles. On its deep surface lie the interosseous muscles, and the deep plantar vessels and nerves.

Action.—The actions of the muscles of this group are indicated by the names of the individual muscles. The abductor and the oblique head of the adductor are also flexors of the first phalanx. All the muscles of the group aid in extending the second phalanx. The transverse head of the adductor serves to draw together the heads of the metatarsals after they have been separated by the weight of the body during the tread.

Variations.—The extent of fusion of the abductor and adductor with the two heads of the short flexor varies considerably. The abductor may receive an accessory fasciculus from the medial border of the foot. Either the adductor or the flexor brevis may send a tendon to the base of the first phalanx or to the short flexor tendon of the second toe. The adductor shows frequent variations in relation to its metatarsal attachments, owing to the fact that originally a fasciculus from the body of the second (and third) metatarsal was probably normally present and the transverse head was more developed (Leboucq). The **opponens hallucis** is a fasciculus occasionally found which extends from the short flexor or the medial intermuscular septum to the body of the first metatarsal. This muscle is normal in some monkeys. An **adductor digiti secundi** has been seen to arise from various sources and become attached to the lateral side of the plantar surface of the base of the first phalanx of the second toe. This muscle may be fused with the oblique adductor. A corresponding muscle is found normally in some apes, and in some of the lower animals there is a special adductor for each toe.

d. Intrinsic Muscles of the Little Toe (figs. 487–489)

In this group belong three muscles, an abductor, a flexor and an opponens. The largest of these, the **abductor digiti quinti,** extends superficially over the lateral margin of the foot from the lateral side of the tuber calcanei to the base of the little toe. The **flexor digiti quinti brevis** is a small, flat muscle which lies on the plantar surface of the fifth metatarsal. The **opponens** is a small muscle lying lateral to this. The two, which are often fused, arise from the cuboid. The flexor brevis is inserted into the plantar side of the base of the first phalanx of the little toe. The opponens is inserted into the lateral surface of the metatarsal. The abductor corresponds to the abductor of the little finger. The opponens and flexor brevis probably correspond to the deep part of the opponens of the little finger. The nerve supply is from the lateral plantar nerve.

The abductor digiti quinti (fig. 487).—*Origin.*—From (1) the lateral process of the tuber calcanei and the lateral and plantar surface of the body of the bone in front of this; (2) the lateral intermuscular septum; (3) the deep surface of the lateral plantar fascia, including the fibrous band extending from the calcaneus to the lateral side of the base of the fifth metatarsal bone.

Structure.—The fiber-bundles run obliquely to a flat tendon of insertion. This begins within the muscle near the calcaneocuboid joint, soon emerges on the medial side of the deep surface, and becomes free near the metatarsophalangeal joint. Considerable individual variation in structure is found.

Insertion.—On the lateral surface of the first phalanx of the little toe and the metatarsophalangeal capsule. Often a slip is sent to the extensor tendon. While usually the muscle

glides over the tuberosity of the fifth metatarsal, it frequently sends a second fasciculus to be attached to this bone (**abductor ossis metatarsi quinti**). A special fasciculus from the tuberosity often constitutes the lateral margin of the muscle.

Nerve-supply.—The nerve arises from the lateral plantar. It may be distributed either near the deep or the superficial surface of the muscle. The former appears to be the case when the muscle is slightly developed. The chief intramuscular branches then extend across the middle third of the constituent fiber-bundles near the deep surface. In case the calcaneometatarsal bundles are well developed, the nerve enters the proximal margin of the muscle and its chief branches extend across the middle third of the more superficial muscle-bundles, finally terminating in the distal margin of the muscle.

Relations.—It is ensheathed by the plantar fascia and the lateral intermuscular septum. It lies superficial to the quadratus plantæ (flexor accessorius), the opponens and flexor brevis of the little toe, the long plantar ligament, and the tendon of the peroneus longus muscle.

The flexor digiti quinti brevis (fig. 489).—*Origin.*—From the sheath of the peroneus longus, the tuberosity of the cuboid, and (3) the base of the fifth metatarsal.

Structure and insertion.—The fiber-bundles take a nearly parallel course, although the belly is slightly fusiform. They are attached by short tendinous bands to the base of the first phalanx of the little toe, the capsule of the corresponding joint, and the aponeurosis on the dorsal surface of the toe.

Nerve-supply.—A branch of the superficial ramus of the lateral plantar nerve sends twigs to the middle third of the plantar surface of this and the following muscle.

Relations.—It is covered medially by the plantar fascia, laterally by the abductor of the fifth toe. Medially it lies superficial to the third plantar interosseous muscle.

The oppenens digiti quinti.—This muscle *arises* from the sheath of the peroneus longus and the tuberosity of the cuboid by a slender tendon which passes over the tuberosity of the fifth metatarsal and gives rise to fiber-bundles which are *inserted* on the lateral surface of the fifth metatarsal. This muscle is not recognized by the NK.

Nerve-supply.—From branches of the nerve to the flexor brevis.

Relations.—It is covered by the abductor of the fifth toe.

Actions.—The abductor and flexor brevis abduct the little toe and flex the first phalanx. They act as extensors of the second phalanx. The opponens serves to draw the little toe medially in a plantar direction.

Variations.—The muscles of this group may be more or less completely fused. The abductor, in addition to the variations mentioned above, may send tendons to the third and fourth metatarsals. The opponens is frequently missing. The **abductor accessorius digiti quinti** is a rare muscle which arises from the lateral process of the tuber of the calcaneus and is inserted into the lateral surface of the base of the first phalanx of the little toe.

e. The Interosseous Muscles (fig. 490)

Two groups of **interosseous muscles** are recognized, a dorsal and a plantar. The **dorsal** are the larger and fill the interspaces. The first two are inserted into each side of the base of the first phalanx of the second toe; the third and fourth into the lateral sides of the bases of the first phalanges of the third and fourth toes. The **plantar interossei** lie on the medial side of the ventral surfaces of the third, fourth, and fifth metatarsals, and are inserted each on the medial side of the base of the first phalanx of the corresponding toe. In the hand the axis about which the interosseous muscles are arranged passes through the middle finger, in the foot through the second toe. The dorsal interossei abduct from, the plantar adduct toward, this axis. The nerve-supply is from the lateral plantar nerve.

The interossei dorsales.—Each of the three lateral dorsal interosseous muscles *arises* from —(1) the sides of the shaft and the plantar surface of the bases of the metatarsal bones bounding the space in which it lies; (2) from the fascia covering it dorsally; and (3) from fibrous prolongations from the long plantar ligament. The first has a similar origin except that it is attached medially to the base of the first metatarsal and to a fibrous arch extending from the base to the head.

Structure.—The component fiber-bundles of each muscle are inserted bipinnately on a tendon which begins high in the muscle and becomes free near the metatarsophalangeal joint.

Insertion.—The first and second on each side of the base of the first phalanx of the second toe. The third and fourth on the lateral side of the bases of the proximal phalanges of the third and fourth toes. Each tendon is adherent to the capsule of the neighboring joint. They send no well marked processes to the extensor tendons, as do those of the hand.

The interossei plantares.—Each plantar interosseus *arises.*—(1) from the proximal third of the medial plantar surface of the shaft and from the base of the metatarsal on which it lies; and (2) from expansions of the long plantar ligament.

Structure and insertion.—The obliquely placed fiber-bundles are longer than those of the dorsal interossei, and are inserted in a tendon which lies near the medial border of the muscle, becomes free near the metatarsophalangeal joint, and is inserted into a tubercle on the medial side of the base of the first phalanx of the digit to which it goes.

Nerve-supply.—From the deep branch of the lateral plantar nerve several rami are given off for the interossei. The nerve of each muscle enters the plantar surface in the proximal third. The interosseous muscles of the fourth interspace, however, are usually supplied by a branch from the superficial ramus of the lateral plantar nerve.

Relations.—The interosseous muscles are covered on the plantar surface by a thin fascia on which the deep branches of the lateral plantar nerve and vessels run. The first dorsal inter-

osseous adjoins medially the flexor hallucis brevis and laterally on the plantar surface of the second metatarsal, adjoins the second dorsal interosseous. Dorsal and plantar interossei then alternate across the plantar surface of the foot until the fifth metatarsal is reached. Here the third plantar interosseous adjoins the flexor brevis of the little toe.

Action.—The chief axis of the foot may be taken to extend through the second toe. The dorsal interosseous muscles abduct—pull the digits to which they are attached away from this axis; the plantar interosseous muscles adduct—pull the digits toward the axis. The interossei all flex the first row of phalanges.

Variations.—The second dorsal interosseous may have no attachment to the third metatarsal.

Bursæ

B. intermetatarsophalangeæ.—Four bursæ between the neighboring sides of the heads of the metatarsal bones and dorsal to the transverse capitular ligaments. **B. mm. lumbricalium.**

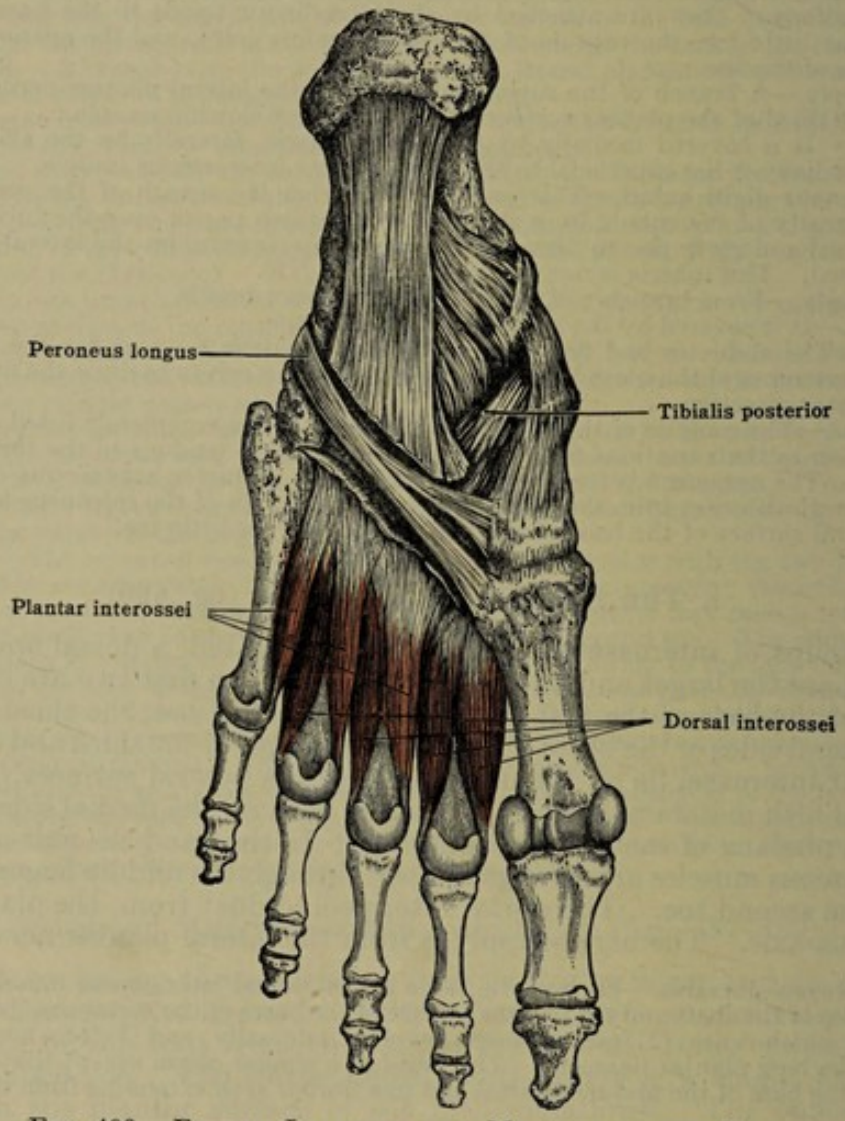

Fig. 490.—Fourth Layer of the Muscles of the Sole.

Between the ends of the tendons of the lumbrical muscles and the transverse capitular ligaments. The three medial are more constant than the lateral.

For other bursæ in the foot, see pp. 549, 551 and 557.

MUSCLES GROUPED ACCORDING TO FUNCTION

The exact functions of many of the muscles have not yet been decisively determined. Anatomical studies, the construction of mechanical models, the electrical stimulation of the musculature, and observation of the muscular activities of normal individuals and of individuals in whom given muscles or sets of muscles are absent or paralysed, have all proved valuable methods of investigation, but each method has its drawbacks, and knowledge of the part actually played by individual muscles in the normal activities of the body is as yet merely approximate. Owing to the influence of gravity, the relations of other muscles to the skeleton, and similar factors, a given muscle may perform functions which would

not be deduced from a simple study of the relations of the muscle to the skeleton. Thus through the action of gravity the iliacus flexes not only the hip, but also the knee, and the hamstring muscles flex the hip while flexing the knee. The functions ascribed to various muscles in the following table, although an attempt has been made to base them upon the more recent work on the action of the muscles, must be taken to be merely approximately correct.

The *axes* about which a bone moves at a given joint are frequently complex. For practical purposes, however, it is usually possible to determine an approximate axis about which any given movement takes place. From this standpoint diarthrodial joints may be divided into three groups, uniaxial joints, biaxial joints and multiaxial joints.

In the *uniaxial joints* movements of note may be made merely about one approximated axis. If a muscle acts on such a joint it exerts an effective pull either in one direction about this axis or in the opposite direction. Most joints of this sort are of the hinge-type, like those between the phalanges, and the movements are flexion and extension. In some joints as at the joint between the dens and atlas the joint is of the pivot-type and the movement is one of rotation in one direction or the other.

In *biaxial joints* there are two approximated primary axes of movement. Muscles acting on such joints may cause movement about either axis or about intermediate axes, the resultant of simultaneous movement about both primary axes. Joints of this sort are usually either of the saddle-type, like the carpo-metacarpal joint of the thumb, or of the condyloid type, like the wrist-joint. About one axis we usually get flexion and extension, about the other axis, abduction and adduction. A given muscle may cause movement about one axis or about both axes.

In *multiaxial joints* movements may be made about axes in three planes, each plane vertical to each of the other planes, and about various intermediate axes. Joints of this type are called ball-and-socket joints, although they are not always, like the shoulder- or hip-joints, similar in form to an ordinary mechanical ball-and-socket joint.

Muscles producing a movement in a common direction are called *synergists*, those which produce movements in opposite directions are called *antagonists*. If all joints were of the uniaxial type it would be relatively easy to arrange the muscles acting on the joints into synergists and antagonists although even in such joints a muscle might be so attached that it would be a flexor after flexon has started, an extensor after extension has started. In case of biaxial, and still more so in case of multiaxial joints, the direction of pull exerted by a given muscle with respect to a given axis varies so much with the positions of the articulating bones that muscles which in one position are antagonists in another position become synergists during the same general movement. Thus when the arm is at the side the clavicular and spinous portions of the deltoid are adductors, and the acromial portion is an abductor of the arm; but after the arm has been raised a certain distance all parts become abductors.

In the following table an attempt has been made to include the names of the main muscles acting upon the chief axes of each joint or joint groups of the head, trunk and limbs. In this table have been included not only the voluntary muscles described in the preceding section, but also several described in other parts of the book.

1. Facial muscles. (Cf. p. 396)

These serve essentially to contract the various visceral orifices of the head or to retract the tissue surrounding them. They do not act on joints.

Ear.

Retractors: auricularis anterior, superior, and posterior.

Orbit.

(*a*) Retractor: epicranius (occipitofrontalis). The levator palpebræ superioris raises the upper eyelid.

(*b*) Contractors: orbicularis oculi, corrugator, and procerus.

Nasal orifice.

(*a*) Dilators: angular head of the quadratus labii superioris, transverse portion of the nasalis, and the dilatores naris.

(*b*) Contractors: pars alaris of the nasalis and the depressor septi nasi.

Oral orifice.

(*a*) Retractors:

Upward: zygomaticus, quadratus labii superioris, caninus.

Lateralward: zygomaticus, risorius, platysma, triangularis, buccinator.
Downward: triangularis, quadratus labii inferioris, platysma.
(*b*) Contractors: orbicularis oris, compressor labii, incisivus labii inferioris and superioris.
(*c*) Protractors of the lips: incisivus labii inferioris and superioris, mentalis.

2. Muscles acting on the eyeball (see Section on Eye).
To adduct the pupil: rectus medialis.
To abduct the pupil: rectus lateralis.
To direct the pupil upward: rectus superior, in association with the obliquus inferior.
To direct the pupil downward: rectus inferior, in association with the obliquus superior.

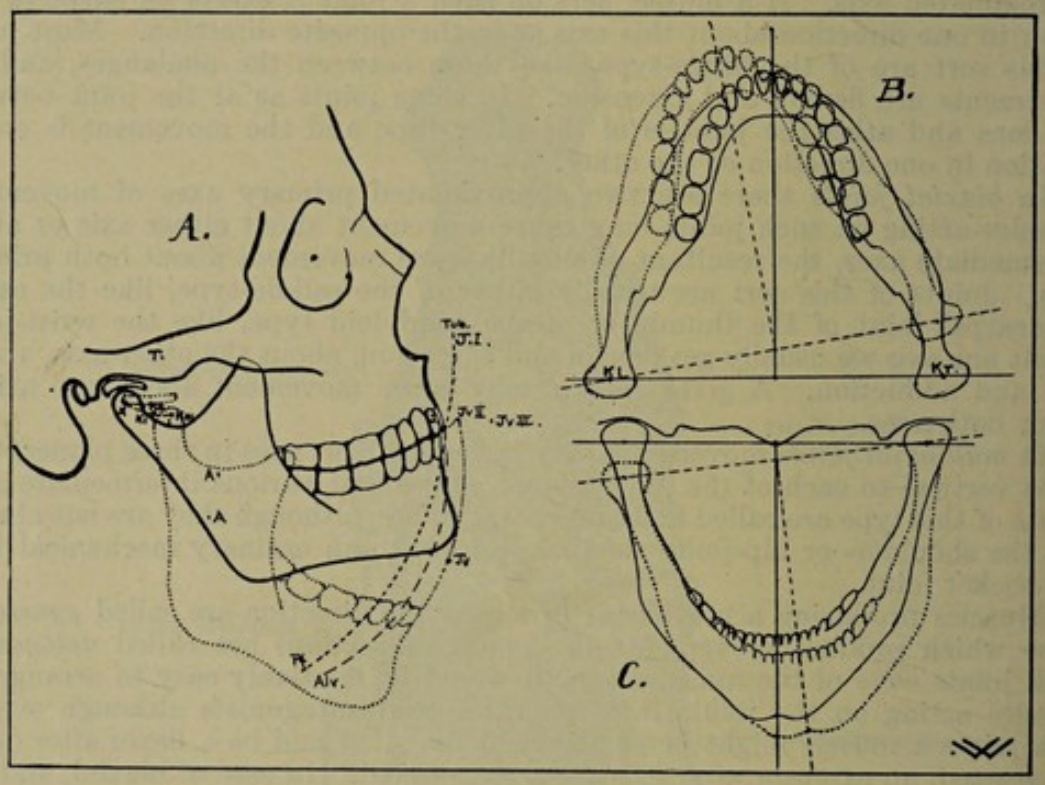

FIG. 491.—CHIEF AXES IN MOVEMENTS OF THE MANDIBLE. (After Fick.)

A. Movement about transverse axes *T* through the articular tubercles of the temporal bones and *K* through the condyles of the mandible. *K*, K^{I}, K^{II}, K^{III}, successive positions of *K* as the mouth is opened. *J*, *JvII*, movement of the top edge of the incisors in protrusion of the mandible. *JvIII*, position of top edge of the incisors in extreme protrusion of the mandible. Dotted line *JI–Pf*, movement of top edge of central incisors when there is no protrusion of the mandible. Dotted line *JvII–Jv*, movement of the top edge of central incisors when the mandible is protruded.

B. Movement of mandible as seen from above about vertical axis through left condyle at *Kl*. The line *Kl*, *Kr* indicates the position of the tranverse axis about which elevation and depression of the lower teeth takes place.

C. Mandible viewed from behind. Abduction about sagittal axis through right condyle.

3. Muscles acting on the mandible (cf. pp. 285, 405).

(*a*) Transverse axis above the articular tubercles of the temporal bones (fig. 491 A (T)). As the articular disk glides forward over the articular tubercle it in part moves about an axis above this tubercle, in part takes a more horizontal course than if confined to movement about this axis. The condyles to some extent move forward on the lower surface of the disk. As the mandible moves forward it is depressed slightly so as to permit the incisor teeth of the lower jaw to pass those of the upper jaw.

Retraction of mandible	*Protraction of mandible*
Right and left temporal muscles, posterior two-thirds.	Right and left external pterygoids.

Protraction of the jaw is aided by the internal pterygoid and masseter muscles and the anterior part of the temporal. The digastric is an accessory retractor.

(*b*) Transverse axis through condyles of mandible (fig. 491 A (K)).

Elevation of mandible	*Depression of mandible*
Temporal muscles	Digastric muscles
Internal pterygoids	Geniohyoids
Masseters	Mylohyoids

In the elevation and depression of the anterior part of the mandible the articular disks and the condyles are pulled forward as the mandible swings about the transverse axis through the condyles. The region of the ramus near where the stylomandibular and sphenomandibular ligaments are attached moves comparatively little as the mouth opens. While some investigators have contended that these ligaments fix the jaw and make a transverse axis of movement, this is denied by others. (See Fick, bibliography.)

(*c*) Rotation about vertical axis through one condyle. (Fig. 491 B (KL)). Slight abduction about anteroposterior axis through same condyle (fig. 491 C).

Rotation about vertical axis left condyle. Upper and lower sets of molars of right side opposed to one another.

Forward movement of lower right molars	*Backward movement* of lower right molars
Right external pterygoid muscle	Right digastric muscle.

The right internal pterygoid, masseter and anterior third of the temporal muscles aid in the forward movement, the posterior two-thirds of the temporal in the backward movement.

4. Muscles acting on the hyoid bone. (Cf. pp. 410, 417.)
   - (*a*) To elevate it: digastric, stylohyoid, styloglossus, mylohyoid, geniohyoid, genioglossus, hyoglossus, and the middle constrictor of the pharynx.
   - (*b*) To depress it: thyrohyoid, sternohyoid, omohyoid, sternothyroid.
   - (*c*) To protract it: genioglossus (inferior portion), geniohyoid, anterior belly of digastric, and the mylohyoid.
   - (*d*) To retract it: posterior belly of digastric, stylohyoid, and the middle constrictor of the pharynx.
5. Muscles acting on the larynx (see Section XI).
   - (*a*) To elevate it: thyrohyoid, stylopharyngeus, pharyngopalatinus, the inferior constrictor of the pharynx, and the elevators of the hyoid.
   - (*b*) To depress it: sternothyroid, sternohyoid, and omohyoid.
   - (*c*) To approximate the vocal folds: cricoarytenoideus lateralis; vocalis; thyroarytenoideus, arytenoideus transversus.
   - (*d*) To make the vocal folds (cords) tense: cricothyroideus.
   - (*e*) To widen the rima glottidis: cricoarytenoideus posterior.
   - (*f*) To shorten and thicken the vocal folds: thyroarytenoideus (externus), vocalis.
   - (*g*) To constrict the aditus and vestibule of the larynx: aryepiglotticus, thyroarytenoideus.
   - (*h*) To widen the aditus and vestibule of the larynx: thyroepiglottideus.
6. Muscles acting on the tongue (see Section X).
   - (*a*) To elevate it: styloglossus (especially along the sides), glossopalatinus, glossopharyngeus, and the elevators of the hyoid bone.
   - (*b*) To depress it: genioglossus (in the center), hyoglossus (at the sides), chondroglossus, and the depressors of the hyoid bone.
   - (*c*) To protrude it: genioglossus (middle and inferior portions).
   - (*d*) To retract it: genioglossus (anterior portion), styloglossus, chondroglossus.
   - (*e*) To shorten it and make it bulge upwards: longitudinalis superior and inferior.
   - (*f*) To narrow it and make it bulge upwards: transversus linguæ.
   - (*g*) To flatten it: verticalis linguæ.

   When the muscles work symmetrically, these movements are symmetrical; when they do not work symmetrically, the tongue is moved from side to side, rotated, etc.
7. Muscles acting on the palate and pharynx (see Section X).
   - (*a*) To narrow the pharyngeal opening of the tuba auditiva (Eustachian tube): levator veli palatini.
   - (*b*) To widen the isthmus of the tuba: levator veli palatini.
   - (*c*) To open the tube: tensor veli palatini, pharyngopalatinus.
   - (*d*) To raise and shorten the uvula: m. uvulæ.
   - (*e*) To depress the soft palate: glossopalatinus, pharyngopalatinus.
   - (*f*) To make tense the soft palate: tensor veli palatini.
   - (*g*) To lift the soft palate: levator veli palatini.
   - (*h*) To approximate the glossopalatine arches; glossopalatinus.
   - (*i*) To approximate the pharyngopalatine arches: pharyngopalatinus, superior constrictor of the pharynx.
   - (*j*) To constrict the pharynx: superior, middle, and inferior constrictors.
   - (*k*) To widen the pharynx: stylopharyngeus and the muscles which protract the hyoid bone.
   - (*l*) To elevate the pharynx: stylopharyngeus, pharyngopalatinus.
8. Muscles acting on the head (cf. pp. 414, 422, 478).

Atlanto-occipital and atlantoepistropheal joints. *Note.*—Flexion and extension (maximum 20° flexion, 30° extension, usually less) and abduction (15° to 20° from the midposition, frequently less) occur chiefly in the atlanto-occipital joints, rotation (about 30° from the midposition) chiefly in the atlantoepistropheal joints. Abduction in the atlanto-occipital joint is accompanied by rotation and extension toward the same side (Fick).

(*a*) Transverse axis above occipital condyles, (fig. 492T).

Extension	*Flexion*
Right and left trapezius	Right and left longus capitis
Right and left semispinalis capitis	Right and left rectus capitis anterior
Right and left obliquus capitis superior	Right and left rectus capitis lateralis

Right and left rectus capitis posterior major
Right and left rectus capitis posterior minor
Right and left splenius capitis muscles

The supra- and infrahyoid muscles working together are accessory flexors. The right and left sternocleidomastoids, and longissimus capitis muscles are accessory extensors.

(*b*) Vertical axis through dens of epistropheus (fig. 492V).

Rotation to right	*Rotation to left*
Left sternocleidomastoid	Right sternocleidomastoid
Left trapezius	Right trapezius
Right splenius capitis	Left splenius capitis
Right longissimus capitis	Left longissimus capitis
Right obliquus capitis inferior	Left obliquus capitis inferior
Right rectus capitis posterior major	Left rectus capitis posterior major
Right longus capitis	Left longus capitis

(*c*) Anteroposterior axis through base of occipital (fig. 492 A).

Lateral movement to right	*Lateral movement to left*
Right sternocleidomastoid and splenius capitis	Left sternocleidomastoid and splenius capitis
Right longissimus capitis	Left longissimus capitis
Right rectus capitis lateralis	Left rectus capitis lateralis
Right obliquus capitis superior	Left obliquus capitis superior
Right semispinalis capitis	Left semispinalis capitis

9. Muscles acting on the vertebral column (fig. 493) (cf. p. 478)
(1) *Cervical region.*

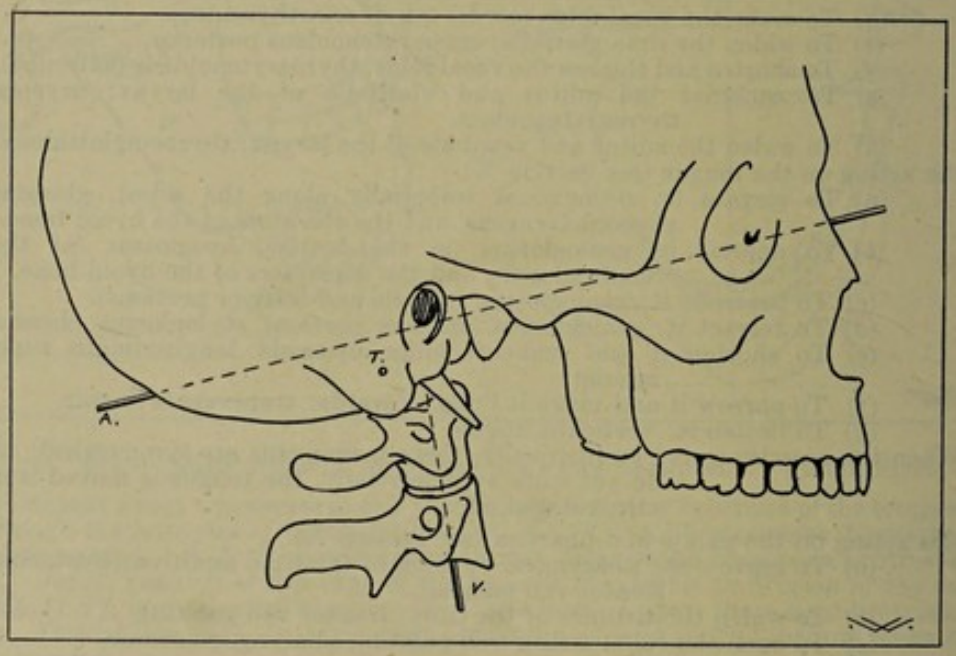

Fig. 492.—Chief Axes of Movement of Skull on Vertebral Column.
A, Sagittal axis; *T*, transverse axis; *V*, perpendicular axis.

(*a*) Transverse axes (fig. 493 A (T)).

Extension	*Flexion*
Splenius capitis and cervicis	Sternocleidomastoid
Semispinalis cervicis and capitis	Longus colli and capitis
Longissimus cervicis	Scaleni
Iliocostalis cervicis	
Spinalis	
Interspinales	
Multifidus	
Rotatores	

(*b*) Oblique axes (fig. 493 A (O)).

Oblique rotation to right	*Oblique rotation to left*
Right splenius capitis and cervicis	Left splenius capitis and cervicis
Right longissimus capitis and cervicis	Left longus capitis and cervicis
Left sternocleidomastoid	Right sternocleidomastoid
Right iliocostalis cervicis	Left iliocostalis cervicis
Left semispinalis cervicis	Right semispinalis cervicis
Left rotatores	Right rotatores

Upper part right longus colli
Lower part left longus colli
Left scaleni
Left trapezius

Lower part right longus colli
Upper part left longus colli
Right scaleni
Right trapezius

(c) Anteroposterior axes (fig. 493 A (F)).

Abduction to right	*Abduction to left*
Right scaleni	Left scaleni
Right sternocleidomastoid	Left sternocleidomastoid
Right splenius capitis and cervicis	Left splenius capitis and cervicis
Right iliocostalis cervicis	Left iliocostalis cervicis
Right longissimus capitis and cervicis	Left longissimus capitis and cervicis
Right semispinalis cervicis	Left semispinalis cervicis
Right intertransverse	Left intertransverse

(2) *Thoracic region.*

(a) Anteroposterior and transverse axes (fig. 493 B (F, T)).

Abduct to right and extend	*Abduct to left and extend*
Right iliocostalis	Left iliocostalis
Right longissimus dorsi	Left longissimus dorsi
Right semispinalis	Left semispinalis
Right multifidus	Left multifidus
Right rotatores	Left rotatores
Right levatores costarum	Left levatores costarum
Right spinalis	Left spinalis

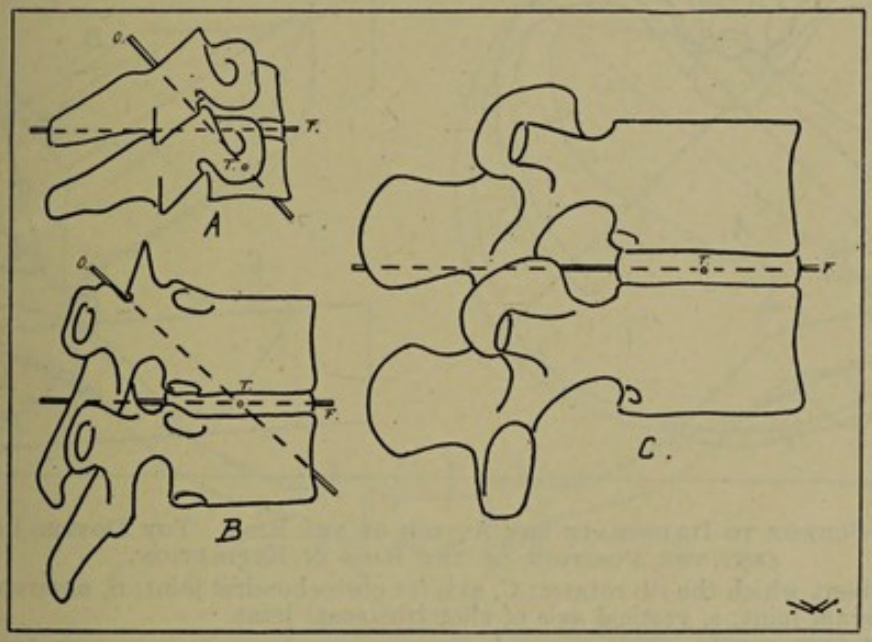

FIG. 493.—CHIEF AXES OF MOVEMENT OF ONE VERTEBRA ON THE NEXT BELOW.
A, cervical, *B*, thoracic and *C*, lumbar vertebræ. *O*, oblique axis in sagittal plane for rotation combined with abduction; *F*, anteroposterior axis in sagittal plane for abduction; *T*, transverse axis in frontal plane for flexion and extension.

(b) Oblique axes (fig. 493 B (O))

Oblique rotation to right	*Oblique rotation to left*
Left semispinalis	Right semispinalis
Right iliocostalis	Left iliocostalis
Left multifidus	Right multifidus
Left rotatores	Right rotatores
Right levatores costarum	Left levatores costarum
Left obliquus abdominis ext.	Right obliquus abdominis ext.
Right obliquus abdominis int.	Left obliquus abdominis int.

(3) *Lumbar region.*

(a) Transverse axes (fig. 493 C (O))

Extension	*Flexion*
Right and left quadratus lumborum	Right and left abdominal muscles
Right and left sacrospinalis	
Multifidus	
Right and left inter-transverse	
Right and left interspinal	

(*b*) Anteroposterior axes (fig. 493 C (F))

Abduction to right	*Abduction to left*
Right quadratus lumborum	Left quadratus lumborum

The psoas muscles are powerful accessory flexors and abductors of the lumbar region of the spinal column. The right abdominal muscles abduct to the right, the left to the left.

10. Muscles acting on the thorax (fig. 494 A, B and C)

Longitudinal axes through necks of ribs, anteroposterior and vertical axes through rib cartilages near chondrosternal joints. The costochondral and interchondral joints are also involved.

Inspiration.—Shafts of ribs swing outwards and upwards, costochondral angles flattened, sternum elevated and protracted.	*Expiration.*—Shafts of ribs swing inwards and downwards, costochondral angles increased, sternum depressed and retracted.
External intercostals	Internal intercostals (costal part)
Interchondral muscles	Subcostals
	Transversus thoracis

The extensors of the thoracic region of the spine aid in inspiration. In forced inspiration the scalene, the sternocleidomastoid, the rhomboids and serratus anterior, the serratus posterior superior, the trapezius and pectoralis minor, latissimus dorsi, pectoralis major and subclavius may be brought into play. The abdominal muscles and the muscles of the pelvic outlet are essentially antagonists of the diaphragm. The abdominal muscles, the quadratus lumborum-

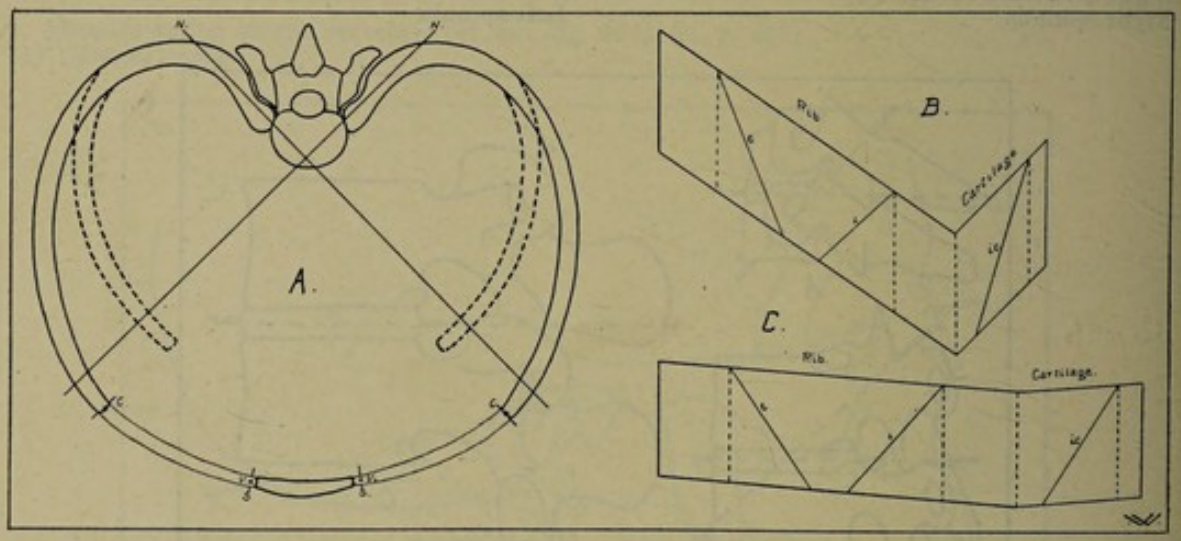

FIG. 494A.—SCHEME TO ILLUSTRATE THE ACTION OF THE RIBS. THE DOTTED LINES REPRESENT THE POSITION OF THE RIBS IN EXPIRATION.

N, axis about which the rib rotates; *C*, axis for costochondral joint; *S*, anteroposterior axis of chondrosternal joint; *v*, vertical axis of chondrosternal joint.

FIG. 494B–C (After Fick).—HAMBERGER'S SCHEME FOR ILLUSTRATING THE ACTION OF THE INTERCOSTAL MUSCLES.

B. Rib depressed. C. Rib elevated.

e, external intercostal; *i*, internal intercostal; *ic*, interchondral part of internal intercostal

the iliocostalis, the longissimus dorsi and the serratus posterior inferior lower the thorax in forced expiration. The relatively simple explanation of the action of the intercostal muscles given by Hamberger in 1748 and illustrated in fig. 494 B and C has been questioned by Hoover, Arch. Int. Med. vol. 30, p. 1, 1922.

The diaphragm plays an essential part in inspiration although according to Fick the part played by the diaphragm is frequently overestimated.

11. Muscles acting on the abdomen. (Cf. p. 488.)
   - (*a*) Constriction of the abdominal cavity: obliquus abdominis externus and internus, the transversus and rectus abdominis and the diaphragm, levator ani, and coccygeus.
   - (*b*) Reduction of pressure in the abdominal cavity: the muscles of inspiration, with the exception of the diaphragm, serve to lessen the compression of the abdominal viscera.

12. Action of the muscles of the perineal region. (Cf. p. 505.)
   - (*a*) To close anal canal: sphincter ani externus.
   - (*b*) To constrict the anal portion of the rectum: levator ani (pubococcygeal portion).
   - (*c*) To constrict the bulbus urethræ and the corpus cavernosum urethræ (corpus spongiosum): bulbocavernosus.
   - (*d*) To elevate the prostate gland: levator ani.
   - (*e*) To constrict the vagina: bulbocavernosus, levator ani (pubococcygeal portion), constrictor vaginæ.

(*f*) To assist in erection of penis and clitoris: ischiocavernosus, bulbocavernosus, and sphincter urethræ membranaceæ.

(*g*) To compress the urethra and the bulbourethral (Cowper's) or the great vestibular (Bartholin's) gland: sphincter urethræ membranaceæ and the transversus perinei profundus.

(*h*) To support and lift the pelvic floor: levator ani, coccygeus, transversus perinei profundus and superficialis.

13. Muscles acting on the shoulder-girdle at the sternoclavicular joint (fig. 495) (cf. pp. 310, 414, 424, 436).

It is assumed that movement at the acromioclavicular joint, while enabling the scapula to accommodate itself to the chest wall, at the same time increases the extent of the rotation of the scapula about the clavicular (acromiosternal) axis.

(*a*) Dorsoventral axis (fig. 495)

Abduction (*scapula raised*)	*Adduction* (*scapula depressed*)
Levator scapulæ	Pectoralis minor
Trapezius (upper part)	Subclavius
	Trapezius (lower part)

The lower part of the serratus anterior is an accessory adductor. The pectoralis major (lower part) and latissimus dorsi, adductors of the arm, also indirectly adduct the scapula. The clavicular part of the sternocleidomastoid and the middle part of the serratus anterior are accessory abductors.

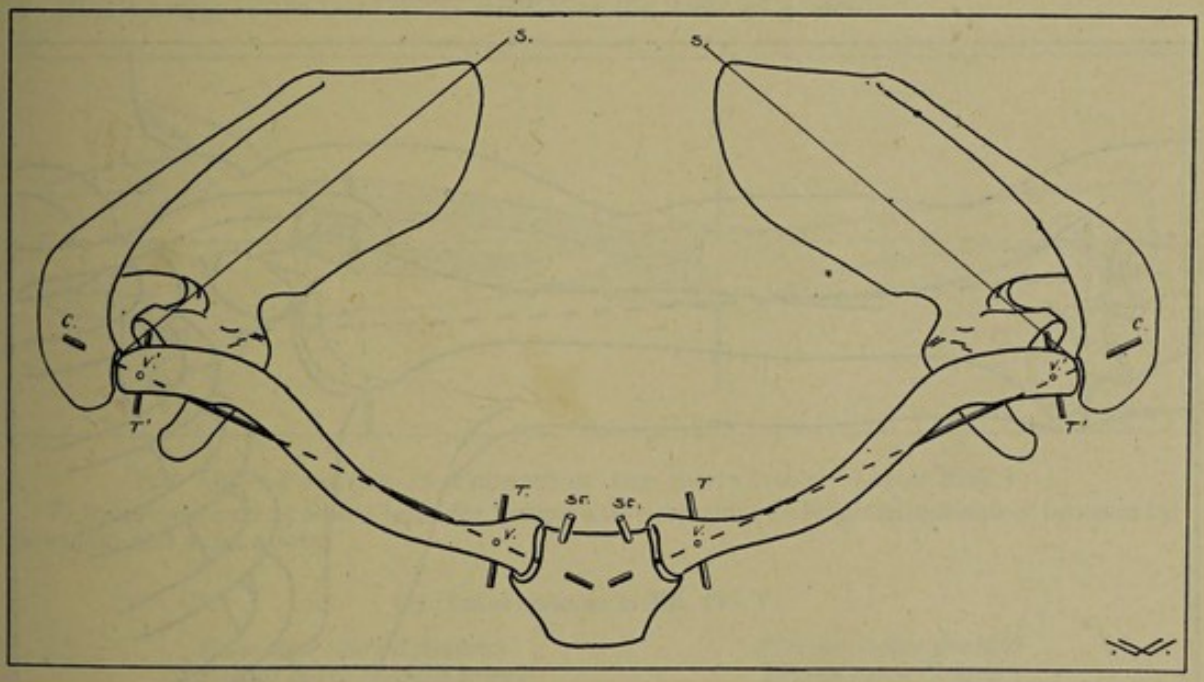

FIG. 495.—CHIEF AXES OF MOVEMENT OF THE SHOULDER GIRDLE.

Viewed from above. *S*, scapular axis; *C*, clavicular axis; *V*, vertical axis through sternal end of clavicle; *V'*, vertical axis through acromial end of clavicle; *St*, sternal axis for dorsoventral movements at sternoclavicular joint; *T*, ventrodorsal axis for elevation and depression about the sternoclavicular joint; *T'*, dorsoventral axis for acromioclavicular joint.

(*b*) Vertical axis (fig. 495)

The clavicle moves on the interarticular disk about a vertical axis through the head of the clavicle; the clavicle and disk move about an oblique axis through the sternum.

Retraction (*scapula carried backward*)	*Protraction* (*scapula carried forward*)
Rhomboids	Serratus anterior
Trapezius (middle part)	Pectoralis minor
(The latissimus dorsi aids this movement)	(The pectoralis major, upper sternal part, aids this movement)

(*c*) Clavicular axis (fig. 495)

Rotation in the direction of supination (*glenoid cavity turned upward*)	*Rotation in direction of pronation* (*glenoid cavity turned downward*)
Trapezius	Pectoralis minor
Serratus anterior (lower part)	Rhomboidius major

In the upward rotation the acromion and outer end of the clavicle are elevated and pulled backwards, as well as rotated. The reverse is true of the downward rotation. The pectoralis major (pectoral portion), and latissimus dorsi are accessory rotators in the direction of pronation.

14. Muscles acting on the shoulder-joint (fig. 496) (cf. pp. 317, 430).

(*a*) Dorsoventral axis (fig. 496 A)

Abduction	*Adduction*
Deltoid	Pectoralis major (lower part)
Supraspinatus	Latissimus dorsi
	Teres major

With the arm at the side the clavicular and spinal parts of the deltoid are adductors but as the arm is abducted these parts become abductors. The subscapularis meanwhile changes from an abductor to an adductor. The long head of the biceps and the upper part of the infraspinatus are strong accessory abductors. The long head of the triceps, the coracobrachialis, the short head of the biceps and the teres minor are strong accessory adductors when the arm is at the side.

(*b*) Transverse axis, arm at side; perpendicular axis, arm at 90° (fig. 496 P)

Extension	*Flexion*
Deltoid (spinal part)	Deltoid (clavicular part)
	Pectoralis major (clavicular part)
	Coracobrachialis

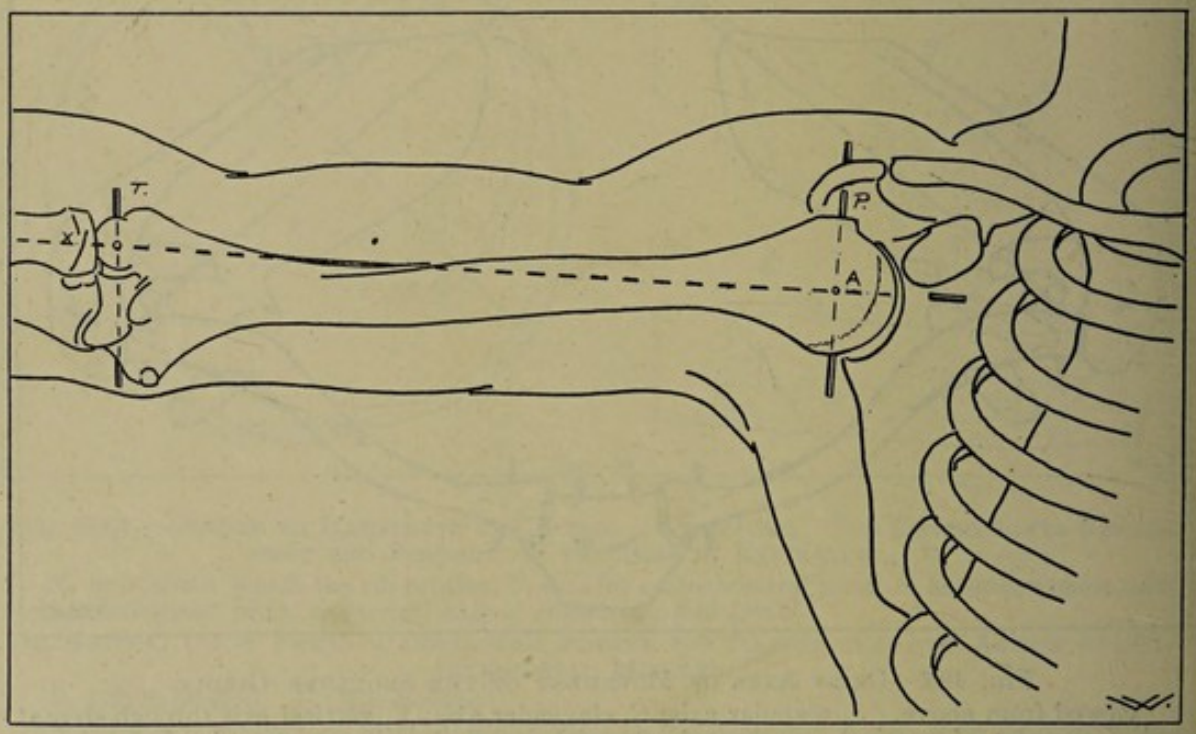

Fig. 496.—Chief Axes of Movement at Shoulder and Elbow Joints.

A, dorsoventral axis of shoulder-joint for abduction and adduction; *P*, perpendicular axis of shoulder-joint, arm adducted for flexion and extension. When the arm is at the side this axi; passes transversely through the body; *A*–*X*, longitudinal axis through humerus, for rotations *T*, transverse axis through humerus for flexion and extension at elbow joint.

The latissimus dorsi, teres major, and subscapularis (lower part), when the arm is at the side are strong accessory extensors; the short head of the biceps is a strong accessory flexor. The subscapularis is a powerful accessory flexor when the arm is abducted. The infraspinatus is a flexor.

(*c*) Humeral axis (fig. 496 A–X).

Lateral rotation (*supination*)	*Medial rotation* (*pronation*)
Infraspinatus	Subscapularis
Teres minor	

The spinal part of the deltoid is also a lateral rotator. The adductor muscles, the clavicular part of the deltoid, and the long head of the biceps are strong accessory medial rotators. An important function of the coracobrachialis muscle and of the scapular attachments of the biceps and triceps muscles appears to be to hold the head of the humerus in the glenoid cavity.

15. Muscles acting on the forearm at the elbow-joint (figs. 496, 497) (cf. p. 444, 446, 449).

Transverse axis (figs. 496, 497 T)

Extension	*Flexion*
Triceps	Brachialis
Anconeus	Brachioradialis

The biceps muscle, a powerful flexor when the forearm is supinated, is a much weaker one when the forearm is pronated. The pronator teres and extensor carpi rad. long. are strong accessory flexors of the elbow-joint, the flexor carpi radialis, extensor carpi radialis brevis and palmaris longus are weaker accessory flexors.

16. Muscles acting on the radioulnar joints (figs. 497, 498) (cf. p. 449).

In the ordinary use of the upper extremity, supination of the foreman is usually accompanied by extension at the elbow-joint and lateral rotation at the shoulder-joint; pronation with flexion at the elbow-joint and medial rotation at the shoulder-joint.

Longitudinal axis

Supination	*Pronation*
Biceps	Pronator teres
Supinator	Pronator quadratus

The brachioradialis and extensor carpi rad. long. bring the forearm into an intermediate position. When the arm is extended they supinate, but as the arm is flexed they tend more and more to bring the arm into a pronate position. The flexor carpi radialis is a powerful accessory pronator.

17. Muscle acting on the hand at the wrist-joint (fig. 498) (cf. p. 449).

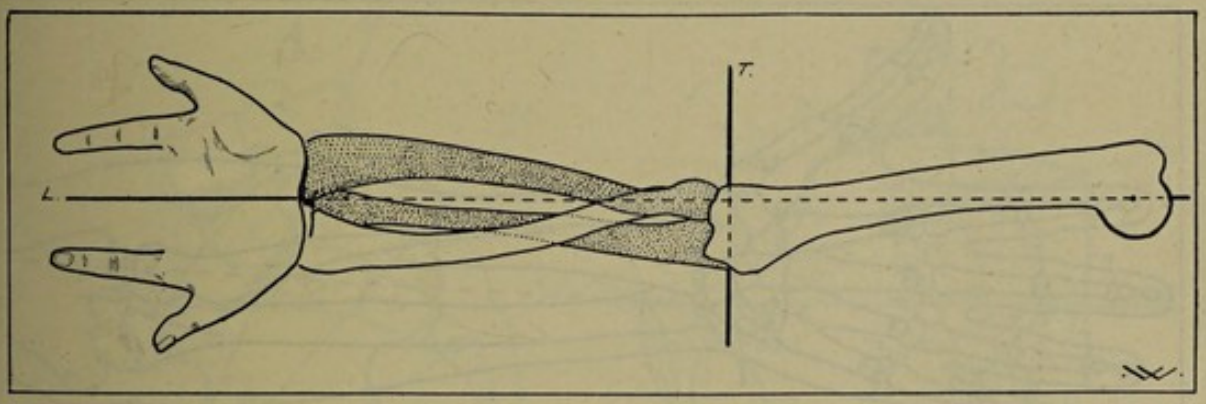

FIG. 497.—FOREARM IN PRONATION AND SUPINATION. (After Fick.)

T, transverse axis at elbow-joint for flexion and extension; *L*, longitudinal axis of forearm for pronation and supination.

(*a*) Transverse axis (fig. 498 T)

Extension (*dorsal flexion*)	*Flexion* (*volar flexion*)
Extensor carpi radialis brevis	Flexor carpi ulnaris
Extensor carpi radialis longus	Flexor carpi radialis
Extensor carpi ulnaris	Palmaris longus

The long flexors and extensors of the thumb and fingers are accesory flexors and extensors of the wrist-joint. The long abductor of the thumb is also an accessory flexor of the wrist.

(*b*) Dorsoventral axis (fig. 498 V)

Radial abduction	*Ulnar abduction*
Extensor carpi radialis longus	Flexor carpi ulnaris
Extensor carpi radialis brevis	Extensor carpi ulnaris

The abductor pollicis longus and extensor pollicis longus muscles are powerful accessory radial abductors.

18. Muscles acting on the carpometacarpal joints (fig. 498) (cf. p. 472). Combined transverse and perpendicular axes (A and T)

Thumb

According to Fick and others there is some voluntary rotation possible at the first carpometacarpal joint.

Abduct and repose	*Adduct and oppose*
Abductor pollicis longus	Opponens
Abductor pollicis brevis	Adductor

The extensors of the thumb are accessory reposers. The long and short flexors aid in opposing.

Little finger

Abduct and repose	*Adduct and oppose*
Extensor carpi ulnaris	Opponens

The abductor digiti quinti and extensor digiti quinti proprius aid in reposing; the third volar interosseous, the fourth lumbrical and the flexors of the little finger in opposing.

19. Muscles acting on the metacarpophalangeal joints (fig. 498).

(*a*) Transverse axes

Extension	*Flexion*
Thumb	
Extensor pollicis brevis	Flexor pollicis brevis

The extensor pollicis longus is an accessory extensor. The adductor and abductor brevis and the flexor pollicis longus are accessory flexors.

Little finger

Extensor digiti quinti proprius	Flexor digiti quinti brevis Fourth lumbrical Third volar interosseous

The abductor and long flexors of the little finger are accesory flexors of this joint.

Other fingers

Extension	*Flexion*
Extensor digitorum communis	Lumbricals
Extensor indicis proprius	Interossei

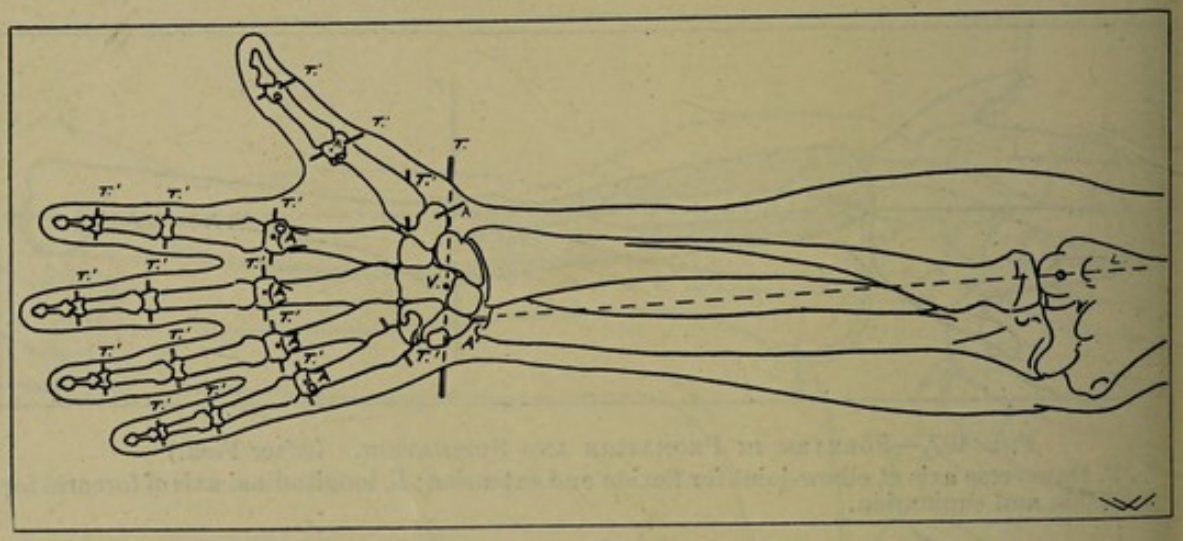

FIG. 498.—CHIEF AXES OF MOVEMENT OF FOREARM, WRIST AND HAND.

L, longitudinal axis of forearm for pronation and supination; *T*, compromise transverse axis for flexion and extension at wrist; *V*, volardorsal axis through carpus for ulnar and radial abduction of the hand; *T'*, transverse axes for flexion and extension of the thumb and fingers; *A*, volardorsal axes for radial and ulnar abduction of the thumb and fingers.

The flexor sublimus and flexor profundus are accessory flexors of these joints.

(*b*) Perpendicular axes

Abduct from the long axis of the middle finger	*Adduct toward the long axis of the middle finger*
1st and 2nd lumbricals	Volar interossei
Dorsal interossei	3d and 4th lumbricals
Abductor digiti quinti	

20. Muscles acting on the interphalangeal joints (fig. 498).

Transverse axes

Extension	*Flexion*
Thumb	
Extensor pollicis longus	Flexor pollicis longus

The flexor pollicis brevis and abductor pollicis brevis are accessory extensors of this joint.

Fingers; proximal joints

Interossei	Flexor digitorum sublimis
Lumbricals	
Abductor digiti quinti	

Fingers; distal joints

Extension	*Flexion*
Interossei	Flexor digitorum profundus
Lumbricals	
Abductor digiti quinti	

The extensor digitorum communis, extensor indicis proprius and extensor digiti quinti proprius are accessory extensors of the joints.

21. Muscles acting on the pelvis.

Thoracic and thoracolumbar joints (fig. 499).

Vertical spinal axes

Rotation of pelvis to right	*Rotation of pelvis to left*
Left internal oblique	Right internal oblique
Right external oblique	Left external oblique
The intrinsic dorsal muscles also play a part.	See action of muscles on the vertebral column.

Lumbar and lumbosacral joints (figs. 493, 499).

(*a*) Ventrodorsal axes

Abduction of pelvis to right	*Abduction of pelvis to left*
Right quadratus lumborum	Left quadratus lumborum
Right sacrospinalis	Left sacrospinalis

The abdominal, the latissimus dorsi and the psoas muscles are accessory abductors.

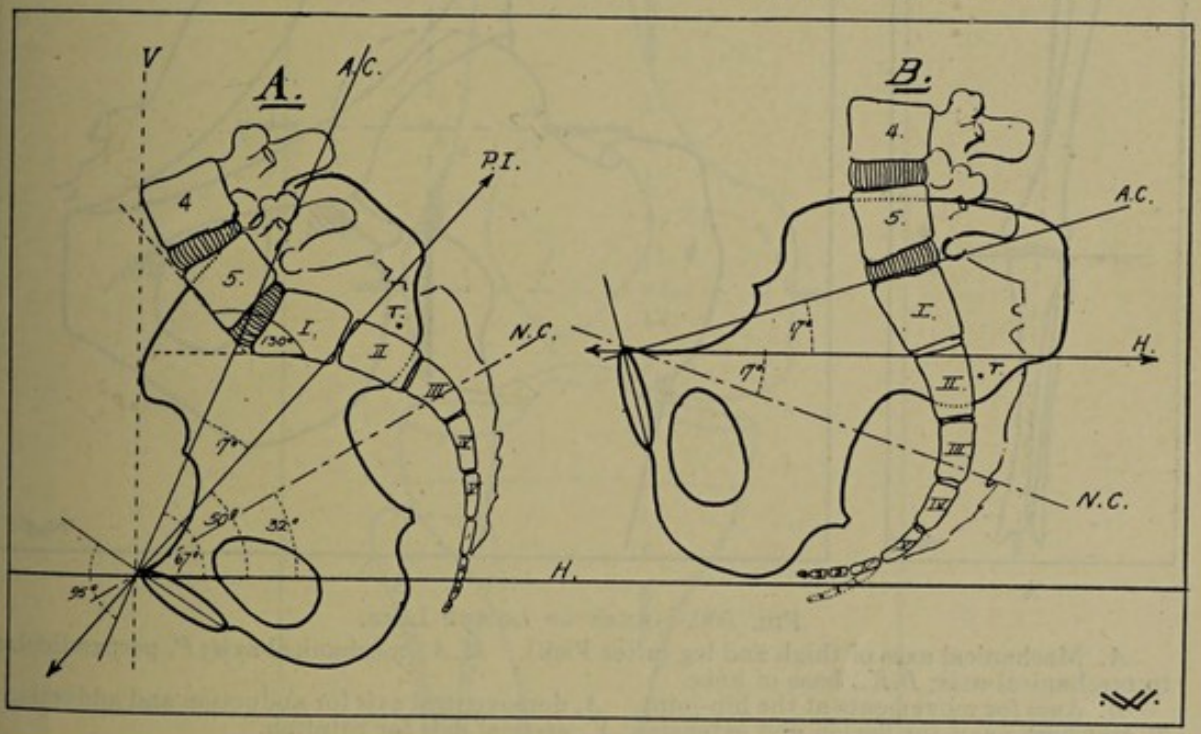

FIG. 499.—EXTENSION AND FLEXION OF THE PELVIS. (After Fick.)

A, pelvis, standing position; *B*, pelvis, sitting position; *A.C.*, anatomical conjugate; *N.C.* normal conjugate; *H*, horizontal plane; *V*, vertical plane; *P.I.*, pelvic inclination; *T*, approximate position for transverse axis in movements at the sacroiliac joint.

(*b*) Transverse axes

Extension of pelvis	*Flexion of pelvis*
Quadratus lumborum	Rectus abdominis
Sacrospinalis	Oblique abdominal muscles
	Psoas minor

The psoas major muscle is a powerful accessory flexor of the pelvis, the latissimus dorsi is an accessory extensor.

22. Muscles acting on the thigh at the hip-joint (fig. 500 B) (cf. pp. 521, 530).

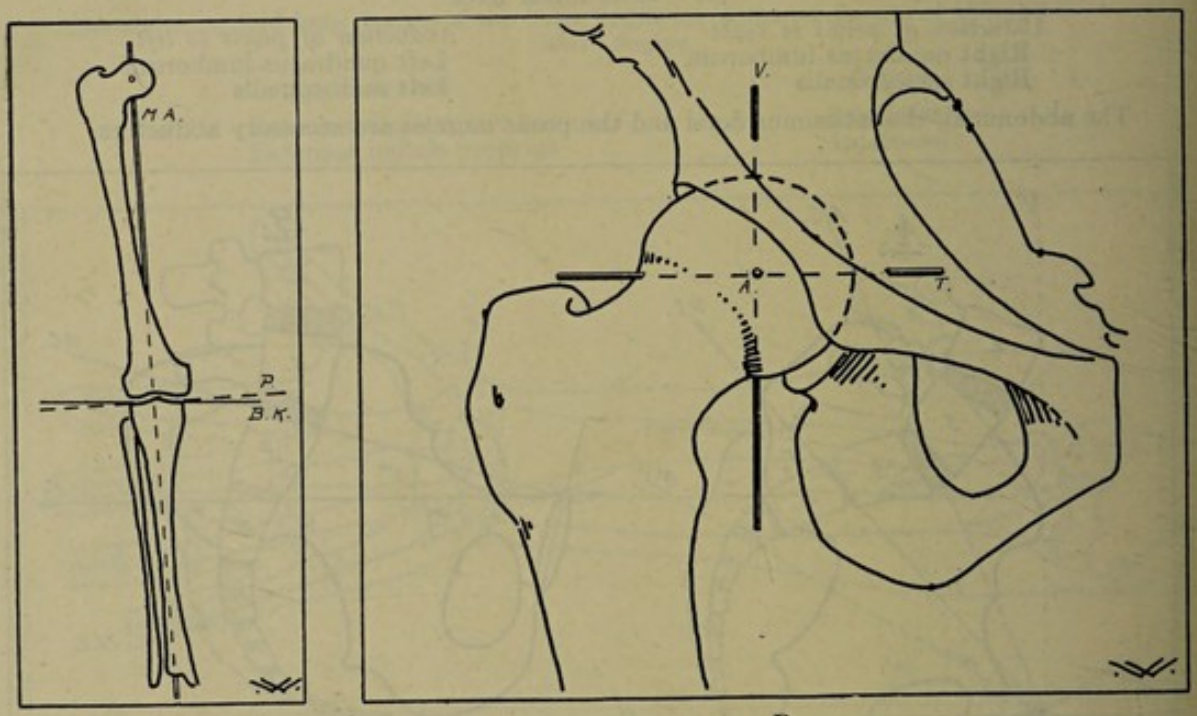
(*a*) Transverse axes

Extension	*Flexion*
Gluteus maximus	Iliopsoas
	Pectineus

The adductor magnus (posterior lower part) and also the hamstring muscles are accessory extensors; the gluteus medius, piriformis and obturator internus are weaker accessory extensors. The rectus femoris and the adductor longus and brevis, the obturator externus,

tensor fasciæ latæ, and sartorius, are powerful accessory flexors of the hip-joint; the gluteus minimus, adductor minimus, gracilis and quadratus femoris are weaker accessory flexors.

(*b*) Ventrodorsal axis



Abduction	*Adduction*
Gluteus medius	The adductors
Gluteus minimus	Pectineus
Piriformis	Obturator externus
Tensor fasciæ latæ	

The rectus femoris, and sartorius are accessory abductors. The gluteus maximus and quadratus femoris are powerful accessory adductors in the standing position. The gracilis, adductor minimus, biceps, semitendinosus, semimembranosus and obturator internus are weaker accessory adductors.

(*c*) Vertical axis (thigh flexed 90°)

Abduction	*Adduction*
Gluteus maximus	Iliopsoas

(In addition to the abductors and adductors given above.)

A B

FIG. 500.—AXES OF LOWER LIMB.

A. Mechanical axes of thigh and leg (after Fick). *M.A.*, mechanical axis; *P*, perpendicular to mechanical axis; *B.K.*, base of knee.

B. Axes for movements at the hip-joint. *A*, dorsoventral axis for abduction and adduction: *T*, transverse axis for flexion and extension; *V*, vertical axis for rotation.

(*d*) Femoral axis

Lateral rotation	*Medial rotation*
Quadratus femoris	Gluteus minimus (ventral part)
Obturator internus and gemelli	Gluteus medius (ventral part)
Obturator externus	Tensor fasciæ latæ
Piriformis	

The gluteus maximus is a powerful lateral rotator as well as an extensor; the rectus femoris, the lower part of the adductor magnus, the biceps, sartorius, gracilis and the dorsal part of the gluteus medius are accessory lateral rotators. The iliopsoas and the adductors longus, brevis and minimus are strong medial rotators; the pectineus, semitendinosus, semimembranosus and tensor fasciæ latæ are weaker accessory medial rotators.

23. Muscles acting on the leg at the knee-joint (fig. 501) (cf. pp. 530, 550).

(*a*) Transverse axis

Extensors	*Flexors*
Quadriceps femoris	Semimembranos
	Semitendinosusu
	Biceps
	Gracilis
	Sartorius
	Popliteus

The gastrocnemius is a powerful accessory flexor of the knee-joint. The gluteus maximus and tensor fasciæ latæ through the iliotibial band help to hold the extended knee firm.

(*b*) Tibial axis (knee flexed)

Lateral rotation	*Medial rotation*
Biceps	Semimembranosus
Tensor fasciæ latæ	Semitendinosus
	Sartorius
	Popliteus
	Gracilis

24. Muscles acting on the foot at the ankle-joint (fig. 502) (cf. p. 543).

Transverse axis

Extension (plantar flexion)	*Flexion* (hyperextension)
Gastrocnemius	Tibialis anterior
Soleus	Peroneus tertius
Peroneus longus	
Tibialis posterior	
Peroneus brevis	

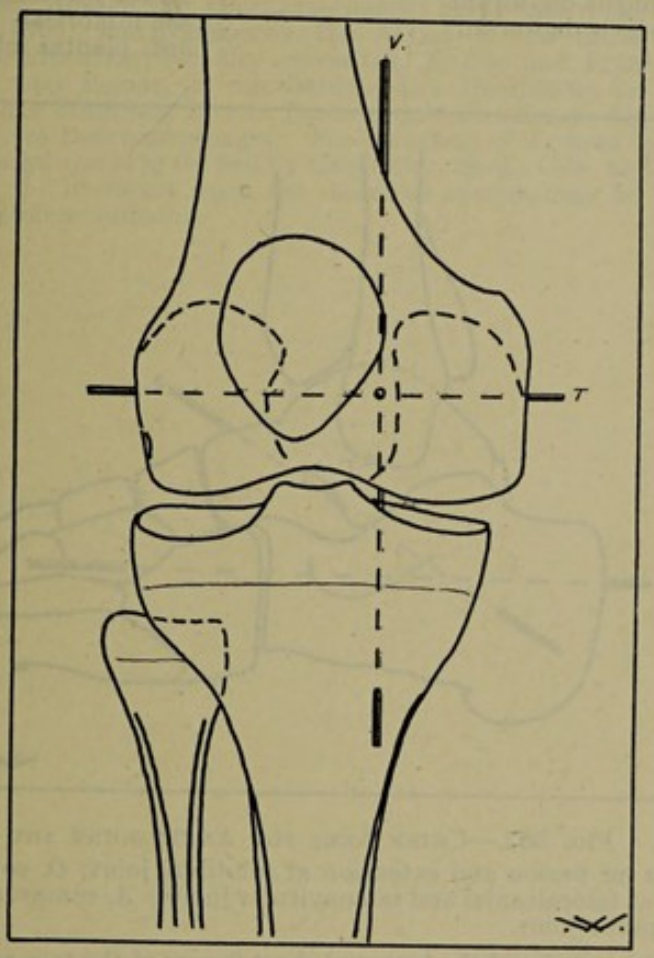


FIG. 501.—AXES OF MOVEMENT AT KNEE-JOINT.
T, transverse axis, for flexion and extension. V, vertical (tibial) axis, for lateral and medial rotation.

The long extensors of the toes and the peroneus tertius flex; the long flexors of the toes extend the foot at this joint.

25. Muscles acting on the foot at the inferior articulation of the talus (artic. talocalcanea and talocalcaneonavicularis) (fig. 502).

Talocalcaneal axis

Inversion (adduction)	*Eversion* (abduction)
Tibialis posterior	Peroneus longus
	Peroneus brevis
	Peroneus tertius

The gastrocnemius, soleus, flexor hallucis longus, flexor digitorum longus and tibialis anterior are accessory inverters at this joint; the extensor digitorum longus and extensor hallucis longus are accessory everters.

26. Muscles acting on the foot at Chopart's joint (talonavicular-calcaneocuboid joints).

Calcaneo-midmetatarsal axis

Inversion (medial rotation)	*Eversion* (lateral rotation)
Tibialis posterior	Peroneus longus
	Peroneus brevis
	Peroneus tertius

The tibialis anterior, flexor digitorum longus, flexor hallucis longus, and extensor hallucis longus are accessory inverters at this joint; the extensor digitorum longus is an accessory everter.

27. Muscles acting on the metatarsophalangeal joints.

(*a*) Transverse axes

Extension	*Flexion*
Big toe	
Extensor hallucis longus	Flexor hallucis brevis.

The abductor and adductor hallucis muscles and the flexor hallucis longus are accessory flexors.

Little toe	
Extensor longus digitorum	Flexor brevis digiti quinti
Extensor brevis digitorum	4th lumbrical
	3rd. plantar interosseus

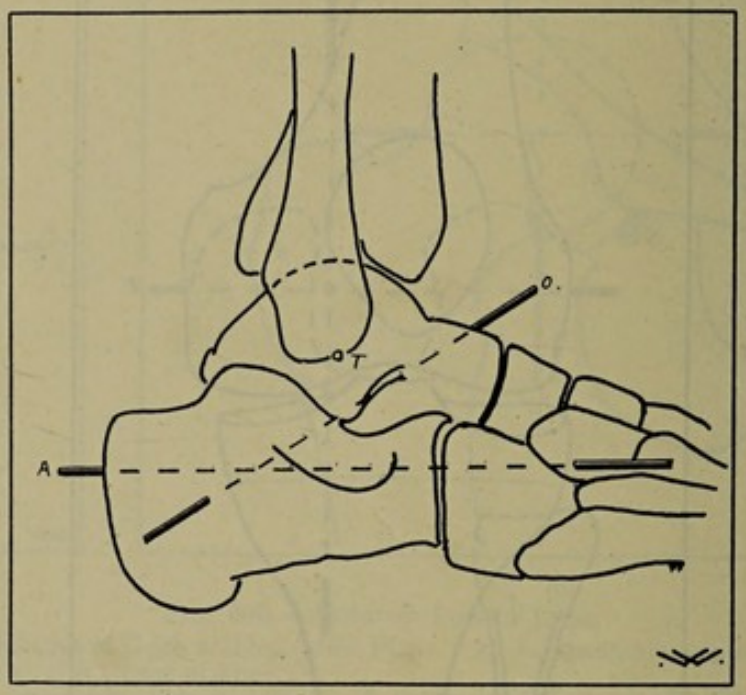

FIG. 502.—CHIEF AXES FOR ANKLE-JOINT AND FOOT.

T, transverse axis for flexion and extension at talotibial joint; *O*, compromise axis for inversion and eversion at talocalcanial and talonavicular joints; *A*, compromise axis for inversion and eversion at Chopart's joint.

The abductor digiti quinti and the long and short flexors of the toes are accessory flexors of this joint.

Other toes	
Extensor longus digitorum	1st., 2nd., and 3d. lumbricals
Extensor brevis digitorum	Dorsal interossei
	1st. and 2nd. plantar interossei

The long and short flexors of the toes are accessory flexors at these joints.

(*b*) Perpendicular axes

Abduction from long axis through second toe	*Adduction toward long axis through second toe*
Abductor hallucis	Adductor hallucis
Dorsal interossei	Plantar interossei
1st. lumbrical	2nd., 3d., and 4th. lumbricals
Abductor digiti quinti	

The transverse head of the adductor of the big toe draws the distal ends of the metatarsals closer together. The axes for this slight movement pass through the cuneiform and cuboid bones.

28. Muscles acting on the interphalangeal joints.

Transverse axes	
Extension	*Flexion*
Big toe	
Extensor hallucis longus Extensor hallucis brevis	Flexor hallucis longus
Other toes	
Extensor digitorum longus Extensor digitorum brevis	Flexor digitorum longus Quadratus plantæ Flexor digitorum brevis (2nd. phalanx only)

The adductors and abductors of the big and little toes may be accessory extensors of the interphalangeal joints.

SECTION VI

THE BLOOD-VASCULAR SYSTEM

By H. D. SENIOR, M.D., F.R.C.S.

PROFESSOR OF ANATOMY, NEW YORK UNIVERSITY

THE organs of circulation consist of a system of tubes or vessels which during life are filled with fluid constantly moving in one direction. The major portion of the system is concerned with the continuous distribution of blood throughout the body and is called the **hemal or blood-vascular** system. A circumscribed part of the hemal circulation is differentiated into a rhythmically contracting propulsory organ called the heart. The minor portion of the system is called the **lymphatic system.** The lymphatic vessels convey fluid, the lymph, from the tissues to the hemal system.

The essential functions of the blood-vascular system are performed by the smallest of all the blood-vessels, the **capillaries** [vasa capillaria], which form a network pervading practically all the tissues of the body. Blood is carried to and from the capillaries by larger vessels called the **arteries** and **veins** respectively. The heart receives blood from the veins and propels it, in turn, into the arteries.

In order to distribute oxygen to the tissues, the blood must of necessity pass through the respiratory organ before being delivered to the body at large. In gill-breathing vertebrates, the blood, having received oxygen in its passage through the gills, passes on to the tissues. The entire circuit is here accomplished by a single continuous chain of vessels in which capillaries occur twice, once in the gills and again in the organs and tissues in general. In man, as in other higher vertebrates, lungs assume the function of the gills. Having received oxygen in the lungs the blood is returned again to the heart before being redistributed throughout the body. There are thus in man two separate circuits or systems of blood-vessels, one traversing the lungs and a second ramifying throughout the body. The former is known as the **pulmonary** circulation; the latter as the **systemic.** Each has its own arteries, capillaries and veins; the heart is common to both. From the time of birth the heart is longitudinally divided into right and left halves, so that the two streams which enter it are entirely separated. The blood entering the left side of the heart has issued from the pulmonary circulation to be driven into the systemic; the blood entering the right side, having traversed the systemic circuit, is returned again to the lungs.

The heart and blood-vessels have a continuous lining of flattened cells called endothelium; the hemal system is, therefore, a closed circuit.* The main thickness of the heart, arteries and veins consists of additional tissue developed around the endothelial lining. It is due to this tissue that the blood is continuously delivered to, and withdrawn from, the capillaries under suitable conditions of pressure and velocity. The heart is mainly composed of rhythmically contracting muscle and its valves are so arranged that the blood contained within it is driven intermittently in one direction. The walls of the largest arteries are formed to a great extent of elastic tissue, and, being constantly under tension from within, are instrumental in converting the stream, intermittently received from the heart, into a continuous flow. The walls of the medium sized to smallest arteries are mainly muscular. The smallest arteries are microscopic in size and known as **arterioles** [arteriolæ]. The muscular arteries are capable of general or local alterations of caliber; they are thus largely concerned in the maintenance of the arterial pressure and in the regulation of the volume of blood which enters given localities under varying conditions. The veins have much thinner walls than the arteries, and the venous pressure is extremely low.

When an artery divides, the combined caliber of its branches is greater than that of the vessel itself. Since the arteries divide repeatedly the bed of the blood-stream increases in proportion as the vessels diminish in size. The rate of increase, slow at first, becomes enormous in the arterioles. Conversely, the bed of flow diminishes as the heart is approached from the venous side. The velocity of flow in the capillaries must necessarily be much lower than in the great arteries and veins. From the relative slowness of the blood flow in the systemic capillaries, it has been estimated that their total bed is eight hundred times greater than that of the main arterial stem.

Variations.—The distribution of the chief arteries and veins of different individuals varies so slightly in the aggregate that the descriptions given by anatomists nearly two hundred years ago differ but slightly from those in current use. Deviations from the usual type of vascular

* There remains some doubt as to whether this statement is applicable to the spleen. That it is applicable to the bone marrow was shown by Doan and by Drinker, Drinker and Lund in 1922.

distribution are occasionally encountered in the adult, however, and their presence seems always to depend upon some disturbance of the usual course of development. When once the primitive vessels have made their appearance, the progress of vascular development is characterized by the successive appearance of alternative arterial or venous channels for the transit of blood to, or from, the capillaries of the various regions of the body. Some of the earlier channels persist throughout development; while others, remaining for a shorter or longer period, eventually disappear. Others, again, by forming connections with their fellows, or with channels of later development, may take a larger or smaller share in the composition of one or more of the adult arteries or veins. The normal vascular pattern of the human body, having been repeatedly modified during the progress of development, may be said, at length, to attain its permanent form. The production of an adult vascular system of so-called normal type in any particular individual, depends, therefore, upon the exact repetition of a complicated series of developmental changes. Should one of the numerous embryonic vessels concerned in the process fail to perform its customary role, some noticeable departure from the normal type will be encountered in the adult vascular system. Variations thus produced are more prone to occur in some regions than in others. Apart from such extensive anomalies as those in which imperfections of the aorta or pulmonary artery occur in association with arrested development of the cardiac septa, variations of blood-vessels are not, as a rule, attended with impairment of function. A list of the chief variations in the arteries and veins is given later, in connection with their morphogenesis.

In the following section the heart and pericardium will first be considered followed by the arteries and veins.

A. THE HEART AND PERICARDIUM

1. THE HEART

The **heart** [cor] is a hollow organ principally composed of muscle, the **myocardium.** It is lined internally by **endocardium** which is continuous with the intima of the blood-vessels. Externally, it is covered by the **epicardium,** a serous membrane continuous with the serous lining of the pericardium. The form of the heart, when removed from the body without previous hardening, is that of a fairly regular truncated cone. The **base** [basis cordis] is poorly circumscribed but corresponds, in the general way, to the area occupied by the roots of the great vessels and the portion of the heart-wall between them. The base of the heart is held in position chiefly by the great vessels, which are attached to the pericardium. It is not fixed, however, for during systole the base performs a greater excursion than does the apex. The remainder of the organ is capable of free movement within the pericardial cavity.

The interior of the heart is longitudinally divided into right and left cavities by a septum passing from base to apex. Each cavity is subdivided into an **atrium** [atrium cordis] and a **ventricle** [ventriculus cordis], the former receiving the ultimate venous trunks and the latter giving rise to the main arteries. Thus the left atrium receives the four pulmonary veins, and the right atrium the superior and inferior vena cava and the coronary sinus; the aorta issues from the left ventricle and the pulmonary artery from the right. The ventricles, which constitute the major portion of the heart, may be recognized by their very thick walls. The atria have thinner walls and are less capacious than the ventricles; projecting from each is a diverticulum or **auricle** [auricula cordis]. The auricles (which receive their name from their resemblance to dog's ears) partially embrace the roots of the pulmonary artery and aorta.

Orientation of the heart.—The apex of the heart [apex cordis] points forward, to the left and downward. The base is directed backward, to the right and upward. The longitudinal axis of the heart forms an angle of about 40° with the horizontal plane and also with the median sagittal plane of the body.

The long axis of the heart is therefore slightly more horizontal than vertical, and slightly more anteroposterior than transverse, and the atria are posterior to, rather than above the ventricles. To arrive approximately at the direction of the longitudinal axis of the heart, it is necessary to select the central point of the base. By cutting the vessels short in several hearts, hardened by formalin before removal, a point immediately to the left of the right lower pulmonary vein was selected in determining the data above given. A steel pin was passed through this point to the apex cordis, and the angles controlled by frontal and transverse sections of the thorax. Mention of angular measurements of the axis of the heart could be found only in the text-books of Testut and Luschka; the former gives 40° to the horizontal plane, the latter 60° to the midsagittal. Luschka's angle appears to be too large; but further investigation in this direction is desirable

Size and weight.—The heart measures about 12.5 cm. (5 in.) from base to apex in the adult, and 8.7 cm. (3½ in.) at its broadest, and 6.2 cm. (2½ in.) at its thickest portion. In the male its weight averages about 312 gm. (eleven ounces), and in the female about 255 gm. (nine ounces). The weight of the heart forms approximately 0.4 to 0.45 per cent. of the total

body-weight in the male of normal build and about 0.53 per cent. in the female; in emaciated individuals it usually weighs relatively more, and relatively less in the fat. The *volume* of the heart in diastole may be estimated during life in cubic centimeters by the use of the following formula, 0.53 A $^{3}/_{2}$, A being the X-ray silhouette of the diastolic area in square centimeters, after making due allowance for divergence of rays (Bardeen). The heart weight may be computed by multiplying 1/20 A $^{3}/_{2}$ by 0.0055.

EXTERIOR OF THE HEART

In hearts which have been hardened by injection before removal from the body, the regularity of the heart-cone is disturbed by a well-marked triangular

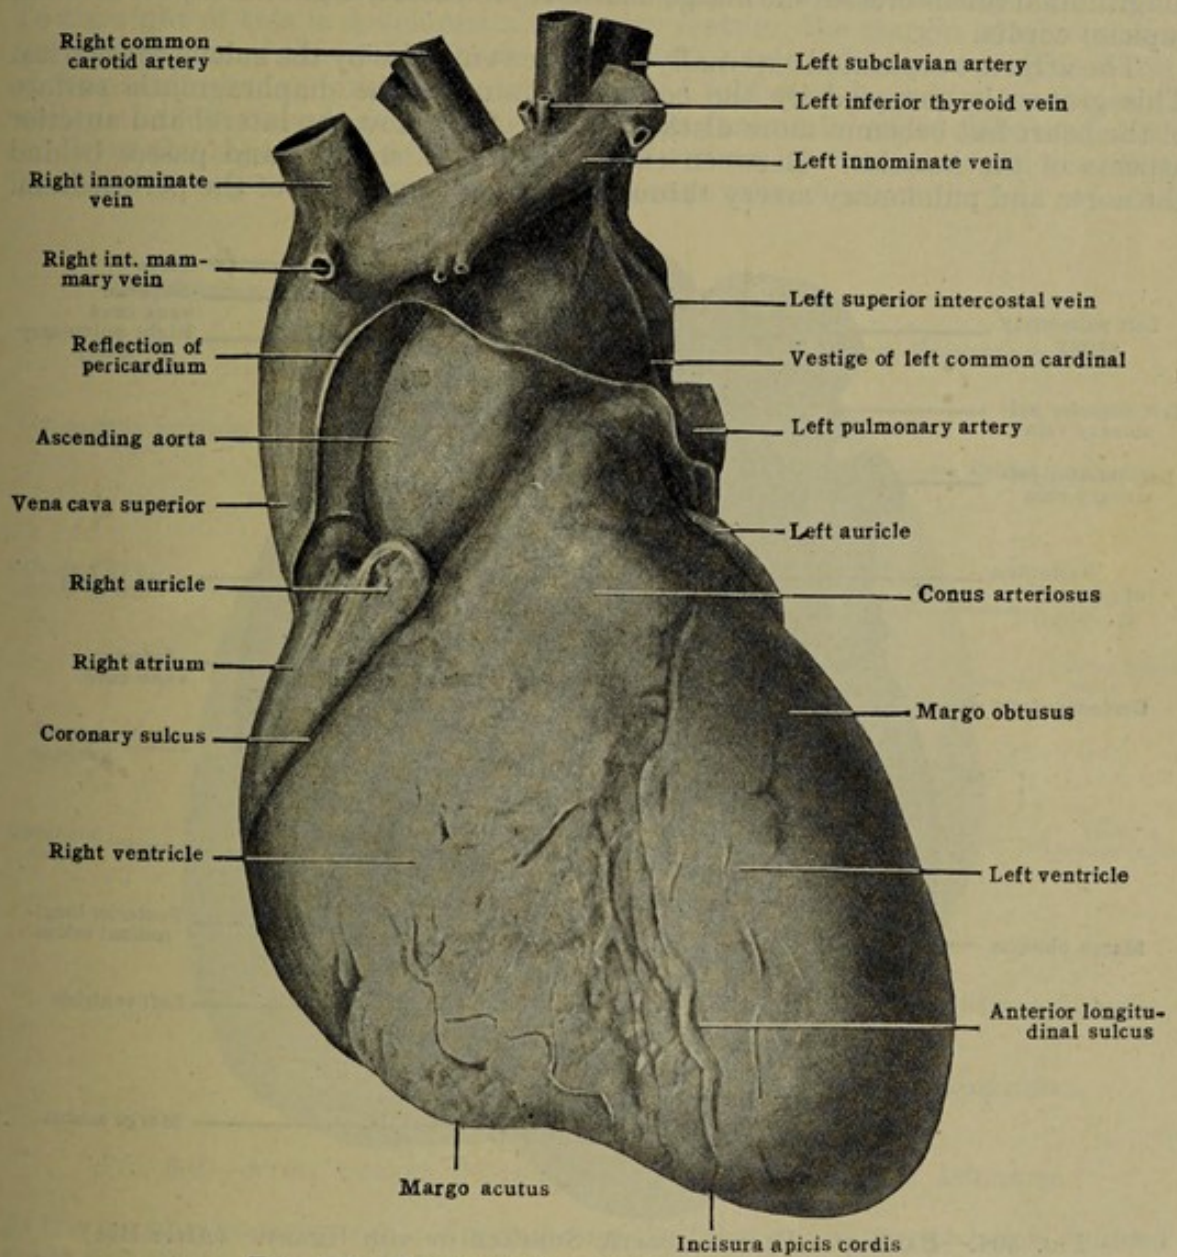

FIG. 503.—STERNOCOSTAL SURFACE OF THE HEART.

facet, imparted by contact with the diaphragm. This facet is the **diaphragmatic surface** [facies diaphragmatica], which is directed downward and slightly backward (fig. 505). It ends abruptly along a sharp margin extending from the apex toward the right. This margin is the **margo acutus** (fig. 503); it separates the diaphragmatic surface from the sternocostal surface. The other margin of the diaphragmatic surface is more rounded and shades gradually into the rounded margo obtusus (fig. 506), which passes almost insensibly into the sternocostal surface. The convex **sternocostal** surface [facies sternocostalis] (fig. 503), directed forward and somewhat upward and to the right, is triangular and bounded below by the margo acutus. To the left it goes over into the margo obtusus along a line extending from the apex of the heart to the root of the pulmonary artery. The **margo obtusus** corresponds to the rounded left side of the left ventricle.

The interventricular sulcus is a slightly marked groove indicating the separation of the ventricles upon the exterior of the heart. It lodges coronary blood-vessels and a moderate quantity of fat which can be seen through the epicardium. The part of this groove seen on the sternocostal surface is the **sulcus longitudinalis anterior.** It runs obliquely over the upper part of the margo obtusus on to the sternocostal surface. Crossing the margo acutus to the right of the apex it is continuous with the **sulcus longitudinalis posterior** upon the diaphragmatic surface. The diaphragmatic surface is formed about equally by the right and left ventricles, and the sternocostal surface mainly by the right. Where the longitudinal sulcus crosses the margo acutus it produces a slight notch, the **incisura (apicis) cordis.**

The atria are separated externally from the ventricles by the **sulcus coronarius.** This groove is occupied by the coronary sinus on the diaphragmatic surface of the heart but becomes more distinct as it passes below the lateral and anterior aspects of the auricles. Between the auricles it is shallow and passes behind the aorta and pulmonary artery through the transverse sinus of the pericardium.

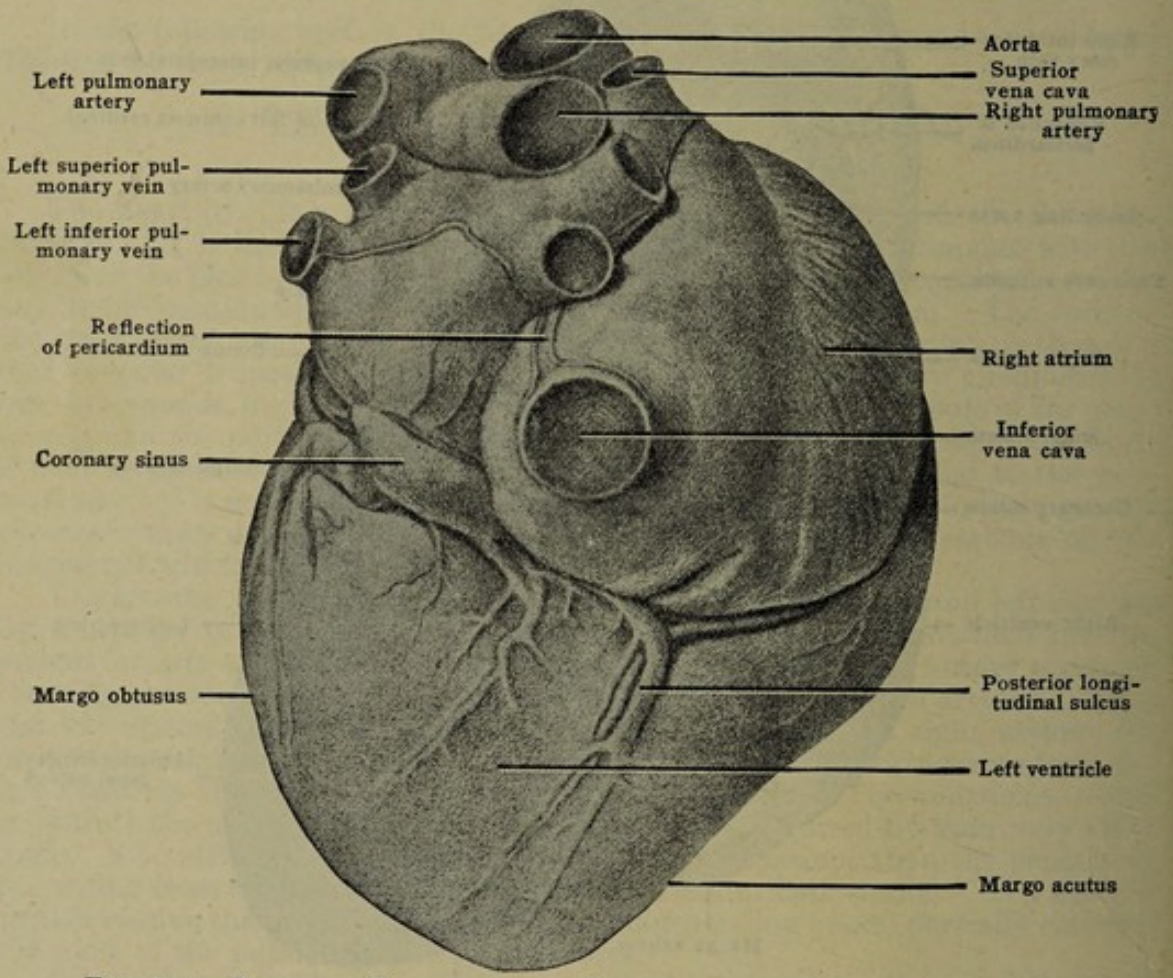

FIG. 504.—BASE AND DIAPHRAGMATIC SURFACE OF THE HEART. (After His.)

ATRIAL PORTION

The **atrial portion of the heart** is situated behind, and slightly to the right of and above, the ventricular portion. On the external surface, its separation into right and left atria is not indicated posteriorly, except in distended hearts (such as that shown in fig. 504); in these it is marked by a slight groove connecting the left sides of the superior and inferior vena cava. The auricles are separated anteriorly by the deep notch which lodges the aorta and pulmonary artery. A slight groove on the back of the right atrium which connects the right sides of the superior and inferior vena cava, is the **sulcus terminalis** (figs. 504, 505). This represents the right limit of what was, in the embryo, the sinus venosus, the embryonic sinus venosus having become an integral part of the adult right atrium. The superior and the inferior cava join the posterior part of the right atrium above and below, respectively. The coronary sinus courses downward, backward and to the right to enter the right atrium anteriorly to and somewhat

above the place of entrance of the inferior vena cava. The four pulmonary veins run nearly transversely and somewhat forward into the right and left sides of the left atrium.

The interior of the atrial portion of the heart is divided into right and left cavities by the **septum atriorum.** This septum is a composite structure, having been developed (see p. 603) in two independent parts, neither of which is a complete septum in itself. The two incomplete septa, however, partly overlap one another so that, by lateral fusion at the time of birth, they together produce the impervious structure of the adult heart (fig. 505). Of these septa, the first to be formed is the **membranous septum** [pars membranacea septi atriorum]. To the right of this is developed a muscular septum, the margin of which forms the greater part of the **limbus fossæ ovalis** of the adult right atrium. The margin of the membranous septum is recognizable as a fold of endocardium on the septal wall of the left atrium; it is called the **valvula foraminis ovalis** (falx septi NK).

Upon the septal wall of the adult **right atrium** [atrium dextrum] (fig. 508), immediately above the inferior cava is the **fossa ovalis,** of which the floor is formed

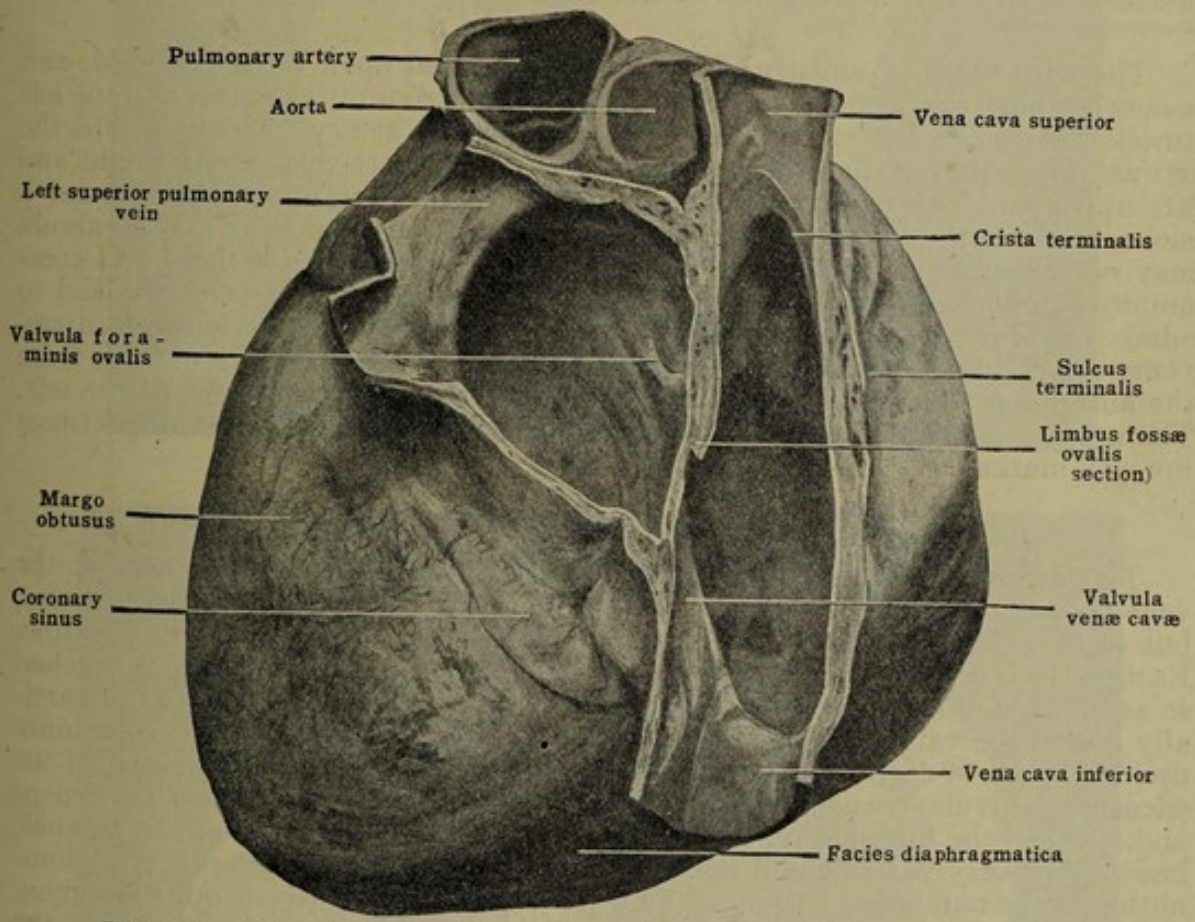

FIG. 505.—ATRIA OPENED POSTERIORLY TO SHOW THE SEPTUM ATRIORUM.

by the membranous septum. Surrounding the fossa ovalis except below (indeed producing the fossa) is the limbus fossæ ovalis which is continuous anteriorly and below with the **valvula venæ cavæ** (inferioris Eustachii). Anterior to the fossa ovalis is the orifice of the coronary sinus, which is guarded by the **valvula sinus coronarii** (Thebesii) (fig. 508). Leading from the front of the atrium forward and slightly downward and to the left is the **ostium venosum** of the right ventricle (right atrioventricular orifice) guarded by the tricuspid valve. Above and behind the venous ostium is the auricle, the exterior of which is in contact medially with the root of the aorta. To the right of the superior and inferior caval orifices there is a vertical ridge, the **crista terminalis,** which corresponds to the sulcus terminalis on the exterior (figs. 505, 508).

The portion of the atrium bounded laterally by the crista terminals and medially by the septum atriorum is smooth, the **sinus venarum**; in the embryo it is separated from the atrial cavity proper by the right and left sinus valves. The crista terminalis marks the original line of attachment of the right sinus valve. The valve itself has disappeared, excepting the lower part which persists as the caval and the coronary valves. These valves vary in size considerably in different specimens, and are frequently netlike from numerous perforations.

The conversion of a portion of a single valve into two separate parts, which meet at an acute angle, is brought about by local blending between the sinus valve and an embryonic structure called the sinus-septum. This septum is a ridge dividing the right horn of the sinus venosus from the transverse portion of the sinus (the coronary of the adult); it probably contributes somewhat to the formation of both the coronary and caval valves. The left sinus valve usually disappears by blending with the septum atriorum, becoming a part of the limbus fossæ ovalis; it occasionally remains partially separate in the adult.

The interior of the right auricle and of the portion of the atrium upon the lateral side of the crista terminalis is thrown into ridges, **musculi pectinati** (trabeculæ carneæ NK), by prominent bands of the atrial myocardium. The musculi pectinati end abruptly by joining the crista. The orifice of the superior cava has no valve and is directed downward and somewhat forward; below it, on the posterior wall of the atrium, there has been described the **tuberculum intervenosum** (Loweri).

Apart from the posterior circumference of the superior cava itself and the limbus fossæ ovalis, the human heart appears to contain nothing in this region that could be described as a tubercle. The fossa ovalis is just above (almost within) the inferior caval orifice. Opening into the right atrium, particularly upon the septal and right lateral walls, are numerous *foramian venarum minimarum* (Thebesii).

The **left atrium** [a. sinistrum] (fig. 504) is situated upon the left side of, and somewhat posteriorly to the right. It is behind the root of the aorta, and the left auricle lies to the left of the root of the pulmonary artery. Opening into the left atrium posteriorly, on the right and left sides, respectively, are the right and left upper and lower pulmonary veins. The valvula foraminis ovalis forms a more or less distinct crescentric ridge on the septal wall (fig. 505). The valvula may not be attached to the limbus fossæ ovalis, in which case there is a communication between the two atria. This, however, does not necessarily lead to admixture of arterial and venous blood during life. The **ostium venosum** (atrioventricular orifice) of the left ventricle, guarded by the mitral valve, leads from the anterior part of the atrium forward and slightly downward and to the left. The interior of the left atrium proper is smooth; in the auricle musculi pectinati are well marked.

ATRIOVENTRICULAR VALVES

The **atrioventricular valves** (figs. 507, 508, 509) are attached around the venous ostia of the ventricles in such a way as to give freely into the ventricles, but to prevent regurgitation of blood into the atria during ventricular systole. Each valve is continuous along its line of attachment, but its free edge is notched so as to produce an irregular margin; some of the notches are so deep as to partially divide the valve into cusps. The right atrioventricular valve is commonly divided by three deep notches into three cusps; this valve is therefore called the **tricuspid** [valvula tricuspidalis]. The left is similarly divided into two cusps and is called the **bicuspid** [v. bicuspidalis] or **mitral.** The depth of the notches, however, is very variable and there may be an increase or (more rarely) a diminution in the number of cusps; the addition of subsidiary cusps is quite common. Each valve cusp is tied down to the **papillary muscles** [mm. papillares] of the ventricle by **chordæ tendineæ.** The latter are fibrous cords, generally branched, of varying thickness. The thinnest cords are attached to the free margin of the cusp; those of intermediate thickness to the ventricular surface a few millimeters from the free margin, and the thickest to the ventricular surface near the attached margin. The valves are smooth and glistening on the atrial aspect, but rough and fasciculated, from the attachment of the chordæ, on the ventricular aspect. The cusps of the *mitral valve* are called *anterior* and *posterior* (velum septale or aorticum and dorsale NK); those of the *tricuspid*, *anterior*, *posterior* and *medial* (velum ventrale, dorsale and septale NK). Each cusp receives chordæ from more than one papillary muscle and each papillary muscle sends chordæ to more than one cusp. The chordæ tendineæ of the mitral valve are thicker than those of the tricuspid.

VENTRICULAR PORTION

The **ventricles** form the greater part of the heart. In the adult the relation of the ventricles to one another is as follows. The left [ventriculus sinister] has the form of a narrow cone, the apex of which forms the apex of the heart.

The right ventricle [ventriculus dexter] is crescentic in section and appears to be partially wrapped around the right or lower wall of the left ventricle which forms the septum ventriculorum (fig. 506). The **left ventricle** forms the margo obtusus of the heart, about half the diaphragmatic surface, and a small part of the sternocostal surface. The **right ventricle** forms about half the diaphragmatic surface and the major part of the sternocostal surface; it takes no share in the formation of the apex of the heart.

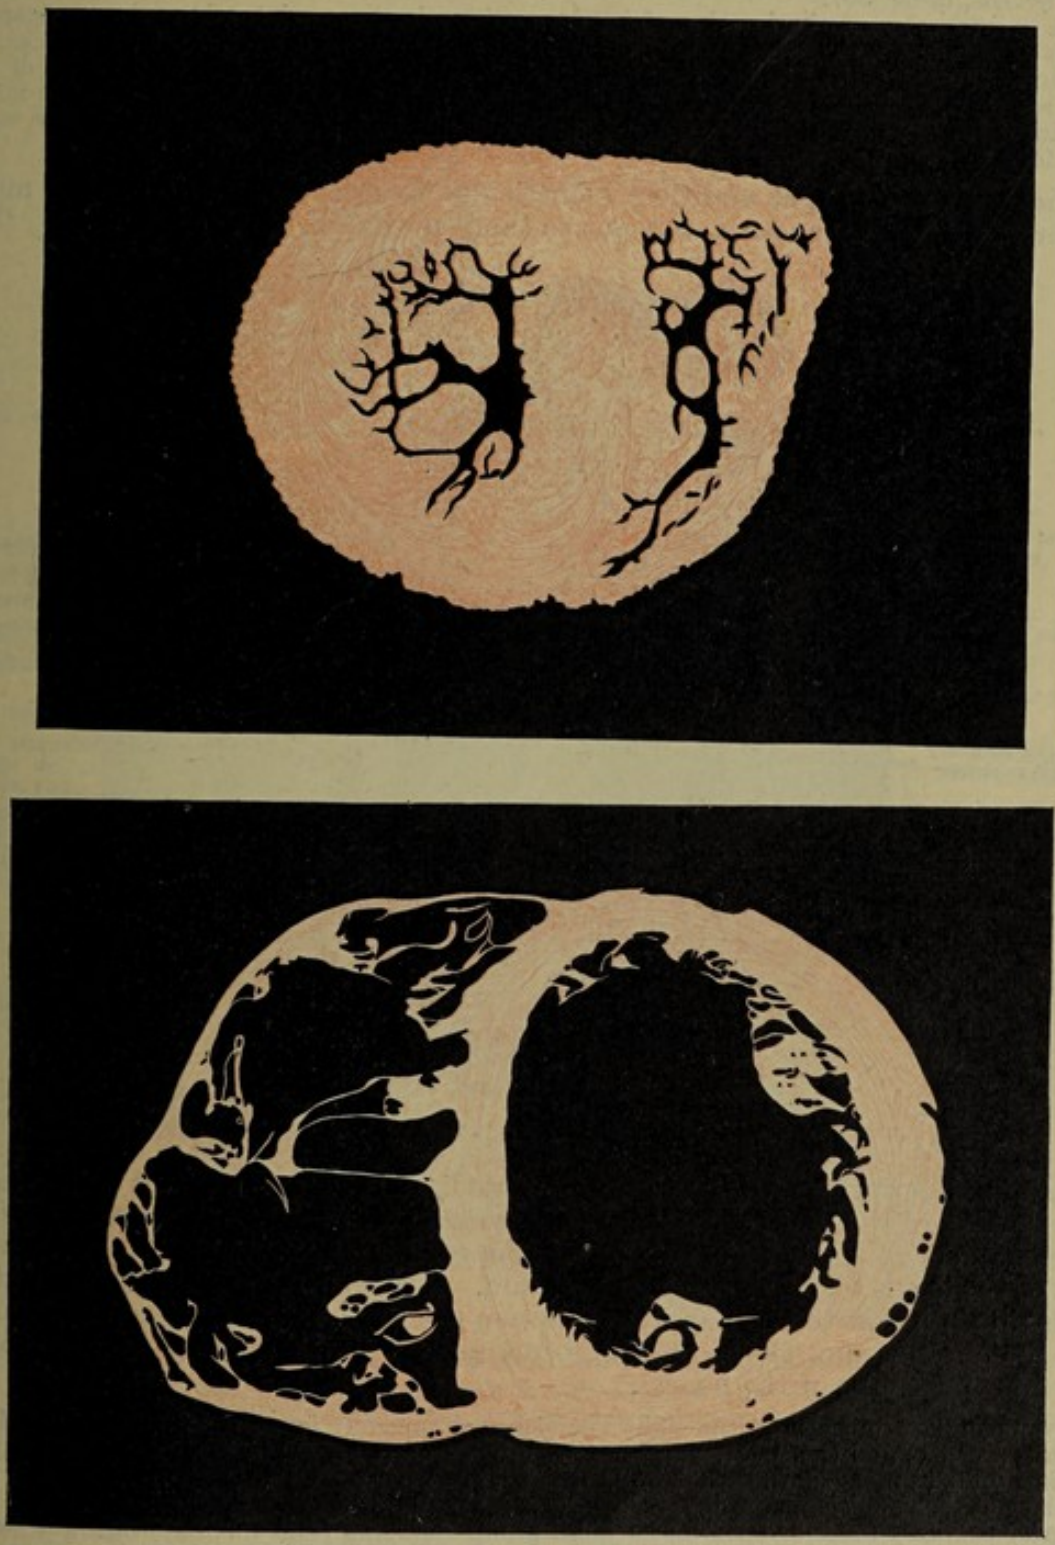

FIG. 506.—SECTION OF THE VENTRICLES IN SYSTOLE AND DIASTOLE. (After Krehl.)

The **interventricular septum** [septum ventriculorum] is thick and muscular except for a small area near the root of the aorta which is membranous [septum membranaceum ventriculorum]. The latter can be seen from the left ventricle in the angle between the attached edges of the right and posterior aortic valves (fig. 509). The membranous septum is partly concealed on the right side by the medial cusp of the tricuspid valve which is attached to it near its upper end.

The portion of the membranous septum above the attachment of the medial tricuspid cusp is therefore atrioventricular, since it intervenes between the right atrium and the left ventricle.

The membranous septum is the extreme lower part of the independent septum (s. aorticum) which divides the aortic root from the pulmonary artery and conus arteriosus. The aortic septum partially subdivides, also, the right ventricle by separating the conus arteriosus from the remaining part of the interior. The relation borne by the part of the aortic septum which intervenes between the conus arteriosus and aortic root to the septum ventriculorum is well shown by His, in fig. 507.

The greater part of the interior of both ventricles is thrown into ridges by myocardial bundles of large size. These fasciculi [**trabeculæ cordis**] either stand out in relief only, or, by being undermined, form bands enveloped by endothelium. A careful examination of the endocardium of fresh hearts will reveal a plexiform network of **Purkinje fibers.** These fibers, belonging to the atrioventricular conducting system, become visible to the naked eye when the endocardium has been exposed to the air long enough to become partially dry.

The wall of the **right ventricle** [ventriculus dexter] (figs. 507, 508) is much thicker than that of the atria, but not so thick as that of the left ventricle. The

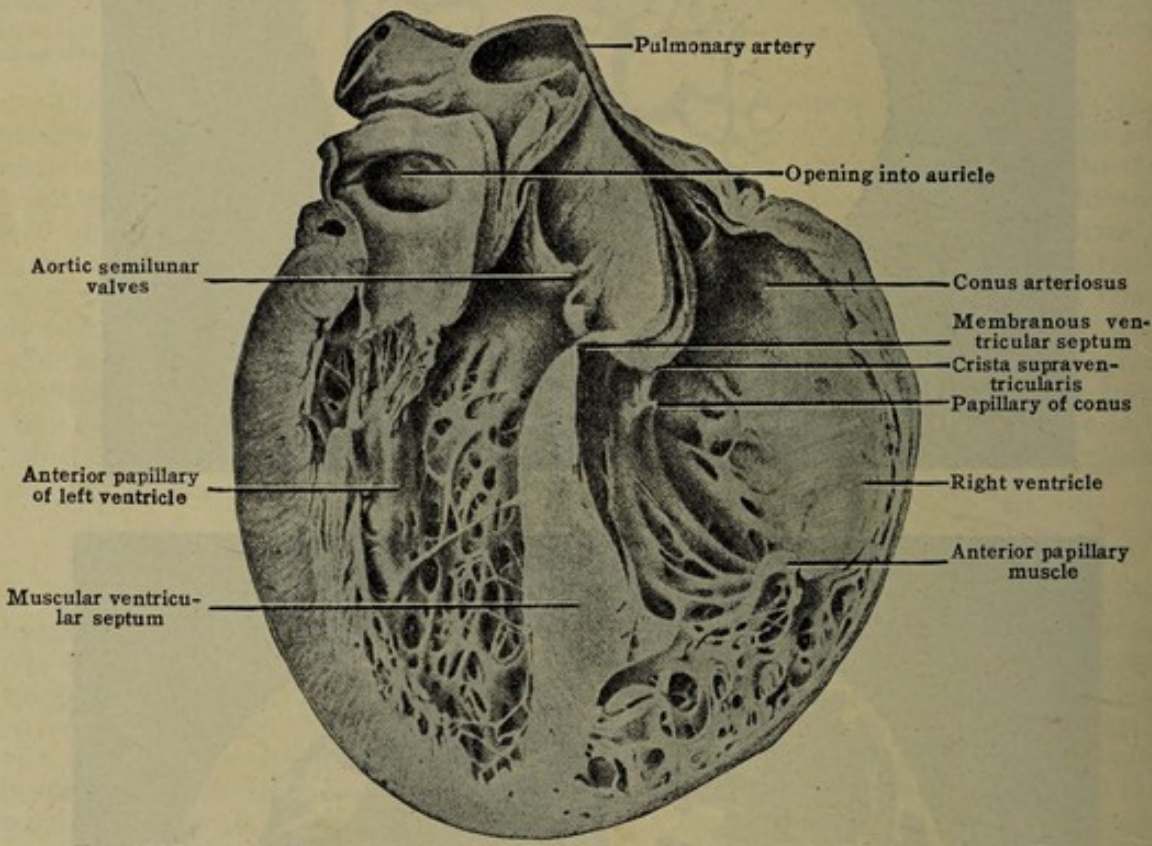

FIG. 507.—THE INTERIOR OF THE VENTRICLES, ANTERIOR HALF. (After His.)

upper and anterior part of the right ventricle lies in front of the root of the aorta. This portion of the ventricle is called the **conus arteriosus** and is separated from the remainder of the right ventricle by a muscular spur which extends from the back of the conus to the right venous ostium. The spur is the **crista supraventricularis;** its relation to the partition between the conus and aorta, and to the septum membranaceum, shows that it forms part of the embryonic aortic septum (see morphogenesis of the heart).

Two papillary muscles in the right ventricle are constant in position, the large **anterior papillary muscle,** and the small **papillary muscle of the conus** (Luschka). The anterior papillary is situated on the sternocostal wall, near the junction of this with the septal wall. The papillary of the conus is placed just below the septal end of the crista supraventricularis. The **posterior papillary muscles** form an irregular group springing from the diaphragmatic wall of the ventricle. Some of the chordæ tendineæ stretch directly from the septal wall (with or without small muscular elevations at their bases) to the medial cusp of the tricuspid valve. The chordæ tendineæ from the anterior papillary go to the anterior and posterior cusps; those from the conus papillary to the medial and anterior, and those from the posterior papillary muscles to the medial and posterior cusps of the tricuspid valve, respectively.

A band of myocardium is often found to extend from the septal wall of the right ventricle to the anterior papillary muscle; this is the **moderator band,** which contains a part of the right limb of the atrioventricular bundle. If the moderator band joins the anterior papillary near its base, as it frequently does, it is difficult to distinguish it from the trabeculæ cordis which ordinarily occupy this situation.

The term moderator band was originally applied to this bridge or band of muscle under the impression that it prevented overdistention of the ventricle. Since the discovery of the conducting system of the heart it has been known that there is always a band which conducts the right limb of the atrioventricular bundle from the septum to the anterior papillary muscle. Whether the band is isolated from the other trabeculæ, and therefore readily recognizable, appears to depend somewhat upon the relation of the base of the papillary muscle to the septum ventriculorum.

The wall of the **left ventricle** [ventriculus sinister] (figs. 507, 509) is very thick except at the extreme apex, and at the membranous septum. In the left

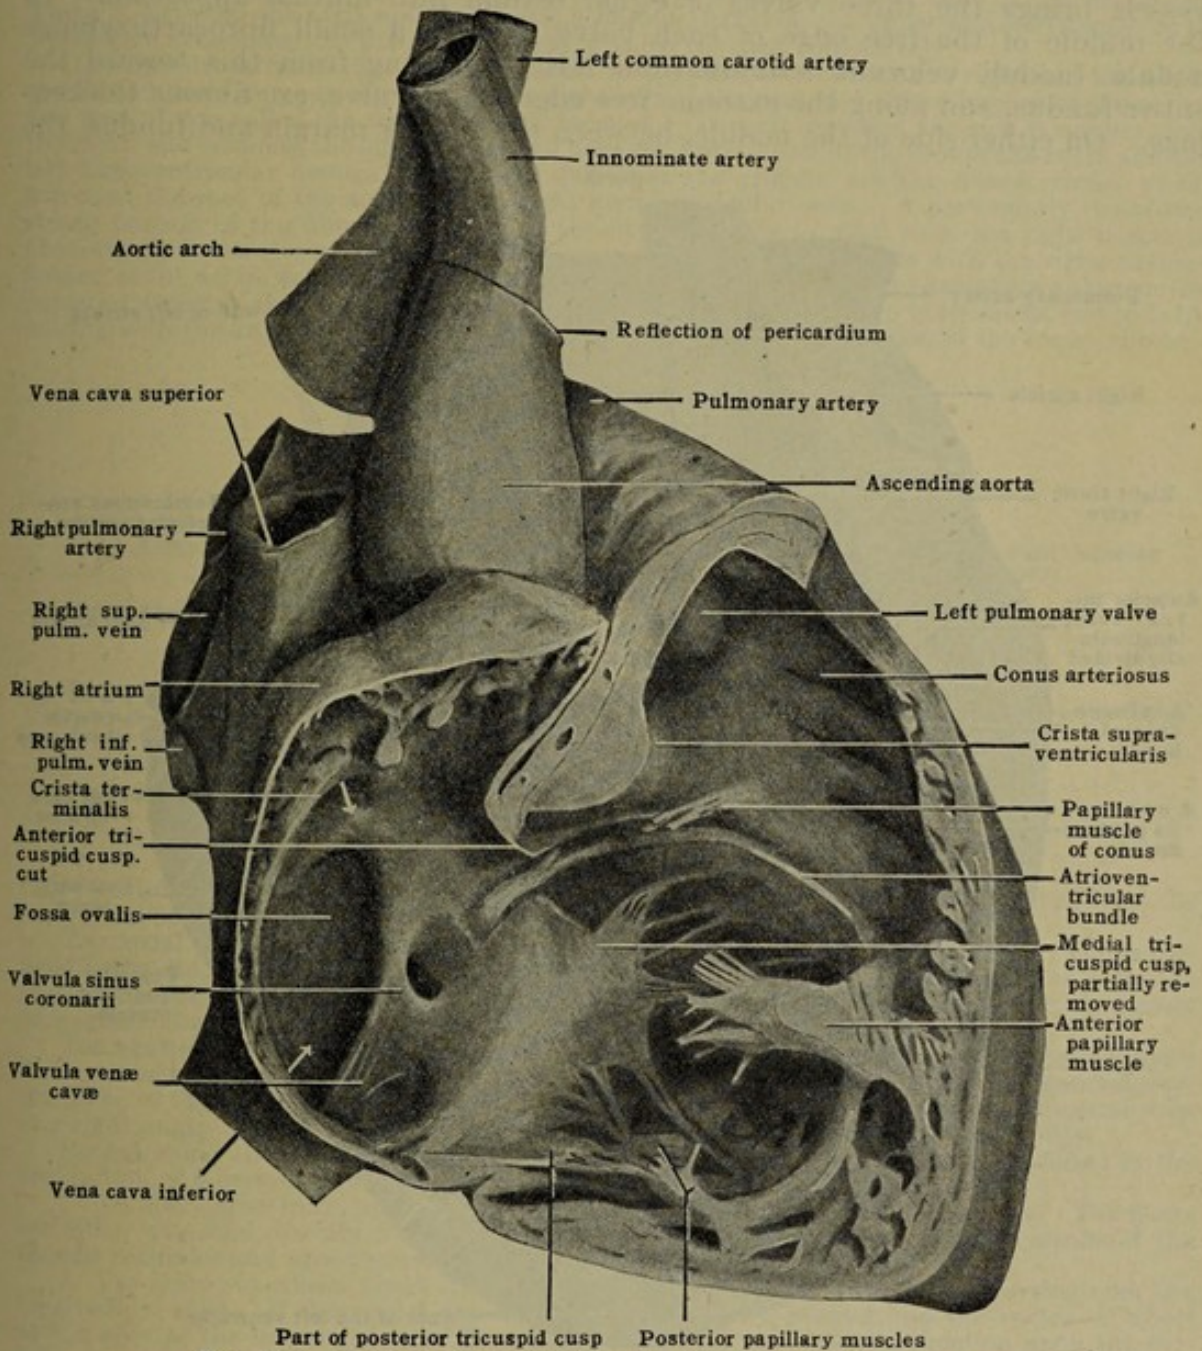

FIG. 508.—INTERIOR OF THE RIGHT ATRIUM AND VENTRICLE.
The atrioventricular bundle is dissected out.

ventricle are two large papillary muscles, generally known as **anterior** and **posterior**; both send chordæ tendineæ to each cusp of the mitral valve. On the septal wall of the ventricle the left limb of the atrioventricular bundle can usually be seen as a broad, flattened band beneath the endocardium. The band appears just below the septum membranaceum and divides into strands which go to the two papillarly muscles. The strands in many places bridge across part of the ventricle to reach the papillary muscles, covered only by tubes of endocardium.

These bridging strands connecting the papillary muscles with the septum ventriculorum, which were formerly called 'false chordæ tendineæ,' are exactly comparable to the moderator band of the right ventricle which occasionally consists of atrioventricular bundle and endocardium only.

SEMILUNAR VALVES

The **semilunar valves** [valvulæ semilunares] guard the arterial ostia of the ventricles. The aortic ostium is directed upward and slightly forward and to the right; the pulmonary backward and slightly upward and to the left. Each valve, of which there are three to each ostium, is a pocket-like fold of endocardium strengthened by fibrous tissue (fig. 510). The free edge of each valve is directed away from the ventricle, so that excess of pressure within the great vessels brings the three valves of either ostium into mutual apposition. In the middle of the free edge of each valve there is a small fibrocartilaginous **nodule** (noduli velorum semilunarium NK); radiating from this toward the entire fundus, and along the extreme free edge of the valve, are fibrous thickenings. On either side of the nodule, between the thicker margin and fundus, the

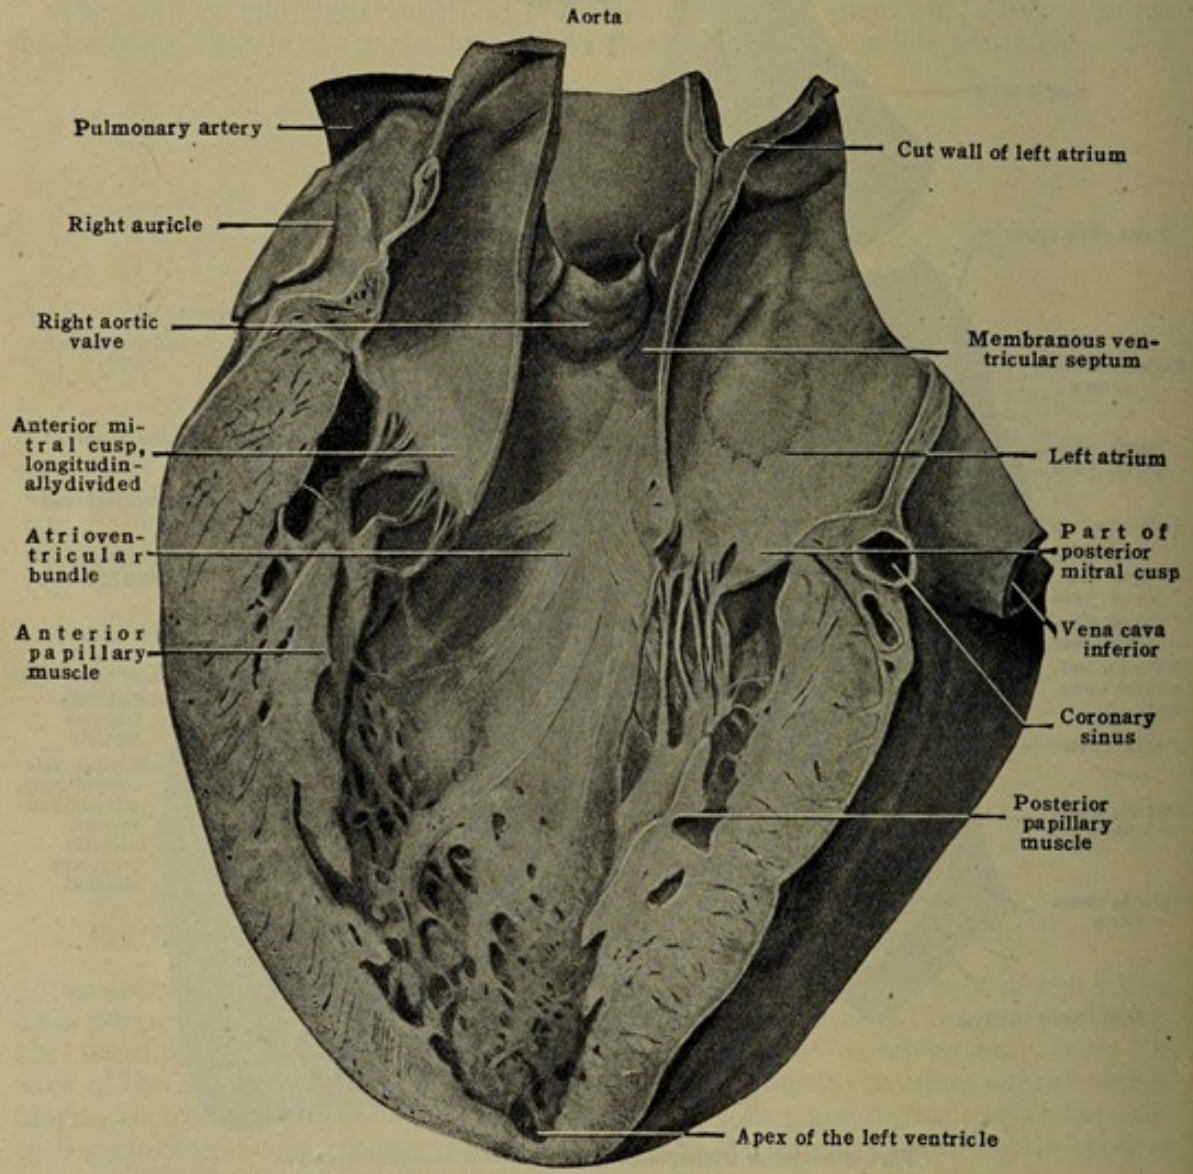

FIG. 509.—LEFT VENTRICLE AND PART OF THE ATRIUM.
The aorta is opened through the anterior cusp of the mitral valve. The plainly visible left limb of the atrioventricular bundle has been accentuated.

valve is thin over a crescentic area called the **lunula** (lunulæ velorum semilunarium NK).

The aortic valves are called the right, left, and posterior; the pulmonary valves, the right, left, and anterior.* The aortic semilunar valves are stronger

* These BNA names of the aortic and pulmonary valves are not based upon their relative positions in the body. From transverse sections through the thorax (see any good atlas) it may be seen that one aortic valve is anterior, one pulmonary valve posterior, and the other aortic and pulmonary valves are right and left. If the removed heart is held so that the ventricles are on the right and left of the septum, respectively, the valves take the positions indicated by the BNA. The names given by the BNA to the valves, although conventional (like many other terms of orientation applied to parts of the heart), are convenient, particularly from

than the pulmonary; opposite them there are three dilations in the aortic wall, the aortic sinuses [**sinus aortæ**] or sinuses of Valsalva. From the right and left sinuses the right and left coronary arteries, respectively, arise.

After ventricular systole the increased pressure in the great vessels distends the valves with blood. The noduli meet in the center and the lunulæ, coming into mutual contact, produce a triradiate line of contact between the valves.

ARCHITECTURE OF THE MYOCARDIUM

In the adult heart the myocardium of the atria is separate from that of the ventricles. There is, between the atria and ventricles, a fibrous partition, the upper and lower surfaces of which give attachment to the muscle fibers of these cavities, respectively.

The **fibrous partition** (fig. 511) is thickest in the interval between the right and left atrioventricular ostia immediately behind the right end of the posterior circumference of the aorta; this part of it is called the right *trigonum fibrosum*. The *left trigonum fibrosum* is smaller than the right, and occupies the angular interval between the left side of the root of the aorta and the left atrioventricular ostium. Spreading out from the trigona are the *annuli fibrosi* which surround the root of the aorta and the two atrioventricular ostia. A particularly dense and strong portion of the fibrous partition of the heart extends forward from the right trigonum fibrosum; it forms the *septum membranaceum ventriculorum* and blends with the right circumference of the aortic annulus. From the anterior aspect of the aorta it passes forward upon the posterior aspect of the conus arteriosus, where it is known as the *tendon of the conus*, and ends by uniting with the annulus fibrosus of the pulmonary ostium. The tendon of the conus, the septum membranaceum and the greater part of the right trigonum fibrosum are derived from the embryonic aortic septum.

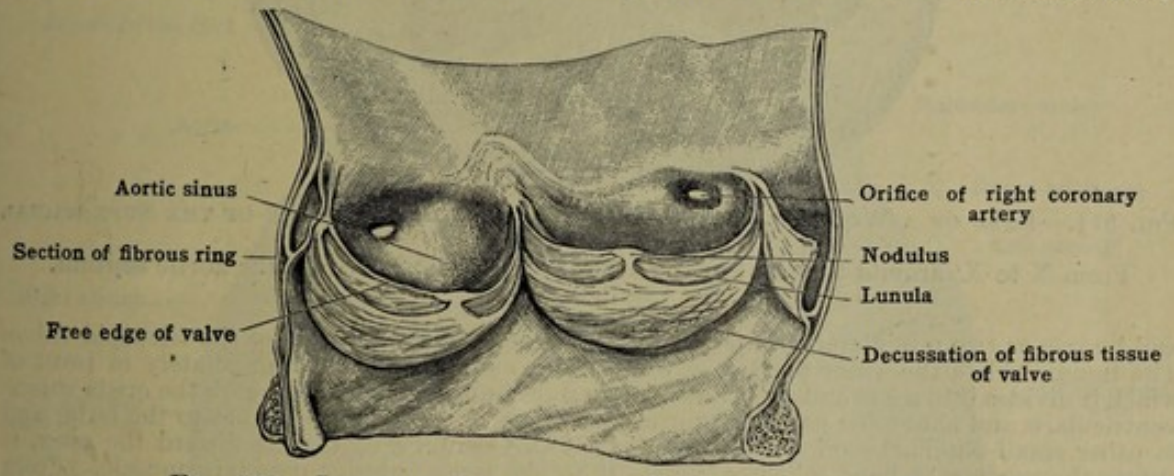

FIG. 510.—INTERIOR VIEW OF THE AORTIC SEMILUNAR VALVES.

The **atrial musculature** is attached to the trigona and atrioventricular rings. The superficial fibers are attached to both rings and either encircle both atria in one loop, or enter the septum and form a figure 8. The deeper fibers are attached to one ring and encircle one atrium only; some fibers encircle only the auricle.

The **ventricular musculature** is very complex and consists of numerous superimposed layers distinguished from one another by the direction taken by the muscles fibers. In a general way, the fibers of the deepest layer have a direction crossing those upon the surface of the same area at a right angle. The intervening layers of fibers pass through all stages of obliquity.

Recent work upon the origin and distribution of the ventricular fibers has resulted in the recognition of a certain uniformity of behavior, thus:—

1. All fibers arise from, and are inserted into, the fibrous partition at the base. The fibers are either attached directly to the trigona or annuli, or indirectly to them by means of the chordæ tendineæ and atrioventricular valves.

2. The more superficial fibers (fig. 512) tend to encircle the entire heart, passing over the longitudinal sulci. If they enter the septum they do so by passing into the vortex or whorl at the apex of the left ventricle. These fibers have always a definite direction upon the surface, i.e., from right to left upon the sternocostal surface and from left to right on the diaphragmatic (fig. 511).

3. The deeper fibers all enter the septum, and pass across it in a direction oblique or perpendicular to its longitudinal axis. They completely encircle one or both ventricles forming, in the latter case, a double loop (fig. 513).

During systole, as a result of this arrangement:—(1) The papillary muscles and the longitudinal and anteroposterior axes of the ventricles are simultaneously shortened. (2) There is a movement of torsion or 'wringing' which reduces the ventricular cavities to their minimum dimensions.

Conducting system.—Although the ordinary myocardium of the atria is distinct from that of the ventricles there is, at one place, a connection between them. This connection is effected by means of a small band of muscle which differs histologically from ordinary heart muscle. It

---

a developmental standpoint. The NK recommends velum semilunare dextrum, sinistrum and ventrale for the valvulæ aortæ; and velum semilunare dextrum, sinistrum and dorsale for the valvula arteriæ pulmonalis.

is known as the **atrioventricular bundle** (fasciculus atrioventricularis NK), and serves to transmit the atrial rhythm of contraction to the ventricles.

The atrioventricular bundle begins in the septal wall of the atrium a short distance in front of the coronary orifice (fig. 508). It has an expanded free end, the **atrioventricular node,** from which branches pass to be quickly lost in the atrial myocardium. The bundle passes through the right trigonum fibrosum (in the position marked X) into the musculature of the interventricular septum. In this it passes downward and forward, covered by endocardium

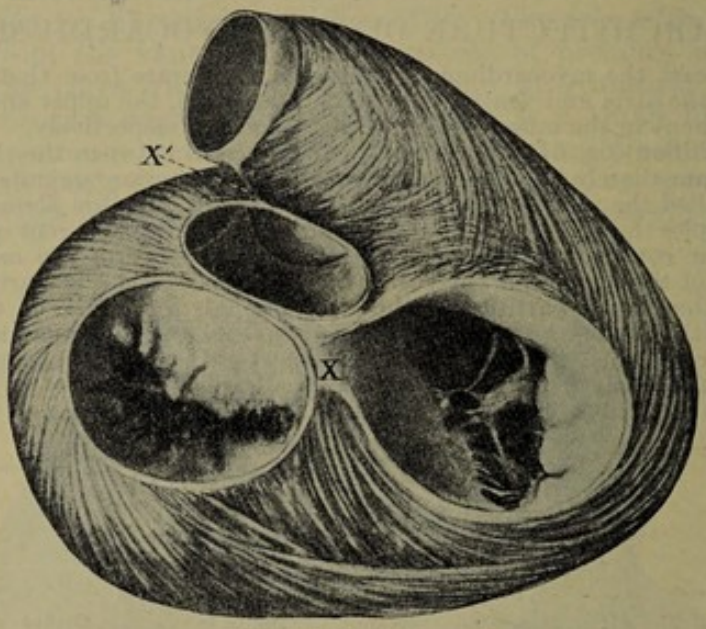

FIG. 511.—BASE OF A WELL DEVELOPED HEART SHOWING THE COURSE OF THE SUPERFICIAL MUSCLE FIBERS.
From X to X′ around the front of the aorta indicates the course of the aortic septum. (Mall, ×¾.)

and by one or two millimeters of myocardium, beneath the medial cusp of the tricuspid valve. The bundle skirts the lower margin of the septum membranaceum, immediately in front of which it divides into a left and right limb. The right limb now passes beneath the crista supraventricularis and above the papillary muscle of the conus, giving off branches to the latter and to other small papillaries on the septum (fig. 508). Bending somewhat toward the apex, it enters the moderator band which conducts it to the large anterior papillary muscle. From here it passes along one of the trabeculæ connected with the sternocostal wall of the ventricle, or in the wall itself, to reach the posterior papillary muscle or muscles. The right limb is compact

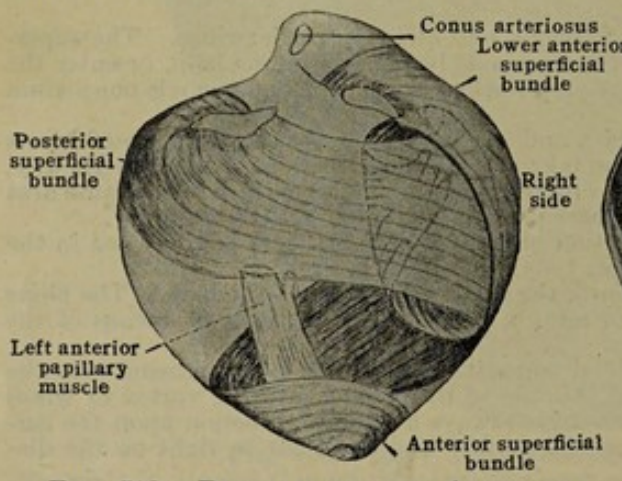

FIG. 512.—DIAGRAM OF ONE ANTERIOR AND ONE POSTERIOR SUPERFICIAL BUNDLE OF CARDIAC MUSCLE FIBERS SEEN FROM BEHIND. (After MacCallum.)

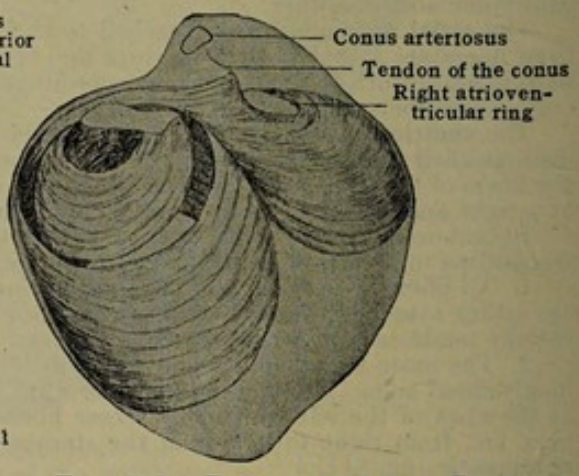

FIG. 513.—DIAGRAM OF A DEEPER BUNDLE OF MUSCLE FIBERS. (After MacCallum.)

and rounded and in the intact heart is usually invisible from the endocardial side except near the root of the moderator band or in the band itself.

The left limb of the bundle pierces the interventricular septum and appears in the left ventricle a little below the septum membranaceum. It forms a flat, wide band immediately beneath the endocardium, which usually cannot be stripped off without injuring the bundle (fig. 509). It passes along the septal wall toward the apex and divides into two parts, which again subdivide to be distributed to the anterior and the posterior papillary muscles. The branches for the papillary muscles may reach them by traversing the trabeculæ carneæ in the neighborhood, or they may form thin strands which, covered by endocardium only, bridge the gap between the septum and the papillary muscles.

In addition to the comparatively distinct branches to the papillary muscles of both ventricles, the bundle gives off finer fibers which form a subendocardial plexus. This plexus, visible to the naked eye (p. 592) is made up of fibers having a structure similar to those of the ventricular portion of the bundle. Its ramifications occupy the entire ventricular part of the heart except an area on the two sides of the interventricular septum below the aortic and pulmonary valves and about the half of each of the papillary muscles toward the chordæ tendineæ. The fibers were described by Purkinje as long ago as 1845 (Arch. f. Anat., Physiol. u. wiss. Med.) but it was not until 1906, thirteen years after the discovery of the bundle by W. His, Jr., that Tawara (Das Leitungssystem des Saügetierherzens, Fischer, Jena) recognized their significance.

There is another node of muscle having characters similar to that of the conducting system, although not connected with it except by myocardium of the ordinary character. This is the sinus-node which is situated at the upper end of the crista terminalis of the right atrium.

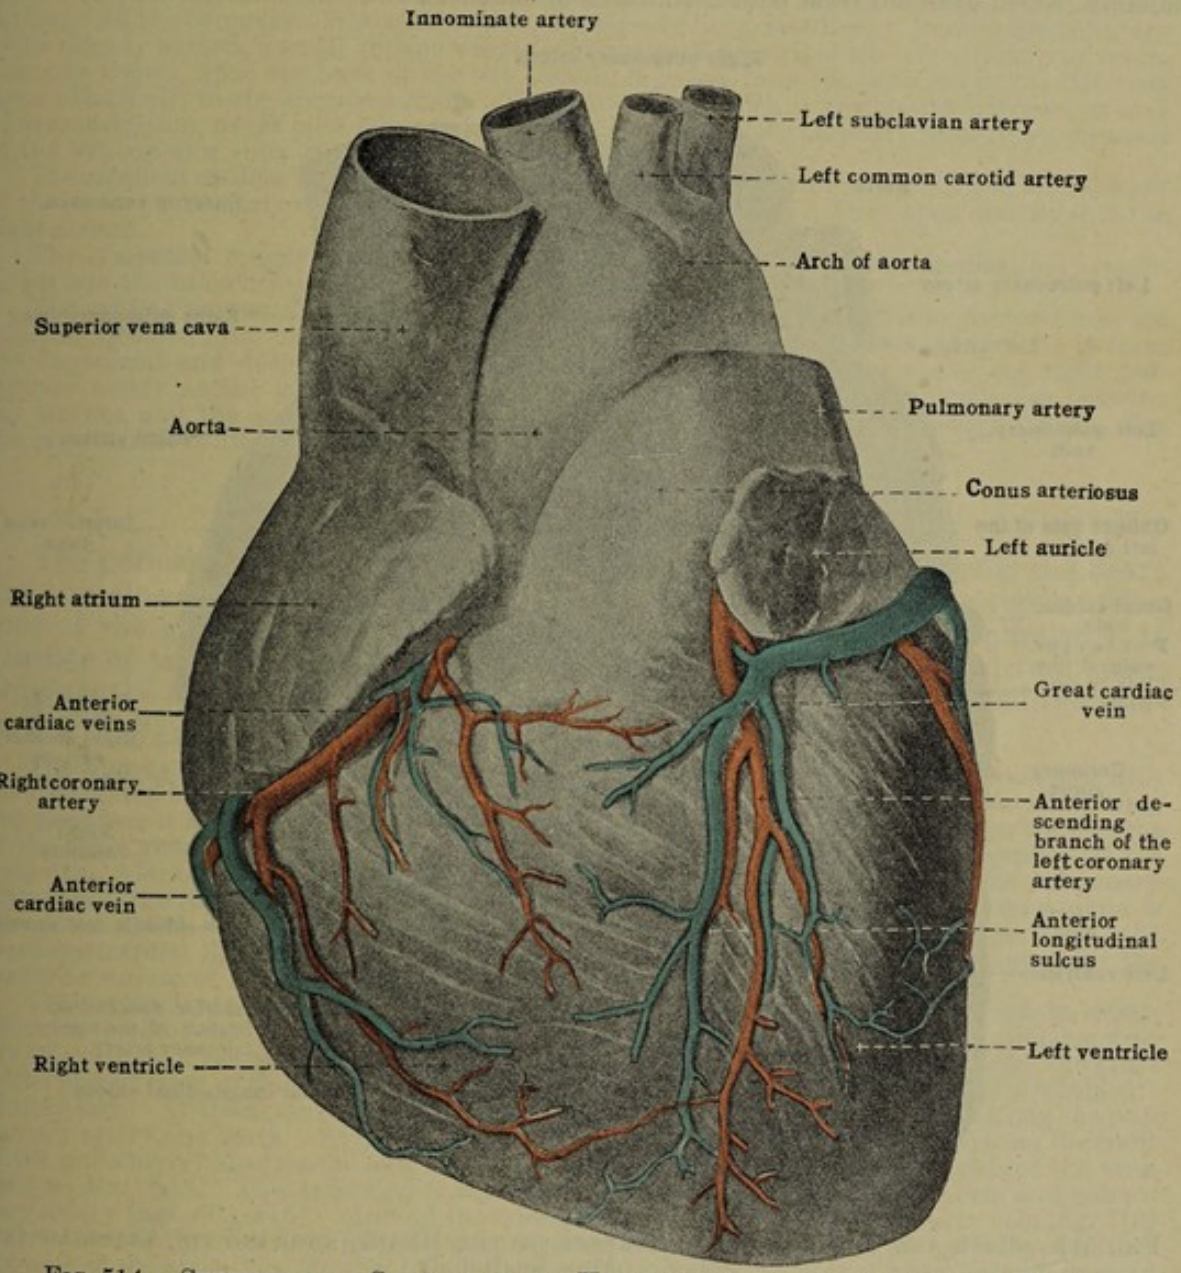

FIG. 514.—STERNOCOSTAL SURFACE OF THE HEART, SHOWING ITS ARTERIES AND VEINS. (After Spalteholz.)

VESSELS AND NERVES OF THE HEART

The arteries.—There are two coronary arteries, the right and left; the former takes origin from the right sinus of the aorta and the latter from the left.

The **right coronary** artery [a. coronaria dextra] passes forward between the pulmonary artery and the right atrium, and then follows the right coronary sulcus to the diaphragmatic surface of the heart (fig. 514), to anastomose with the left coronary artery. The **posterior descending** branch [ramus descendens posterior] arises at the posterior longitudinal sulcus. It passes in the furrow between the ventricles toward the apex, near which it anastomoses with branches derived from the left coronary artery. The right coronary artery supplies branches to the right atrium and to the root of the pulmonary artery and aorta; also a branch that descends near the margo acutus (**right marginal**), and a second (**preventricular**) that runs to the anterior wall of the right ventricle. It supplies both ventricles and the septum.

The **left coronary** artery [a. coronaria sinistra] passes for a short distance forward, between the pulmonary artery and the left auricle, and then divides into two principal branches, one of

which, the **anterior descending branch,** runs in the anterior longitudinal sulcus to the apex of the heart, around which it sends branches to anastomose with the right coronary; while the other, the **circumflex** [ramus circumflexus], winds to the diaphragmatic surface in the coronary groove, to anastomose with the corresponding twigs of the right artery. In this course it gives off a branch which follows the margo obtusus (**left marginal**) as well as smaller branches to the left atrium, both ventricles, and the commencement of the aorta.

Although *anastomoses* occur between the two coronary arteries, these are by no means extensive in the adult, and are not sufficiently free to allow of the establishment of a satisfactory collateral circulation in the case of the blocking of one coronary artery. Interference with the cardiac circulation is apt to produce rapid pathological changes in the heart musculature, provided it is sudden in occurrence. If obliteration of the artery take place gradually, however, some relief may be afforded by the establishment of a collateral circulation through the venæ minimæ, which open out from both the atrial and ventricular cavities and communicate with

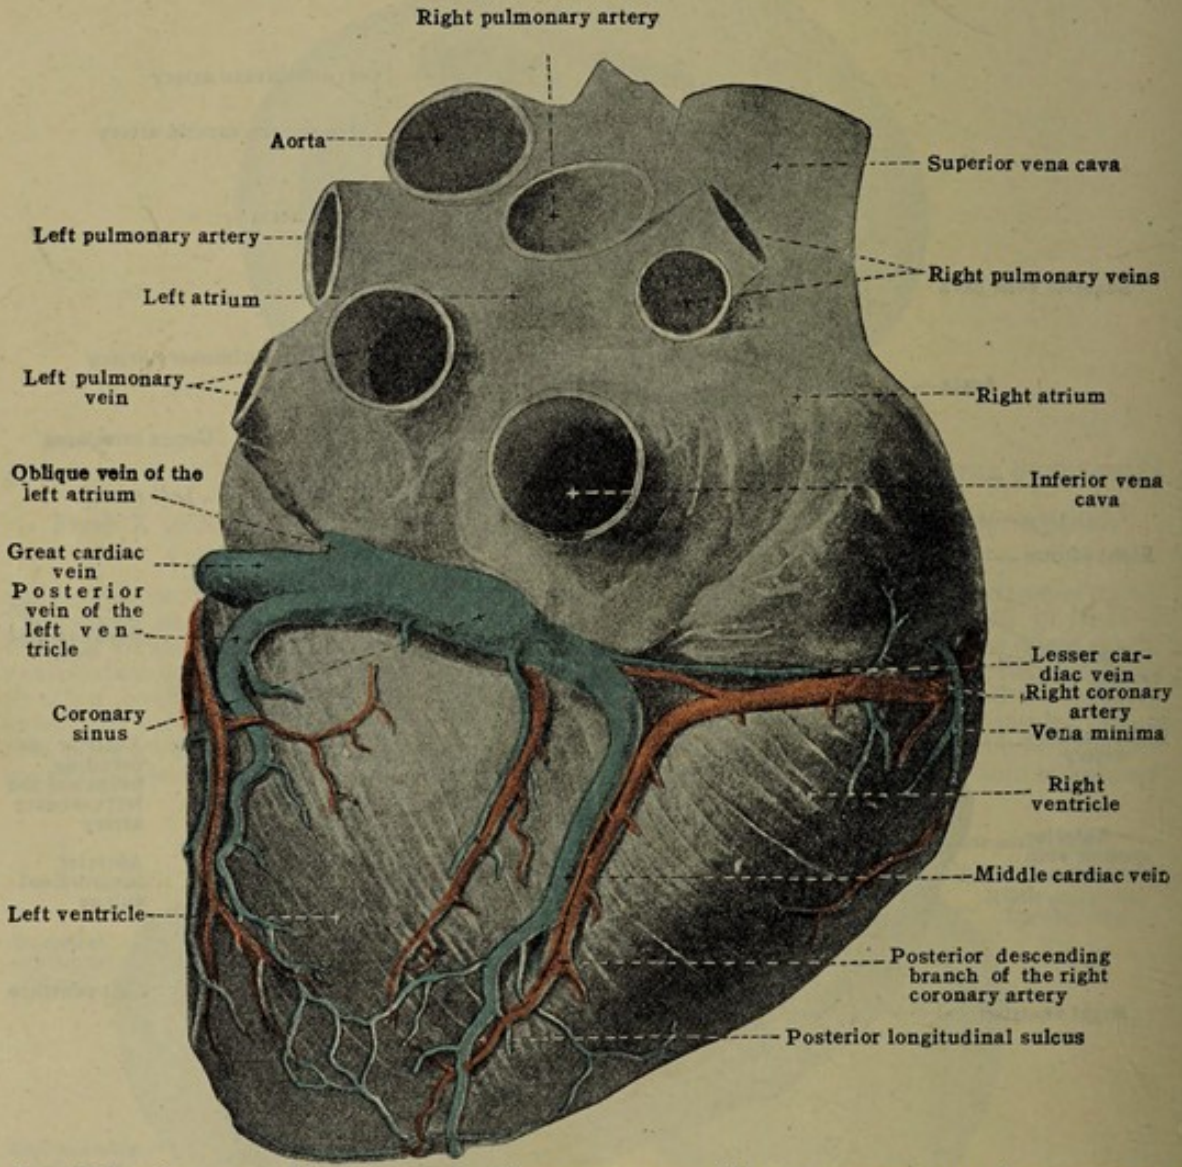

FIG. 515.—BASE AND DIAPHRAGMATIC SURFACE OF THE HEART, SHOWING ITS ARTERIES AND VEINS. (After Spalteholz.)

he finer branches of the cardiac veins, and also with the general capillary network in the cardiac walls. During embryonic life, anastomosis between the two coronary arteries appears to be much freer. Absence of the root of either the right or the left coronary artery has been reported, the remaining root supplying the entire heart. The communicating vessel is usually a large ramus circumflexus of the left coronary.

The **cardiac veins** accompany the coronary arteries and return the blood from the walls of the heart.

The **great cardiac** vein [v. cordis magna], (fig. 514) runs in the anterior longitudinal sulcus, passing round the left side of the heart in the coronary sulcus to terminate in the commencement of the coronary sinus. Its mouth is usually guarded by two valves. It receives small veins from the left atrium and ventricle, all of which are guarded by valves.

The **middle cardiac** vein [v. cordis media] (v. longitudinalis dorsalis cordis NK), sometimes the larger of the two chief veins, communicates with the foregoing at its commencement above the heart apex. It ascends in the posterior longitudinal groove, receiving blood from the ventricular walls, and joins the coronary sinus through an orifice guarded by a single valve, close to its termination.

The **posterior vein of the left ventricle** [v. post. ventriculi sinistri], lies upon the posterior surface of the ventricle and, receiving branches from it, passes upward to terminate directly in the coronary sinus.

The **anterior cardiac** veins [vv. cordis anteriores] consist of several small branches from the front of the right ventricle, which vary in number; they either open separately into the right atrium or join the lesser cardiac vein (fig. 514).

The **small cardiac** vein [v. cordis parva] is a small vessel which receives branches from both the right atrium and ventricle, and winds around the right side of the heart, in the coronary sulcus, to terminate in the coronary sinus. The NK includes both anterior cardiac and small cardiac veins under *vv. cordis minores.*

The **coronary sinus** [sinus coronarius] (fig. 515) may be regarded as a much dilated terminal portion of the great cardiac vein. It is about 2.5 cm. (1 in.) in length, is covered by muscular fibers from the atrium, and lies in the coronary sulcus below the base of the heart. Its cardiac orifice, with the coronary (Thebesian) valve, has already been described. Besides the tributary veins already named, a small **oblique vein** [v. obliqua atrii sinistri] of the left atrium may sometimes be traced, upon the back of the left atrium; it passes from the ligament of the left vena cava (Marshall) to the coronary sinus. This little vein, which is not always pervious or easy of demonstration, never possesses a valve at its orifice. Like the coronary sinus it is a remnant of the left superior vena cava of early fetal life.

The **smallest cardiac** veins [vv. cordis minimæ] drain blood from the septum and lateral walls of the atria, particularly the right; also from the conus arteriosus. They open directly into the right atrium.

The **lymphatic** vessels of the heart pass chiefly through the anterior mediastinal lymph-nodes into the bronchomediastinal trunk. (See Section VII.)

The **cardiac nerves,** derived from the vagus and the cervical sympathetic, descend into the superior mediastinum, passing in front of and behind the arch of the aorta; they unite to form the superficial and deep cardiac plexuses. The superficial plexus lies above the right pulmonary artery as the latter passes beneath the aortic arch. The deep plexus lies between the trachea and the arch of the aorta, above the bifurcation of the pulmonary trunk. For the connections of the plexuses see section on NERVOUS SYSTEM.

2. THE PERICARDIUM

The **pericardium** is a cone-shaped, fibroserous sac which surrounds the heart and contains a small amount of fluid [liquor pericardii]. Its apex is above at the root of the great vessels, and its base below, adherent to the diaphragm. It consists of an outer *fibrous* layer and an inner *serous* layer. The virtual space between the serous pericardium and the epicardium is commonly called the *pericardial cavity.*

The **fibrous layer** is strong and inelastic, made of interlacing fibers. Its connection with the central tendon of the diaphragm is intimate, particularly in the region of the caval opening, but elsewhere it is attached loosely by means of areolar tissue. Above, it is lost on the sheaths of the great vessels, all of which receive distinct investments, with the single exception of the vena cava inferior, which pierces it from below. The aorta, vena cava superior, the pulmonary artery, and the four pulmonary veins, are all ensheathed in this manner. The pericardium is connected above with the deep cervical fascia. Two variable bands of fibrous tissue, the **sternopericardial ligaments** connect the front of the pericardium above and below, with the posterior surface of the sternum.

The **serous layer** is smooth and glistening and consists of connective tissue, rich in elastic fibers, covered by endothelium. It lines the interior of the fibrous layer and is continuous with the epicardium or serous covering of the heart. The reflection of the serous layer from the heart to the fibrous layer of the pericardium occurs both at the arterial and at the venous attachments of the heart. At the arterial attachment a simple tube of epicardium is reflected along the pulmonary artery and aorta. At the venous attachment the serous layer is reflected from the front of the pulmonary veins on the left, and from the front of these and from the roots of the vena cava on the right. This reflection is separated above from that around the aorta and pulmonary artery (figs. 503, 516). Around the lower margin of the left lower pulmonary vein (fig. 516) and the root of the vena cava inferior, this reflection is continuous with an arched reflection from the back of the atria (figs. 503, 516). The latter reflection forms a pocket which extends upward upon the posterior aspect of the atria which is called the *oblique sinus* of the pericardium.

Between the reflections of the epicardium at the arterial and venous attachments of the heart there is a dorsal communication between the right and left sides of the pericardial cavity. This is the **transverse sinus** of the pericardium [s. transversus pericardii]; it passes behind the aorta and pulmonary artery and in front of the superior cava and left atrium. During early embryonic life the sinus transversus is closed by the dorsal mesocardium (see p. 605).

The **ligament of the left superior cava** [lig. venæ cavæ sinistræ] (figs. 503, 516) is a doubling of the serous layer which passes between the left pulmonary artery above and the left superior pulmonary vein below. It contains, besides some fatty and areolar tissue, the shrunken remains of the left vena cava superior.

The ligament is usually connected above with the left superior intercostal vein by means of a small tributary of the latter. Passing from its lower end to the left end of the coronary sinus is the small **vena obliqua atrii sinistri** (oblique vein of Marshall). The root of the left superior intercostal (and the adjacent part of the left innominate) vein; the vein passing from the superior intercostal to the lig. venæ cavæ sinistræ; the oblique vein of the left atrium, and the coronary sinus all represent parts of the embryonic left vena cava superior.

Relations.—In front of the pericardium are found the thymus gland or its remains, areolar tissue, the sternopericardial ligaments, the left transversus thoracis muscle, the internal mammary vessels, the anterior margins of the pleural sac and lungs, and the sternum. Laterally, it is overlapped by the lungs with their pleural sacs, and it is in contact with the phrenic nerves and their accompanying vessels. Posteriorly, it is in relation with the esophagus and vagus nerves, the descending aorta, the thoracic duct and vena azygos, and the roots of the lungs. Below it is separated by the diaphragm from the stomach and the left lobe of the liver.

Vessels.—The arteries of the pericardium are derived from the pericardiac, esophageal, and bronchial branches of the thoracic aorta and from the internal mammary and phrenic arteries.

RELATIONS OF THE HEART AND PERICARDIUM TO THE THORACIC WALL

Heart (fig. 517 A and B).—The **base** of the heart is opposite the fifth to the ninth thoracic vertebra *posteriorly*. *Anteriorly* the **apex** is in the fifth intercostal space, 7.5 to 8 cm. (3 to

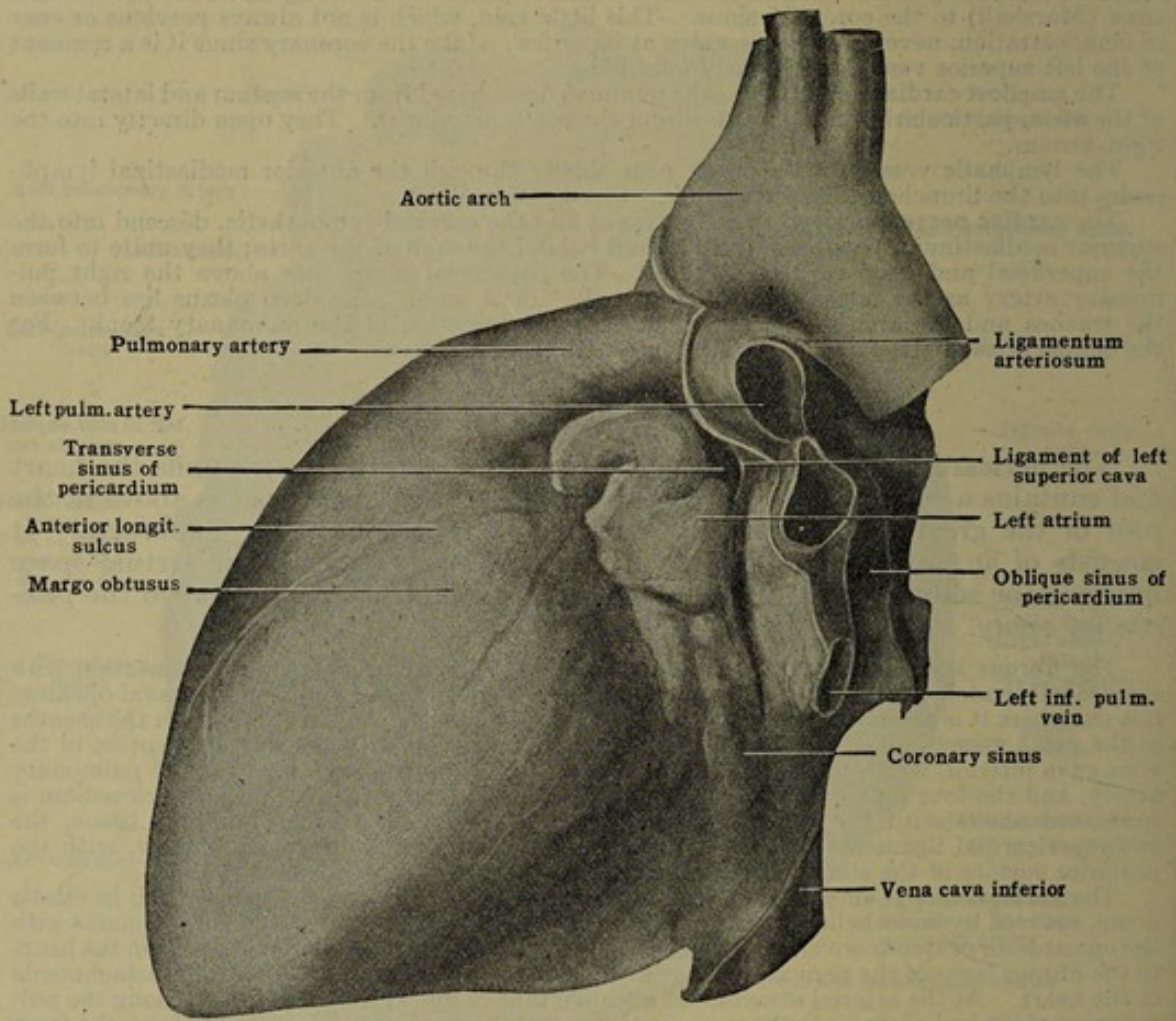

FIG. 516.—LEFT POSTERIOR VIEW OF THE HEART TO SHOW THE REFLECTIONS OF THE PERICARDIUM.

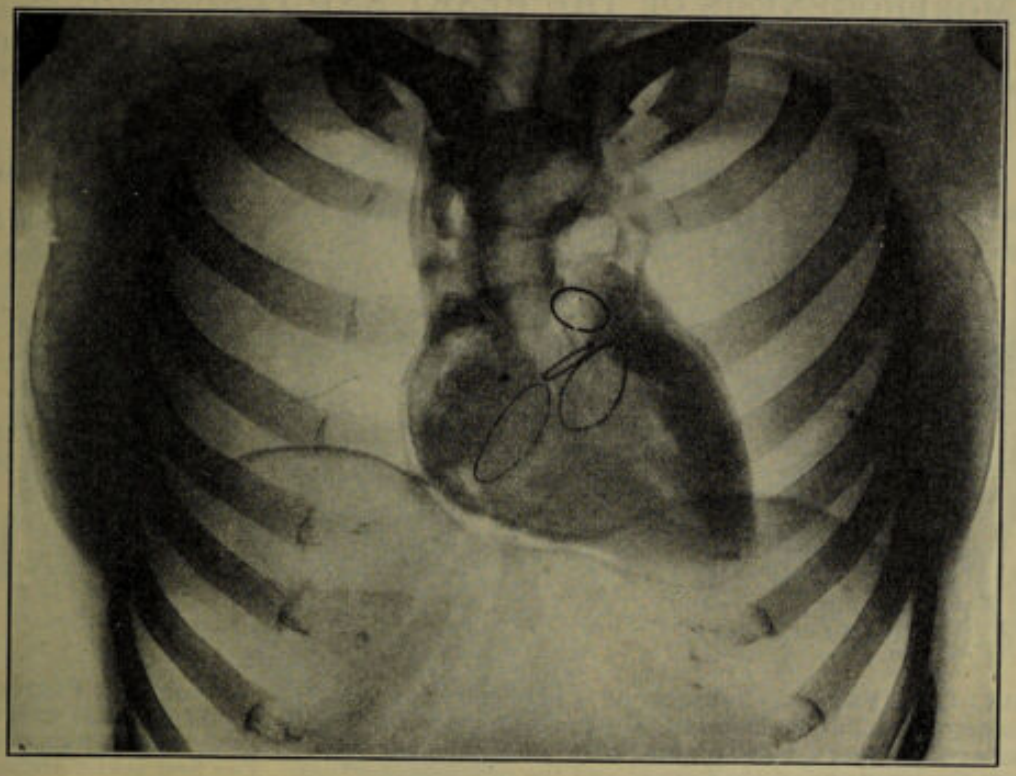
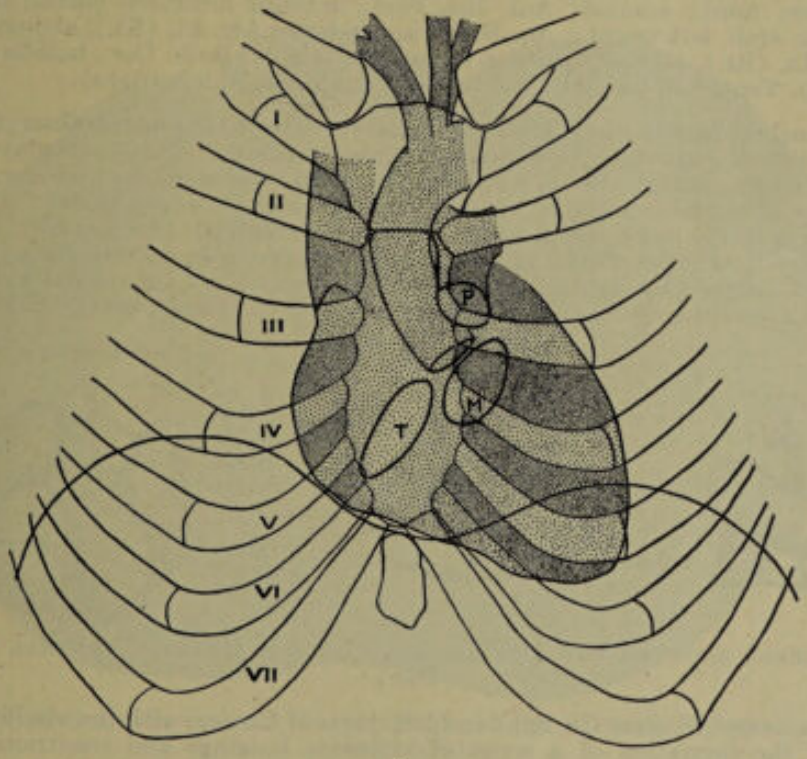


3¼ in.) from the median line. The **base** (above) corresponds to a line (A) drawn from a point 1 cm. (⅖ in.) below the second left chondrosternal articulation, and 3 cm. (1⅕ in. from the median line, to another point (the same distance from the median line) 1 cm. above the right third chondrosternal articulation. The **margo acutus**, or lower border corresponds to a line (B) drawn from the apex through the xiphisternal articulation, to a point on the sixth costal cartilage 2 cm. to the right of the median line. The **right border** of the heart may be indicated approximately by a line (slightly convex to the right) joining the right ends of A and B. The **left border** corresponds to a line (slightly convex to the left) joining the left end of A to the apex.

If a line be drawn from the upper margin of the left third chondrosternal articulation to the right edge of the sternum in the fifth intercostal space, its upper end will lie over the center of the **pulmonary ostium**, and its lower two-thirds (approximately) will overlie the main axis of the **tricuspid ostium**. The **aortic ostium** is immediately to the left of the line mentioned above, with its center at the left edge of the sternum opposite the third space. The **mitral ostium** is very largely behind the third left interspace; its upper end is behind the third cartilage, its lower behind the left margin of the sternum opposite the fourth cartilage and space.



Of the **ostia** of the heart, the pulmonary is nearest the anterior thoracic wall, the aortic is slightly in advance of the tricuspid, and the mitral is the deepest of all.

The **pericardium** follows the heart closely. The upper end (apex) in the subject used in preparing fig. 503 extended up, behind the sternum, to the lower margin of the first costal cartilage on the right and the upper margin of the second on the left. The lower margin (base)

corresponds anteriorly with the line of the margo acutus of the heart. The pericardium is uncovered by pleura in the anterior mediastinum, which is limited on the right by the median line from the level of the fourth chondrosternal to that of the sixth. The limits of the anterior mediastinum to the left and below are subject to some variation (see pleura, p. 1334).

A

B

FIG. 517.—A, TELEROENTGENOGRAM OF A FORMALIN PREPARATION OF THE ANTERIOR THORACIC WALL WITH THE HEART, PERICARDIUM AND DIAPHRAGM IN SITU. (LE WALD, × ⅓) B, EXPLANATORY OUTLINE DRAWING, TRACED FROM THE NEGATIVE AND CONTROLLED BY STEREOSCOPIC VIEWS.

The ostia have been accurately fitted with wire rings. *P*, pulmonary ostium; *M*, mitral, *T*, tricuspid; aortic ostium is unlabelled; I–VII, right costal cartilages.

Paracentesis of pericardium.—While the seat of election must here remain an open question, each case requiring a decision for itself, the one most suitable on the whole is the fifth left space, avoiding injury to the internal mammary artery and the pleura, of which the line of reflection has been shown to vary.

In **incision of the pericardium** to establish free drainage, a portion of the fifth or sixth left costal cartilage should be carefully resected, the internal mammary artery tied, the transversus thoracis (triangularis sterni) scratched through, and the pleural reflection pushed aside.

MORPHOGENESIS OF THE HEART AND PERICARDIUM

The heart is formed by the blending in the median line of two longitudinal endothelial tubes, bounded dorsally by the ventral aspect of the foregut of the early embryo and ventro-

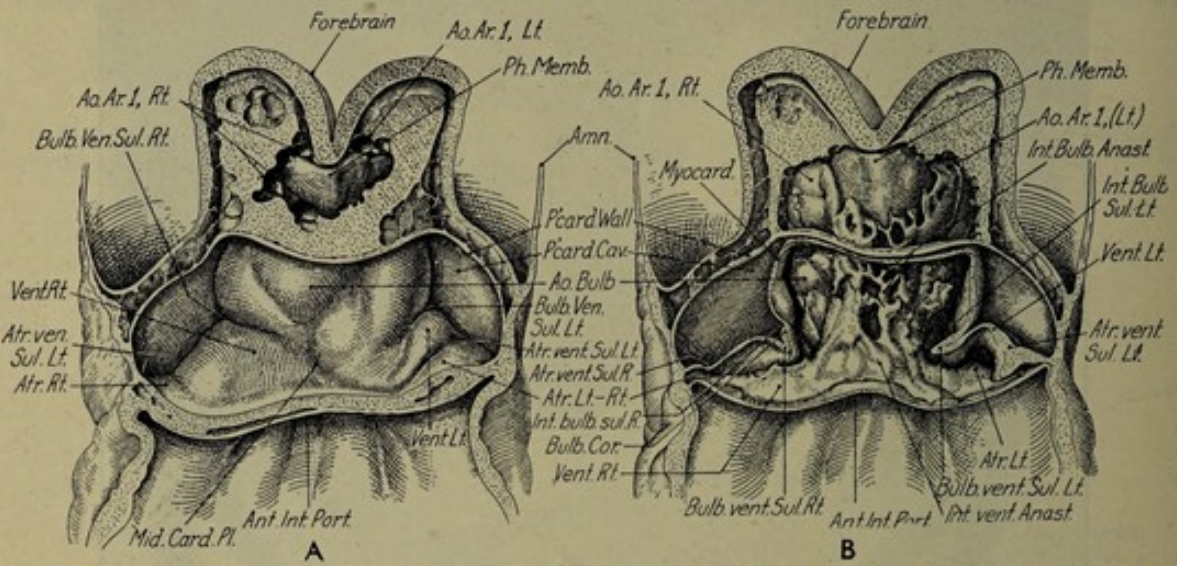


FIG. 518.—THE VENTRAL SURFACE OF A HORIZONTALLY CUT MODEL OF THE PERICARDIAL REGION OF A 2.5 MM. EMBRYO (UNIV. OF CHICAGO COLL. NO. 3709). (C. L. Davis '27.)

The section opens the amnion, pericardium and the gut and cuts the head in such a way as to expose the blind end of the foregut and the first aortic arches. The first aortic arches have been removed in A and cleared of mesoderm in B. The ventral wall of the myoepicardial mantle has been removed in B.

Abbreviations: Amn., amnion; Ant. Int. Port., anterior intestinal portal; Ao. Ar. 1, Lt. (Rt.), first aortic arch, left (right); Ao. Bulb., aortic bulb; Atr. Lt. (Rt.), atrium, left (right); Atr. vent. Sul. Lt. (Rt.), atrio-ventricular sulcus, left (right); Bulb. Cor., bulbus cordis (conus arteriosus); Bulb. Vent. Sul. Lt. (Rt.), bulbo-ventricular sulcus, left (right).

laterally by splanchnic mesoderm. The endothelial tubes form the **endocardium**; the splanchnic mesoderm in relation with them becomes the **myoepicardium.** The double layer of splanchnic mesoderm which unites the myoepicardium with the somatic mesoderm forms the (temporary) dorsal mesocardium; a ventral mesocardium is never present (Davis). The somatic mesoderm of the heart region becomes the **pericardium.** (See fig. 518.)

The originally straight heart-tube grows rapidly and becomes tortuous, since its length soon exceeds the limit assigned by its fixed arterial and venous ends. Its arterial end is continued into the truncus arteriosus, which is later divided into the pulmonary artery and the ascending

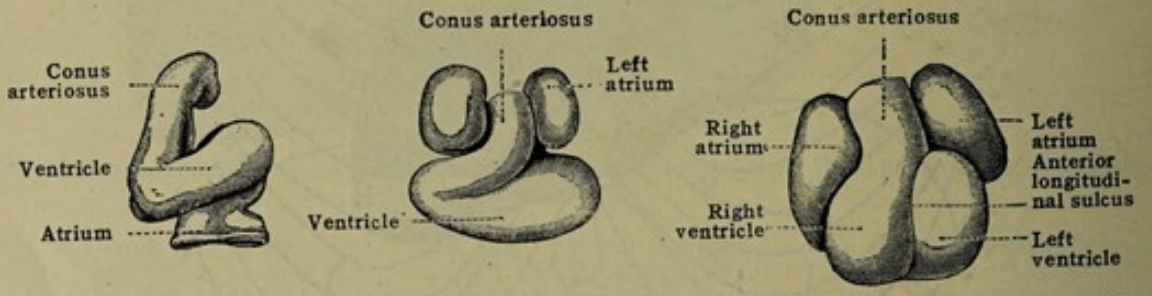

FIG. 519.—MODELS SHOWING THE DEVELOPMENT OF THE HEART. VENTRAL VIEW. (After His.)

aorta. Its venous end receives the right and left ducts of Cuvier, with the vitelline and umbilical veins. By the formation of a series of alternate bulgings and constrictions the heart becomes differentiated into the sinus venosus, atrium, ventricle and conus arteriosus, counting from the venous to the arterial end. These parts by a process of progressive differentiation and shifting (fig. 519) soon occupy relative positions somewhat approaching those of the adult.

The sinus venosus lies on the dorsal wall of the atrium, and is composed of right and left horns united by a median portion. The sinus is separated from the atrium by a sagitally directed slit-like opening, guarded by right and left lateral valves which project into the atrium. The atrium is wide, being prolonged into a ventrally projecting pouch on either side, the future right and left auricle. The ventricle is situated caudally and somewhat ventrally to the atrium. The right limb of the common ventricle, which leads into the conus arteriosus, is the future right ventricle; the left limb, connected with the atrium, is the future left ventricle. The communication between the atrium and the ventricle, known as the atrial canal (fig. 520), is indicated on the exterior by a constriction; its interior consists of a transversely placed slit.

The conus arteriosus is continued from the ventricle without obvious constriction and passes over into the truncus arteriosus.

The **sinus venosus** early loses its bilateral symmetry owing to the rapid enlargement of the right sinus-horn. This horn soon receives, through the proximal portion of the right vitelline vein (*vena cava inferior*), all the blood from the left vitelline and both umbilical veins. The right common cardinal (duct of Cuvier) eventually gains ascendency over the left and becomes

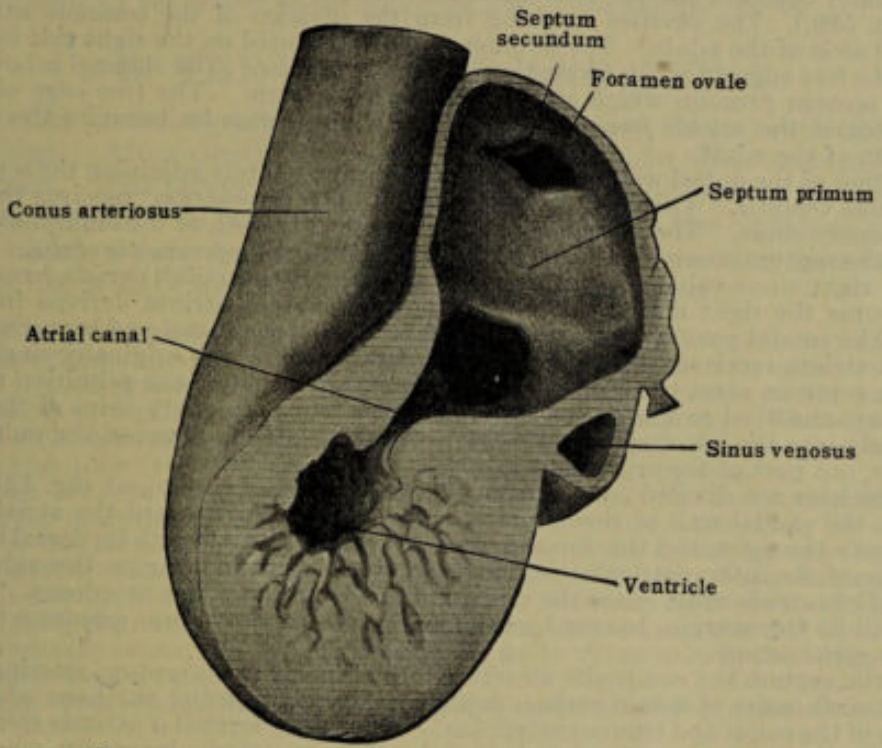

FIG. 520.—SAGITTAL SECTION THROUGH A RECONSTRUCTION OF THE HEART OF A 9 MM. HUMAN EMBRYO SEEN FROM THE LEFT SIDE. (Tandler, ×75.)

FIG. 521.—RECONSTRUCTION OF THE HEART OF AN 11 MM. HUMAN EMBRYO. CAUDAL VIEW (Mall, ×50.)

The lower part of the ventricular portion has been cut off. Connective tissue septa colored yellow. *Ao*, aorta; *Ap*, anterior papillary muscle; *La*, left atrium; *Lo*, left venous ostium; *Lp*, large (anterior) papillary muscle of right ventricle; *Mpm*, medial papillary muscle; *PP*, posterior papillary muscle; *P*, pulmonary artery; *RA*, right astrium; *SV*, septum ventriculorum.

the *vena cava superior*. The left horn of the sinus venosus, which now drains the dwindling left common cardinal (duct of Cuvier) (*left superior cava*) and the coronary veins, become the *coronary sinus*. The right horn gradually becomes absorbed into the right end of the atrial cavity and the superior and inferior cava and the coronary sinus acquire separate openings in that chamber.

In the **atrium** a septum begins early to grow from the ventrocephalic wall of the atrium, toward the atrial canal. As the interatrial communication (ostium primum) around the edge of

the growing septum is becoming narrow a perforation occurs near the attached margin of the septum (ostium secundum); the *septum primum* thus remains incomplete (fig. 520). To the right of the septum primum another septum (s. secundum) is formed later; this never stretches completely across the atrium and is rather a crescentic ridge than a true septum. Until the free edges of the two septa overlap one another there is a direct passage leading from one side of the atrium to the other; when overlapping finally occurs, the interatrial communication (foramen ovale) becomes oblique but persists until birth. (For fetal relations, see p. 37; for adult, see p. 589.) The cavities resulting from the division of the common atrium are the *right and left atria* of the adult. The foramen ovale is bounded on the right side by the septum secundum the free edge of which forms the *limbus fossæ ovalis*. The channel is bounded on the left by the septum primum which slants into the left atrium. The free edge of the septum primum becomes the *valvula foraminis ovalis*, while the remainder becomes the membranous atrial septum of the adult.

The portion of the dorsal wall of the right atrium immediately adjoining the septa is derived from the sinus venosus. This part of the atrium (the *sinus venarum*) receives the venæ cavæ and the coronary sinus. The left sinus-valve is attached to both of the embryonic atrial septa and assists the septum secundum in the formation of the *limbus foraminis ovalis*. The cephalic part of the right sinus-valve disappears along the line of the (adult) *crista terminalis*, which therefore forms the right margin of the portion of the right atrium derived from the sinus venosus. The caudal part of this valve persists as the *inferior caval and coronary valves*.

The left atrium receives, through the dorsal mesocardium, the originally single pulmonary vein. This common stem is absorbed into the atrial wall; later, the primitive right and left tributaries are absorbed in a similar way, leaving the four pulmonary veins of the adult opening separately into the left atrium. The part of the left atrium between the pulmonary veins is, therefore, not part of the original atrial wall.

The **ventricles** are divided by a septum (*s. musculare ventriculorum*) (fig. 521, *SV*) which grows from the caudal wall of the common ventricular cavity toward the atrial canal. The canal moves to the right, and the dorsal part of the septum blends with its dorsal lip. The free ventral edge of the interventricular septum helps to bound the foramen through which blood from the left ventricle must enter the right on its way to the conus arteriosus. The foramen persists until its free margin, having been joined by the aortic septum, becomes the circumference of the *aortic ostium*.

The **aortic septum** is a composite structure formed partly by a septum growing between the fourth and sixth pairs of aortic arches, and partly by endocardial swellings which appear in the interior of the conus and truncus arteriosus. When fully formed it extends spirally along the truncus and conus, and enters the right half of the common ventricular cavity, where it joins the right side of the free edge of the interventricular septum. The septum is spirally curved in such a way that the blood from the left ventricle passes no longer through the right ventricle but traverses a channel (*the aorta*) through the conus and truncus to the first four pairs of aortic arches. The blood from the right ventricle passes through *the pulmonary* division of the conus and truncus arteriosus, anteriorly and to the left of the aorta, into the sixth arches. Further differentiation brings about the external separation of the aorta from the pulmonary artery, but their common covering of epicardium persists as such in the adult. The lower end of the aortic septum persists in the adult as the *septum membranaceum ventriculorum* and the *crista supraventricularis*, the relations of which to the septum musculare are well shown in fig. 507. During the formation of the aortic septum four endocardial swellings appear at the distal part of the interior of the conus. These are arranged as smaller and larger opposite pairs; the smaller and larger swellings, therefore, alternating around the lumen. The larger pair of swellings assists (by partial blending) in the formation of the aortic septum. When the septum is complete, half of each of the larger swellings is contained in the aorta and half of each in the pulmonary artery. One of the smaller swellings remains in the aorta and one in the pulmonary artery, so that there are now three swellings in each vessel. Each of these six swellings becomes undermined to form a *semilunar valve* of the adult.

The atrioventricular valves.—The interior of the ventricular cavity, which is at first smooth, becomes undermined in an irregular way, to form a system of myocardial trabeculæ. The lips of the transversely directed atrial canal become thickened into prominent anterior and posterior endocardial cushions; these project into the ventricular cavity and become involved in its myocardial trabecular system. The atrial canal, which has now moved to the right, becomes divided sagittally, into a right and a left *venous ostium venosum*, by the septum primum. The interventricular septum joins the ventricular side of the posterior endocardial cushion. The anterior and posterior endocardial cushions blend with one another and with the septum primum to form an atrioventricular valve-cusp on either side of the interventricular septum, viz., the anterior cusp of the mitral in the left ostium, and the medial cusp of the tricuspid in the right. The posterior cusp of the mitral and the anterior and posterior cusps of the tricuspid are formed later, partly from endocardial tubercles developing in either ostium, and partly by a process of undermining of the ostia from the ventricular side. The atrial musculature extends into the atrioventricular valves and remains for a while continuous with the trabecular system of the ventricles. This connection between atrial and ventricular musculature eventually becomes non-muscular. Muscle is found at the basal region of the valve-cusps in the adult, and occasionally persists in the chordæ tendineæ.

The connection between the atrial and ventricular musculature is not confined to that of the valvular and trabecular system. The connection between the atrial and ventricular portions of the myocardium remains complete until the embryo has reached the length of about 11 mm. From that time on the myocardium of the atrioventricular junction begins to be replaced by the developing fibrous annuli of the venous ostia. The original connection between the atrial and ventricular musculature persists at one place only, i. e., the site of the *atrioventricular bundle*.

The **pericardial cavity** is the original cephalic end of the intraembryonic celom (see p. 57). The somatic mesoderm of the pericardial region forms the adult *pericardium*. The splanchnic

mesoderm persists only in the part which furnishes the *myoepicardium*. The dorsal mesocardium, formed by the splanchnic mesoderm, is a transitory structure. It persists at the arterial and venous ends of the heart only, and the orifice made by its loss between becomes the *sinus transversus pericardii* of the adult.

During development, the heart and pericardium migrate from a point opposite the cephalic end of the pharynx to the region of the caudal end of the esophagus. This migration is evidenced in the adult by the course of the recurrent and of the cardiac nerves.

B. THE ARTERIES AND VEINS

The **arteries** [arteriæ], proportionately to their size, have much thicker walls than the veins. After death the smaller arteries retain their natural form, but are contracted. The larger arteries are flattened by the pull of the longitudinal elastic fibers in their wall, and contain no clot; except at the orifice of some larger branch, in which a very small clot is usually found. In a very general way the thickness of the wall of an artery is proportional to caliber.

The larger arteries usually take a direct course and branch dichotomously. In descriptive anatomy if dichotomous branches are of nearly equal size it is common for each to take another name; if one branch preponderates in size, it usually retains the name of the parent trunk, while the smaller is regarded as a collateral branch [vas collaterale]. There are numerous exceptions to dichotomous branching; branches may run perpendicularly or recurrently to the vessel from which they arise; or several branches may arise simultaneously.

Anastomosis between large or medium sized arteries occurs less frequently than in veins of corresponding magnitude. Anastomoses do occur, however, particularly in the form of arches, such as the palpebral, plantar and volar arches, or the arches between the intestinal arteries. This form of anastomosis is sometimes called inosculation. Between smaller arteries anastomosis is usually free as in the case, for instance, of the articular retia. In some organs anastomosis (excepting capillary) between neighboring arteries can scarcely be said to exist at all; the a. centralis retinæ affords a good example, as do the arteries of the brain, spleen, and kidney; such arteries are called terminal.

The larger arteries are supplied by *vasa vasorum*, frequently arising from their own recurrent branches.

The **veins** [venæ] have thin walls, and after death are either collapsed or filled with clot or discolored serum. They are characterized by the presence of valves.

Frequent anastomoses occur between veins of all sizes; plexuses are of frequent occurrence. *Venæ comitantes* are veins which, usually in pairs, accompany many of the larger arteries; they communicate with one another, around the artery, very freely. Veins do not primitively accompany arteries. In the case of the extremities the primitive veins ramify upon the surface of the limb. The deep veins of the limbs are of later formation and to them the superficial veins subsequently become tributary.

The veins from the stomach, spleen, pancreas and intestine are collected into a large trunk, the **portal vein**. This does not open into the vena cava inferior directly, but breaks up into numerous capillaries (sinusoids) in the liver. From these the blood is returned, through the hepatic veins, to the inferior cava.

Many veins are provided with **valves**, the free borders of which are directed toward the heart. In the small veins the valves are single; in the larger veins they are usually double, rarely treble. Valves are much more numerous in the veins of infants than those of the adult; their number diminishes progressively with advancing age. Valves are most numerous in the superficial veins, and in the deep veins of the extremities; in many veins of the head and neck valves occur only at the point of termination in a larger trunk.

The cranial *venous sinuses* are modified veins, consisting of intima only which lines channels in the fibrous dura mater. The venous spaces in cavernous tissue, such as occurs in the corpora cavernosa, may be looked upon as specially modified veins. Neither these nor the cranial sinuses are provided with valves.

The larger veins, like the arteries, have *vasa vasorum*.

The section dealing with arteries and veins is divided as follows: 1, pulmonary artery and veins; 2, the systemic arteries; and, 3, the systemic veins. At the ends of the second and third divisions are brief accounts of morphogenesis and variations.

1. THE PULMONARY ARTERY AND VEINS

The **pulmonary artery** [a. pulmonalis] (fig. 522) and its branches differ from all other arteries in the body in that they contain venous blood. It arises as a short, thick trunk from the **conus arteriosus** of the right ventricle, and, after a course of about 5 cm. (2 in.) within the pericardium, divides into a right and a left branch, which pass to the right and the left lung respectively.

The **trunk of the pulmonary artery** at its origin is somewhat anterior to the ascending aorta, and slightly overlaps that vessel. It curves upward, backward, and to the left, around the front and left side of the ascending aorta; having

reached the concavity of the aortic arch, on a plane posterior to the ascending aorta, it divides into its right and left branches, which diverge from each other at an angle of about 130°. The division of the pulmonary artery occurs immediately to the left of the second left chondrosternal articulation.

In the fetus, the pulmonary artery continues its course upward, backward, and to the left under the name of the **ductus arteriosus (Botalli)**, and opens into the descending aorta just below the origin of the left subclavian artery. Soon after birth, the lumen of the ductus arteriosus becomes obliterated, and its wall is represented in postnatal life by a fibrous cord, the **ligamentum arteriosum** (chorda ductus arteriosi NK) (fig. 522).

Relations.—In front, the trunk of the pulmonary artery is separated from the remains of the thymus gland by the pericardium. The artery lies, at its commencement, behind the upper margin of the third left chondrosternal articulation. The right margin of the artery is behind the second piece of sternum but the greater part of the vessel is behind the medial end of the second intercostal space.

Behind, it lies successively upon the ascending aorta and the left atrium.

To the **right** are the ascending aorta, the right atrium, the right coronary artery, and the cardiac nerves.

To the **left** are the pericardium, the left pleura and lung, the left auricle, the left coronary artery, and the cardiac nerves.

The **right pulmonary artery** [ramus dexter] longer than the left, passes almost horizontally under the arch of the aorta to the root of the right lung, where it divides into two branches, one for the lower lobe and another which subdivides to supply the upper and middle lobes. These branches follow the course of the bronchi, dividing and subdividing for the supply of the lobules of the lung. The terminal branches do not anastomose with each other.

Relations.—In its course to the lung it has **in front** of it the ascending aorta, the superior vena cava, the phrenic nerve, the anterior pulmonary plexus and the reflection of the pleura. **Behind** is the right bronchus, which separates it from the azygos vein. **Above** is the arch of the aorta, and **below** are the left atrium and the upper right pulmonary vein.

At the root of the lung it has the right bronchus **above** and **behind** it; the pulmonary veins **below** and in **front.** Crossing in front of it and the other structures forming the root of the lung are the phrenic nerve and the anterior pulmonary plexus; behind are the azygos vein, the vagus nerve, and the posterior pulmonary plexus.

The **left pulmonary artery** [ramus sinister], shorter and slightly smaller than the right, passes in front of the descending aorta to the root of the left lung, where it divides into two branches for the supply of the upper and lower lobes respectively. These divide and subdivide as on the right side.

Relations.—At the root of the lung it has the left bronchus **behind** and also **below** it, in consequence of the more vertical direction taken by the left bronchus than by the right. **Below** and **in front** are the pulmonary veins, while passing from the artery and the upper left pulmonary vein is the ligament of the left superior cava. Crossing in front of it and the other structures forming the root of the lung are the phrenic nerve and the anterior pulmonary plexus. Crossing behind it are the descending aorta, the left vagus nerve, and the posterior pulmonary plexus.

The **pulmonary veins** [vv. pulmonales] (figs. 516, 522) return the aërated blood from the lungs to the heart. They are usually four in number, superior and inferior, of the right and left sides. Occasionally, however, there are three pulmonary veins on the right side, the result of the vein from the middle lobe of the right lung opening separately into the left atrium instead of joining as usual the upper of the two right pulmonary veins. The relations of the pulmonary veins to the pulmonary arteries and bronchi at the roots of, and within the lungs are given with the anatomy of the lungs (Section X).

The pulmonary veins are about 15 mm. in length. In the pericardium the upper of the **right pulmonary veins** [vv. pulmonales dextræ] passes behind the superior vena cava. The lower crosses behind the right atrium. The superior vein receives the vein from the right middle lobe and runs below and in front of the right pulmonary artery.

The **left pulmonary veins** [vv. pulmonales sinistræ] enter the left atrium about 3 cm. in front of the veins of the right side. The superior vein is below the left pulmonary artery.

2. THE SYSTEMIC ARTERIES

THE AORTA

The **aorta** (fig. 523) is the main systemic arterial trunk, and from it all the systemic arteries are derived. It begins at the left ventricle of the heart, and

ascends near the anterior thoracic wall as high as the second right chondrosternal articulation [**aorta ascendens**]. It then turns backward and to the left forming an arch [**arcus aortæ**] which reaches the posterior thoracic wall at the left side of the fourth thoracic vertebra. From here it runs downward along the vertebral column [**aorta descendens**] through the thorax and abdomen and ends by dividing, opposite the fourth lumbar vertebra, into the right and left common iliac arteries. From the point of bifurcation a small vessel, the middle sacral, is continued down the middle line in front of the sacrum and coccyx. The middle sacral represents the sacrococcygeal aorta.

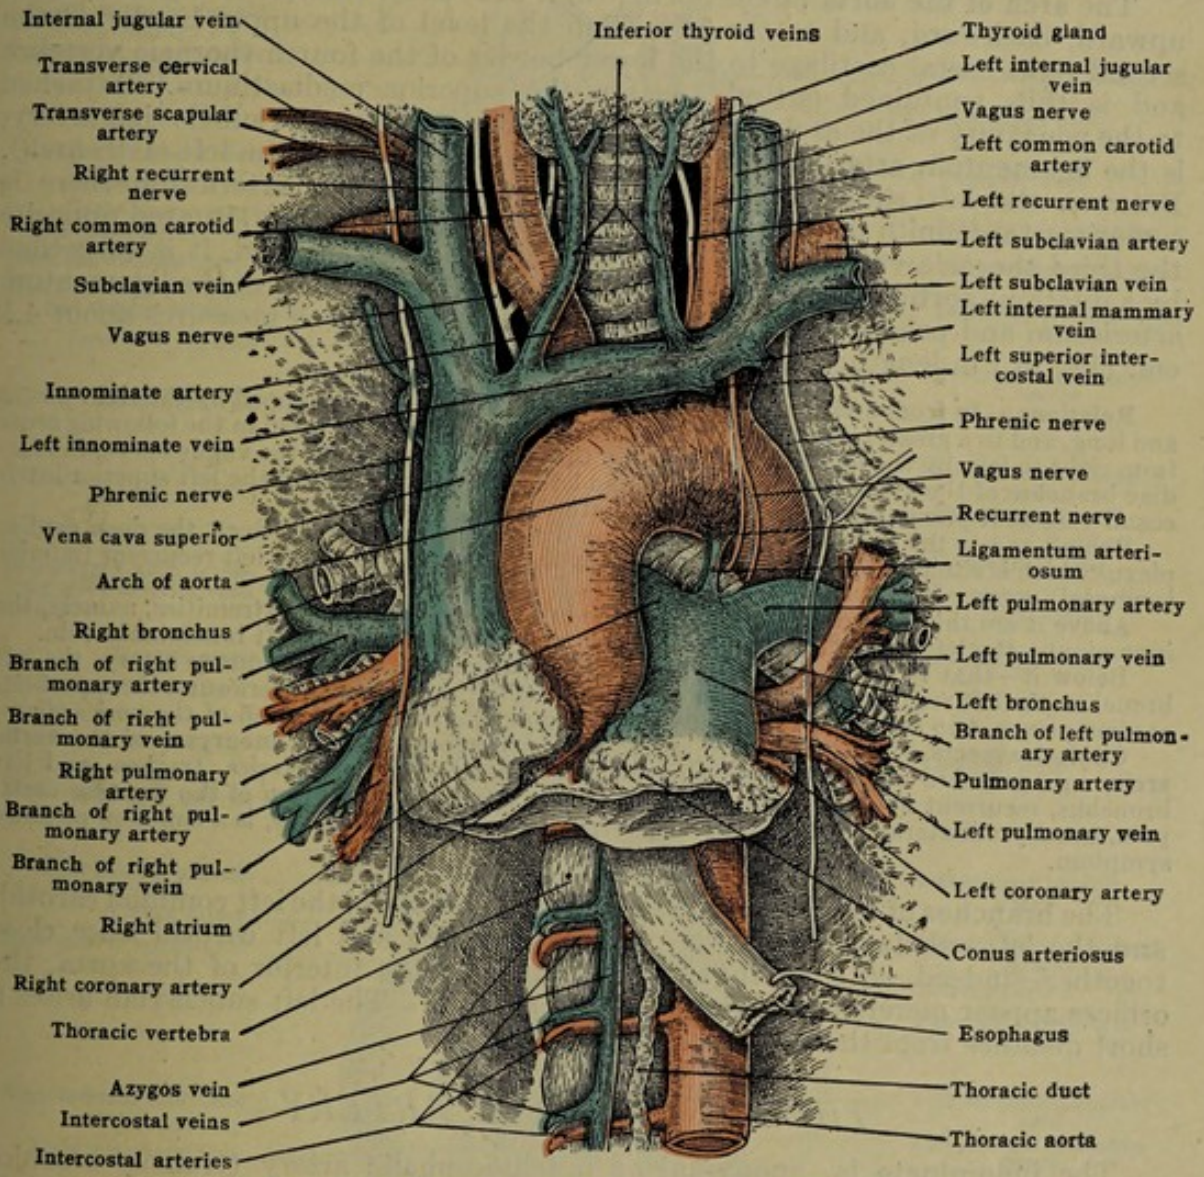

FIG. 522.—THE GREAT VESSELS OF THE THORAX.
(Modified from a dissection in St. Bartholomew's Hospital Museum.)

THE ASCENDING AORTA

The **ascending aorta** [aorta ascendens] (fig. 523) begins at the upper part of the left ventricle, on a level with the third intercostal space, and ascends behind the sternum to the upper border of the right second chondrosternal articulation. It measures about 5 to 5.5 cm. (2 to 2¼ in.), forming, as it ascends, a gentle curve with its convexity to the right. It is enclosed within the pericardium, being invested, together with the pulmonary artery, in a common sheath formed by the serous layer of that membrane. A dilation known as the **bulbus aortæ** occurs immediately above the heart upon which are three localized bulgings, known as the **aortic sinuses** (of Valsalva); they are placed, one to the right, one to the left, and one posteriorly. From the right and left are derived the coronary arteries of the heart. (See HEART.)

Relations.—**In front** the ascending aorta is overlapped at its commencement by the right auricle, conus arteriosus and pulmonary artery. Higher up, as the pulmonary artery and auricle diverge, it is separated from the manubrium by the pericardium, the remains of the thymus

gland, and by the loose tissue and in the superior mediastium. It is here slightly overlapped also by the right pleura and by the edge of the right lung in full inspiration. The root of the right coronary artery is also in front. **Behind** are the left atrium of the heart, the right pulmonary artery, the right bronchus, and the anterior right deep cardiac nerves. On the **right side** it is in contact, below with the right atrium, and above with the superior vena cava. On the **left side** are the pulmonary artery and the branches of the right superficial cardiac nerves.

Branches.—The right and left coronary arteries have already been described (p. 597).

The Arch of the Aorta

The **arch of the aorta** [arcus aortæ] (figs. 522, 523), extends in a gentle curve upward, backward, and to the left, from the level of the upper border of the second right costal cartilage to the lower border of the fourth thoracic vertebra and is thus contained entirely within the superior mediastinum. Attached to the concavity of the arch, just beyond the origin of the left subclavian artery, is the **ligamentum arteriosum** (vestige of the dorsal part of the left sixth arch). Between the left subclavian artery and the ligamentum arteriosum there is sometimes a definite constriction of the arch (**isthmus aortæ**) situated opposite the third thoracic vertebra. When the isthmus is well marked, it is succeeded by a dilation (**aortic spindle**) which begins in the neighborhood of the ligamentum arteriosum and passes over the descending aorta. The arch measures about 4.5 cm. (1⅘ in.) in length.

Relations.—In front and to the left, the aortic arch is slightly overlapped by the right pleura and lung, and to a greater extent by the left pleura and lung. It is crossed in the following order from right to left, by the left phrenic nerve, by the cardiac branches of the vagus nerve, the cardiac branches of the sympathetic nerve, by the left vagus nerve, and by the left superior intercostal vein as it passes up to the left innominate vein.

Behind and to the right are the trachea, the esophagus, the thoracic duct, the deep cardiac plexus which is situated on the trachea just above its bifurcation, and the left recurrent (inferior laryngeal) nerve.

Above it are the three chief branches for the head, neck, and upper extremities, namely, the innominate, the left carotid, and the left subclavian arteries, and the left innominate vein.

Below it—that is, in its concavity—are the bifurcation of the pulmonary artery, the left bronchus, the left recurrent (inferior laryngeal) nerve, the ligamentum arteriosum, the superficial cardiac plexus, two or more bronchial lymphatic glands, and the reflection of the pericardium.

Clinical aspects.—Many pressure symptoms may accompany an **aneurysm of the aortic arch**; e.g., pressure on the left innominate vein, the three large arteries, trachea, and left bronchus, recurrent nerve, esophagus, and thoracic duct. In **aneurysm of the thoracic aorta,** pain, usually unilateral, referred to the corresponding intercostal nerves, is a common pressure symptom.

The **branches of the aortic arch** are:—the innominate, the left common carotid, and the left subclavian arteries. The innominate and left carotid arise close together—indeed, so close that, when seen from the interior of the aorta, the orifices appear merely separated by a thin septum. The left subclavian arises a short distance from the left carotid.

THE INNOMINATE ARTERY

The **innominate** [a. anonyma] or brachiocephalic artery (truncus brachiocephalicus NK) (fig. 522), the largest branch of the arch of the aorta, extends upward and a little forward and to the right, as high as the upper limit of the right sternoclavicular joint where it bifurcates into the right common carotid and right subclavian arteries. It lies obliquely in front of the trachea, and measures from 3.7 to 5 cm. (1½ to 2 in.).

Relations.—In front of the artery are the manubrium, the origins of the sternohyoid and sternothyroid muscles, the right sternoclavicular joint and the remains of the thymus gland. The left innominate vein crosses the root of the vessel, and the inferior thyroid and thyroidea ima veins descend obliquely over it to end in the left innominate vein. The inferior cervical cardiac branches of the right vagus nerve pass in front of it on their way to the deep cardiac plexus. **Behind,** it lies on the trachea, crossing that tube obliquely from left to right and coming into contact above with the right pleura. To the **right side** are the right innominate vein, the right vagus and the pleura. To the **left side** are the left common carotid, the remains of the thymus gland, the right inferior thyroid vein, and, at a higher level, the trachea.

The **branches of the innominate artery** are:—(1) The right common carotid; and (2) the right subclavian. These are terminal branches. There are usually no collateral branches from this vessel, but at times the thyroidea ima may arise from it.

The **thyroidea ima** artery, which occurs in about 10 per cent. of subjects, ascends on the front of the trachea to the thyroid gland. It may be large, in which case it might complicate the low operation of tracheotomy. It does not always arise from the innominate, but occasionally from the arch of the aorta (see fig. 584) or from the right common carotid.

THE COMMON CAROTID ARTERIES

The **common carotid** arteries [aa. carotides co n munes] right and left, pass up deeply from the thorax on either side of the neck to about the level of the upper

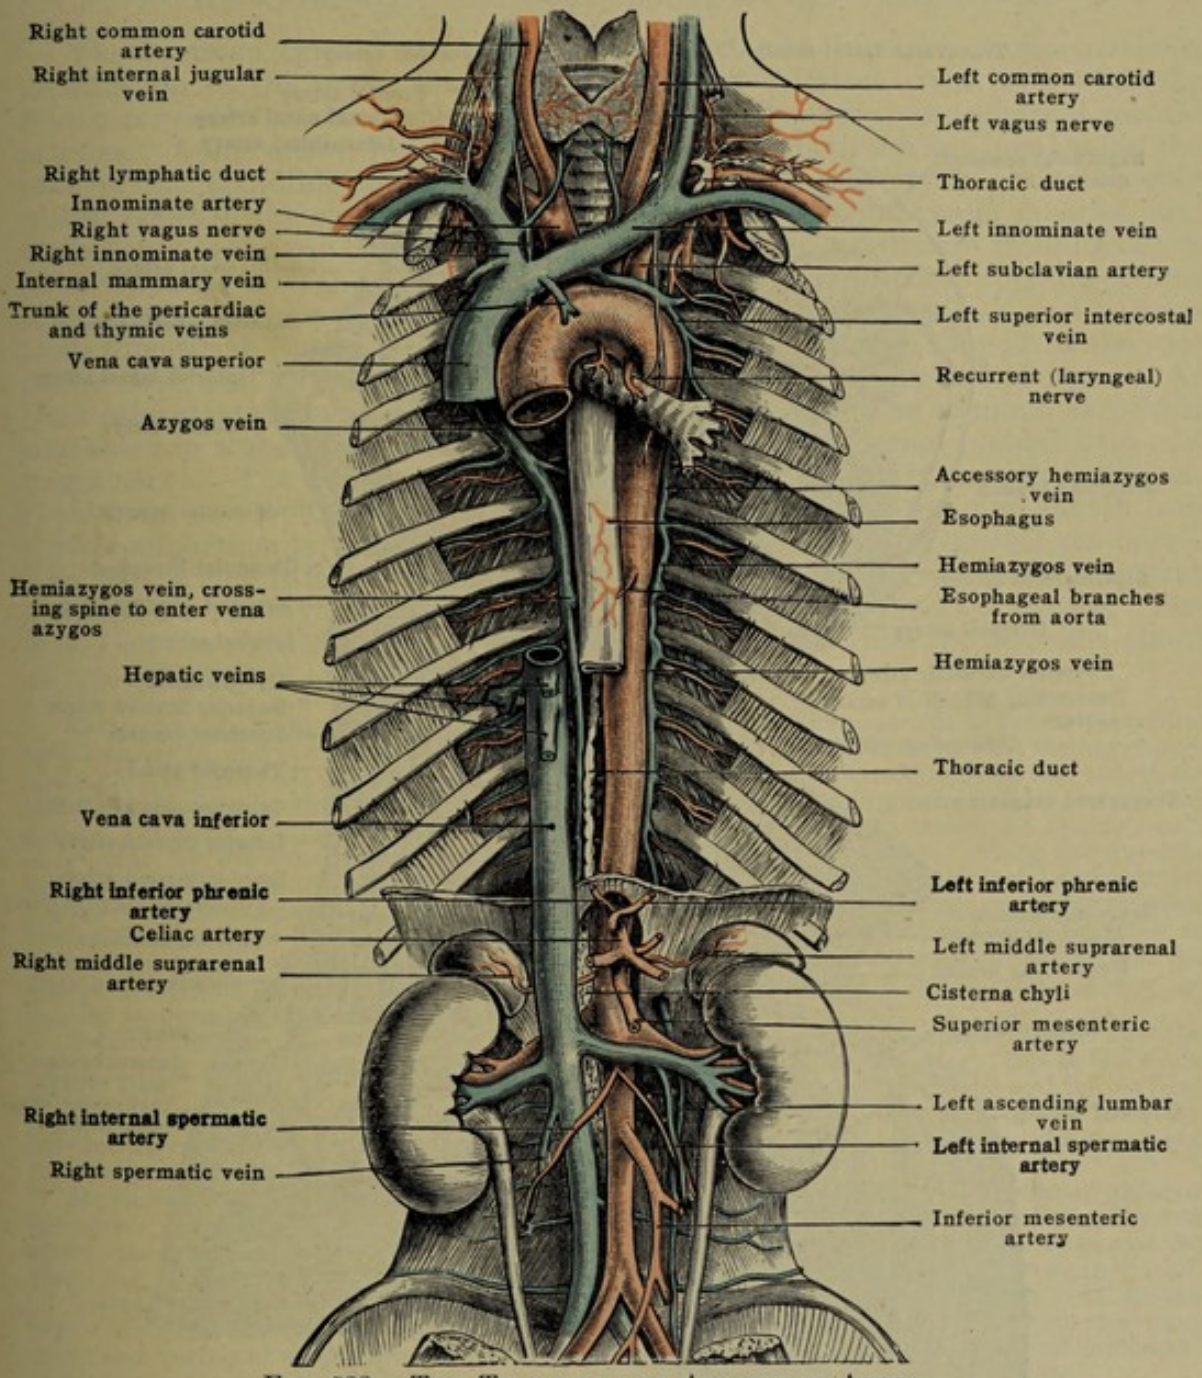

FIG. 523.—THE THORACIC AND ABDOMINAL AORTA.

border of the thyroid cartilage, where each divides into the external and internal carotid. The **external carotid artery** supplies the structures at the upper part of the neck, the larynx, pharynx, tongue, face, the structures in the pterygoid region, the scalp and the membranes of the brain. The **internal carotid** gives off no branch in the neck, but enters the cranium and supplies the greater part of the brain, the structures contained in the orbit and portions of the membranes of the brain.

The common carotid artery on the right side arises from the bifurcation of the innominate at the upper limit of the sternoclavicular joint; on the left side from the arch of the aorta a little to the left of the innominate artery, and on a plane somewhat posterior to that vessel (fig. 523). The portion of the left common

carotid artery which extends from the arch of the aorta to the upper limit of the sternoclavicular articulation lies deeply in the chest, and requires separate description; but above the level of the sternoclavicular joint the relations of the right and left carotids are practically the same.

THORACIC PORTION OF THE LEFT COMMON CAROTID ARTERY

Within the thorax the left common carotid is deeply placed behind the manubrium of the sternum, and is overlapped by the left lung and pleura. It

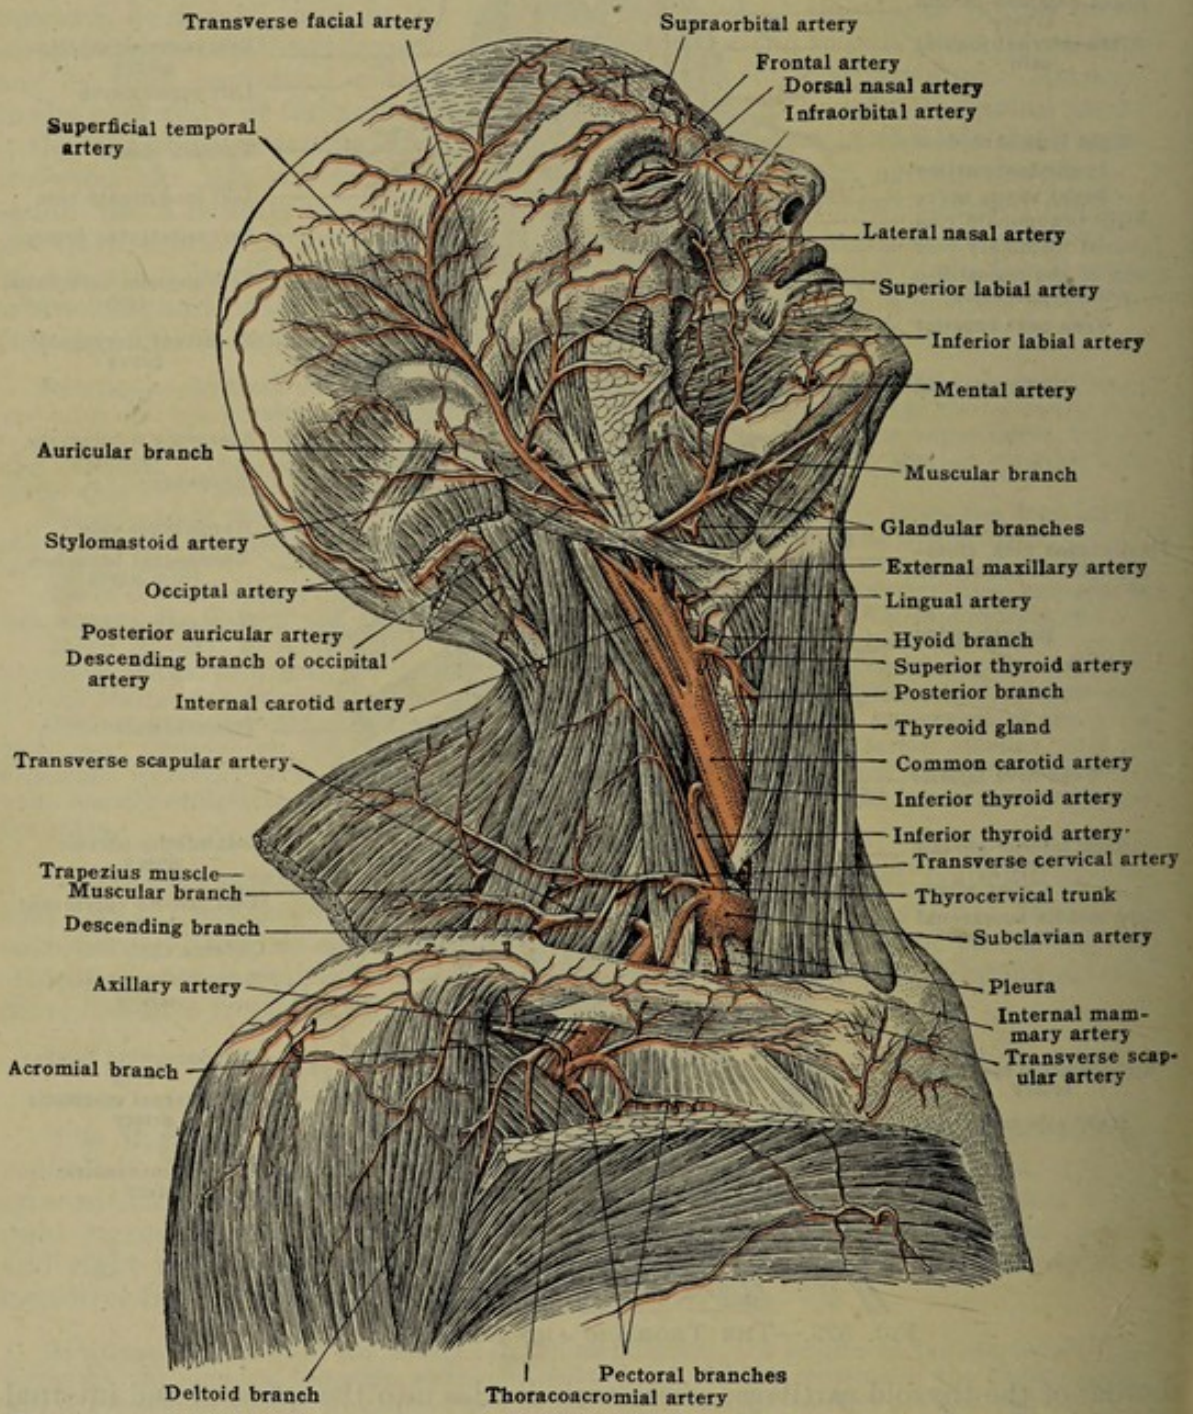

FIG. 524.—ARTERIES OF THE HEAD AND NECK. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

In this case the external maxillary artery ends after having given origin to the lateral nasal branch through which it inosculates with the dorsal nasal artery from the ophthalmic. The angular artery proper is absent. (Cf. fig. 529.)

arises from the middle of the aortic arch, close to the left side of the innominate artery, and a little posterior to the vessel, and ascends obliquely in front of the trachea to the left sternoclavicular articulation, above which its relations are similar to those of the right common carotid (fig. 523).

Relations.—In front, but at some little distance, are the manubrium and the origins of the left sternohyoid and sternothyroid muscles. In contact with it are the remains of the thymus gland, and the loose connective tissue and fat of the superior mediastinum. Crossing its root is the left innominate vein. **Behind,** it lies successively upon the trachea, the left recurrent (laryngeal) nerve, the esophagus (which here inclines a little to the left) and the thoracic duct. To its **right side** is the root of the innominate artery, and higher up are the trachea and the inferior thyroid veins. To its **left side,** but on a posterior plane, are the left subclavian artery and the left vagus nerve; and, slightly overlapping it, the edge of the left pleura and lung.

THE COMMON CAROTID ARTERY IN THE NECK

The **common carotid artery in the neck** extends from the sternoclavicular articulation to the upper border of the thyroid cartilage on a level with the fourth cervical vertebra, where it divides into the external and internal carotid arteries. A line drawn from the sternoclavicular joint to a point just behind the neck of the mandible would indicate its course. The artery is at first deeply placed beneath the sternomastoid, sternohyoid, and sternothyroid muscles, and at the level of the top of the sternum is only 2 cm. (¾ in.) distant from its fellow of the opposite side, and merely separated from it by the trachea. As the carotid arteries run up the neck, however, they diverge in the form of a V and become more superficial, though on a plane posterior to that in which they lie at the root of the neck, and are separated from each other by the larynx and pharynx. At their bifurcation they are about 6 cm. (2¼ in.) apart. The common carotid is contained in a sheath of fascia common to it and the internal jugular vein and vagus nerve. The artery, vein, and nerve, however, are not in contact, but separated from one another by fibrous septa, which divide the common sheath into three compartments: one for the artery, one for the vein, and one for the nerve. The vein, which is larger than the artery, lies to the lateral side, and somewhat overlaps it. The vagus nerve lies behind and between the two vessels. The artery on the right side measures about 9.5 cm. (3¾ in.); on the left side, about 12 cm. (4¾ in.) in length (fig. 524).

Relations.—In front the common carotid is covered by the skin, superficial fascia, platysma, and deep fascia, and is more or less overlapped by the sternomastoid muscle. At the lower part of the neck it is covered in addition by the sternohyoid and sternothyroid muscles and anteriorly to these is crossed by the anterior jugular vein. In many cases it is overlapped by the thyroid gland. Opposite the cricoid cartilage it is crossed obliquely by the omohyoid muscle, and, above this, by the superior thyroid vein, and the sternomastoid artery. Along the anterior border of the sternomastoid there is sometimes a communication between the facial and anterior jugular veins, which, as it crosses the line of the carotid artery, is in danger of being wounded during the operation for ligature. The ramus descendens n. hypoglossi generally descends in front of the carotid sheath, being there joined by one or two communicating branches from the second and third cervical nerves. At times this nerve runs within the sheath. There are usually two lymphatic glands about the bifurcation of the artery.

Behind, the common carotid lies on the longus colli and scalenus anterior below, and the longus capitis (rectus capitis anterior major) above. Posterior to the artery, but in the same sheath, is the vagus nerve; and posterior to the sheath, the cervical sympathetic and the cervical cardiac branches of the sympathetic and vagus nerves. At the lower part of the neck the inferior thyroid artery courses obliquely behind the carotid, as does likewise the recurrent (inferior laryngeal) nerve.

Medially, from below upward, are the trachea and esophagus, with the recurrent (inferior laryngeal) nerve in the groove between them, the terminal branches of the inferior thyroid artery, the lateral lobe of the thyroid gland, the cricoid cartilage, the thyroid cartilage and the lower part of the pharynx. At the angle of bifurcation is the **carotid gland** [glomus caroticum].

Laterally are the internal jugular vein and the vagus nerve. On the right side, at the root of the neck, the vein diverges somewhat from the artery, leaving a space in which the vagus nerve and vertebral artery are exposed. On the left side the vein approaches and somewhat overlaps the artery, there being no interval corresponding to that on the right side.

Ligature of the common carotid is usually performed at the 'seat of election,' where the vessel is more superficial, *above the omohyoid.* An incision with its center opposite the cricoid is made 7.5 cm. (3 in.) long in the line of the carotid artery. The deep fascia along the anterior border of the sternomastoid having been divided, the cellular tissue beneath is opened up, the omohyoid identified and drawn down or divided. The sternomastoid is next drawn well laterally, and the artery felt for. At this stage, such veins as the communication between the common facial and the anterior jugular and the superior and middle thyroids may give trouble. The sheath is next opened well to the medial side, opposite to the cricoid cartilage, the ascending cervical, when seen, being avoided. If the internal jugular be distended, it may be drawn aside with a blunt hook, or pressure made lightly in the upper angle of the wound. The needle should be passed from the lateral side in very close proximity to the lateral and back part of the artery, as so to avoid the vein and vagus. Ligature *below the omohyoid* is rendered more difficult by the presence of the anterior jugular, the pretracheal muscles, an overlapping thyroid gland, especially if enlarged, the greater depth of the artery, especially on the left side and, here also, the closeness of the internal jugular. **Ligature of the external carotid,** otherwise

difficult, is rendered very simple by first exposing the bifurcation of the common carotid artery, the incision similar to the last being prolonged upward. Here the facial and lingual veins and hypoglossal nerve cross the trunk, over which also lie some of the deep cervical glands. The ligature is usually placed between the superior thyroid and lingual branches.

The **collateral circulation** (fig. 525), after ligature of the common carotid, is carried on chiefly by the anastomosis of the internal carotid with the internal carotid of the opposite side

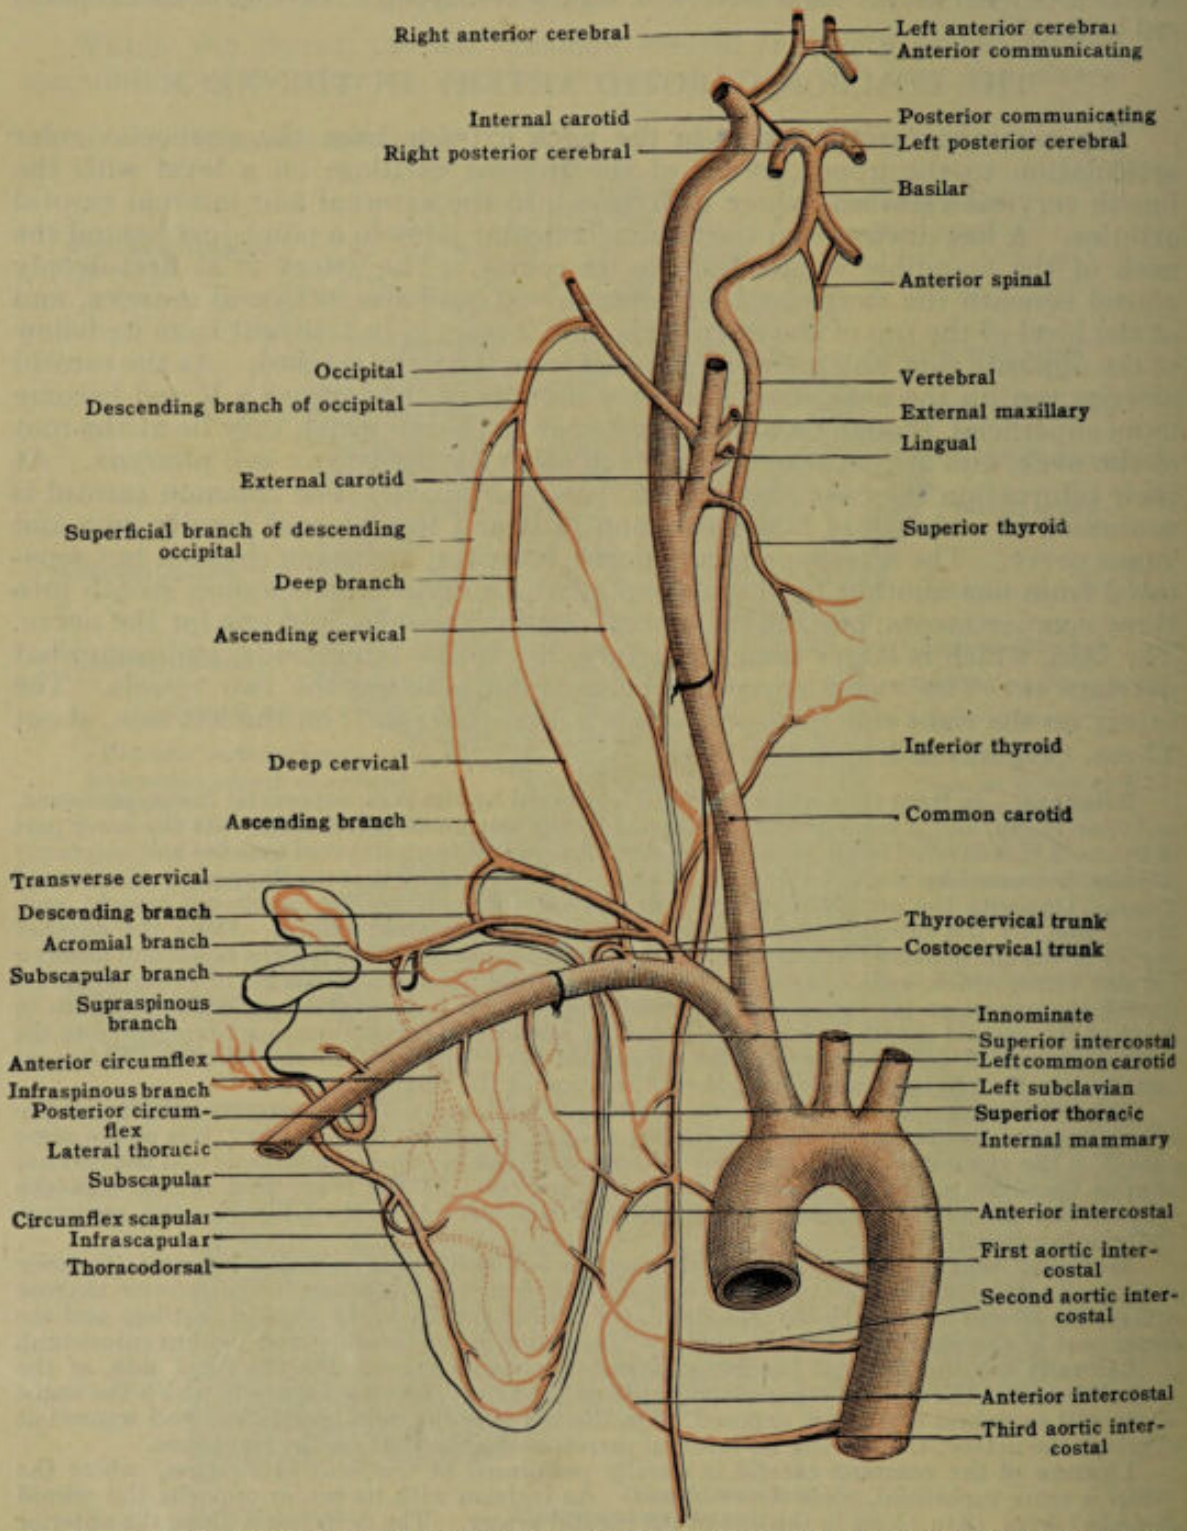

FIG. 525.—THE COLLATERAL CIRCULATION AFTER LIGATURE OF THE COMMON CAROTID AND SUBCLAVIAN ARTERIES.

(A ligature is placed on the common carotid and on the third portion of the subclavian artery.)

and with both vertebral arteries through the circle of Willis; by the inferior thyroid with the superior thyroid; by the deep cervical branch of the costocervical trunk with the descending branch of the occipital; by the superior thyroid, lingual, external maxillary (facial), occipital, and temporal, with the corresponding arteries of the opposite side, and by the ophthalmic with the angular. The anastomosis between the deep cervical branch of the costocervical trunk with the descending branch of the occipital is an important one; it is situated deeply at the back of the neck, between the semispinalis capitis (complexus) and cervicis muscles.

Branches.—The common carotid is unbranched except at its termination, and consequently does not diminish in size as it runs up the neck. It is often a little swollen just below its bifurcation, a condition that should not be mistaken for an aneurismal dilation. Its terminal branches are (1) external and (2) internal carotid arteries.

THE EXTERNAL CAROTID ARTERY

The **external carotid** artery [a. carotis externa] (figs. 524, 526), the smaller of the two branches into which the common carotid divides at the upper border of the thyroid cartilage, is distributed to the anterior part of the neck, the face, and the cranial region, including the skin, the bones, and the dura mater. It is at first medial to the internal carotid; but as it ascends in the neck it forms a

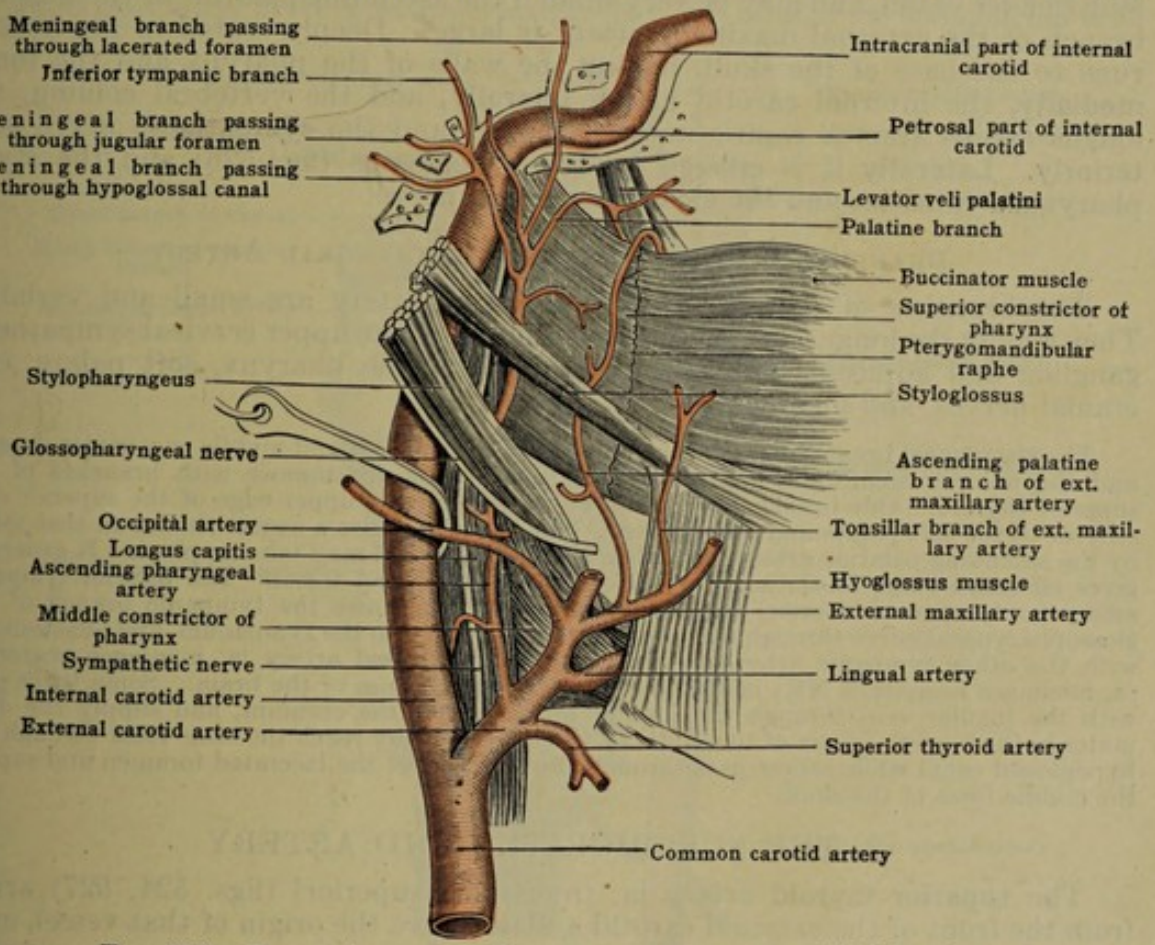

FIG. 526.—RIGHT ASCENDING PHARYNGEAL ARTERY. (Walsham.)
The internal carotid artery is hooked aside.

gentle curve, with its convexity forward, and, running slightly backward as well as upward, terminates opposite the neck of the mandible by dividing into the internal maxillary and superficial temporal arteries. It here lies superficial to the internal carotid from which it is separated by a portion of the parotid gland. At its origin it is overlapped by the anterior margin of the sternomastoid, and is covered by the superficial fascia, platysma, and deep fascia. Higher up the neck it is deeply placed, passing beneath the stylohyoid muscle, the posterior belly of the digastric muscle and the hypoglossal nerve; and finally becomes embedded in the parotid gland, where it divides into its terminal branches. It is separated from the internal carotid artery posteriorly by the stylopharyngeus muscle, the glossopharyngeal nerve, the pharyngeal branch of the vagus nerve, a portion of the parotid gland, and the stylohyoid ligament. It measures about 6.5 cm. (2⅗ in.) in length.

Relations.—Laterally, in addition to the skin, superficial fascia, platysma, and deep fascia, it has the hypoglossal nerve, the lingual, common facial and posterior facial veins, the posterior belly of the digastric and stylohyoid muscles, the superior cervical lymphatic glands, branches of the facial nerve, and the parotid gland. The sternomastoid also overlaps it in the natural state of the parts. **Behind,** it is in relation with the internal carotid, from which it is separated by the stylopharyngeus muscle, the glossopharyngeal nerve, the pharyngeal branch of the vagus nerve, the stylohyoid ligament, and the parotid gland. The superior laryngeal nerve

crosses behind both the external and internal carotid arteries. **Medially,** it is in relation with the hyoid bone, the pharyngeal wall, the stylomandibular ligament, which separates it from the submaxillary gland, and the parotid gland.

The **branches of the external carotid** are usually given off in the following order, from below upward:—(1) Ascending pharyngeal; (2) superior thyroid; (3) lingual; (4) external maxillary (facial); (5) sternocleidomastoid; (6) occipital; (7) posterior auricular; (8) superficial temporal; (9) internal maxillary.

1. THE ASCENDING PHARYNGEAL ARTERY

The **ascending pharyngeal** artery [a. pharyngea ascendens] (fig. 526) is usually the first or second branch of the external carotid. Occasionally it comes off near the bifurcation of the common carotid from the common carotid itself. It is a long slender vessel, and may be very small if the ascending palatine or the tonsillar branch of the external maxillary artery is large. Deeply seated in the neck it runs to the base of the skull, having the walls of the pharynx and the tonsil **medially,** the internal carotid artery **laterally,** and the vertebral column, the longus capitis (rectus capitis anterior major) and the sympathetic nerve **posteriorly. Laterally** it is crossed by the styloglossus (fig. 526) and the stylopharyngeus muscles and the glossopharyngeal nerve.

Branches of the Ascending Pharyngeal Artery

The branches of the ascending pharyngeal artery are small and variable. They supply the longus and rectus capitis muscles, the upper cervical sympathetic ganglion and adjacent lymph-nodes, as well as the pharynx, soft palate, ear, cranial nerves, and meninges.

The **pharyngeal** branches [rr. pharyngei] supply the superior and middle constrictor muscles and the mucous membrane lining them. These vessels anastomose with branches of the superior thyroid. One branch (the **palatine**) passes over the upper edge of the superior constrictor to the soft palate and its muscles. This branch follows a course similar to that taken by the ascending palatine artery, and when the latter is small may take its place. It generally gives off small twigs to the auditory (Eustachian) tube and tonsil. The **inferior tympanic** artery [a. tympanica inferior] (or cervicalis NK) accompanies the tympanic branch of the glossopharyngeal nerve through the tympanic canaliculus into the tympanum, and anastomoses with the other tympanic arteries. The **posterior meningeal** artery [a. meningea posterior] (a. meningea occipitalis NK) is distributed to the membranes of the brain. Some twigs pass with the jugular vein through the jugular foramen into the cranium, and supply the dura mater in the posterior fossa of the skull. Others occasionally reach the same fossa through the hypoglossal canal while others pass through the cartilage of the lacerated foramen and supply the middle fossa of the skull.

2. THE SUPERIOR THYROID ARTERY

The **superior thyroid** artery [a. thyreoidea superior] (figs. 524, 527) arises from the front of the external carotid a little above the origin of that vessel, and, coursing forward, medially, and then downward, in a tortuous manner, supplies the depressor muscles of the hyoid bone, the larynx, the thyroid gland, and the lower part of the pharynx. The artery at first runs forward and a little upward, just below the greater cornu of the hyoid bone. In this part of its course it lies in the superior carotid triangle, and is quite superficial, being covered only with the integument, fascia and platysma. It next turns downward, and passes beneath the omohyoid, sternohyoid and sternothyroid muscles, and ends at the upper part of the thyroid gland in the terminal glandular branches. The superior thyroid vein passes below the artery on its way to the internal jugular vein. The superior thyroid is the artery most commonly divided in cases of suicidal wounds of the throat.

Branches of the Superior Thyroid Artery

The named **branches of the superior thyroid artery** are:—(1) The hyoid; (2) the sternomastoid; (3) the superior laryngeal; (4) the cricothyroid; (5) anterior; (6) posterior; and (7) glandular.

(1) The **hyoid** branch [r. hyoideus] is usually a small twig which passes along the lower border of the hyoid bone, lying on the thyrohyoid membrane under cover of the thyrohyoid and sternohyoid muscles. It supplies the infrahyoid bursa and the thyrohyoid muscle, and anastomoses with its fellow of the opposite side, and with the hyoid branch of the lingual. When the latter artery is small, the hyoid branch of the superior thyroid is usually comparatively large, and *vice versa.*

(2) The **sternomastoid** branch [r. sternocleidomastoideus] (fig. 527) courses downward and backward across the carotid sheath, and entering the sternomastoid supplies the middle portion of that muscle. It gives off slender twigs to the thyrohyoid, sternohyoid, and omohyoid muscles and to the platysma and integument. It lies usually somewhere in the upper part of the incision for tying the common carotid above the omohyoid muscle.

(3) The **superior laryngeal** artery [a. laryngea superior] (fig. 527) passes medially beneath the thyrohyoid muscle, and, perforating the thyrohyoid membrane along with the internal branch of the superior laryngeal nerve, supplies the intrinsic muscles and mucous lining of the larynx. Its further distribution within the larynx is given with the description of that organ. This branch sometimes arises from the external carotid direct. It may enter the larynx by passing through a foramen in the thyroid cartilage.

(4) The **cricothyroid** [r. cricothyreoideus] passes across the cricothyroid membrane at the lower border of the thyroid cartilage. It anastomoses with its fellow of the opposite side, and usually sends a small branch through the membrane to the interior of the larynx. Occasionally a considerable twig descends over the cricoid cartilage to enter the isthmus of the thyroid gland. The cricothyroid is sometimes of comparatively large size. In order to avoid injuring the cricothyroid artery in the operation of laryngotomy, it is usual, if the operation has to be

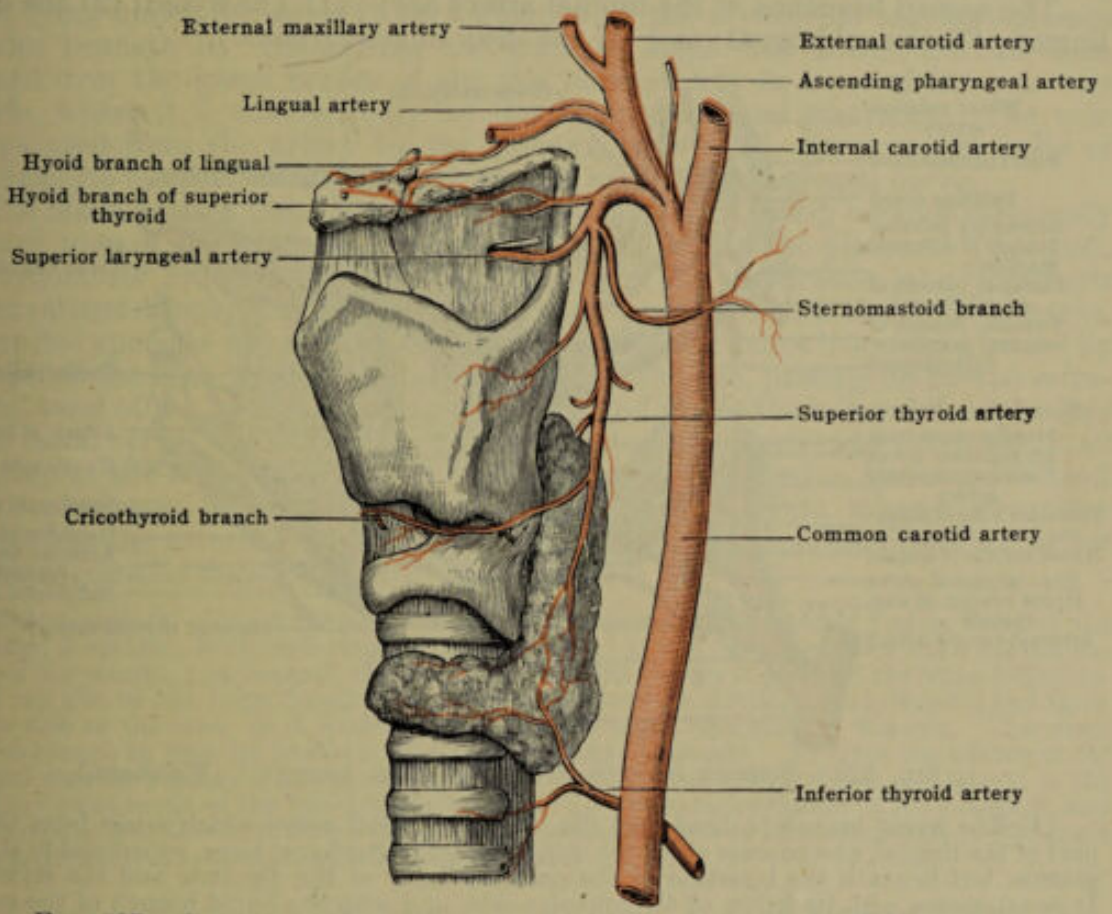

FIG. 527.—SCHEME OF LEFT SUPERIOR THYROID ARTERY. (Walsham.)

done in a hurry to make the incision through the cricothyroid membrane in a transverse direction, and as near to the cricoid cartilage as possible.

(5) The **anterior** branch [r. anterior] is the larger of the terminal branches, supplying the isthmus and the neighboring part of the lateral lobe of the thyroid gland.

(6) The **posterior** branch [r. posterior], also terminal, but much smaller than the anterior, supplies the posterior part of the lateral lobe, and sends branches to the inferior constrictor of the pharynx and to the esophagus. It anastomoses with the ascending branches of the inferior thyroid artery.

(7) The **glandular** branches [rr. glandulares] are the ultimate twigs, arising from the anterior and posterior terminal branches, for the supply of the thyroid gland.

3. THE LINGUAL ARTERY

The **lingual** artery [a. lingualis] (fig. 528) arises from the front of the external carotid, between the superior thyroid and external maxillary (facial) arteries, often as a common trunk with the latter vessel, and nearly opposite or a little below the greater cornu of the hyoid bone. It may, for purposes of description, be divided into two portions: the **first,** or **oblique,** extends from its origin to the posterior edge of the hyoglossus muscle and the **second,** or **horizontal** portion, which lies medially to the hyoglossus and divides at the anterior border of that muscle into its two terminal branches, the sublingual and the deep lingual. The

first or oblique portion is situated in the superior carotid triangle, and is superficial, being covered merely by the integument, platysma, and deep fascia. Here it lies on the middle constrictor muscle and superior laryngeal nerve. After ascending a short distance, it curves downward and forward beneath the hypoglossal nerve, and, in the **second part of its course,** runs horizontally along the upper border of the hyoid bone, beneath the hyoglossus, by which it is separated from the hypoglossal nerve and its vena comitans, and the posterior belly of the digastric and the stylohyoid muscles. It lies successively on the middle constrictor of the pharynx and the genioglossus and is covered posteriorly by the hyoglossus muscle.

The lingual artery is most easily ligated in *Lesser's triangle*, which is found by the hypoglossal nerve above and the two bellies of the digastric muscle below.

Branches of the Lingual Artery

The named **branches of the lingual artery** are:—(1) The hyoid; (2) the dorsal lingual; (3) the sublingual; and (4) the deep lingual (ranine).

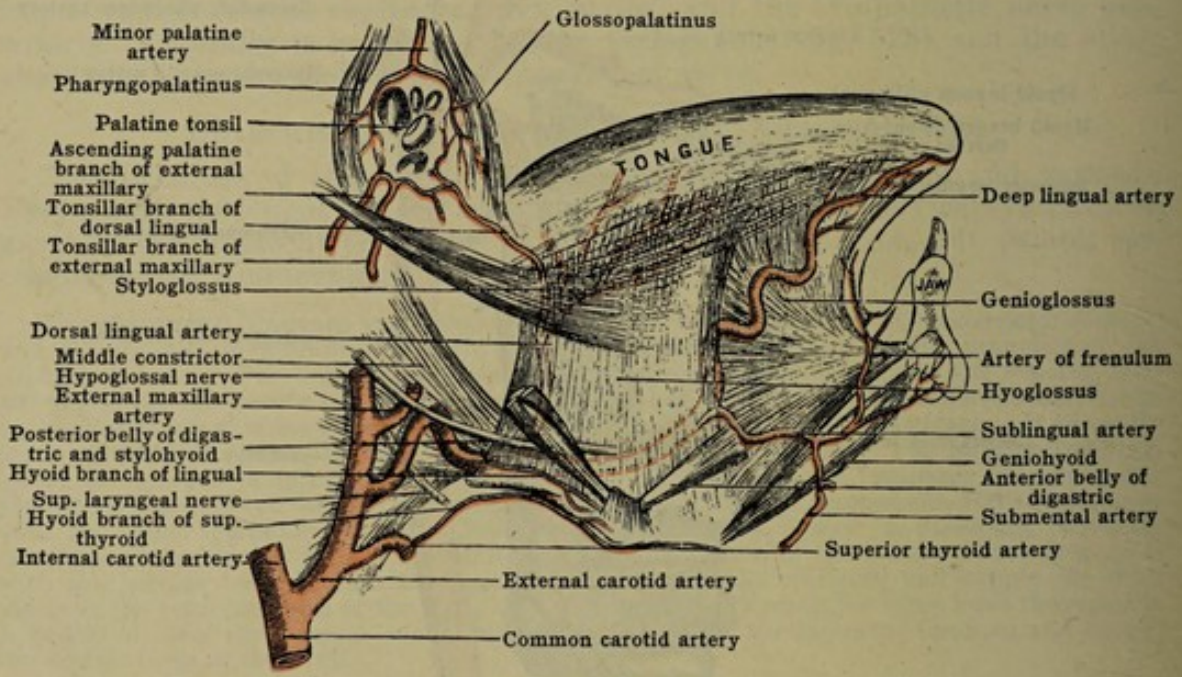

Fig. 528.—Scheme of the Right Lingual Artery. (Walsham.)

(1) The **hyoid** branch [r. hyoideus] (fig. 528) is a small vessel which arises from the first part of the lingual, and courses along the upper border of the hyoid bone, superficial to the hyoglossus, but beneath the insertion of the posterior belly of the digastric and the stylohyoid. It anastomoses with its fellow of the opposite side, and with the hyoid branch of the superior thyroid artery, and supplies the contiguous muscles.

(2) The a. **dorsalis linguæ** (fig. 528) arises from the second portion of the lingual artery, usually under cover of the posterior edge of the hyoglossus muscle. It ascends to the back of the dorsum of the tongue, and dividing into branches, supplies the mucous membrane on each side of the V formed by the vallate papillæ. It also supplies the palatine arches (pillars)and the tonsil, where it anastomoses with the other faucial and tonsillar arteries. Instead of a single artery, as above described, there may be several small vessels running directly to the parts mentioned. The artery anastomoses in the mucous membrane by very small branches with the vessel of the opposite side; but the anastomosis is so minute that when one lingual artery is injected the injection merely passes across to the opposite side at the tip of the tongue; and when the tongue is divided accurately in the middle line, as in the removal of one-half of that organ, practically no hemorrhage occurs.

(3) The **sublingual** artery [a. sublingualis] (fig. 528), one of the terminal branches, arises at the anterior margin of the hyoglossus. It passes beneath the mylohyoid to the sublingual gland, which it supplies, and finally it usually anastomoses with the submental artery, a branch of the external maxillary (facial). It also supplies branches to the side of the tongue, and gives off a terminal twig, which anastomoses beneath the mucous membrane of the floor of the mouth (to which it also gives twigs) with the artery of the opposite side. The **artery of the frenulum** is usually derived from this vessel (fig. 528).

(4) The **deep lingual** [a. profunda linguæ] or ranine artery, the other terminal branch of the lingual, courses forward beneath the mucous membrane, on the lower surface of the tongue, to the tip. It lies upon the lateral side of the genioglossus, between that muscle and the inferior lingualis, and is accompanied by the lingual vein and terminal branch of the lingual nerve. It follows a very tortuous course, so that it is not stretched when the tongue is protruded. Branches are given off from it to the contiguous muscles and mucous membrane. Near the tip of the tongue it communicates with its fellow of the opposite side.

4. THE EXTERNAL MAXILLARY (FACIAL) ARTERY

The **external maxillary** or **facial** artery [a. maxillaris externa] (a. facialis NK) (figs. 529, 533) arises immediately above the lingual from the fore part of the external carotid, sometimes in common with the lingual. It courses forward and upward in a tortuous manner to the mandible and, passing over the body of that bone at the anterior edge of the masseter muscle, winds obliquely upward and forward over the face to the medial angle of the eye, where it anastomoses, under the name of the **angular artery,** with the dorsal nasal branch of the ophthalmic. It is described as having two portions—the cervical and the facial.

The **cervical portion** (fig. 529) ascends tortuously from its origin from the external carotid upward and forward beneath the posterior belly of the digastric, the stylohyoid muscle and the hypoglossal nerve. Then, making a turn, it runs horizontally forward for a short way beneath the jaw, either imbedded in, or lying under the submaxillary gland with the mylohyoid and styloglossus muscles beneath it. On leaving the gland it loops first downward and then upward over the lower border of the jaw immediately in front of the masseter muscle, where it is covered only by the integument and platysma. The vein is separated from the artery by the submaxillary gland, the posterior belly of the digastric muscle, the stylohyoid muscle, and the hypoglossal nerve.

The **facial portion** (fig. 529) of the external maxillary artery ascends tortuously forward toward the angle of the mouth, passing under the platysma (risorius), the zygomatic muscle, the zygomatic head of the quadratus labii superioris (zygomaticus minor), and the zygomatic and buccal branches of the facial nerve. It here lies upon the jaw and the buccinator muscle. Thence it courses upward by the side of the nose toward the medial angle of the eye, passing under the infraorbital head of the quadratus labii superioris, and under the infraorbital branches of the facial nerve. It lies on the caninus (levator anguli oris) and the infraorbital branches of the fifth nerve and its termination is embedded in the angular head of the quadratus labii superioris. The anterior facial vein takes a straighter course than the external maxillary artery and is usually separated from the latter by the zygomatic muscle.

Clinical aspects.—The external maxillary artery crosses the mandible just in front of the masseter; if divided, both ends must be ligated here. It can be felt again a little behind the angle of the mouth, just beneath the mucous membrane (where it gives off the labial branches, which can also be felt, lying deeply, if the lip is taken between the finger and thumb); and again by the side of the nose, as it runs up to the medial angle (canthus) of the eye. The small angular branch is, from its position, always troublesome to secure. To trace the **course of the external maxillary** artery a line should be drawn from a point a little above and lateral to the tip of the great cornu of the hyoid to the lower part of the anterior border of the masseter, and thence to one lateral to and above the angle of the mouth, and so onward, lateral to the angle of the nose, up to the medial angle of the eye.

Branches of the External Maxillary Artery in the Neck

The **branches of the external maxillary artery in the neck** are:—(1) The ascending palatine; (2) the tonsillar; (3) the glandular; (4) the submental.

(1) The **ascending palatine** [a. palatine ascendens] (figs. 526, 529).—the first branch of the external maxillary, but often a distinct branch of the external carotid—ascends between the internal and external carotids, and then between the styloglossus and stylopharyngeus muscles, and on reaching the wall of the pharynx is continued upward between the superior constrictor and internal pterygoid muscles toward the base of the skull as high as the levator veli palatini, where it divides into two branches, a palatine and a tonsillar. One of these branches, the **palatine,** passes with the levator veli palatini over the curved upper margin of the superior constrictor to the soft palate. It anastomoses with its fellow of the opposite side and with the descending palatine branch of the internal maxillary, also with the ascending pharyngeal, which often to a great extent supplies the place of this artery. The other branch, the **tonsillar,** supplies the tonsil and the auditory (Eustachian) tube, anastomosing with the tonsillar branch of the external maxillary (facial) and ascending pharyngeal arteries. The ascending palatine artery supplies the muscles between which it runs on its way to the palate.

(2) The **tonsillar** branch [r. tonsillaris] (fig. 529) ascends between the styloglossus and internal pterygoid muscles to the level of the tonsil, where it perforates the superior constrictor muscle of the pharynx, and ends in the tonsil, anastomosing with the tonsillar branch of the ascending palatine and with the other tonsillar arteries fig. 528). It gives branches also to the root of the tongue.

The ascending palatine artery and the tonsillar tend to vary inversely in size, and either may be small or absent when the ascending pharyngeal is large. There is also a compensatory adjustment between the size of these three arteries and that of the minor palatine branches of the descending palatine.

(3) The **glandular** branches [rr. glandulares] are distributed to the submaxillary gland as the artery is passing through or beneath that structure. A small twig from one of these branches usually supplies the submaxillary (Wharton's) duct.

(4) The **submental** artery [a. submentalis] (fig. 529) comes from the external maxillary as the latter lies under cover of the submaxillary gland and, passing forward on the mylohyoid muscle between the base of the jaw and the anterior belly of the digastricus, supplies these structures and the overlying platysma and integuments. It anastomoses with the sublingual artery.

Branches of the External Maxillary Artery on the Face

From the **lateral** or **concave** side of the artery are given branches which supply the masseter muscle and anastomose with the masseteric and buccinator

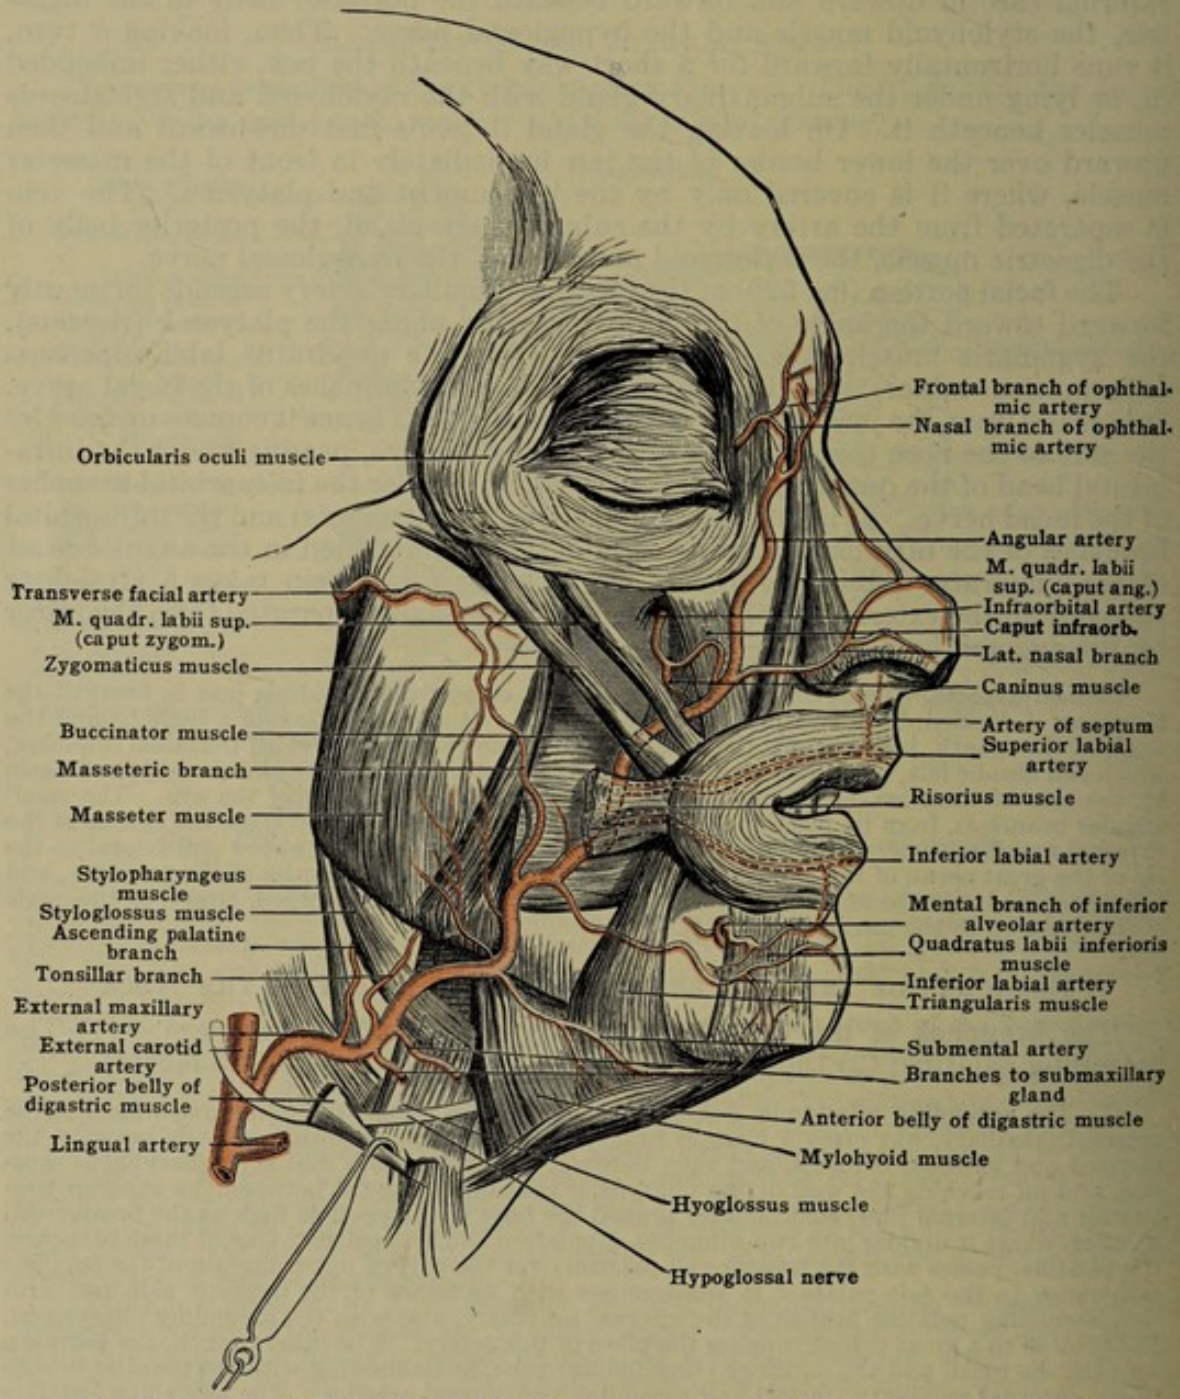

Fig. 529.—Right External Maxillary Artery and Branches. (Walsham.)

branches of the internal maxillary artery and with the transverse facial and infraorbital arteries.

From the **medial** or **convex** side the following larger and named vessels are given:—(1) The inferior labial; (2) the superior labial; and (3) the angular.

(1) The **inferior labial** artery [a. labialis inferior] arises at the angle of the mouth (fig. 533) and runs in the lower lip within the substance of the orbicularis oris, close to the mucous mem-

brane. It anastomoses with the artery of the other side. Frequently an additional branch sepass from the external maxillary to the lower lip.

(2 The **superior labial** artery [a. labialis superior] arising from the external maxillary higher than the inferior (fig. 533), passes forward beneath the zygomaticus, and then, like the inferior labial, courses tortuously along the lower margin of the upper lip between the orbicularis oris and the mucous membrane, about 1.2 cm. (½ in.) from the junction of the mucous membrane and the skin. It is usually larger than the inferior labial. It anastomoses with its fellow of the opposite side, and gives off a small artery to the septum—**arteria septi nasi.** Compression of this vessel will sometimes control hemorrhage from the nose.

(3) The **angular** artery [a. angularis] (fig. 529) is the terminal branch of the external maxillary. It supplies the nose and anastomoses at the medial angle of the eye with the dorsal nasal branch of the ophthalmic. It lies to the medial side of the lacrimal sac and supplies that structure and the lower part of the orbicularis oculi, beneath which a branch anastomoses with the infraorbital artery.

5. THE STERNOCLEIDOMASTOID ARTERY

The **sternocleidomastoid** artery [a. sternocleidomastoidea] arises from the posterior side of the external carotid at the point where the carotid is crossed by the digastric muscle. It hooks over the loop formed by the hypoglossal nerve and follows the accessory nerve into the sternocleidomastoid muscle. It is frequently a branch of the occipital artery.

6. THE OCCIPITAL ARTERY

The **occipital** artery [a. occipitalis] (fig. 530) is usually a vessel of considerable size. It comes off from the posterior part of the external carotid opposite the external maxillary (facial), or else a little higher than that vessel. It then winds upward and backward to the interval between the mastoid process of the temporal bone and transverse process of the atlas, and, after running horizontally backward in a groove on the mastoid portion of the temporal bone, again turns upward, and ends by ramifying in the scalp over the back of the skull, extending as far forward as the vertex.

The vessel may be divided into three parts—viz., that anterior to the sternomastoid muscle; that beneath the sternomastoid; and that posterior to the sternomastoid.

In the **first part of its course** the occipital artery is covered by the integument and fascia, and is more or less overlapped by the posterior belly of the digastric muscle, the parotid gland, and posterior facial (temporomaxillary) vein. It is crossed by the hypoglossal nerve as the latter winds forward over the carotid vessels to reach the tongue. It successively crosses in front of the internal carotid artery, the hypoglossal nerve, the vagus nerve, the internal jugular vein and the accessory nerve.

In the **second part of its course** it sinks deeply beneath the digastric muscle into the interval between the mastoid process of the temporal bone and the transverse process of the atlas. It is here covered by the sternomastoid, splenius capitis, and longissimus capitis muscles and by the origin of the digastric; and lies, first on the rectus capitis lateralis, which separates it from the vertebral artery, then in a groove, the occipital groove, on the mastoid portion of the temporal bone, and then on the insertion of the superior oblique muscle.

In the **third part of its course** it enters the triangular interval formed by the diverging borders of the splenius capitis and the superior nuchal line of the occipital bone. Here it lies beneath the integuments and the aponeurosis uniting the occipital attachments of the sternomastoid and trapezius, and rests upon the semispinalis capitis (complexus) just before the insertion of that muscle into the occipital bone. In company with the greater occipital nerve, it perforates the aponeurosis, or less often the posterior belly of the epicranius (occipitofrontalis), and follows roughly, but in a tortuous course, the line of the lambdoid suture, lying between the integument and the cranial aponeurosis. In the scalp it divides into several large branches, which ramify over the back of the skull and reach as far forward as the vertex. They anastomose with the corresponding branches of the opposite side, and with the posterior auricular and the superficial temporal arteries.

Branches of the Occipital Artery (Fig. 530)

The **branches of the occipital artery** are:—(1) The muscular; (2) the meningeal; (3) the auricular; (4) the mastoid; (5) the descending; (6) the occipital.

(1) The **muscular** branches [rr. musculares] (fig. 530) supply the sternocleidomastoid and adjacent muscles. One of these branches may take the place of the sternomastoid branch of the external carotid. The hypoglossal nerve then loops around it, and not, as a rule, around the occipital.

(2) The **meningeal** branches [rr. meningei] (fig. 532), one or more in number, are long slender vessels which leave the occipital artery as it crosses the internal jugular vein and, ascend with it through the jugular or hypoglossal foramen, and are distributed to the dura mater lining the posterior fossa of the skull.

(3) The **auricular** branch [r. auricularis] ascends over the mastoid process to the back of the ear, and supplies the auricle. It sometimes takes the place of the posterior auricular artery (fig. 530).

(4) The **mastoid** branch [r. mastoideus] is a small twig that passes into the skull through the mastoid foramen, supplying the dura mater, the diploë, the walls of the transverse sinus, and the mastoid cells.

(5) The **descending** or **princeps cervicis** [r. descendens] (fig. 530), the largest of the branches of the occipital, arises from that artery just before it emerges from beneath the splenius, and, descending for a short distance between the splenius and semispinalis capitis (complexus), divides into a superficial and a deep branch. The **superficial branch** perforates the splenius, supplies branches to the trapezius, and anastomoses with the ascending branch of the transverse cervical artery. The **deep branch** passes downward between the semispinalis capitis (complexus) and colli, and anastomoses with the deep cervical branch of the costocervical

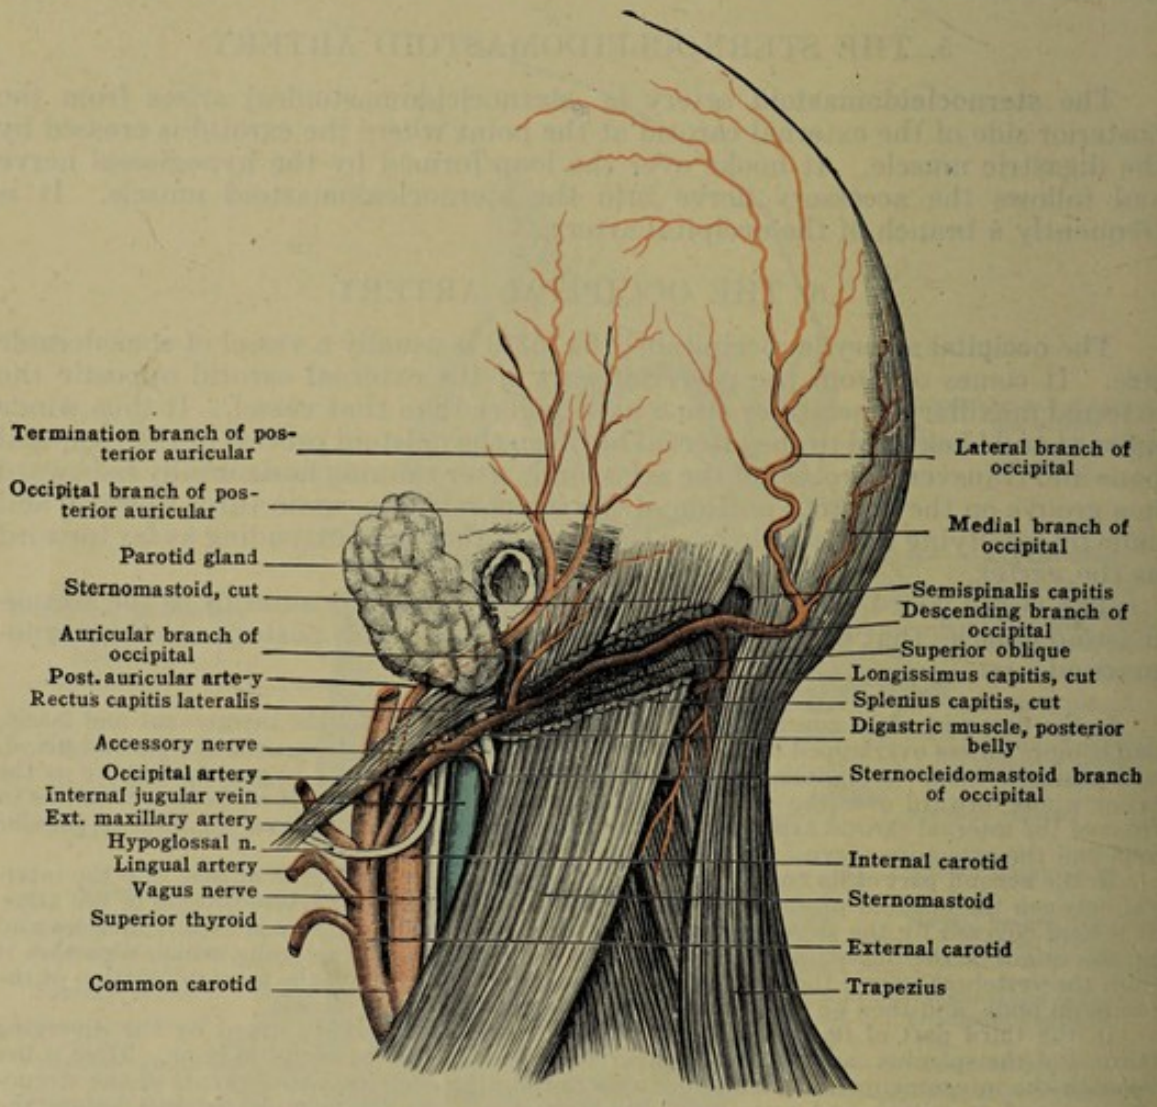

FIG. 530.—LEFT OCCIPITAL AND POSTERIOR AURICULAR ARTERIES. (Walsham.)

trunk and with branches of the vertebral. The anastomoses between the above-mentioned arteries form important collateral channels after ligature of the common carotid and subclavian arteries (fig. 525).

(6) The **occipital** or **terminal** branches [rr. occipitales] (fig. 530), usually two in number, named from their position medial and lateral, ramify over the scalp, and have already been described. The medial branch generally gives a twig which enters the parietal foramen (parietal artery) and is distributed to the dura mater. The occipital artery may also give off the stylomastoid, the posterior auricular, or the ascending pharyngeal arteries.

7. THE POSTERIOR AURICULAR ARTERY

The **posterior auricular** artery [a. auricularis posterior] (a. retroauricularis NK) (fig. 530) arises from the posterior part of the external carotid artery, usually immediately above the posterior belly of the digastric, about the level of the tip of the styloid process. Occasionally it arises under cover of the digastric, quite close to, or as a common trunk with, or as a branch of, the occipital. It courses upward and backward in the parotid gland to the notch between the margin of the external acoustic meatus and the mastoid process, where it divides

into branches. In this course it rests on the styloid process, crosses the accessory nerve, and is crossed by the facial nerve.

Branches of the Posterior Auricular Artery

The **branches of the posterior auricular artery** are:—(1) the stylomastoid; (2) the auricular; (3) the occipital (fig. 530).

The posterior auricular also gives branches to the parotid gland and to the posterior belly of the digastric, the stylohyoid, and auricularis posterior (retrahens aurem) muscles.

(1) The **stylomastoid** artery [a. stylomastoidea] follows the facial nerve through the stylomastoid foramen into the tympanic cavity. In the facial canal it gives origin to **mastoid** branches (rr. mastoidei) to the mastoid cells and a branch (r. stapedius) to the stapedius muscle and tendon. At the iter chordæ posterius, it gives the **posterior tympanic** artery [a. tympanica posterior]. This artery follows the chorda tympani nerve and gives branches to the posterior part of the tympanic membrane which anastomose with the anterior tympanic artery, a branch of the internal maxillary. It then ramifies on the promontery, giving branches to the stapes and to the secondary tympanic membrane, and ends by anastomosing with the superior tympanic artery from the middle meningeal, with the anterior tympanic branch of the internal maxillary, and with the caroticotympanic branch of the internal carotid.

(2) The **auricular** branch [r. auricularis] passes upward behind the ear and beneath the auricularis posterior (retrahens aurem), supplying the medial surface of the auricle and adjacent skin. It anastomoses with the posterior branch of the superficial temporal artery. The branches to the auricle not only supply the back of that structure, but some perforate the cartilage, and others turn over its free margin to supply the lateral surface; there they anastomose with the anterior auricular branches from the temporal.

(3) The **occipital** branch [r. occipitalis] passes upward and backward, crossing the aponeurotic insertion of the sternomastoid muscle. It gives a branch to the posterior belly of the epicranius (occipitofrontalis), and anastomoses with the occipital artery.

8. THE SUPERFICIAL TEMPORAL ARTERY

The **superficial temporal** artery [a. temporalis superficialis] (fig. 524), is the smaller of the two terminal divisions of the external carotid, though apparently the direct continuation of that vessel. It arises opposite the neck of the mandible and, under cover of the parotid gland, passes upward in the interval between the condyle and the external acoustic meatus to the zygoma, lying on the capsule of the temporomandibular joint. Thence it ascends over the posterior zygomatic root and the temporal aponeurosis for about 4 or 5 cm. (1½ or 2 in.), and there divides into frontal and parietal branches. It is surrounded by a dense plexus of sympathetic nerves, and is accompanied by the auriculotemporal nerve, which lies beneath and generally a little behind it. It is crossed by the temporal and zygomatic branches of the facial nerve, and by the auricularis anterior (attrahens aurem) muscle. As it crosses the zygoma it can be readily felt pulsating immediately in front of the auricle, and in this situation can be compressed against the bone. It is here quite superficial, being merely covered by the integuments and a delicate prolongation from the cervical fascia (fig. 524).

Branches of the Superficial Temporal Artery

The **branches of the superficial temporal** artery are:—(1) The parotid; (2) the transverse facial; (3) the anterior auricular; (4) the zygomatico-orbital; (5) the middle temporal; (6) the frontal; (7) the parietal.

(1) The **parotid** branches [rr. parotidei] are small twigs arising in the substance of the parotid gland.

(2) The **transverse facial** [a. transversa faciei] is the largest branch of the temporal. It sometimes arises from the external carotid as a common trunk with the temporal. It is at first deeply seated in the substance of the parotid gland, but soon emerging from the upper part of the anterior border of the gland, courses transversely across the masseter muscle about a finger's breadth below the zygoma. The parotid duct runs below it, and the zygomatic (infraorbital) branches of the facial nerve about it. It supplies the parotid gland, the masseter muscle, and the skin of the face, and anastomoses with the infraorbital, the buccal, and the external maxillary (facial) arteries.

(3) The **anterior auricular** branches [rr. auriculares anteriores] (rr. praeauriculares NK) are three or four in number and supply the tragus, the pinna, and the lobule of the ear, and to some extent the external acoustic meatus.

(4) The **zygomatico-orbital** artery [a. zygomaticoorbitalis] (fig. 537), in some cases a branch of the deep temporal, passes forward along the upper border of the zygoma in the fat between the superficial and deep layers of the temporal aponeurosis and, after giving branches to the orbicularis oculi, sends one or more twigs into the orbit through foramina in the aygomatic (malar) bone to anatomose with the lacrimal and palpebral branches of the ophthalmic.

(5) The **middle temporal** artery [a. temporalis media] (fig. 533), arises just above the zygoma, and, perforating the temporal aponeurosis and temporal muscle, ascends on the squa-

mous portion of the temporal bone, and anastomoses with the posterior deep temporal artery.

(6) The **frontal** or **anterior terminal** branch [r. frontalis] ramifies tortuously in an upward and forward direction over the front part of the skull. It lies first between the skin and temporal fascia and then between the skin and epicranial aponeurosis. It supplies the anterior belly fo the epicranius (occipitofrontalis) and the orbicularis oculi muscles, and anastomoses with the supraorbital and frontal branches of the ophthalmic and with the corresponding artery of the opposite side. The secondary branches given off from this vessel to the scalp run from bfeore backward.

(7) The **parietal** or **posterior terminal** branch [r. parietalis] ramifies on the side of the head between the skin and temporal fascia. Its branches anastomose in front with the anterior terminal branch; behind with the posterior auricular and occipital arteries and above, across the vertex of the skull, with the corresponding artery of the opposite side.

The arteries of the scalp include the terminal branches of the superficial temporal, together with those of the supraorbital and frontal arteries anteriorly and the posterior auricular and

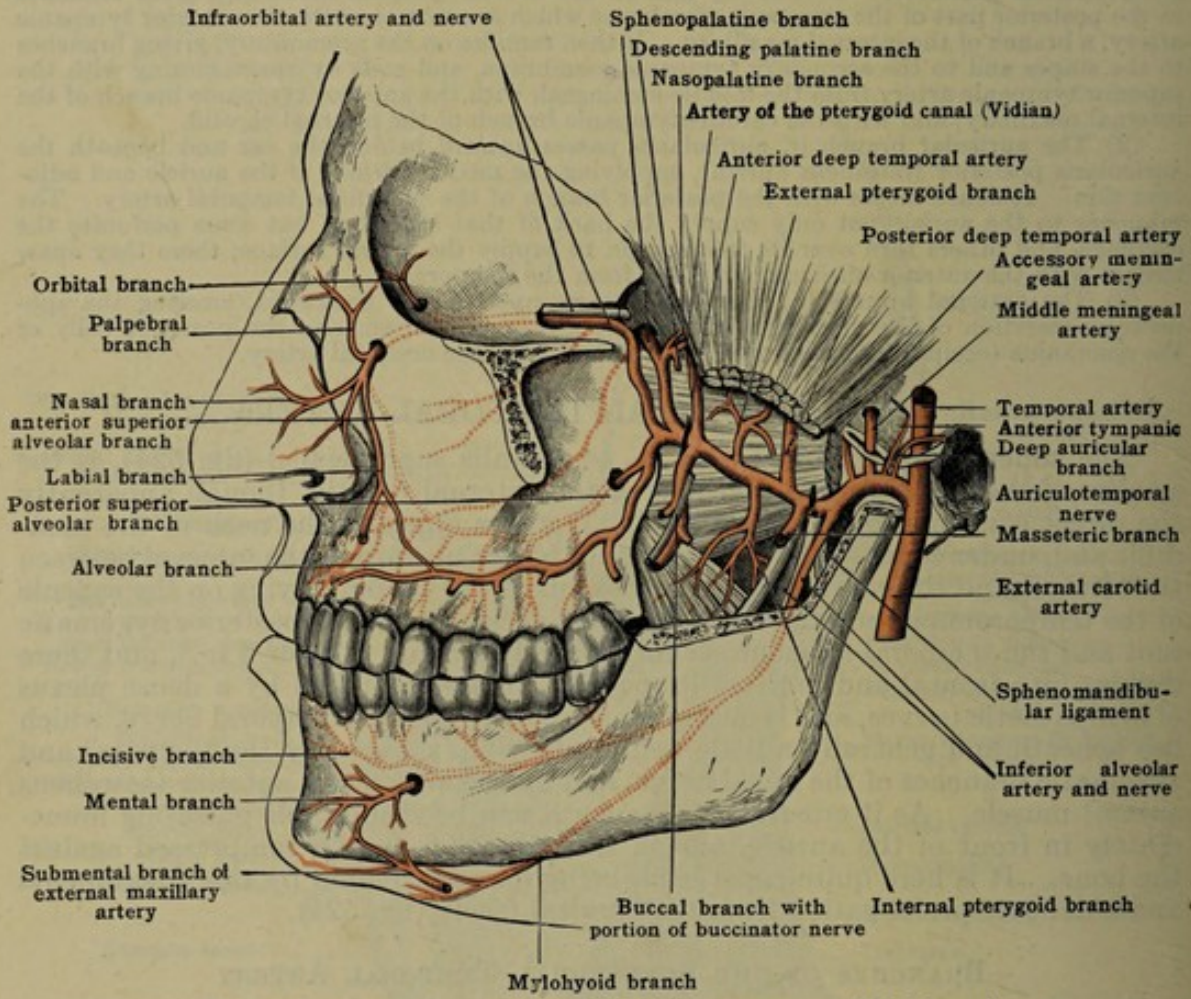

FIG. 531.—LEFT INTERNAL MAXILLARY ARTERY. (Walsham.)

occipital arteries posteriorly. These vessels are peculiar in their location superficial to the deep fascia, which in the scalp is represented by the epicranial aponeurosis. On account of this position of the vessels, a large flap of scalp may be detached above without perishing, as it carries its own vascular supply. From the density of the subcutaneous layer in which the vessels run, they cannot collapse and bleed freely, being difficult to ligate. Finally, on account of their position over adjacent bone, ill-applied pressure may lead to sloughing.

9. THE INTERNAL MAXILLARY ARTERY

The **internal maxillary** artery [a. maxillaris interna] (a. maxillaris NK) (fig. 531) is the larger of the two terminal divisions of the external carotid. It arises opposite the neck of the mandible in the substance of the parotid gland, and, passes forward, between the mandible and the sphenomandibular ligament and then in contact with the external pterygoid muscle, between the heads of origin of which it sinks deeply into the pterygopalatine (sphenomaxillary) fossa, and there breaks up into its terminal branches. It is divided for description into three portions: mandibular, pterygoid, and pterygopalatine.

(1) In the **first part of its course** (the **mandibular portion**) the artery lies between the neck of the mandible and the sphenomandibular ligament, taking a horizontal course forward, nearly parallel to and a little below the auriculo-

temporal nerve and the external pterygoid muscle. It is here embedded in the parotid gland, and usually crosses in front of the inferior alveolar (dental) nerve.

(2) In the **second part of its course** (the **pterygoid portion**) the artery may lie laterally or medially to the external pterygoid muscle. In the first case it passes between the two pterygoid muscles and the ramus of the jaw, and then turns upward over the lateral surface of the external pterygoid, medial to the temporal muscle, to reach the interval between the two heads of the external pterygoid, and sinks into the pterygopalatine fossa. In the second case it is covered by the external pterygoid muscle till it reaches the interval between its two heads, where, forming a projecting loop, it turns into the pterygopalatine fossa.

(3) In the **third part of its course** (the **pterygopalatine portion**) the artery lies in the pterygopalatine fossa beneath the maxillary division of the fifth nerve and in close relationship with the sphenopalatine (Meckel's) ganglion, and there breaks up into its terminal branches.

Branches of the Internal Maxillary Artery

The **branches of the internal maxillary artery** are:—

(A) **From the first part**:—(1) The deep auricular; (2) the anterior tympanic; (3) the middle meningeal; (4) the inferior alveolar (dental); (5) the accessory miningeal (sometimes). All these vessels pass through bony or cartilaginous canals.

(B) **From the second part**:—(1) The masseteric; (2) the posterior deep temporal; (3) the pterygoid; (4) the buccal; and (5) the anterior deep temporal. All these branches supply muscles.

(C) **From the third part**:—(1) The posterior superior alveolar (dental); (2) the infraorbital; (3) the descending palatine; (4) the a. canalis pterygoidei or Vidian; and (5) the sphenopalatine. All these branches pass through bony canals.

Branches of the First Part of the Internal Maxillary Artery

(1) The **deep auricular** artery [a. auricularis profunda] (fig. 531) passes upward in the substance of the parotid gland behind the capsule of the temporomandibular joint, and, perforating the bony or cartilaginous wall of the external acoustic meatus, supplies the skin of that passage and the membrana tympani. It gives a branch to the joint as it passes behind the temporomandibular articular capsule.

(2) The **anterior tympanic** artery [a. tympanica anterior] (a. tympanica maxillaris NK) is a long slender vessel, which runs upward behind the condyle of the jaw to the petrotympanic (Glaserian) fissure, through which it passes to the interior of the tympanum. Here it supplies the lining membrane of that cavity and anastomoses with the other tympanic arteries, forming with the posterior tympanic artery, from the stylomastoid artery a vascular circle around the membrana tympani. This circle is more distinct in the fetus than in the adult.

(3) The **middle meningeal** artery [a. meningea media] (a. meningea temporalis NK) is the largest branch of the internal maxillary artery. It arises between the sphenomandibular ligament and the ramus of the jaw, and under cover of the external pterygoid passes directly upward through the foramen spinosum into the cranium, accompanied by two veins and by filaments of the sympathetic nerve. In this part of its course it is crossed by the chorda tympani nerve; just before it enters the foramen is embraced by the two heads of origin of the auriculotemporal nerve (fig. 531). On entering the skull it ramifies between the bone and dura mater, supplying both structures. It at first ascends for a short distance in a groove on the greater wing of the sphenoid, and then divides into two branches, an anterior and a posterior, both accompanied by venous sinuses.

The **anterior branch** passes upward, in the groove on the greater wing of the sphenoid, on to the parietal bone at its anterior and inferior angle; here the groove becomes deepened and often bridged over by a thin plate of bone, being converted for 6 to 12 mm. (¼ to ½ in.) or more into a distinct canal. The situation of this part of the artery is indicated on the exterior of the skull by a spot 3.7 cm. (1½ in.) behind, and about 2.5 cm. (1 in.) above, the zygomatic process of the frontal bone. The anterior branch continues along the anterior border of the parietal bone nearly as far as the superior sagittal sinus, and gives in its course, but especially posteriorly, large branches which ramify in an upward and backward direction in grooves on the parietal bone (fig. 532). When near the lateral end of the superior orbital fissure, it gives an **orbital** or **lacrimal** branch, which enters the orbit at the outermost part of that fissure, or sometimes through a minute foramen, just lateral to it and anastomoses with the lacrimal branch of the ophthalmic.

The **posterior branch** passes backward over the squamous portion of the temporal bone; and thence on to the parietal bone, behind the anterior branch. This branch and its collaterals extend upward as far as the sagittal sinus, and backward as far as the transverse (lateral) sinus.

In addition to its terminal anterior, and terminal posterior branches, the middle meningeal gives off:—(*a*) **Ganglionic** branches to the semilunar (Gasserian) ganglion and its sheath of

dura mater. (*b*) A **superficial petrosal** branch [r. petrosus superficialis], which enters the hiatus of the facial canal in company with the large superficial petrosal nerve and anastomoses with the terminal branch of the stylomastoid artery. (*c*) A **superior tympanic** artery [a. tympanica superior], which enters the tympanum through the petrosquamous fissure and anastomoses with the other tympanic arteries. (*d*) **Anastomotic** or **perforating** branches which pierce the greater wing of the sphenoid bone, and anastomose with the deep temporal arteries.

(4) The **inferior alveolar** artery [a. alveolaris inferior] (a. alveolaris mandibularis NK) (fig. 531), arising from the internal maxillary as it lies between the sphenomandibular ligament and neck of the jaw, courses downward to the mandibular foramen, which it enters in company with, and a little behind and lateral to, the inferior alveolar nerve. It then passes along the canal in the interior of the bone, giving off branches to the molar, premolar, and canine teeth. On reaching the mental foramen it divides into two branches, the incisive and the mental. The incisive continues its course in the bone, supplies branches to the incisor teeth, and anastomoses with the artery of the opposite side. The **mental** branch [r. mentalis] passes through the mental foramen in company with the mental branch of the inferior alveolar nerve, and emerges on the chin under cover of the quadratus labii inferioris. It anastomoses above with the inferior labial (coronary) artery and below with the submental. Near its origin the artery gives off (*a*) a **lingual** or **gustatory** branch which accompanies and supplies the lingual nerve, and ends

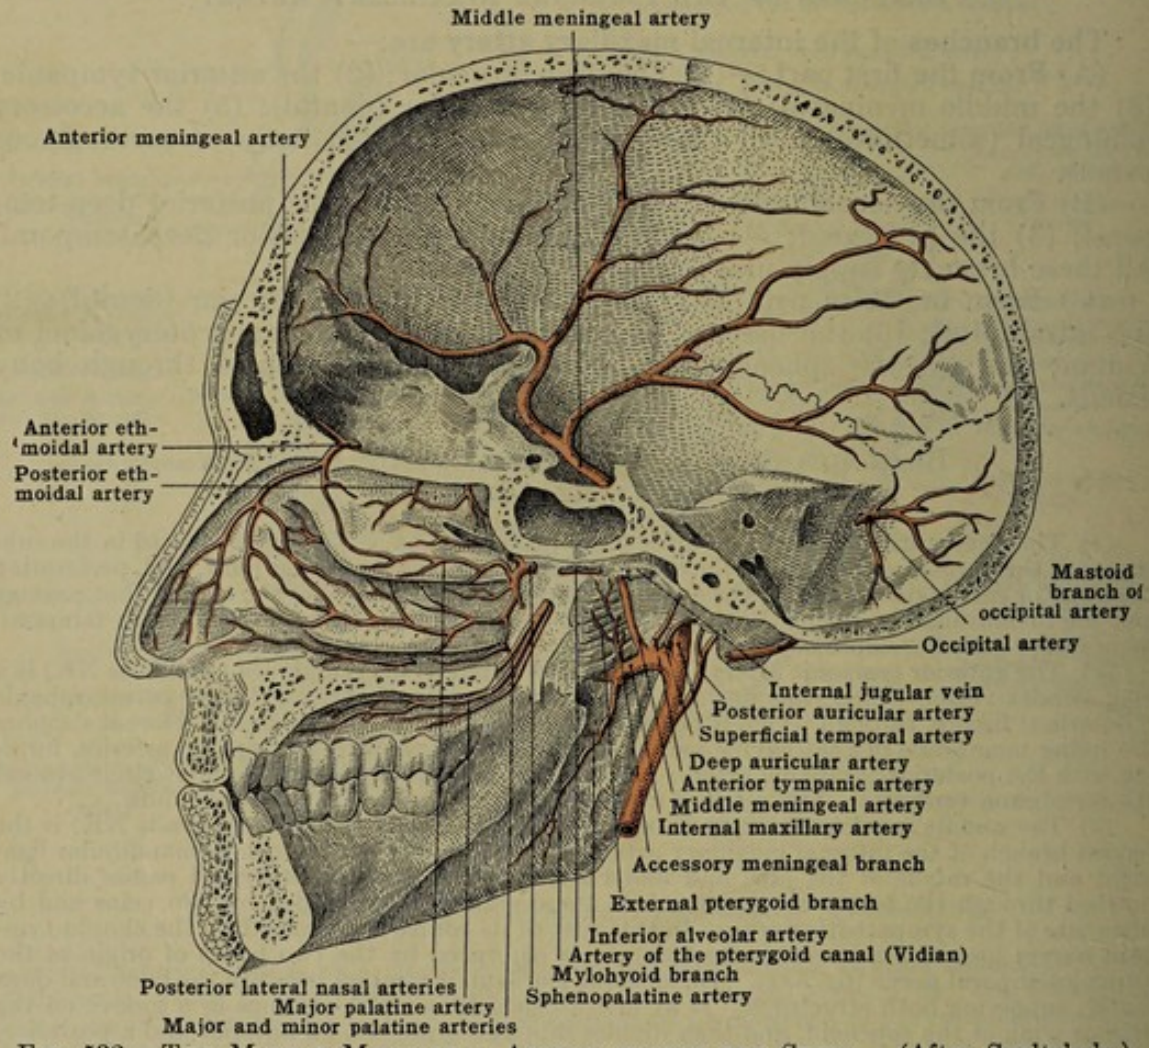

FIG. 532.—THE MIDDLE MENINGEAL ARTERY WITHIN THE SKULL. (After Spalteholz.)

in the mucous membrane of the mouth; and, just before it enters the mandibular foramen, a (*b*) **mylohyoid** branch [r. mylohyoideus], which accompanies the nerve of that name along the groove in the mandible and after supplying the mylohyoid muscle, anastomoses with the sublingual and submental arteries.

(5) The **accessory or small meningeal** branch [r. meningeus accessorius] arises either from the internal maxillary a little in front of the middle meningeal, or as a branch of the latter vessel. It passes upward along the course of the mandibular division of the fifth nerve, and, entering the skull through the foramen ovale, is distributed to the semilunar (Gasserian) ganglion, to the walls of the cavernous sinus and to the dura mater in the neighborhood.

BRANCHES OF THE SECOND PART OF THE INTERNAL MAXILLARY ARTERY

The branches of the second portion of the internal maxillary all supply muscles. They are:—(1) The masseteric; (2) the posterior deep temporal; (3) the pterygoid; (4) the buccal; and (5) the anterior deep temporal

(1) The **masseteric** artery [a. masseterica] comes from the internal maxillary as the latter is passing from between the neck of the jaw and the sphenomandibular ligament. It passes.

with the masseteric nerve through the mandibular (sigmoid) notch in the mandible and supplies the masseter muscle. Some filaments perforate the muscle and anastomose with the transverse facial and with the masseteric branches of the external maxillary (facial).

(2) The **posterior deep temporal** artery [a. temporalis profunda posterior] (a.t.p. aboralis NK) arises, as a rule, from the internal maxillary in common with the masseteric, or a little beyond that branch. It passes upward beneath the temporal muscle in a slight groove on the anterior margin of the squamous portion of the temporal bone, supplying the temporal muscle, the pericranium and the external layer of the bone. It anastomoses with the other temporal arteries.

(3) The **pterygoid** branches [rr. pterygoidei] are short trunks which pass into and supply the internal and external pterygoid muscles.

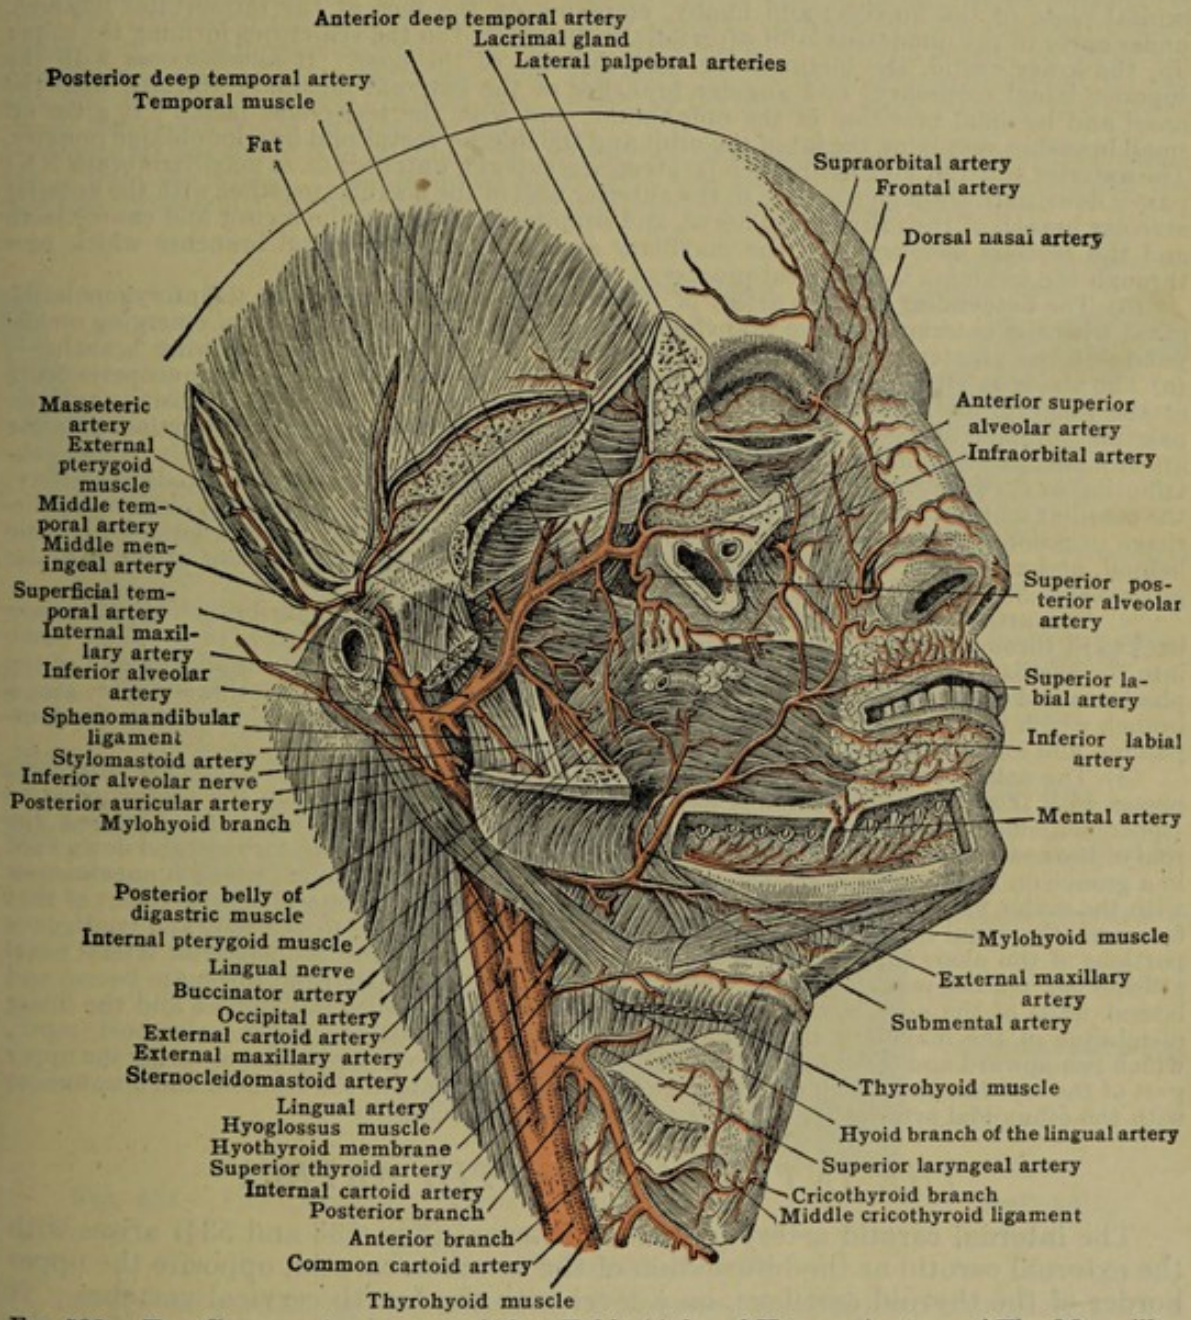

FIG. 533.—THE CAROTID ARTERIES. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

(4) The **buccal** artery [a. buccinatoria] (fig. 533) courses forward and downward with the buccal nerve to the buccinator muscle, lying in close contact with the medial side and anterior margin of the tendon of the temporal muscle and coronoid of the lower jaw. It supplies the buccinator muscle and mucous membrane of the mouth, and anastomoses with the external maxillary (facial), transverse facial, and infraorbital arteries.

(5) The **anterior deep temporal** artery [a. temporalis profunda anterior] (a.t.p. oralis NK) ascends beneath the temporal muscle in a slight groove on the greater wing of the sphenoid bone. It supplies the muscle, pericranium, and subjacent bone, and gives small branches through minute foramina in the zygomatic (malar) bone. Some of these last branches enter the orbit and anastomose with the lacrimal artery; others emerge on the face and anastomose with the transverse facial artery.

BRANCHES OF THE THIRD PART OF THE INTERNAL MAXILLARY ARTERY

The branches of the third part of the internal maxillary artery, like those of the first part, all pass through bony canals. They are the following:—(1) The posterior superior alveolar

(dental); (2) the infraorbital; (3) the descending palatine; (4) the artery of the pterygoid canal (Vidian); and (5) the sphenopalatine.

(1) The **posterior superior alveolar (dental)** artery [a. alveolaris superior posterior] (a. a. maxillaris aboralis NK) arises from the internal maxillary as the latter is passing into the pterygopalatine (sphenomaxillary) fossa, and descends in a tortuous manner in a groove on the back of the body of the maxilla. It gives off branches to the maxillary sinus, to the molar and premolar teeth, the gums, and to the buccinator muscle.

(2) The **infraorbital** artery [a. infraorbitalis] arises from the internal maxillary, generally as a common trunk with posterior alveolar (dental). It then passes forward and a little upward through the pterygopalatine (sphenomaxillary) fossa; then forward in company with the infraorbital branch of the fifth nerve, first along the groove, and then through the canal in the orbital plate of the maxilla; and finally, emerging on the face at the infraorbital foramen, under cover of the quadratus labii superioris, is distributed to the structures forming the upper lip, the lower eyelid, the lacrimal sac, and the side of the nose. It anastomoses with the superior labial (coronary) and angular branches of the external maxillary (facial), with the nasal and lacrimal branches of the ophthalmic, and with the transverse facial. It gives off small branches supplying the fat of the orbit and the inferior rectus and inferior oblique muscles. The **anterior superior alveolar** branch [a. alveolaris superior anterior] (a. a. maxillaris oralis NK) passes downward through a groove in the anterior wall of the maxilla, together with the anterior alveolar branch of the infraorbital nerve, and supplies branches to the incisor and canine teeth and the mucous membrane of the maxillary sinus. It has also **nasal** branches which pass through the foramina in the nasal process of the maxilla.

(3) The **descending palatine** artery [a. palatina descendens] descends in the pterygopalatine canal with the anterior palatine branch of the sphenopalatine ganglion. On emerging on the palate at the greater (posterior) palatine foramen, it divides into the following branches—(*a*) The **major palatine** artery [a. palatina major], which courses forward in the mucoperiosteum at the junction of the hard palate with the alveolar process as far as the incisive (anterior palatine) foramen, where it anastomoses with the sphenopalatine artery; and (*b*) **minor palatine** arteries [aa. palatinæ minores], which pass backward and downward into the soft palate, contributing to the supply of that structure, and anastomosing with the ascending palatine artery, the tonsillar and the ascending pharyngeal. After the operation for cleft palate, serious hemorrhage occasionally occurs from the major palatine artery. The foramen is situated a little behind, and medial to, the last molar tooth, and almost immediately in front of the hamular process (fig. 532).

4) The **arteria canalis pterygoidei or Vidian** artery is a long slender branch which passes backward through the pterygoid (Vidian) canal in company with the nerve of the same name into the cartilage of the lacerated foramen. It gives off branches which supply the roof of the pharynx, and anastomose with the ascending pharyngeal and sphenopalatine arteries; also a branch which is distributed to the auditory (Eustachian) tube; and one which enters the tympanum, and anastomoses with the other tympanic arteries.

(5) The **sphenopalatine** [a. sphenopalatina], the terminal branch of the internal maxillary, passes with the nasopalatine branch of the sphenopalatine ganglion from the pterygopalatine (sphenomaxillary) fossa into the nose through the sphenopalatine foramen. Crossing the roof of the nose in the mucoperiosteum, it passes to the septum, and runs forward and downward in a groove on the vomer toward the incisive (anterior palatine) foramen, where it anastomoses with the major palatine artery, which enters the nose through the lateral compartment of that foramen (the canal of Stenson). In this course it gives branches to the roof and contiguous portions of the pharynx, and to the sphenoidal cells. It gives also the **posterior lateral nasal** arteries [aa. nasales post. laterales], which ramify over the nasal conchæ (turbinate bones) and lateral walls of the nose, and give twigs to the ethmoidal and frontal sinuses and the lining membrane of the maxillary sinus; and the **posterior septal** arteries [aa. nasales post. septi], which run upward and forward, giving small twigs to the mucous membrane covering the upper part of the septum, and which pass through the cribriform plate of the ethmoid and anastomose with the ethmoidal arteries (perforating or meningeal branches).

THE INTERNAL CAROTID ARTERY

The **internal carotid** artery [a. carotis interna] (figs. 533 and 534) arises with the external carotid at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage, on a level with the fourth cervical vertebra. It is at first placed a little laterally to the external carotid, but as it ascends in the neck it lies medially and slightly posteriorly to the external carotid. The internal carotid passes up the neck, in front of the transverse processes of the upper cervial vertebræ, lying upon the longus capitis (rectus capitis ant. major), to the carotid foramen, thence through the carotid canal in the petrous portion of the temporal bone. It makes at first a forward and medial turn and then a second turn upward, above the cartilage occupying the foramen lacerum. Within the cranium, it makes a sigmoid curve on the side of the body of the sphenoid bone, and terminates, after perforating the dura mater, by dividing opposite the anterior clinoid process, in the lateral fissure (fissure of Sylvius), into the anterior and middle cerebral arteries. For the so-called 'carotid sinus,' see p. 1026.

In its course up the neck it often forms one or more curves, especially in old people. Between the internal and the external carotids, at their angle of divergence, is situated the **carotid body** or gland [glomus caroticum].

1. The Cervical Portion

Relations.—In the neck (fig. 533) the artery is at first comparatively superficial, having **laterally** to it, as it lies in the superior carotid triangle, the skin, superficial fascia, platysma and deep fascia, and the overlapping edge of the sternomastoid muscle. As it ascends, it becomes deeply placed, beneath the internal jugular vein and the parotid gland. It is crossed by the posterior belly of the digastric and stylohyoid muscles, the hypoglossal nerve, and the occipital and posterior auricular arteries. Still higher it is separated anteriorly from the external carotid artery by the stylopharyngeus muscle, the glossopharyngeal nerve, the pharyngeal branch of the vagus nerve, and by the stylohyoid ligament.

Behind, it lies upon the longus capitis (rectus capitis anticus major), which separates it from the transverse processes of the three upper cervical vertebræ, on the superior cervical ganglion of the sympathetic nerve, and on the vagus nerve. Near the base of the skull, the hypoglossal, vagus, glossopharyngeal, and accessory nerves cross obliquely behind it, and separate it from the internal jugular vein, which, as the artery is about to enter the carotid canal, also forms one of its posterior relations.

On its **medial side** it is in relation with the pharynx, the superior constrictor muscle separating it from the tonsil. The ascending pharyngeal and ascending palatine arteries, and the auditory (Eustachian) tube and levator veli palatini muscles, are also medial to it.

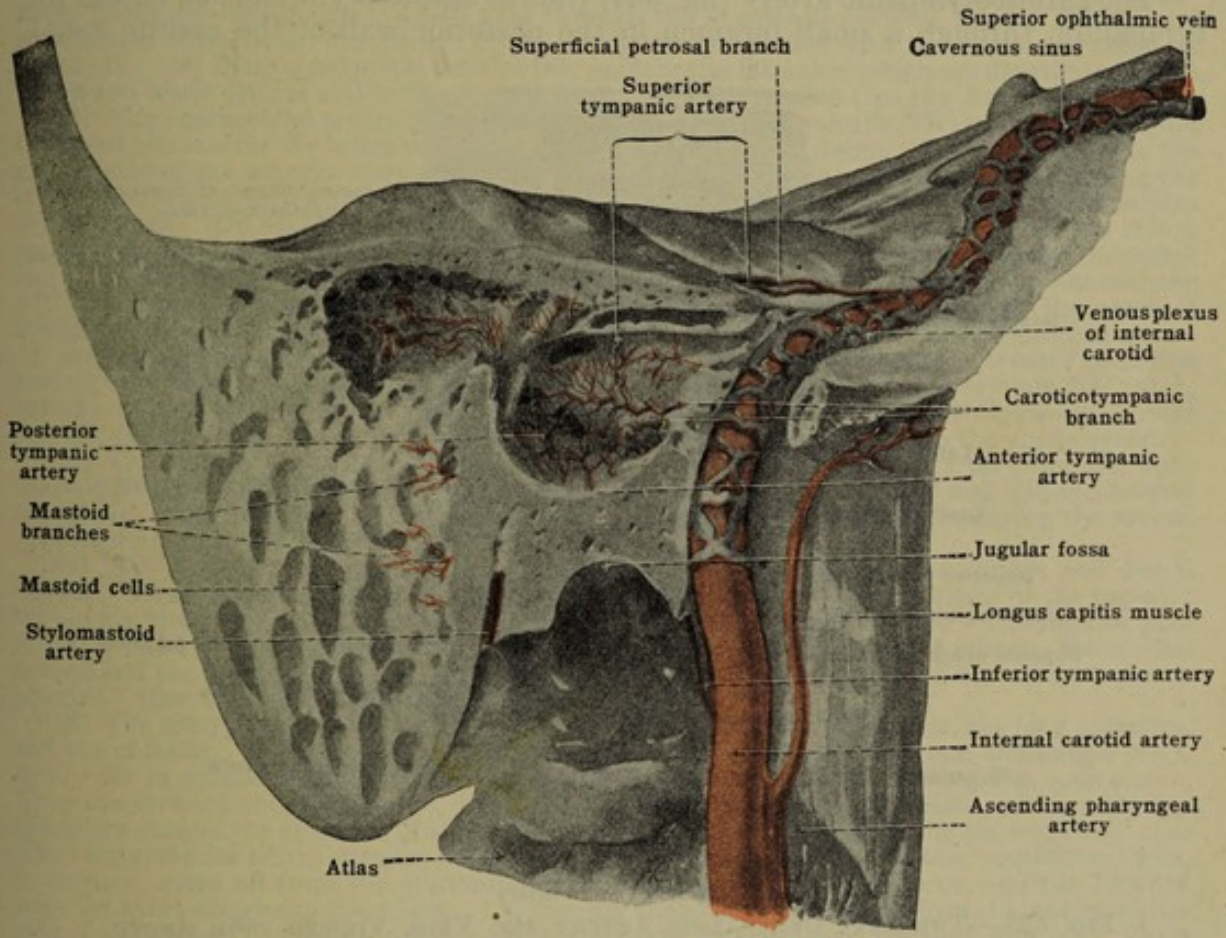

Fig. 534.—The Internal Carotid Artery in the Canal. (After Spalteholz.)

2. The Petrosal Portion

The **petrosal portion** (fig. 534) is situated in the carotid canal in the petrous portion of the temporal bone. It is here separated from the walls of the canal by a prolongation downward of the dura mater. In this part of its course it first ascends in front of the tympanum and cochlea of the internal ear; it then turns forward and medially, lying a little to the medial side of and behind the auditory (Eustachian) tube, and enters the cranial cavity by turning upward above the cartilage filling the foramen lacerum, lying upon the lingula of the sphenoid bone. In this part of its course it is accompanied by the ascending branches from the superior cervical ganglion of the sympathetic. These form a plexus about the artery, but are situated chiefly on its lateral side. It is also surrounded by a number of small veins, which receive tributaries from the tympanum and open into the cavernous sinus and internal jugular vein.

3. The Intracranial Portion

On entering the cranium the internal carotid first ascends upon the medial side of the lingula along the lateral part of the body of the sphenoid. It then follows the carotid sulcus forward and slightly downward along the medial wall of the cavernous sinus (fig. 536). Here it has the sixth nerve immediately lateral to it, and is covered by the lining membrane of the sinus. Again turning upward, it pierces the dura mater on the medial side of the anterior clinoid process, and passes between the second and third nerves to the anterior perforated

substance. At the medial end of the lateral (Sylvian) fissure it pierces the arachnoid and divides into its two terminal branches, the anterior and middle cerebral. As it lies above the foramen lacerum, the artery is crossed on its lateral side by the great superficial petrosal nerve as the latter goes to join the great deep petrosal from the carotid plexus to form the nerve of the pterygoid canal (Vidian).

Branches of the Internal Carotid Artery

The **cervical portion** has no branches. The **petrosal portion** gives off the caroticotympanic. The **branches of the intracranial portion** are:—(2) ophthalmic; (3) posterior communicating; (4) choroid; (5) anterior cerebral; (6) middle cerebral.

As the internal carotid artery lies on the medial side of the cavernous sinus, it also gives off the following small branches—branches to the walls of the cavernous sinus, to the pituitary body, to the semilunar (Gasserian) ganglion and to the dura mater. These anastomose with anterior branches of the middle meningeal.

1. THE CAROTICOTYMPANIC ARTERY

The **caroticotympanic artery** (fig. 534) [ramus caroticotympanicus] enters the tympanum through a small foramen in the posterior wall of the carotid canal,

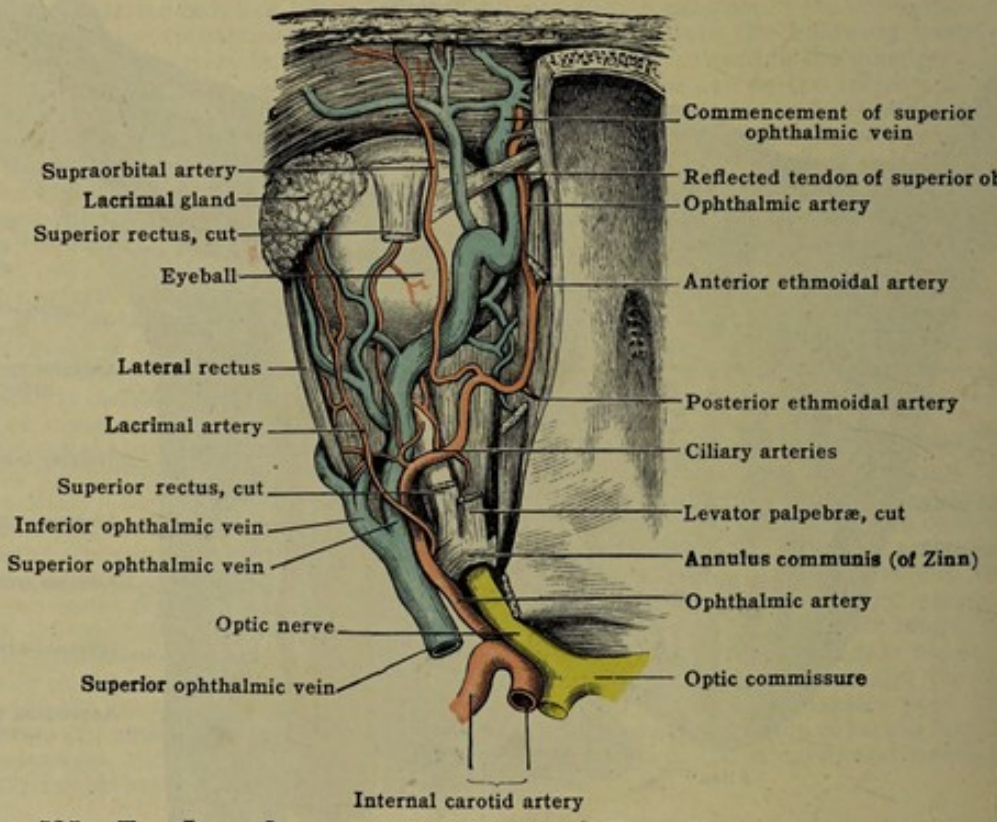

Fig. 535.—The Left Ophthalmic Artery and Vein, Viewed from Above.

and contributes to the blood-supply of that cavity. It anastomoses on the promontory with the tympanic branches of the stylomastoid, internal maxillary, and middle meningeal arteries.

2. THE OPHTHALMIC ARTERY

The **ophthalmic** artery (fig. 535) arises from the internal carotid immediately below the anterior clinoid process just as the latter vessel is passing through the dura mater. Entering the orbit through the optic foramen below and laterally to the optic nerve, it at once perforates the sheath of dura mater which is prolonged through the optic foramen on both artery and nerve. It then runs in a gentle curve with a lateral convexity below the optic nerve and lateral rectus, being here crossed by the nasociliary (nasal) nerve. Turning forward and upward, it passes over the optic nerve, to its medial side. Thence it runs obliquely beneath the superior rectus in front of the nasociliary (nasal) nerve under the lower border and pulley of the superior oblique, but above the medial rectus, and continues its course to the medial palpebral region, where it divides into the frontal and dorsal nasal branches.

Branches of the Ophthalmic Artery

The **branches of the ophthalmic artery** are:—(1) the lacrimal; (2) the supra-orbital; (3) the central artery of the retina; (4) the muscular; (5) the ciliary; (6) the posterior ethmoidal; (7) the anterior ethmoidal; (8) the medial palpebral; (9) the frontal; and (10) the dorsal nasal.

(1) The **lacrimal** artery [a. lacrimalis], is usually the first and often the largest branch of the ophthalmic. It arises between the superior and lateral rectus on the lateral side of the optic nerve from the ophthalmic, soon after that vessel has entered the orbit. At times it is given off from the ophthalmic, or from the middle meningeal artery outside the orbit, and then usually passes into that cavity through the superior orbital (sphenoidal) fissure. It runs forward along the lateral wall of the orbit with the lacrimal nerve, above the upper border of the lateral rectus, to the lacrimal gland, which it supplies. In this course it furnishes the following branches:—(*a*) **Recurrent,** one or more branches which pass backward through the superior orbital (sphenoidal) fissure, and anastomose with the lacrimal branch of the middle meningeal artery. The anastomosis is sometimes of large size, and then takes the chief share in the formation of the lacrimal artery. (*b*) **Muscular** branches, distributed chiefly to the lateral rectus. (*c*) **Zygomatic** branches—small twigs, which pass through the zygomatico-orbital (malar) canals, and anastomose with the orbital branch of the middle temporal, and with the transverse facial on the cheek. (*d*) **Lateral palpebral** arteries [aa. palpebrales laterales] which are distributed to the upper and lower eyelids and to the conjunctiva. (*e*) **Ciliary.** See Ciliary Arteries below.

(2) The **supraorbital** artery [a. supraorbitalis] (a. frontalis lateralis NK) usually arises from the ophthalmic after the latter vessel has crossed over the optic nerve. Passing upward to the medial side of the superior rectus and levator palpebræ, it runs along the upper surface of the latter muscle with the frontal nerve in the orbital fat, but beneath the periosteum, to the supra-orbital notch. On emerging on the forehead beneath the orbicularis oculi, it divides into a superficial and a deep branch, the former ramifies between the skin and epicranius (occipito-frontalis), the latter between the epicranius and the pericranium. Both branches anastomose with the anterior branches of the superficial temporal, the angular branch of the external maxillary (facial), and the transverse facial artery. The branches of the supraorbital are:—(*a*) **periosteal,** to the periosteum of the roof of the orbit; (*b*) **muscular,** to the levator palpebræ and superior rectus; (*c*) **diploic,** given off as the artery is passing through the supraorbital notch, enters a minute foramen at the bottom of the notch and is distributed to the diploë and frontal sinuses; (*d*) **trochlear,** to the pulley of the superior oblique; (*e*) **palpebral,** to the upper eyelid.

(3) The **arteria centralis retinæ,** a small but constant branch, comes off from the ophthalmic close to the optic foramen and, perforating the optic nerve about 6 mm. (¼ in.) behind the globe, runs forward (in the substance of the nerve) to the eyeball, supplying the retina. Its further description is given in the section on the Eye.

(4) The **muscular** branches [rr. musculares] are very variable in their origin and distribution. They may be roughly divided into superior and inferior sets. Those of the superior set supply the superior oblique, the levator palpebræ, and superior rectus. The inferior pass forward, between the optic nerve and the inferior rectus, supplying that muscle, the medial rectus, and the inferior oblique. From the muscular branches are given off the anterior ciliary arteries. (See Ciliary Arteries.)

(5) The **ciliary arteries** are divided into three sets:—The **short posterior,** the **long posterior,** and the **anterior.** (i) The **short posterior** [aa. ciliares posteriores breves] (aa. chorioideæ NK), five or six in number, come off chiefly from the ophthalmic as it is crossing the optic nerve. They run forward about the nerve, dividing into twelve or fifteen small vessels, which perforate the sclera around the entrance of the optic nerve, and are distributed to the choroid coat. (ii) The **long posterior** ciliary arteries [aa. ciliares posteriores longæ], usually two, sometimes three, in number, come off from the ophthalmic on either side of the optic nerve, and run forward with the short ciliaries to the sclera. On piercing the sclera, they course forward, one on either side of the eyeball between the sclera and the choriod, to the ciliary processes and iris. Their further distribution is given under the anatomy of the Eye. (iii) The **anterior ciliary** arteries [aa. ciliares anteriores] (ramuli ciliares NK) are derived from the muscular branches and from the lacrimal. They run to the globe along the tendons of the recti, forming a zone of radiating vessels beneath the conjunctiva. Some of them, the **episcleral arteries** [aa. episclerales], perforate the sclera about 6 mm. (¼ in.) behind the cornea, and supply the iris and ciliary processes. It is these vessels that are enlarged and congested in iritis, forming the circumcorneal zone of redness so characteristic of that disease. They then differ from the tortuous vessels of the conjunctiva in that they are straight and parallel. The other branches constitute the **anterior conjunctival** arteries [aa. conjunctivales anteriores].

(6) The **posterior ethmoidal** artery [a. ethmoidalis posterior] (a. ethmoidalis labyrinthica NK) (fig. 535) runs medially between the superior oblique and medial rectus and, leaving the orbit by the posterior ethmoidal canal, together with the posterior ethmoidal branch of the nasociliary (nasal) nerve, enters the posterior ethmoidal cells, whence it passes through a transverse slit-like aperture between the sphenoid bone and cribriform plate of the ethmoid bone into the cranium. It gives off (*a*) **ethmoidal** branches to the posterior ethmoidal cells; (*b*) **meningeal** branches to the dura mater lining the cribriform plate; and (*c*) **nasal** branches, which pass through the cribriform plate to the superior meatus and upper nasal conchæ, and anastomose with the nasal branches of the sphenopalatine artery (fig. 532).

(7) The **anterior ethmoidal** artery [a. ethmoidalis anterior] (a. ethmoidalis olfactoria NK) (figs. 532, 535), a larger branch than the posterior ethmoidal, arises in front of the latter, passes medially between the superior oblique and medial rectus, and, leaving the orbit through the anterior ethmoidal canal, in company with the anterior ethmoidal nerve, enters the cranial cavity. After running a short distance beneath the dura mater on the cribriform plate of the

ethmoidal bone, it passes into the nose through the horizontal slit-like aperture by the side of the crista galli. Its terminal branch passes along the groove on the under surface of the nasal bone, and emerges on the nose between the bone and lateral cartilage, terminating in the skin of that organ. It gives off the following branches in its course:—(i) **Ethmoidal,** to the anterior ethmoidal cells; (ii) **anterior meningeal** artery, [a. meningea anterior] to the dura mater of the anterior fossa; (iii) **nasal** branches to the middle meatus and anterior part of the nose; (iv) **frontal** branches to the frontal sinuses; (v) **cutaneous,** or **terminal** branches to the skin of the nose.

(8) The **medial palpebral** arteries [aa. palpebrales mediales] arise either separately or by a common trunk from the ophthalmic artery opposite the pulley for the superior oblique. They pass, one above and one below, the medial palpebral ligament and then skirt along the upper and

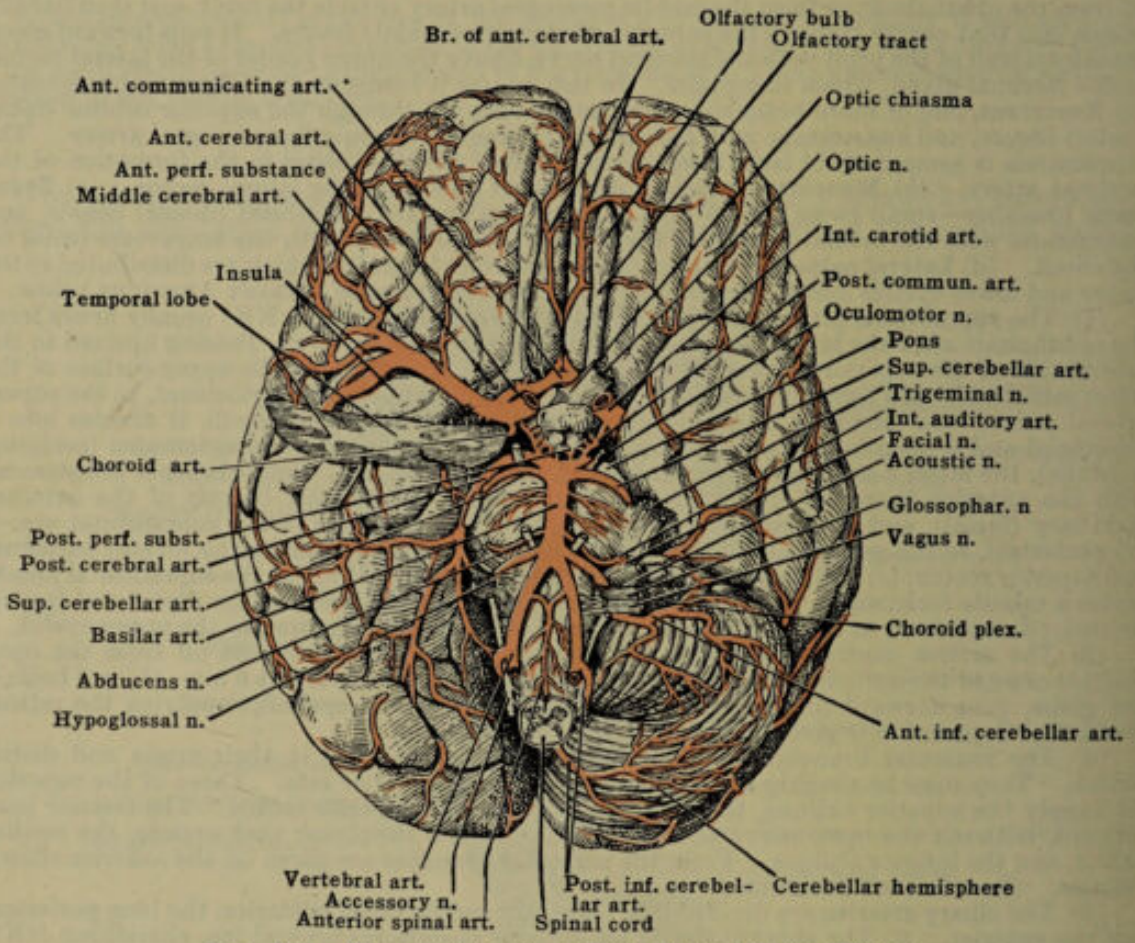

FIG. 536.—THE ARTERIES AT THE BASE OF THE BRAIN.

lower eyelids respectively, near the free margin between the palpebral tarsi and the orbicularis muscle, and form a **superior** and an **inferior tarsal arch** [arcus tarseus superior, inferior] (arcus tarseus frontalis, maxillaris, NK) by anastomosing with the lateral palpebral branches of the lacrimal. The upper medial palpebral arch anastomoses with the supraorbital artery and orbital branch of the temporal artery; the lower with the infraorbital, the angular branch of the external maxillary (facial), and the transverse facial arteries. A branch from the lower medial palpebral artery passes with the ductus nasolacrimalis as far as the inferior meatus. Small twigs, the **posterior conjunctival** arteries [aa. conjunctivales posteriores] (ramuli conjunctivales NK) are also given to the caruncula lacrimalis and conjunctiva.

(9) The **frontal** artery [a. frontalis] the upper of the terminal branches of the ophthalmic, pierces the superior tarsus at the medial angle of the orbit, passes upward over the frontal bone beneath the orbicularis oculi, supplies the structures in its neighborhood. It anastomoses with its fellow of the opposite side, with the supraorbital, and with the anterior division of the superficial temporal artery.

(10) The **dorsal nasal** [a. dorsalis nasi], the lower of the terminal branches of the ophthalmic, leaves the orbit at the medial angle by perforating the tarsus above the medial palpebral ligament. It then descends along the dorsum of the nose, beneath the integuments, and anastomoses with the angular and lateral nasal branches of the external maxillary (facial). It gives off a **lacrimal branch** as it crosses the lacrimal sac.

3. THE POSTERIOR COMMUNICATING ARTERY

The **posterior communicating** artery [a. communicans posterior] (a. com. aboralis NK) (fig. 536) arises from the internal carotid just before the division of that vessel into the anterior and middle cerebral arteries; occasionally it arises from the middle cerebral.

It is a slender vessel which runs backward over the optic tract and pedunculus cerebri along the side of the hippocampal gyrus to join the posterior cerebral. It may be of considerable size, the portion of the posterior cerebral between the basilar and posterior communicating being then as a rule reduced to a mere rudiment. It gives off the following branches:—(*a*) the **hippocampal,** to the gyrus of that name; and (*b*) the **middle thalamic,** to the optic thalamus.

4. THE CHOROID ARTERY

The **choroid** artery [a. chorioidea] is a small but constant vessel (fig. 536) which arises from the back of the internal carotid just laterally to the origin of the posterior communicating.

It passes backward on the optic tract and the pedunculus cerebri, at first lying parallel to and on the lateral side of the posterior communicating artery. It then dips under the edge of the uncinate gyrus and, entering the choroid fissure at the lower end of the inferior cornu of the lateral ventricle, ends in the choroid plexus and supplies the hippocampus and fimbria.

5. THE ANTERIOR CEREBRAL ARTERY

The **anterior cerebral** artery [a. cerebri anterior] (a. cerebri oralis NK) (figs. 536, 539), one of the terminal branches into which the internal carotid divides in the lateral fissure (fissure of Sylvius), supplies a part of the cortex of the frontal and parietal lobes of the brain and a small part of the basal ganglia. It passes at first anteriorly and medially across the anterior perforated substance between the olfactory and optic nerves to the longitudinal fissure where it approaches its fellow of the opposite side and communicates with it by a short transverse trunk, about five mm. long, known as the **anterior communicating** artery [a. communicans anterior] (a. com. oralis NK) (fig. 536). Onward from this point it runs side by side with its fellow in the longitudinal fissure round the genu of the corpus callosum; then, turning backward, it continues along the upper surface of that commissure, and, after giving off large branches to the frontal and parietal lobes, anastomoses with the posterior cerebral artery.

6. THE MIDDLE CEREBRAL ARTERY

The **middle cerebral** artery [a. cerebri media] (figs. 536, 540), the larger of the terminal divisions of the internal carotid, supplies the basal ganglia and part of the cortex of the frontal and parietal lobes. It passes obliquely upward and lateralward into the lateral (Sylvian) fissure, and opposite the insula divides into cortical branches.

Circulus Arteriosus

The four arteries that supply the brain, namely, the two internal carotid arteries and the two vertebrals (which unite to form the basilar), inosculate at the base of the brain to form the circle of Willis [circulus arteriosus (Willisi)]. This so-called circle or heptagon is formed **in front** by the anterior communicating artery, uniting the anterior cerebral arteries of opposite sides; **laterally** by the internal carotids, and by the posterior communicating arteries stretching between these and the posterior cerebrals; **behind** by the two posterior cerebrals, diverging from the bifurcation of the basilar artery (fig. 536).

The free anastomosis between the two internal carotid and the two vertebral arteries serves to equalize the flow of blood to the various portions of the brain. Thus, if one carotid or one vertebral were obstructed, the parts supplied by that vessel would receive their blood through the circle from the remaining pervious vessels. One vertebral artery alone has indeed been found equal to the task of carrying sufficient blood for the supply of the brain after ligature of both the carotids and the other vertebral artery. Further, the circulus arteriosus is the only medium of communication between the ganglionic or central and the peripheral or cortical branches of the cerebral arteries, and between the various ganglionic branches themselves. The ganglionic and the cortical branches form separate and distinct systems, and do not anastomose with each other; the ganglionic arteries, moreover, are so-called end-vessels, and do not anastomose with the neighboring ganglionic branches. The three cerebral arteries, anterior, middle, and posterior may be regarded as branches of the circulus arteriosus (circle of Willis). (For details concerning the distribution of the cerebral arteries see pp. 637, 981.)

THE SUBCLAVIAN ARTERY

The **subclavian artery** on the right side [a. subclavia dextra] arises at the bifurcation of the innominate opposite the upper limit of the right sternoclavicular articulation. On the left side it arises from the arch of the aorta and, as far as the medial border of the scalenus anterior, is situated deeply in the chest.

Beyond the medial border of the scalenus anterior the artery has the same relations on both sides. It courses from this point beneath the clavicle in a slight curve across the root of the neck to the lateral border of the first rib, there to end in the axillary artery. The height to which the artery rises in the neck varies. It is perhaps most commonly about 1.2 cm. (½ in.) above the clavicle. If

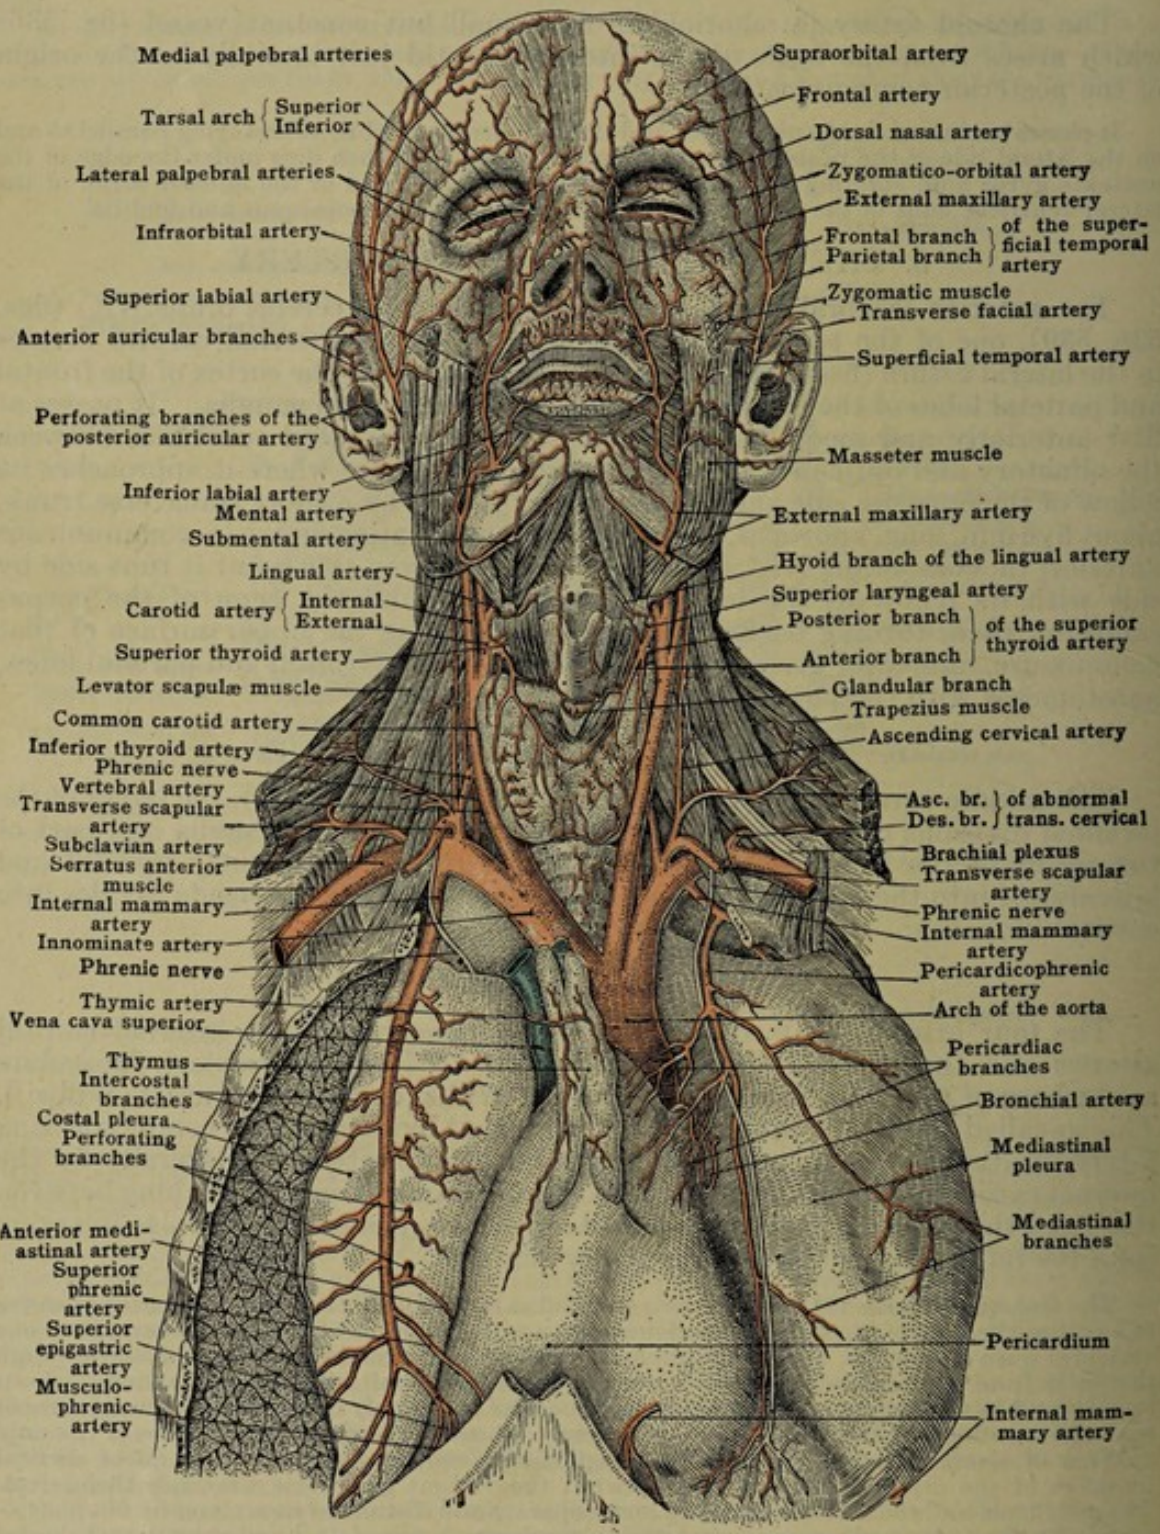

FIG. 537.—THE SUBCLAVIAN ARTERY. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

curved line drawn to represent part of the circumference of a circle having its center at a point on the lower margin of the clavicle 3.7 cm. (1½ in.) from the sternal end of that bone, the line of the artery will be sufficiently well indicated for all practical purposes. In its course the artery arches over the dome of the pleura and gains the groove on the upper surface of the first rib by passing otsteriorly to the scalenus anterior and behind the scalenus medius. Laterally pot he internal jugular veins, each artery is accompanied by the corresponding

vein, the latter lying in front of the scalenus anterior and on a slightly lower plane.

The subclavian artery is divided into three portions—as it lies medial to, posterior to, or lateral to, the scalenus anterior muscle.

THE FIRST OR THORACIC PORTION OF THE LEFT SUBCLAVIAN ARTERY

The **left subclavian** artery [a. subclavia sinistra] (fig. 537) arises from the left end of the arch of the aorta. The first part of the left subclavian is consequently longer than the first part of the right, which arises at the bifurcation of the innominate artery. The artery at its origin is situated deeply in the thorax; as it arises from the aorta it is on a plane posterior to and a little to the left of the thoracic portion of the left common carotid. It first ascends almost vertically and at the root of the neck curves laterally over the apex of the left pleura and lung to the interval between the anterior and middle scalene muscles. Beyond the medial border of the scalenus anterior—that is, in the second and third portions of its course—its relations are similar to those of the right subclavian artery.

Relations.—In front the left subclavian artery is covered by the left pleura and lung, and more superficially by the sternothyroid, sternohyoid, and sternomastoid muscles. It is crossed a little above its origin by the left innominate vein, and higher in the neck near the scalenus anterior by the internal jugular and vertebral veins and by the medial end of the subclavian. The phrenic nerve crosses the artery medially to the scalenus anterior, and then descends parallel with it, but on an anterior plane, to cross the arch of the aorta. The vagus nerve descends parallel with the artery between it and the left common carotid, coming into contact with its anterior surface just before crossing the arch of the aorta. The left cervical cardiac nerves of the sympathetic also descend in front of it on their way to the cardiac plexus. The left *ansa subclavia* also loops in front of the subclavian artery. The left common carotid is situated anteriorly and to its right. The thoracic duct arches over the artery just medially to the scalenus anterior, to empty its contents into the confluence of the internal jugular and subclavian veins (fig. 523).

Behind and somewhat medial to it are the esophagus, thoracic duct, inferior cervical ganglion of the sympathetic, longus colli muscle, and vertebral column. To some extent it is overlapped posteriorly by the left pleura and lung. On its **right side** are the trachea and the recurrent (laryngeal) nerve, and, higher up, the esophagus and thoracic duct. On its **left side** are the left pleura and lung.

Branches.—The vertebral, internal mammary, and thyrocervical trunk (thyroid axis) usually arise from the first portion on the left side. (See p. 642.)

THE FIRST PORTION OF THE RIGHT SUBCLAVIAN ARTERY

The **first portion of the right subclavian artery** (fig. 537) extends from its origin at the bifurcation of the innominate, behind the upper margin of the right sternoclavicular joint, upward and laterally in a gentle curve over the apex of the right lung and pleura to the medial border of the scalenus anterior. It measures about 3 cm. (1¼ in.). In this course it ascends in the neck a variable distance above the clavicle, deeply placed and surrounded by important structures.

Relations.—In front it is covered by the integument, the superficial fascia, the platysma, the deep fascia, by the clavicular origin of the sternomastoid and by the sternohyoid and sternothyroid muscles. It is crossed by the commencement of the innominate, by the internal jugular, and by the vertebral veins; and, in a mediolateral direction, by the vagus and phrenic nerves, and the superior cardiac branches of the sympathetic nerve. A loop of the sympathetic nerve itself also crosses the artery, and forms with the trunk of the sympathetic a ring around the vessel known as the **ansa subclavia** (annulus of Vieussens).

Behind, but separated from the artery by a cellular interval, are the longus colli muscle, the transverse process of the seventh cervical or first thoracic vertebra, the main chain of the sympathetic nerve, the inferior cardiac nerves, the recurrent (laryngeal) nerve, and the apex of the right lung and pleura.

Below, it is in contact with the pleura and lung and the loop of the recurrent (laryngeal) nerve, which winds round the artery from the vagus and ascends behind it to the larynx. The medial end of the subclavian vein is anterior to the lateral end of this part of the artery but on a lower plane.

Branches.—The vertebral, internal mammary, costocervical trunk, and thyrocervical trunk (thyroid axis) arise from this part of the vessel on the right side.

Not uncommonly a small aberrant branch descends from this portion of the right subclavian artery behind the esophagus to join a branch of the aorta opposite the third or fourth thoracic vertebra. This vessel is a vestige of the right dorsal aorta.

THE SECOND PORTION OF THE SUBCLAVIAN ARTERY

The **second portion of the subclavian artery** lies behind the scalenus anterior muscle. It measures about 2 cm. (¾ in.) in length and here reaches highest in the neck. The subclavian vein is separated from the artery by the scalenus anterior, and lies on a lower and anterior plane (fig. 537).

Relations.—In front it is covered by the skin, superficial fascia, platysma, the deep fascia, the clavicular origin of the sternomastoid and by the scalenus anterior. The phrenic nerve—which, in consequence of its oblique course medially downward, crosses a portion of both the first and second part of the subclavian—is separated from the second portion by the scalenus anterior muscle, as is also the subclavian vein which courses on a somewhat lower plane. **Behind** the artery are the apex of the pleura and lung, and a portion of the scalenus medius; also the scalenus minimus (partially or entirely fibrous, known as Sibson's fascia, see p. 421). **Above** is the brachial plexus. **Below** are the pleura and lung.

One **branch** only—the costocervical trunk (superior intercostal)—is, as a rule, given off from this portion of the subclavian; occasionally the transverse cervical or the descending branch of the transverse cervical (posterior scapular artery) arises from it.

THE THIRD PORTION OF THE SUBCLAVIAN ARTERY

The **third portion of the subclavian artery** extends from the lateral margin of the scalenus anterior muscle to the lateral border of the first rib. It is more superficial than either the first or second portion and is in relation with less important structures. It is the longest of the three portions of the subclavian artery, and lies in a triangle—the subclavian triangle—bounded by the sternomastoid, the omohyoid, and the clavicle (fig. 524).

As a rule it gives off no branches. The descending branch of the transverse cervical artery arises from it sometimes however, in which case the ascending branch arises from the thyrocervical trunk. (See fig. 537.)

Relations.—In front it is covered by skin, superficial fascia, platysma, supraclavicular nerves of the cervical plexus, and the anterior and the posterior layer of the deep cervical fascia. Close to the lateral margin of the sternomastoid, the external jugular vein pierces the anterior layer of the deep cervical fascia and, as this vein lies between the two layers of fascia, it receives on its lateral side the transverse scapular (suprascapular), transverse cervical, and other veins of the neck, which together form a plexus of large veins in front of the artery. The nerve to the subclavius and, when present, the accessory branch from this nerve to the phrenic, also cross in front of the artery beneath the posterior layer of fascia.

Behind, the artery is in contact with the scalenus medius, and with the lower trunk of the brachial plexus.

Below, the artery rests in the posterior of the two grooves on the upper surface of the first rib.

Above it is separated by the deep fascia from the posterior belly of the omohyoid. The trunk formed by the fifth and sixth cervical nerves is also above the artery, but on a somewhat anterior plane. The seventh cervical nerve is close to the vessel, and has been mistaken for the artery in the application of a ligature.

The **branches of the subclavian artery** will be described in the following order:—(1) The vertebral artery; (2) the thyrocervical trunk; (3) the internal mammary artery; (4) the costocervical trunk.

1. THE VERTEBRAL ARTERY

The **vertebral** artery [a. vertebralis] (fig. 538) the first, largest and most constant branch, arises from the upper and posterior part of the first portion of the subclavian; on the right side, about 2 cm. (¾ in.) from the origin of the latter vessel from the innominate, on the left side, from the most prominent part of the arch of the subclavian, close to the medial edge of the scalenus anterior muscle. It first ascends vertically to the foramen transversarium of the sixth cervical vertebra and, having passed through that foramen and those of the next succeeding cervical vertebræ as high as the epistropheus (axis), it turns laterally and then ascends to reach the foramen in the transverse process of the atlas; after passing through that foramen it turns backward behind the articular process, lying in the groove on the posterior arch of the atlas. It next pierces the posterior occipitoatlantoid membrane and the dura mater, and enters the cranium through the foramen magnum. Here it passes upward, at first lying by the side of the medulla, then in front of that structure, and terminates at the lower portion of the pons by anastomosing with the vertebral of the opposite side to form the basilar.

The vertebral artery may be divided for purposes of description into four parts: the **first,** or **cervical,** extending from its origin to the transverse process of the sixth cervical vertebra; the **second,** or **vertebral,** situated in the **foramina** transversaria; the **third,** or **occipital,** contained in the suboccipital triangle; and the **fourth,** or **intracranial,** within the cranium.

The first or cervical portion.—The artery here lies between the scalenus anterior and longus colli muscles. **In front** it is covered by the vertebral and internal jugular veins, and is crossed by the inferior thyroid artery, and on the left side, in addition, by the thoracic duct, which runs over it mediolaterally. **Behind,** the artery lies on the transverse process of the seventh cervical vertebra and the sympathetic nerve. To its **medial side** is the longus colli. To its **lateral side** is the scalenus anterior. It gives off as a rule no branch in this part of its course. Occasionally, however, a small branch passes into the foramen transversarium of the seventh cervical vertebra.

The second or vertebral portion.—As the artery passes through the foramina transversaria, it is surrounded by a plexus of veins and by branches of the sympathetic nerve. The cervical nerves lie behind it. Between the transverse processes it is in contact with the intertransverse muscles.

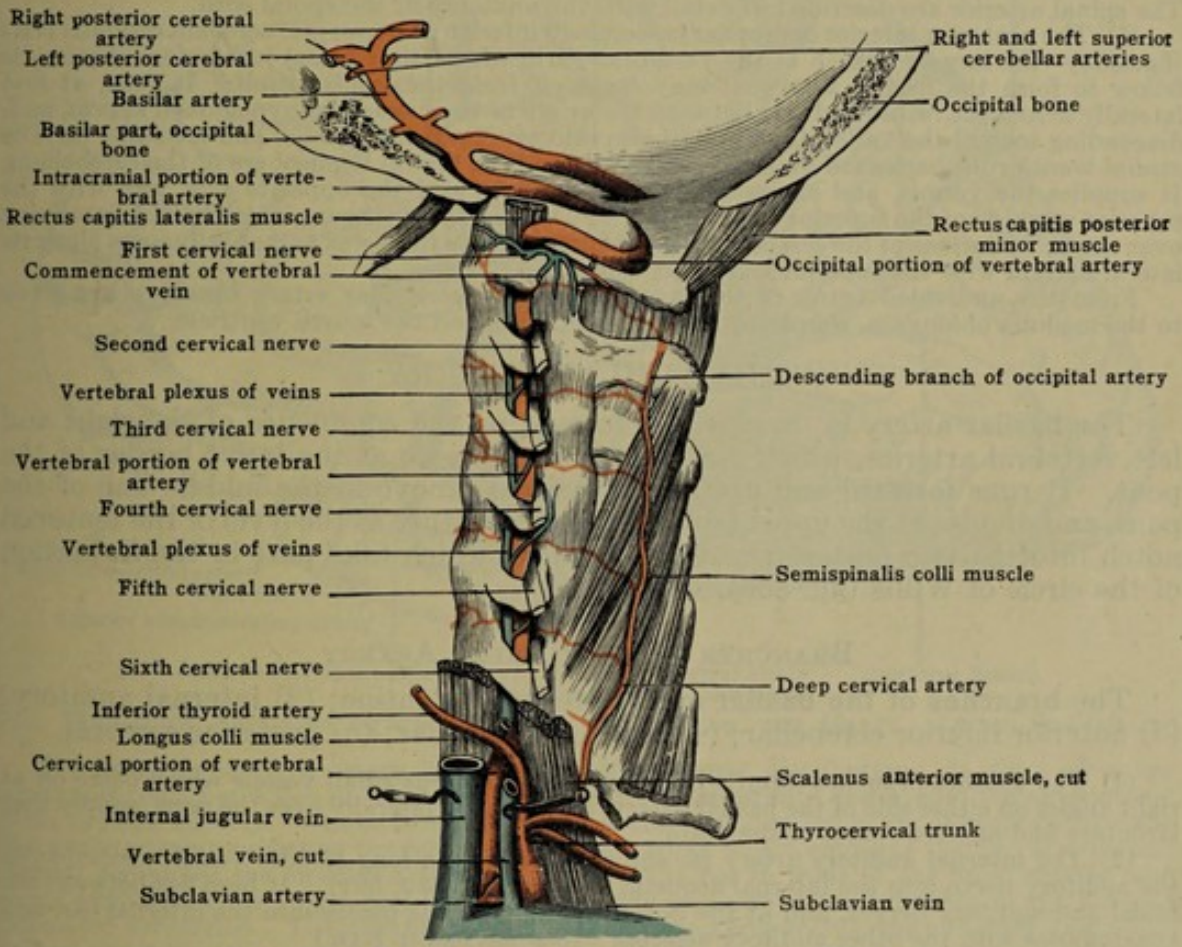

FIG. 538.—THE LEFT VERTEBRAL ARTERY. (Walsham.)
The internal jugular and vertebral veins are hooked aside to expose the artery.

The third or occipital portion.—The artery here lies in the suboccipital triangle, bounded by the superior oblique, inferior oblique, and rectus capitis posterior major muscles. As it winds round the groove on the atlas, it has the rectus capitis lateralis, the articular process, and the posterior occipitoatlantoid membrane **in front** of it; the superior oblique, the rectus capitis posterior major, and the semispinalis capitis (complexus) **behind** it. Separating it from the arch of the atlas, is the first cervical or suboccipital nerve.

The **fourth** or **intracranial portion** extends from the aperture in the dura mater to the lower border of the pons, where it pierces the arachnoid and unites with its fellow to form the basilar artery. It here winds round from the side to the front of the medulla, lying in the vertebral groove on the basilar part of the occipital bone. In this course it passes beneath the first process of the ligamentum denticulatum, and between the hypoglossal nerve in front, and the anterior roots of the suboccipital nerve behind.

BRANCHES OF THE VERTEBRAL ARTERY

The first part of the vertebral artery has no named branches. The second and third parts give off *muscular* branches to the semispinalis and posterior recti and oblique muscles. The second part also gives off five or six, (1) Spinal

branches. The fourth part gives off the following: (2) Posterior meningeal; (3) posterior spinal; (4) anterior spinal; and (5) posterior inferior cerebellar.

(1) The **spinal** branches [rr. spinales] run through the intervertebral foramina into the vertebral canal, and there divide into two branches: one of which ramifies on the backs of the bodies of the cervical vertebræ; while the other runs along the spinal nerves, supplies the cord and its membranes, and anastomoses with the arteries above and below.

(2) The **meningeal** [r. meningeus] is a small branch given off as the vertebral artery pierces the dura mater to enter the cranium. It supplies the bone and dura mater of the posterior fossa of the skull, and anastomoses with the posterior meningeal branches derived from the occipital and ascending pharyngeal arteries. It gives branches to the falx cerebelli.

(3) The **posterior spinal** artery [a. spinalis posterior] runs downward obliquely along the side of the medulla to the back of the cord, down which it passes behind the roots of the spinal nerves, being reinforced by spinal branches accompanying these nerves, in the neck, the thoracic, and in the lumbar region. It can be traced as low as the end of the spinal cord.

(4) The **anterior spinal** artery [a. spinalis anterior] comes off from the vertebral a little below its termination in the basilar artery. Descending with a medial slant in front of the medulla, it unites on a level with the foramen magnum with its fellow of the opposite side. The single vessel thus formed runs downward in front of the spinal cord beneath the pia mater as far as the termination of the cord, being reinforced by the spinal branches on the way down. The spinal arteries are described in detail with the anatomy of the spinal cord.

(5) The **posterior inferior cerebellar** [a. cerebelli inferior posterior] (a. cerebelli caudalis NK) (fig. 536)—the largest branch of the vertebral—arises from that vessel just before it joins its fellow to form the basilar artery; it may come off from the basilar itself. It runs, at first laterally across the restiform body between the origin of the vagus and hypoglossal nerves, and, descending toward the vallecula, there divides into two branches, medial and lateral. (*a*) The *medial branch* runs backward between the vermis and the lateral hemisphere of the cerebellum. It supplies the vermis, and anastomoses with the artery of the opposite side, and with the superior vermian of the superior cerebellar. (*b*) The *lateral branch* runs laterally and, ramifying over the under surface of the cerebellar hemisphere, supplies its cortex and anastomoses along its lateral margin with the superior cerebellar arteries.

From the undivided trunk of the posterior inferior cerebellar artery branches are given to the medulla oblongata, supplying the choroid plexus and the fourth ventricle.

THE BASILAR ARTERY

The **basilar** artery [a. basilaris] is formed by the confluence of the right and left vertebral arteries, which meet at an acute angle at the lower border of the pons. It runs forward and upward in a slight groove in the middle line of the pons, and divides at the upper border of that structure at the level of the tentorial notch into the two posterior cerebral arteries, which take part in the formation of the circle of Willis (fig. 536).

Branches of the Basilar Artery

The **branches of the basilar artery** are:—(1) Pontine; (2) internal auditory; (3) anterior inferior cerebellar; (4) superior cerebellar; (5) posterior cerebral.

(1) The **pontine** branches [rami ad pontem] are numerous small vessels which come off at right angles on either side of the basilar artery, and, passing laterally over the pons, supply that structure and adjacent parts of the brain.

(2) The **internal auditory** artery [a. auditiva interna], a long slender vessel, accompanies the auditory nerve into the internal acoustic meatus (figs. 536, 591). It here lies between the facial and auditory nerves, and at the bottom of the meatus passes into the internal ear, and anastomoses with the other auditory arteries. (See Internal Ear.)

(3) The **anterior inferior cerebellar** [a. cerebelli inferior anterior] (a. cerebelli oralis NK) arises from the basilar soon after its origin, passes laterally and backward across the pons, and then over the brachium pontis to the front part of the under surface of the cerebellum. It anastomoses with the posterior inferior cerebellar artery (fig. 536).

(4) The **superior cerebellar** [a. cerebelli superior] (a. cerebelli dorsalis NK) comes off from the basilar immediately behind its bifurcation into the posterior cerebral arteries. It courses laterally and backward over the pons, in a curve roughly corresponding to that of the posterior cerebral artery, from which it is separated by the third cranial nerve; but, soon sinking into the groove between the pons and the pedunculus cerebri, it curves round the latter onto the upper surface of the cerebellum, lying nearly parallel to the fourth nerve. Here it divides into two branches, medial and lateral. (*a*) The *medial branch* courses backward along the superior vermis, anastomosing with its fellow of the opposite side, and, at the posterior notch of the cerebellum, with the inferior vermian branch of the posterior inferior cerebellar artery. (*b*) The *lateral* runs to the circumference of the cerebellum, anastomosing with the lateral branch of the inferior posterior cerebellar artery.

Branches are given off from the main trunk of the superior cerebellar artery, or from its medial branch to the anterior velum (valve of Vieussens), the corpora quadrigemina, the pineal body, and the choroid plexus.

(5) The **posterior cerebral** arteries [aa. cerebri posteriores] (a. cerebri aboralis NK) are the two terminal branches into which the basilar bifurcates at the upper border of the pons, immediately behind the posterior perforated substance. Each artery runs at first laterally and a little forward across the pedunculus cerebri immediately in front of the third nerve, which separates

it from the superior cerebellar artery. After receiving the posterior communicating artery, which runs backward from the internal carotid, the posterior cerebral turns backward onto the lower surface of the cerebral hemisphere, where it breaks up into branches for the supply of the temporal and occipital lobes (fig. 539).

The **branches of the posterior cerebral artery** are described below in connection with those of the other cerebral arteries.

Distribution of the Cerebral Arteries

Although the brain receives its blood-supply from two distinct sources, namely, from the internal carotids and from the vertebrals, it is convenient to consider together the distribution of the various cerebral branches derived from these stems. The formation of the circulus arteriosus (circle of Willis) and the origin of the anterior, middle and posterior cerebral arteries have already been described (pp. 631, 636). The detailed distribution of these vessels will now be considered. In general, their branches may be divided into *central* or *ganglionic* and *peripheral* or *cortical*.

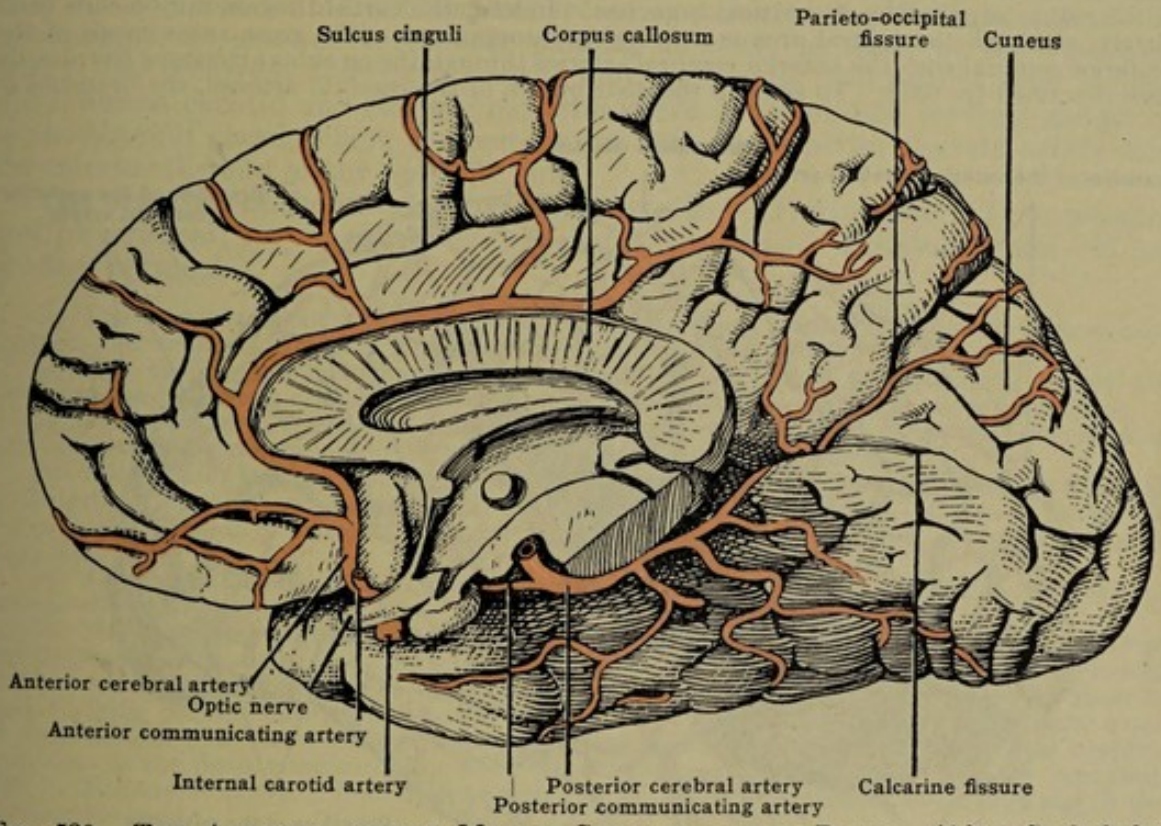

Fig. 539.—The Arteries of the Medial Surface of the Brain. (After Spalteholz.)

The **anterior cerebral artery** has but a limited **central** distribution. It gives off a few inconstant branches which enter the anterior perforated substance and supply the anterior end of the caudate nucleus. One or two of these run to the corpus callosum and septum pellucidum. The **anterior communicating** branch is a transverse trunk which connects the two arteries and thereby completes the circulus arteriosus in front. It lies in front of the optic chiasm, and varies considerably in length and size. It may give off some of the branches to the anterior perforated substance. The **cortical branches** supply the gyrus rectus, the olfactory lobe and a part of the orbital gyri on the ventral surface. On the medial surface branches supply the cortex as far back as the parieto-occipital fissure. These branches are given off as the artery curves around the corpus callosum and some of them curve over onto the lateral surface and supply the superior and middle temporal convolutions. Branches from the anterior cerebral artery also supply the corpus callosum (fig. 539).

The **middle cerebral artery** gives off most of the branches to the basal ganglia and supplies the greater part of the lateral surface of the brain. It runs through the lateral fissure (fissure of Sylvius) (fig. 540). The *branches* of the middle cerebral include the following:

The **central branches** are:—(i) The **caudate**, two or three small branches, which arise from the medial aspect of the artery and pass through the medial part of the floor of the lateral fissure (fissure of Sylvius) to the head of the caudate nucleus. (ii) The **anterolateral** are numerous small arteries which pass through the anterior perforated substance and supply the caudate nucleus (except its head), the internal capsule, and part of the optic thalamus. (iii) The **lenticulostriate**, a larger branch of the anterolateral set, passes through a separate aperture in the lateral part of the anterior perforated substance, runs upward between the lenticular nucleus, which it supplies, and the external capsule, perforates the internal capsule, and terminates in the caudate nucleus. It has been so frequently found ruptured in apoplexy that it was called by Charcot the 'artery of cerebral hemorrhage.' (iv) Sometimes a more or less distinct branch, called **lenticulo-optic**, is distributed to the lateral and hinder portion of the lenticular nucleus and the lateral portion of the optic thalamus.

The **cortical branches** come off opposite the insula. They supply the insula, the inferior frontal gyri, the central gyri (anterior and posterior), the parietal lobules, superior and inferior, the supramarginal, angular, and superior temporal gyri.

The **posterior cerebral** give off both central and cortical branches. The **central branches** are the posteromedial, posterior choroid, and the posterolateral. The **posteromedial** enter the posterior perforated substance and supply the medial portion of the optic thalamus, and the walls of the third ventricle; the **posterior choroid** pass through the transverse fissure to the tela chorioidea (velum interpositum) and chorioid plexus; the **posterolateral** run to the posterior part of the optic thalamus and give branches to the cerebral peduncles and the corpora quadrigemina.

The **cortical branches** of the posterior cerebral supply the entire occipital lobe and all of the temporal lobe except the superior temporal gyrus (fig. 539).

In regard to the cerebral arteries in general it may be said that there is no anastomosis between the cortical and central branches, the two forming distinct and separate systems. The cortical may or may not anastomose with each other, but the communication between the neighboring cortical branches is seldom sufficient to maintain the nutrition of an area when the vessel that normally supplies it is obstructed. The central branches are so-called end-vessels and rarely anastomose with each other. Hence obstruction of the middle cerebral artery leads to softening of the area supplied by its central branches, but not always to softening of the region supplied by its cortical branches. Indeed, the cortical region may escape completely, although the central area is irreparably disorganized. The gross anastomosis of the posterior cerebral with the anterior cerebral arteries through the circulus arteriosus has already been described (p. 631). To sum up the distribution of the cerebral arteries, the branches of

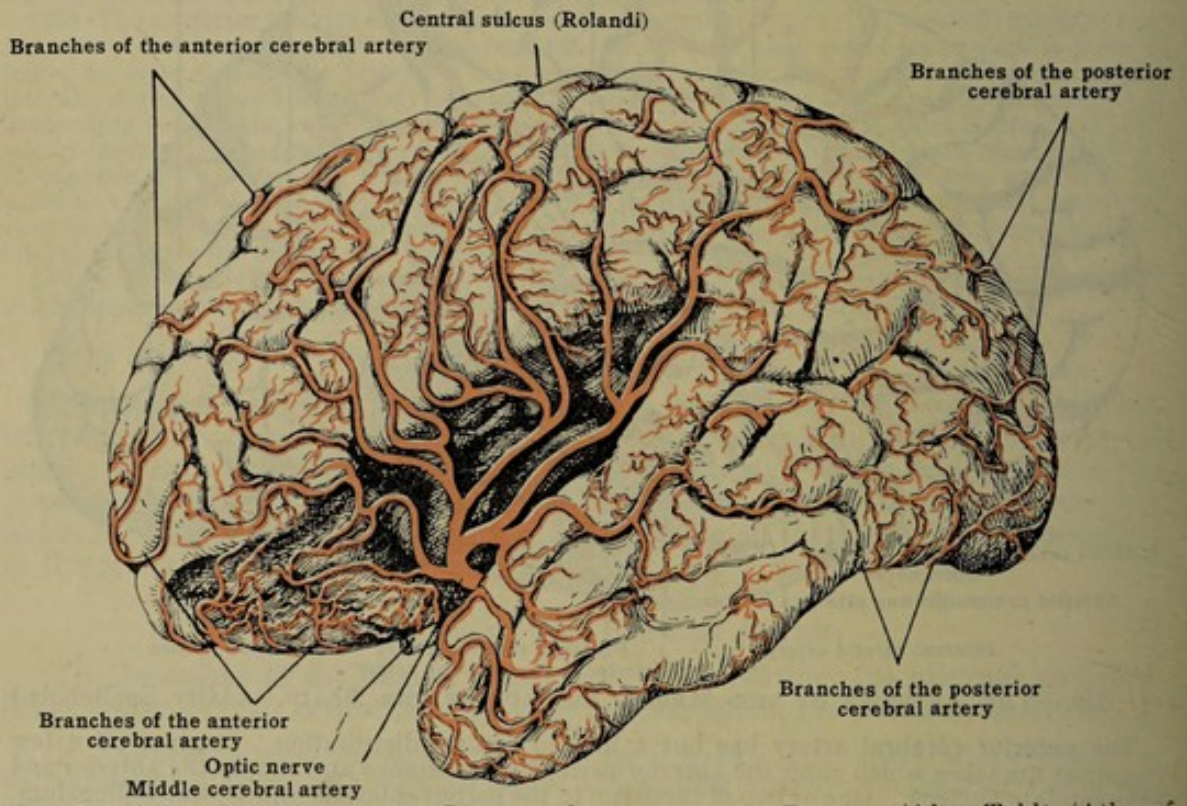

FIG. 540.—THE ARTERIES OF THE LATERAL SURFACE OF THE BRAIN. (After Toldt, 'Atlas of HUMAN ANATOMY,' The Macmillan Company.)

each are divided into the central, or ganglionic and the peripheral or cortical. The central branches arise at the commencement of the cerebral arteries about the circulus arteriosus while the cortical are derived chiefly from the termination of these vessels.

(A) The **central branches** are divided into four sets—two medial and two lateral. 1. The **two medial** are—(1) The **anteromedial,** which arise from the anterior cerebral and the anterior communicating, and supply the fore end of the caudate nucleus, and (2) the **posteromedial,** which arise from the posterior cerebral and supply the medial part of the optic thalamus and neighboring wall of the third ventricle. (2). The **two lateral** are—(1) the **anterolateral,** which arise from the middle cerebral, and, passing through the anterior perforated substance, supply the lenticular nucleus, the posterior part of the caudate nucleus, the internal and external capsules and the lateral part of the optic thalamus; and (2) the **posterolateral,** which arise from the posterior cerebral and supply the hinder part of the optic thalamus, the pedunculus cerebri and the corpora quadrigemina.

(B) The **cortical branches** ramify in the pia mater, giving off branches to the cortical substance, some of which extend through it to the underlying white substance.

It will be seen that the middle cerebral supplies the somesthetic area of the cortex. It also supplies the cortical auditory center, and, in part, the higher visual center. The anterior cerebral supplies only a small part of the somesthetic area, namely, the part of the leg center that occupies the paracentral lobule and the highest part of the anterior central gyrus. The posterior cerebral supplies the visual path from the middle of the tract backward, and the half vision center in the occipital lobe. It supplies also the corpora quadrigemina and the sensory part of the internal capsule.

The branches which supply the cerebellum and brain stem are described in connection with the vertebrals on page 636.

2. THE THYROCERVICAL TRUNK

The **thyrocervical trunk** [truncus thyreocervicalis] or **thyroid axis** arises from the upper and front part of the subclavian artery, usually opposite the internal mammary, and near the medial margin of the scalenus anterior. It is a short thick trunk, and divides almost immediately into three radiating branches—namely, the **inferior thyroid,** the **transverse scapular,** and the **transverse cervical** (figs. 524, 537). It may give off also the **ascending cervical.**

THE INFERIOR THYROID ARTERY

The **inferior thyroid** artery [a. thyreoidea inferior] is the largest of the three branches into which the thyrocervical trunk (thyroid axis) divides, and may arise in a common trunk with the transverse scapular, or as a direct branch of the subclavian. It ascends tortuously passing medially in front of the vertebral artery, the recurrent (laryngeal) nerve and the longus colli muscle, and behind the common carotid and the sympathetic nerve or its middle cervical ganglion, to the thyroid gland, where it anastomoses with the superior thyroid artery and the inferior thyroid of the opposite side.

The branches of the inferior thyroid artery are:—(1) Muscular; (2) esophageal and pharyngeal; (3) tracheal; (4) inferior laryngeal; (5) glandular; and (6) ascending cervical.

(1) The **muscular** branches supply the scalenus anterior, longus colli, sternohyoid, sternothyroid, and omohyoid muscles, and the inferior constrictor muscle of the pharynx.

(2) The **esophageal and pharyngeal** branches [rr. œsophagei et pharyngei] supply the esophagus and pharynx and anastomose with the other arteries supplying those structures.

(3) The **tracheal** branches [rr. tracheales] ramify on the trachea, where they anastomose with the tracheal branches of the superior thyroid and bronchial arteries.

(4) The **inferior laryngeal** artery [a. laryngea inferior] passes along the trachea to the back of the cricoid cartilage in company with the recurrent (laryngeal) nerve. It enters the larynx beneath the inferior constrictor. Its further distribution in that organ is described under LARYNX.

(5) The **glandular** branches [rr. glandulares], are distributed almost entirely to the posterior surface of the thyroid gland.

(6) The **ascending cervical** artery [a. cervicalis ascendens] (figs. 525, 537) is given off from the thyrocervical trunk or from the inferior thyroid as that vessel is passing beneath the carotid sheath. It ascends between the scalenus anterior and the longus capitis (rectus capitis anterior major), lying parallel and medial to the phrenic nerve and behind the internal jugular vein. It anastomoses with the vertebral, ascending pharyngeal and occipital arteries, and supplies branches to the deep muscles of the neck [rr. musculares], to the spinal canal [rr. spinales], and to the phrenic nerve. Two veins accompany the ascending cervical artery and end in the innominate vein.

THE TRANSVERSE SCAPULAR ARTERY

The **transverse scapular** or suprascapular [a. transversa scapulæ] artery passes laterally across the root of the neck, lying first beneath the sternomastoid, and then in the subclavian triangle behind the clavicle and subclavius muscle. At the lateral angle of this space it is joined by the suprascapular nerve, sinks beneath the posterior belly of the omohyoid, and passes over the ligament bridging the scapular notch, the nerve passing through the notch (fig. 545). It then ramifies in the supraspinous fossa of the scapula and, winding downward round the base of the spine over the neck of the scapula, enters the infraspinous fossa. It terminates by anastomosing with the circumflex (dorsal) scapular artery and the descending branch of the transverse cervical (posterior scapular) artery.

As it lies under cover of the sternomastoid muscle, it crosses the phrenic nerve and the scalenus anterior; and as it courses through the subclavian triangle, it is separated by the cervical fascia which descends from the omohyoid to the first rib, from the subclavian artery and brachial plexus of nerves. It is one of the chief vessels by which the collateral circulation is carried on after ligature of the subclavian in the third part of its course. At the lateral part of the subclavian triangle it is covered by the trapezius, and after passing over the transverse scapular ligament it pierces the supraspinous fascia and passes beneath the supraspinatus muscle, ramifying between it and the bone. In the infraspinous fossa it lies between the infraspinatus and the bone. The artery is accompanied by two veins.

The **branches of the transverse scapular** are:—(1) the **nutrient,** to the clavicle; (2) the **acromial** [r. acromialis] to the arterial rete or plexus on the acromial process, to reach which it pierces the trapezius; (3) the **articular,** to the acromioclavicular joint and shoulder-joint; (4) the **subscapular,** given off as the artery is passing over the transverse scapular ligament, descends to the subscapular fossa between the subscapularis and the bone, and anastomoses with the infrascapular branch of the circumflex (dorsal) scapular artery, and with the sub-

scapular and transverse cervical arteries; (5) the **supraspinous** branches, which ramify in the supraspinous fossa, and supply the supraspinatus muscle and the periosteum, and the nutrient artery to the bone; (6) the **infraspinous** branches, which ramify in a similar way in the infraspinous fossa, giving off twigs to the infraspinatus muscle, the periosteum, and the bone.

THE TRANSVERSE CERVICAL ARTERY

The **transverse cervical** artery [a. transversa colli], somewhat larger than the transverse scapular (suprascapular), runs like the latter vessel laterally and transversely across the root of the neck, but on a slightly higher plane, and a little above the clavicle. At its origin from the thyrocervical trunk it lies under the sternomastoid; on leaving the cover of this muscle, it crosses the upper part of the subclavian triangle, lying here only beneath the platysma and cervical

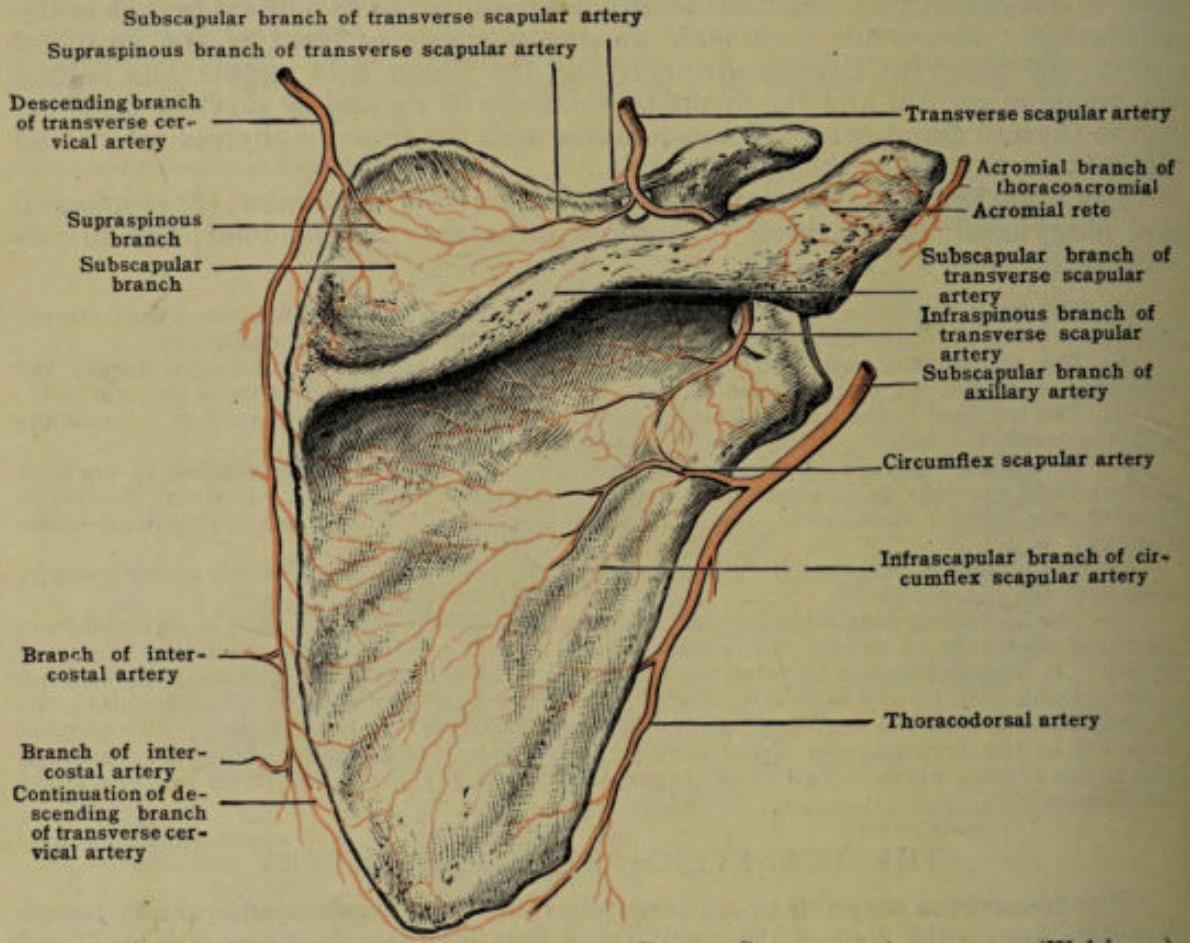

FIG. 541.—SCHEME OF ANASTOMOSES OF THE RIGHT SCAPULAR ARTERIES. (Walsham.)

fascia; further laterally, it passes beneath the anterior margin of the trapezius and omohyoid muscle and, at the lateral margin of the levator scapulæ, divides into a descending (posterior scapular) and an ascending (superficial cervical) branch. In this course it crosses the phrenic nerve, the scalenus anterior, the brachial plexus, and the scalenus medius. Sometimes it passes between the cords of the brachial plexus.

The **branches of the transverse cervical artery** are:—(1) a descending (posterior scapular); and (2) an ascending (or superficial) cervical. The descending branch occasionally arises from the third portion of the subclavian artery.

(1) The **descending branch, or posterior scapular** [r. descendens] the apparent continuation of the transverse cervical artery, begins at the lateral border of the levator scapulæ, and, continuing its course beneath this muscle to the medial angle of the scapula, turns downward and skirts along the vertebral border of the bone, between the serratus anterior (magnus) in front and the levator scapulæ and rhomboideus minor and major behind, to the inferior angle, where it anastomoses with the subscapular artery. It gives off the following branches:—(*a*) **Supraspinous,** which ramifies between the supraspinous muscle and the trapezius, and sends branches through the muscle into the fossa, to anastomose with the transverse scapular artery. (*b*) **Infraspinous** branches, one or more of which enter the infraspinous fossa, and anastomose with the circumflex (dorsal) scapular. (*c*) **Subscapular** branches, which enter the subscapular fossa, and anastomose with the branches of the transverse scapular and subscapular arteries. (*d*) **Muscular** branches, to the muscles between which it runs and to the latissimus dorsi. These branches anastomose with muscular branches of the intercostal arteries.

(2) The **ascending branch** or **superficial cervical artery** [r. ascendens], smaller than the descending branch, ascends under the anterior margin of the trapezius, lying upon the levator scapulæ and splenius muscles. It supplies branches to the trapezius, levator scapulæ, and splenius muscles and to the posterior chain of lymphatic glands. It anastomoses with the superficial ramus of the descending branch of the occipital between the splenius and semispinalis capitis (complexus). It is accompanied by two veins. This artery may arise directly from the thyrocervical trunk or from the third part of the subclavian (fig. 537).

3. THE INTERNAL MAMMARY ARTERY

The **internal mammary** artery [a. mammaria interna] (a. thoracica interna NK) (figs. 537, 542) comes off from the lower part of the first portion of the subclavian, usually opposite the thyrocervical trunk (thyroid axis), close to

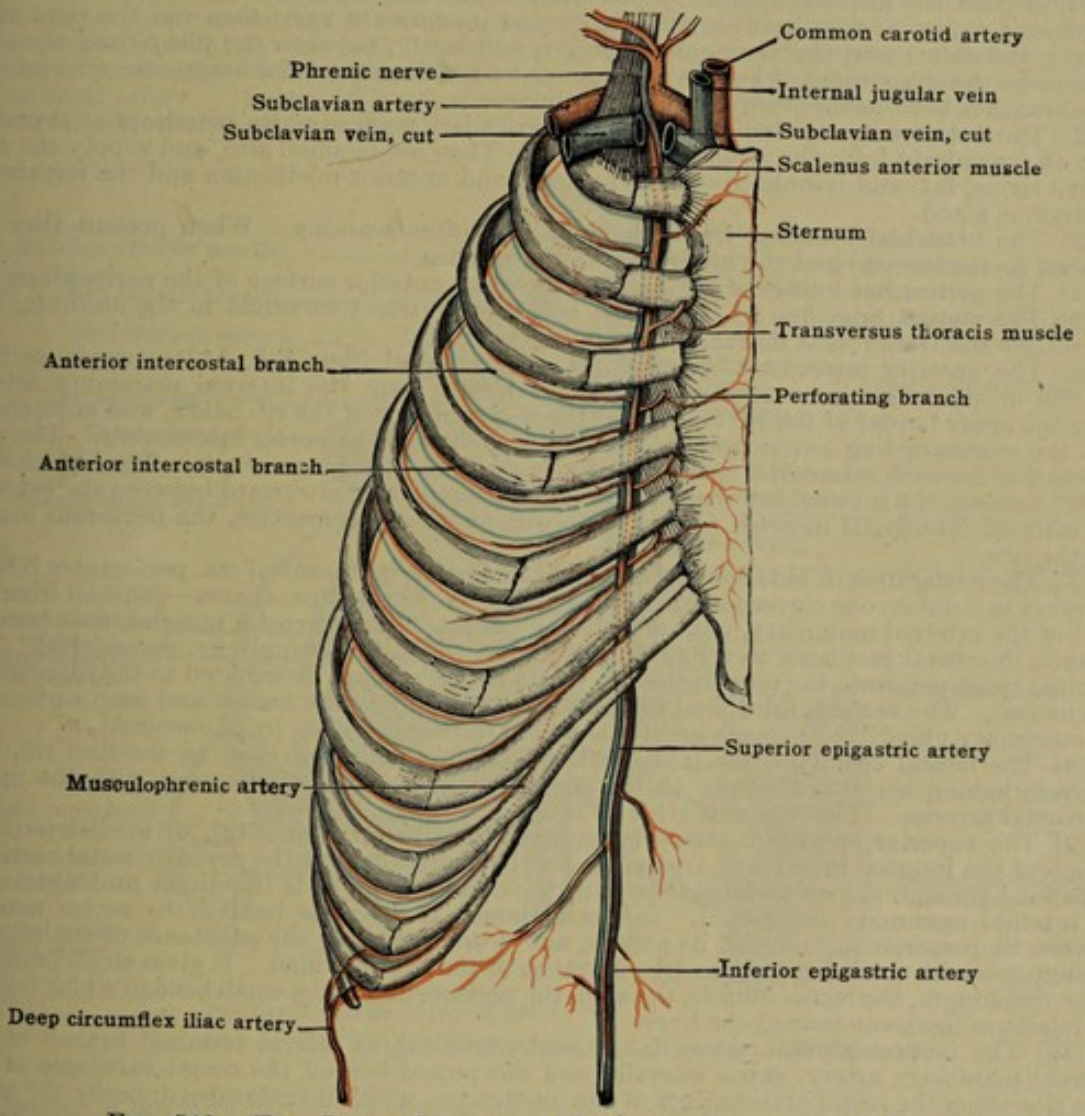

FIG. 542.—THE RIGHT INTERNAL MAMMARY ARTERY. (Walsham.)

the medial edge of the scalenus anterior. It descends with a slight inclination forward and medialward, under cover of the clavicle, and enters the thorax behind the cartilage of the first rib, and thence passes down behind the cartilages of the next succeeding ribs, about 1.2 cm. (½ in.) from the lateral margin of the sternum, to the sixth interspace, where it divides into the **superior epigastric** and the **musculophrenic.** It is accompanied by two veins, which unite into one trunk behind the first intercostal muscle; this passes to the medial side of the artery to open into the corresponding vena innominata, or occasionally on the right side into the vena cava superior. The artery may be divided into two portions, the *cervical* and the *thoracic.*

The **cervical portion** is covered by the sternomastoid muscle, subclavian vein, and internal jugular vein, and is crossed obliquely, in the lateromedial direction, by the phrenic nerve. It rests upon the pleura and courses around the upper part of the innominate vein. There is no branch from this part of the artery.

The **thoracic portion** lies behind the cartilages of the six upper ribs, and in the interspace between the ribs has in front of it the pectoralis major and the internal intercostal muscles and anterior intercostal membranes. Behind, it is in contact above with the pleura, but it is

separated from it lower down by slips of the transversus thoracis (triangularis sterni). On the left side, the artery between the fourth and sixth ribs may be said to be in the anterior mediastinum, the pleura here forming a notch for the heart. In the second and third spaces the artery, if wounded, can easily be tied; but in the fourth space the operation is attended with more difficulty. The remaining spaces are so narrow that a portion of the cartilage would have to be removed to expose the vessel.

The **branches of the internal mammary artery** (fig. 537) are:—(1) The pericardiophrenic; (2) the anterior mediastinal and thymic; (3) the bronchial; (4) the pericardiac; (5) the sternal; (6) the anterior intercostals; (7) the perforating; (8) the lateral costal; (9) the superior epigastric; and (10) the musculophrenic.

(1) The **pericardiophrenic** artery [a. pericardiophrenica], is a long slender vessel which comes off from the internal mammary just after it has entered the chest, and descends with the phrenic nerve, at first between the pleura and innominate vein; then (on the right side) between the pleura and the vena cava superior; and lastly, between the pleura and the pericardium to the diaphragm, where it anastomoses with the other diaphragmatic arteries. It gives branches both to the pleura and pericardium.

(2) The **anterior mediastinal** and **thymic** arteries [aa. mediastinales anteriores et thymicæ] come off irregularly from the internal mammary. They are of small size, and supply the connective tissue, fat, and lymphatics in the superior and anterior mediastina and the remains of the thymus gland.

(3) The **bronchial** branches [rr. bronchiales] are often wanting. When present they are supplied to the bronchi and the lower part of the trachea.

(4) The **pericardiac** branches are distributed to the anterior surface of the pericardium.

(5) The **sternal branches** [rr. sternales] enter the nutrient foramina in the sternum, and also supply the transversus thoracis (triangularis sterni).

(6) The **anterior intercostal** branches [rr. intercostales] (figs. 537, 542)—two in each of the five or six upper intercostal spaces—run laterally from the internal mammary artery, along the lower border of the rib above and the upper border of the rib below, and anastomose with the corresponding anterior and collateral branches of the aortic intercostals. The pair of branches for each intercostal space sometimes arises by a common trunk. The branches lie at first between the internal intercostal muscles and the pleura; afterward between the external and internal intercostal muscles. They supply the contiguous muscles, the pectoralis major, and the ribs.

(7) The **perforating** or **anterior perforating** branches [rr. perforantes] (aa. perforantes NK)—five or six in number, one corresponding to each of the five or six upper spaces—come off from the front of the internal mammary, and, perforating the internal intercostal muscles, pass forward between the costal cartilages to the pectoralis major, which they supply [*rr. musculares*]. The terminal twigs perforate the muscle close to the sternum, and are distributed to the integument [*rr. cutanei*]. The **second, third,** and **fourth perforating** supply the medial and deep surfaces of the mammary gland, and become greatly enlarged during lactation [*rr. mammarii*].

(8) The **lateral costal** branch [r. costalis lateralis] is given off close to the first rib, and descends behind the ribs laterally to the costal cartilages. It anastomoses with the upper intercostal arteries. This vessel is often of insignificant size, or absent.

(9) The **superior epigastric** artery [a. epigastrica superior] (fig. 542), or medial terminal branch of the internal mammary artery, leaves the thorax behind the seventh costal cartilage by passing through the costoxiphoid space in the diaphragm. It is the direct prolongation of the internal mammary downward. In the abdomen it descends behind the rectus muscle, between its posterior surface and its sheath, and, lower, entering the substance of the muscle, anastomoses with the inferior epigastric, a branch of the external iliac. It gives small branches to the diaphragm, the rectus muscle, the skin, the peritoneum, and a small branch which follows the falciform ligament toward the liver.

(10) The **musculophrenic** artery [a. musculophrenica], or lateral terminal branch of the internal mammary artery, skirts laterally and downward behind the costal cartilages of the false ribs along the costal attachments of the diaphragm, which it perforates opposite the ninth rib. It terminates, much reduced in size, at the tenth or eleventh intercostal space by anastomosing with the ascending branch of the deep circumflex iliac artery. It gives off in its course the following small branches:—(*a*) the **phrenic** for the supply of the diaphragm; (*b*) the **anterior intercostals,** two in number for each of the lower five or six intercostal spaces, which are distributed like those to the upper spaces, already described, and anastomose like them with the corresponding anterior branches of the lower aortic intercostals; (*c*) the **muscular** for the supply of the oblique muscles of the abdomen.

4. THE COSTOCERVICAL TRUNK

The **costocervical trunk** [truncus costocervicalis] (figs. 525, 543) is a short stem which arises usually from the back part of the second portion of the subclavian artery, behind the scalenus anterior on the right side, but commonly just medial to that muscle on the left side. Its course is upward and backward above the dome of the pleura and then downward to the thorax, before entering which it divides into its two terminal branches.

The **branches of the costocervical trunk** are:—(1) the superior intercostal and (2) the deep cervical.

(1) The **superior intercostal** [a. intercostalis suprema] (fig. 543) continues the direction of the costocervical trunk, passing downward into the thorax in front of the neck of the first rib.

It sometimes terminates opposite the first intercostal space by becoming the first intercostal artery. Usually, however, it is prolonged downward over the neck of the second rib and supplies the second intercostal space in addition. It communicates with the highest aortic intercostal artery. As it crosses the neck of the first rib the superior intercostal lies upon the ventral side of the first intercostal nerve and to the lateral side of the superior thoracic ganglion of the sympathetic. The branches to the first and second intercostal spaces resemble in course and distribution the succeeding intercostals derived from the thoracic aorta (see p. 661). Like the aortic intercostals they give off **dorsal** [rr. dorsales] and **spinal branches** [rr. spinales]. A small branch representing the right dorsal aorta may arise from the right superior intercostal, costocervical or subclavian artery (see p. 633).

(2) The **deep cervical** artery [a. cervicalis profunda] passes directly backward, first between the seventh and eighth cervical nerves, and then between the transverse process of the seventh cervical vertebra and the neck of the first rib, having the body of the seventh cervical vertebra to its medial side, and the intertransverse muscle to its lateral side. It then turns upward in the groove between the transverse and spinous processes of the cervical vertebræ lying upon the semispinalis colli and covered by the semispinalis capitis (complexus). Between these muscles it anastomoses with the deep branch of the descending branch (princeps cervicis) of the occipital artery. It gives off a spinal branch which enters the vertebral canal through the intervertebral foramen with the eighth cervical nerve.

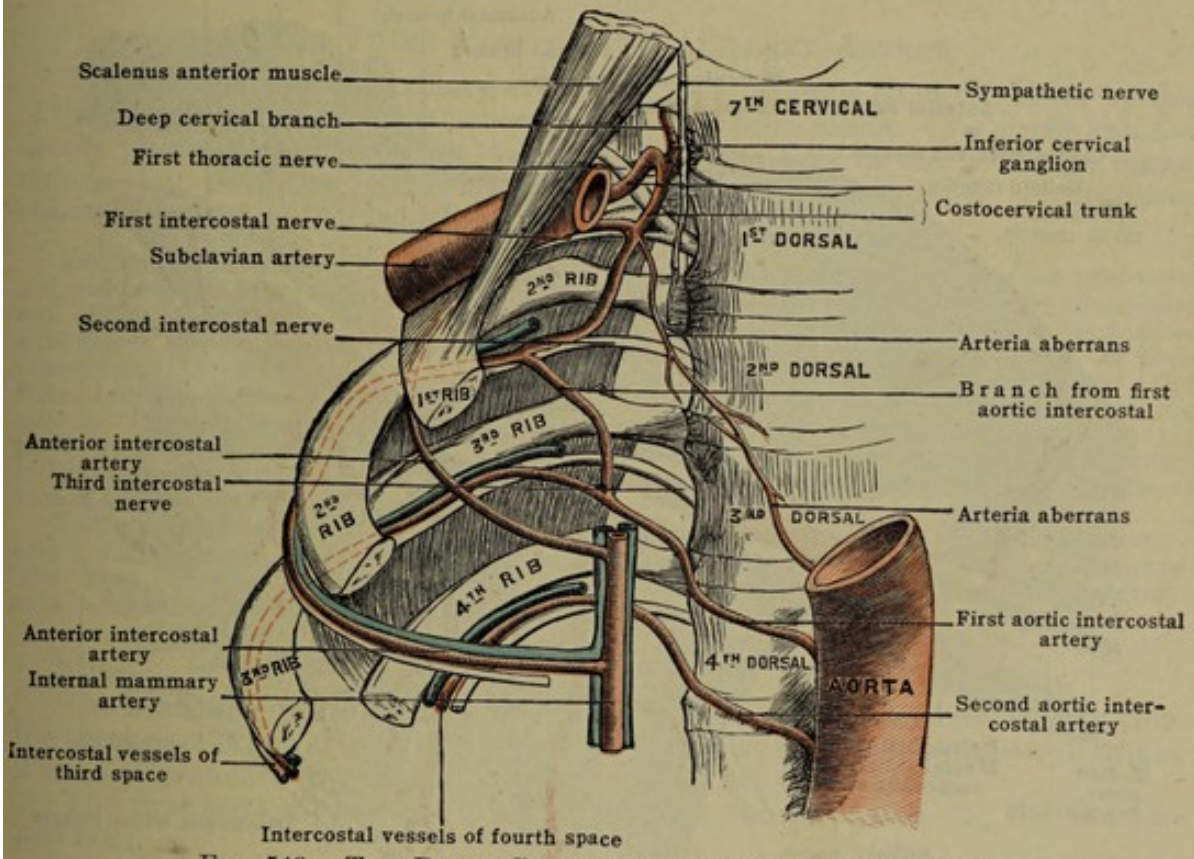

FIG. 543.—THE RIGHT COSTOCERVICAL TRUNK. (Walsham.)

Ligature of the third part of the subclavian artery is best performed by an angular incision, the horizontal portion along the center of the clavicle, and the vertical one along the posterior border of the sternomastoid, with partial division of this and the trapezius when closely adjacent. The chief points to bear in mind are the venous plexus into which the external jugular, transverse cervical, transverse scapular, and cephalic veins enter; the omohyoid and division of the fascia which ties this to the clavicle; identification of the lateral margin of the scalenus anterior and the scalene tubercle; care of the transverse scapular artery and the descending branch of the transverse cervical. The needle is passed from above downward so as not to include the lowest cord of the brachial plexus, the vein, if distended, being depressed with a blunt hook. If the nerve to the subclavius be seen, it must be uninjured, as it occasionally forms an important part of the phrenic. In aneurism of the axillary artery the transverse scapular and transverse cervical vessels may form the main part of the collateral circulation and in exposing the subclavian artery for purposes of ligation they should be carefully preserved.

Collateral circulation after ligature of the second and third parts of the subclavian.—Here the following three sets of vessels are those chiefly involved (fig 525):—

The transverse scapular, the transverse cervical,	with	The thoracoacromial, infra- and subscapular, and circumflex scapular.
The superior intercostal, the aortic intercostals, and the internal mammary,	with	The lateral thoracic and subscapular arteries
Numerous unnamed branches passing through the axilla from branches of the subclavian,	with	Branches of the axillary.

THE AXILLARY ARTERY

The term axillary is applied to that portion of the main arterial stem of the upper limb that passes through the axillary fossa. The **axillary** artery [a. axillaris] (fig. 544) therefore is continuous with the subclavian above and with the brachial below. It extends from the lateral border of the first rib to the lower edge of the teres major muscle, and has the shoulder-joint and the neck of the humerus to its lateral side. When the arm is placed close to the side of the body, the artery forms a gentle curve with its convexity upward; but when the arm is at right angles to the trunk in the ordinary dissecting position, the vessels takes a nearly straight course, which will then be indicated by a line drawn from the middle of the clavicle to the groove on the medial side of the coracobrachialis and biceps muscles. The axillary artery is at first deeply placed beneath the pectoral

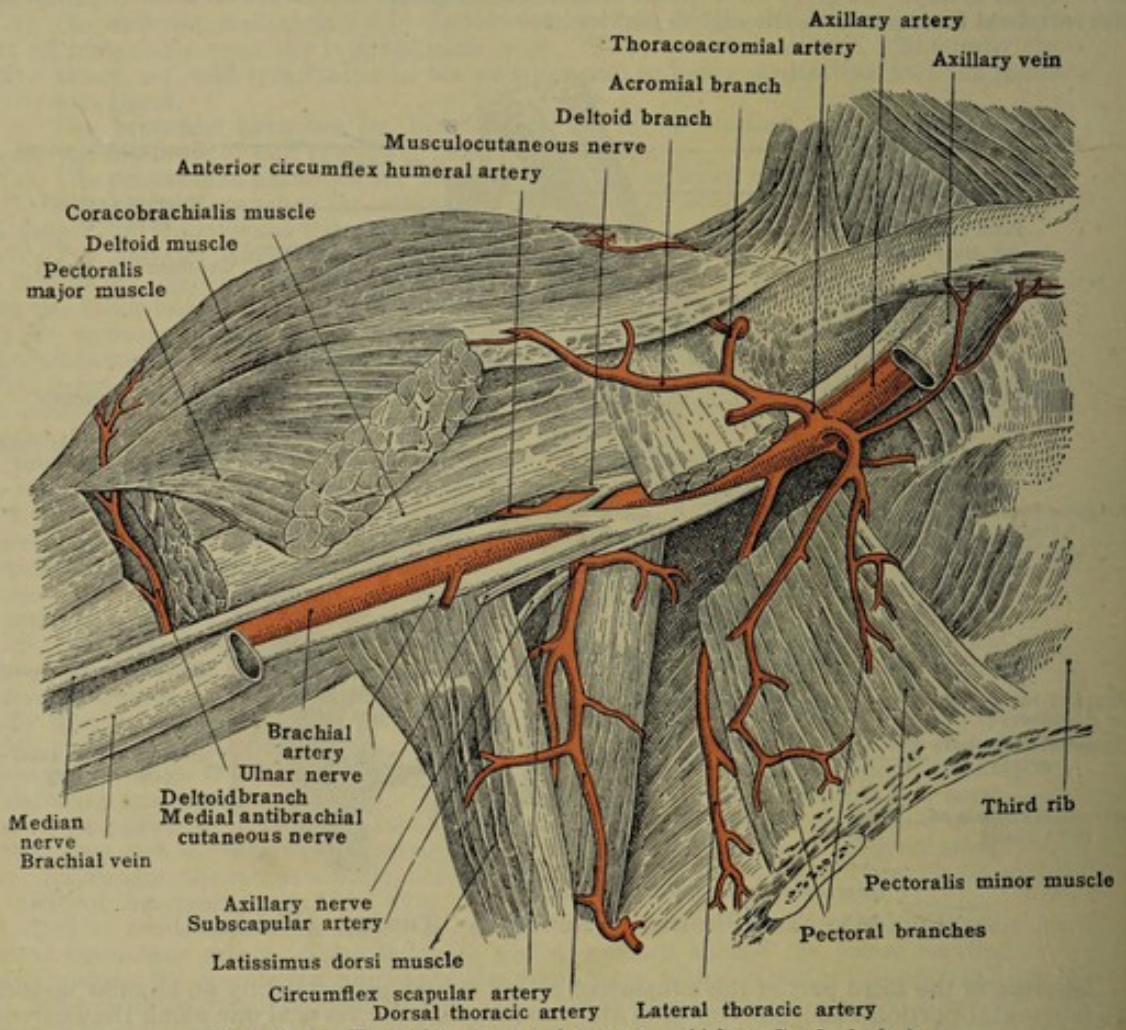

FIG. 544.—THE AXILLARY ARTERY. (After Spalteholz.)

muscles, but its distal end is superficial, being covered only by the skin and the superficial fascia and deep fascia. It is described as having three parts, first, second, and third, which lie respectively above, behind, and below the pectoralis minor.

THE FIRST PART OF THE AXILLARY ARTERY

The **first part of the axillary artery** extends from the lateral border of the first rib to the upper border of the pectoralis minor. It measures about 2.5 cm. (1 in.) in length.

Relations.—In front it is covered by the skin, superficial fascia, the lower part of the platysma, the deep fascia, the pectoralis major, the coracoclavicular (costocoracoid) fascia, the subclavius muscle, and by the clavicle when the arm hangs by the side. The cephalic and thoracoacromial veins and the lateral anterior thoracic nerve and the axillary lymphatic trunk, cross over it. A layer of the prevertebral fascia which has passed under the clavicle also descends in front of it.

Behind, it rests upon the first intercostal space and first intercostal muscle, the first digitation and sometimes a portion of the second digitation of the serratus anterior (magnus) muscle and a part of the second rib. The medial cord of the brachial plexus and the long thoracic nerve, on its way to the serratus anterior muscle, pass behind it. To its **lateral side,** and somewhat on a higher plane, are the lateral and posterior cords of the brachial plexus. To its **medial side,** and on a slightly anterior plane, is the axillary vein. The medial anterior thoracic nerve courses between the vein and the artery.

The Second Part of the Axillary Artery

The **second part of the axillary artery** (fig. 544) lies behind the pectoralis minor deep in the axilla. It measures 3 cm. (a little more than 1 in.) in length.

Relations.—In front, in addition to the pectoralis minor, it is covered by the pectoralis major and the integument. **Behind** it is separated by a considerable interval, containing loose connective tissue and fat, from the subscapularis muscle; the posterior cord of the brachial plexus lies immediately behind it. To the **medial side,** but separated from the artery by the medial cord of the brachial plexus, is the axillary vein. To the **lateral side** is the lateral cord of the brachial plexus, and at some little distance the coracoid process.

It is thus seen that the second portion of the axillary artery is surrounded on three sides by the cords of the brachial plexus.

The Third Part of the Axillary Artery

The **third part of the axillary artery** (fig. 544) extends from the lower border of the pectoralis minor to the lower border of the teres major. Its upper half lies deeply placed within the axilla, beneath the lower edge of the pectoralis major muscle, but its lower half is not covered anteriorly by muscle. It measures about 7.5 cm. (3 in.) in length.

Relations.—In front it has, in addition to the skin and superficial fascia, the pectoralis major above, and lower down the deep fascia of the arm. It is crossed obliquely by the medial root of the median nerve and by the lateral brachial vena comitans. **Behind,** it lies successively upon the subscapularis, the latissimus dorsi, and teres major muscles. From the first-named muscle it is separated at first by a considerable mass of fat and cellular tissue. The radial (musculospiral) and axillary (circumflex) nerves intervene between the artery and the muscles. On its **lateral side** it is separated from the bone by the coracobrachialis, by which it is partly overlapped, this muscle and the short head of the biceps serving as a guide to the artery in ligature. For a part of its course it has also the musculocutaneous nerve and the lateral root of the median nerve to its lateral side.

To the **medial side** it has the axillary vein, the ulnar nerve, the medial antibrachial (internal) and brachial (lesser internal) cutaneous nerves, and the medial root of the median nerve. The ulnar nerve is between the artery and the vein. The medial antibrachial (internal) cutaneous nerve is a little in front of the artery as well as medial to it.

Branches of the Axillary Artery

The **branches of the axillary artery,** with the exception of those arising from the third part of the artery, display great variability in number and site of origin. The chief branches in their most common order are listed below.

The **first part** gives off:—(1) The superior thoracic; and (2) the thoracoacromial.

The **second part** gives off:—(3) The lateral thoracic.

The **third part** gives off:—(4) The subscapular; (5) the anterior humeral circumflex; and (6) the posterior humeral circumflex.

1. The **superior thoracic** [a. thoracalis suprema] is variously given off either directly from the axillary artery, or by a trunk common to it and to the thoracoacromial (see fig. 544). It passes behind the axillary vein across the first intercostal space, supplying the intercostal muscles and the upper portion of the serratus anterior, and anastomoses with the intercostal arteries. At times it sends a branch between the pectoralis major and minor, which then, as a rule, takes the place of the pectoral branch of the thoracoacromial.

2. The **thoracoacromial** or acromiothoracic axis [a. thoracoacromialis] arises from the first part of the axillary just above the upper border of the pectoralis minor. It is a short trunk, and, coming off from the front of the artery, pierces the coracoclavicular fascia, and then divides into three or four small branches, named from their direction:—(*a*) the acromial; (*b*) the deltoid; (*c*) the pectoral, and (*d*) the clavicular.

(*a*) The **acromial** branch [r. acromialis] passes laterally across the coracoid process, frequently through the deltoid muscle, which it supplies, and to the acromion. Here it forms by anastomosing with the anterior and posterior circumflex and transverse scapular (suprascapular) arteries, the so-called acromial rete, or plexus of vessels on the surface of the acromion (fig. 541).

(*b*) The **deltoid** branch [r. deltoideus] runs downward with the cephalic vein in the interval between the pectoralis major and the deltoid, and, supplying lateral offsets to these muscles and the adjacent integument, anastomoses with the anterior and posterior circumflex humeral arteries.

(*c*) The **pectoral** branch [r. pectoralis] passes between the pectoralis major and minor muscles, both of which it supplies. In the female, the branches which perforate the pectoralis major are often of large size, and supply the superimposed mammary gland.

(*d*) The **clavicular** branch passes upward beneath the clavicle, supplies the subclavius muscle, and anastomoses with the transverse scapular artery.

3. The **lateral thoracic** artery [a. thoracalis lateralis] may arise indirectly from the axillary, as a branch of the thoracoacromial or of the subscapular, or may be represented by two or more vessels. It descends along the lower border of the pectoralis minor, under cover of the pectoralis major, to the region of the second to the fourth or fifth intercostal spaces. It supplies both pectoral muscles

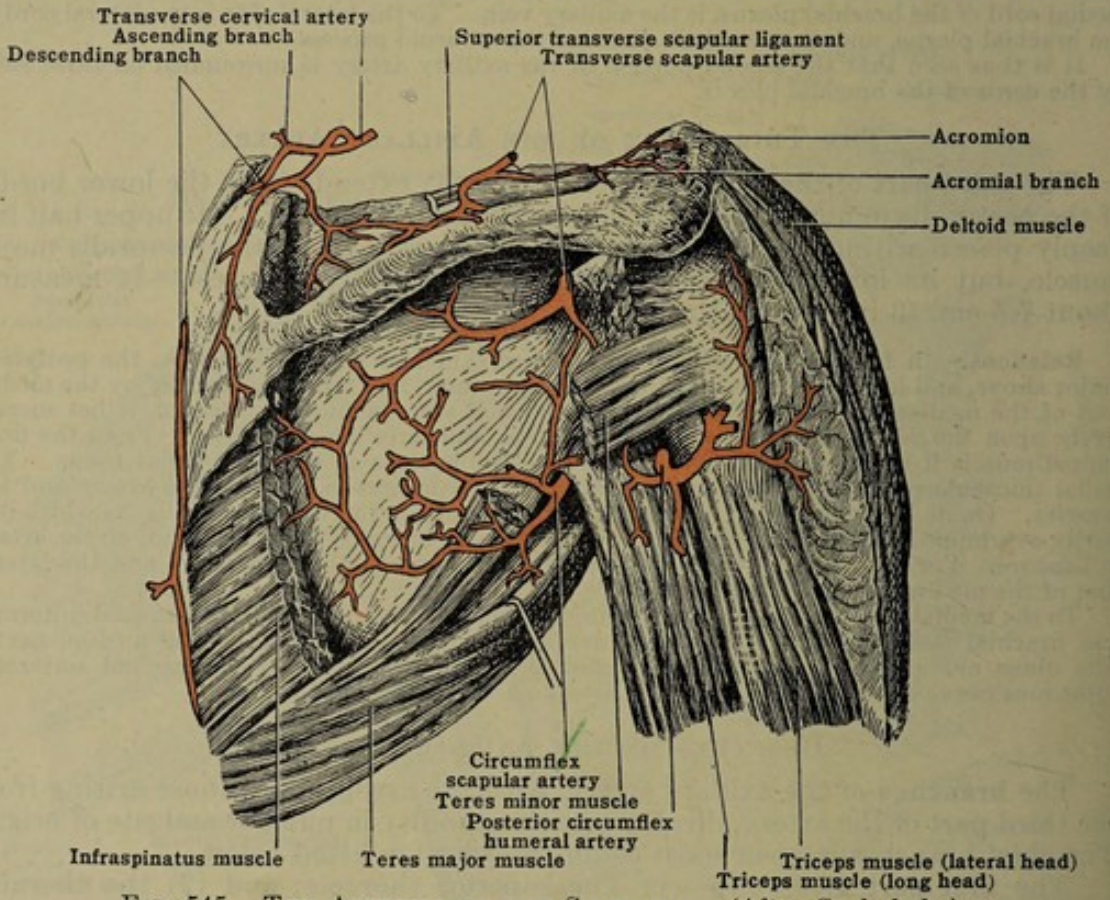

FIG. 545.—THE ARTERIES OF THE SHOULDER. (After Spalteholz.)

and the serratus anterior (magnus), sends branches around the lower border of the pectoralis major to the mammary gland, and terminates in the intercostal muscles by anastomosing with the aortic intercostals and the internal mammary. It also furnishes branches to the lymph-nodes of the axillary fossa. The branches to the mammary gland in the female are often of large size.

4. The **subscapular** artery [a. subscapularis] is the largest branch of the axillary. It arises opposite the lower border of the subscapularis, and runs in a downward and medial direction along the anterior border of that muscle under cover of the latissimus dorsi. It supplies the subscapularis, teres major, latissimus dorsi, and serratus anterior (magnus) muscles, and gives branches to the nodes in the axillary fossa. It is accompanied by two veins, which usually unite and then receive the circumflex (dorsal) scapular vein, and open as a single vein of large size either into the axillary or at the confluence of the medial brachial vena comitans with the basilic vein.

About 2.5 or 3.7 cm. (1 or 1½ in.) from its origin, the subscapular artery divides into two end branches, (1) the circumflex (dorsal) scapular, and (2) the dorsal thoracic.

(1) The **circumflex scapular** artery [a. circumflexa scapulæ], or dorsal scapular, arising from the subscapular, usually at the point above mentioned, passes backward through the triangular space bounded by the subscapularis above, the teres major below, and the long head of

the triceps laterally, and then between the teres minor and the axillary border of the scapula, which it commonly grooves. It thus reaches the infraspinous fossa, where, under cover of the infraspinatus, it anastomoses with the transverse scapular (suprascapular) artery and the descending branch of the transverse cervical (posterior scapular) (fig. 541). As it passes through the triangular space, it gives off a ventral branch which ramifies between the subscapularis and the bone, supplying branches to the subscapularis, to the scapula, and to the shoulder-joint. A second branch is often given off near the triangular space and passes downward between the teres major and teres minor, supplying both muscles (fig. 545).

(2) The **dorsal thoracic** artery [a. thoracodorsalis] continues in the course of the subscapular as far as the angle of the scapula, where it divides into branches which supply the neighboring muscles and anastomose with the circumflex scapular, the descending branch of the transverse cervical (posterior scapular), the lateral thoracic, and intercostal arteries.

5. The **anterior circumflex humeral** artery [a. circumflexa humeri anterior] (ventralis NK) usually quite a small vessel, comes off from the lateral side of the axillary artery, generally opposite the posterior circumflex. It passes beneath the coracobrachialis and short and long heads of the biceps, winding transversely round the front of the surgical neck of the humerus, across the intertubercular (bicipital) groove, and anastomoses with the posterior circumflex and thoracoacromial arteries. It gives off the following small branches:

(*a*) The **bicipital** or ascending, which runs up the intertubercular groove to supply the long tendon of the biceps and the shoulder-joint; and (*b*) a **pectoral** or descending branch, which runs downward along the insertion of the pectoralis major, and supplies the tendon of that muscle.

6. The **posterior circumflex humeral** artery [a. circumflexa humeri posterior] (dorsalis NK) (fig. 545) arises from the posterior aspect of the axillary, just below the lower border of the subscapularis muscle. It passes through the quadrilateral space, bounded by the teres minor above, the latissimus dorsi and teres major below, the humerus laterally, and the long head of the triceps medially, and, winding round the back of the humerus beneath the deltoid, breaks up under cover of that muscle into a leash of branches, which for the most part enter its substance. The axillary (circumflex) nerve and two venæ comitantes run with it. It anastomoses with the anterior circumflex, the arteries on the acromion, and the profunda artery.

In addition to the leash of vessels to the deltoid, it gives off the following small branches: —(*a*) **nutrient,** to the greater tuberosity of the humerus; (*b*) **articular,** to the back of the shoulder-joint; (*c*) **acromial,** to the plexus on the acromion; and (*d*) **muscular,** to the teres minor and long and short heads of the triceps. One or more of these branches to the triceps descend either between the lateral and long head or in the substance of that muscle, to anastomose with an ascending branch from the profunda artery. It is by means of this anastomosis that the collateral circulation is chiefly carried on when the axillary or the brachial artery is tied between the origins of the posterior circumflex and profunda arteries.

THE BRACHIAL ARTERY

The **brachial** artery [a. brachialis] (fig. 546), the continuation of the axillary, extends from the lower border of the teres major to a little below the center of the crease at the bend of the elbow, where it divides, opposite the neck of the radius into the radial and ulnar arteries. The artery is at first medial to the humerus; but as it passes down the arm it gradually gets in front of the bone, and at the bend of the elbow it lies midway between the two epicondyles. Hence, in controlling hemorrhage, the artery should be compressed laterally against the bone in its proximal third, laterally and backward in its middle third, and directly backward in its distal third. Throughout the greater part of its course the artery is superficial, being overlapped slightly on its lateral side by the coracobrachialis and biceps muscles; but at the bend of the elbow it sinks deeply beneath the lacertus fibrosus of the biceps into the triangular interval (antecubital fossa) between the brachioradialis and pronator teres, and bifurcates at the proximal border of the latter muscle (fig. 547). A line drawn from the groove on the medial side of the coracobrachialis and biceps muscles to a point midway between the epicondyles of the humerus will indicate the course of the brachial artery. The artery is accompanied by two veins which frequently communicate across it. In addition to the branches named below, the artery gives off numerous unnamed muscular branches, usually from the lateral side; one in particular, which supplies the biceps muscle, is frequently of large size.

Relations.—In front, the artery is covered by the integument and superficial and deep fasciæ, and at the bend of the elbow by the lacertus fibrosus of the biceps, and in muscular subjects by the overlapping margins of the brachioradialis and pronator teres. In the middle

third of the arm it is crossed obliquely from the lateral to the medial side by the median nerve, and at the bend of the elbow by the median cubital vein, the bicipital fascia intervening.

Behind, it lies successively on the long head of the triceps, from which it is separated by the radial (musculospiral) nerve and profunda brachii artery, on the medial head of the triceps, on the insertion of the coracobrachialis, and thence to its bifurcation on the brachialis muscle.

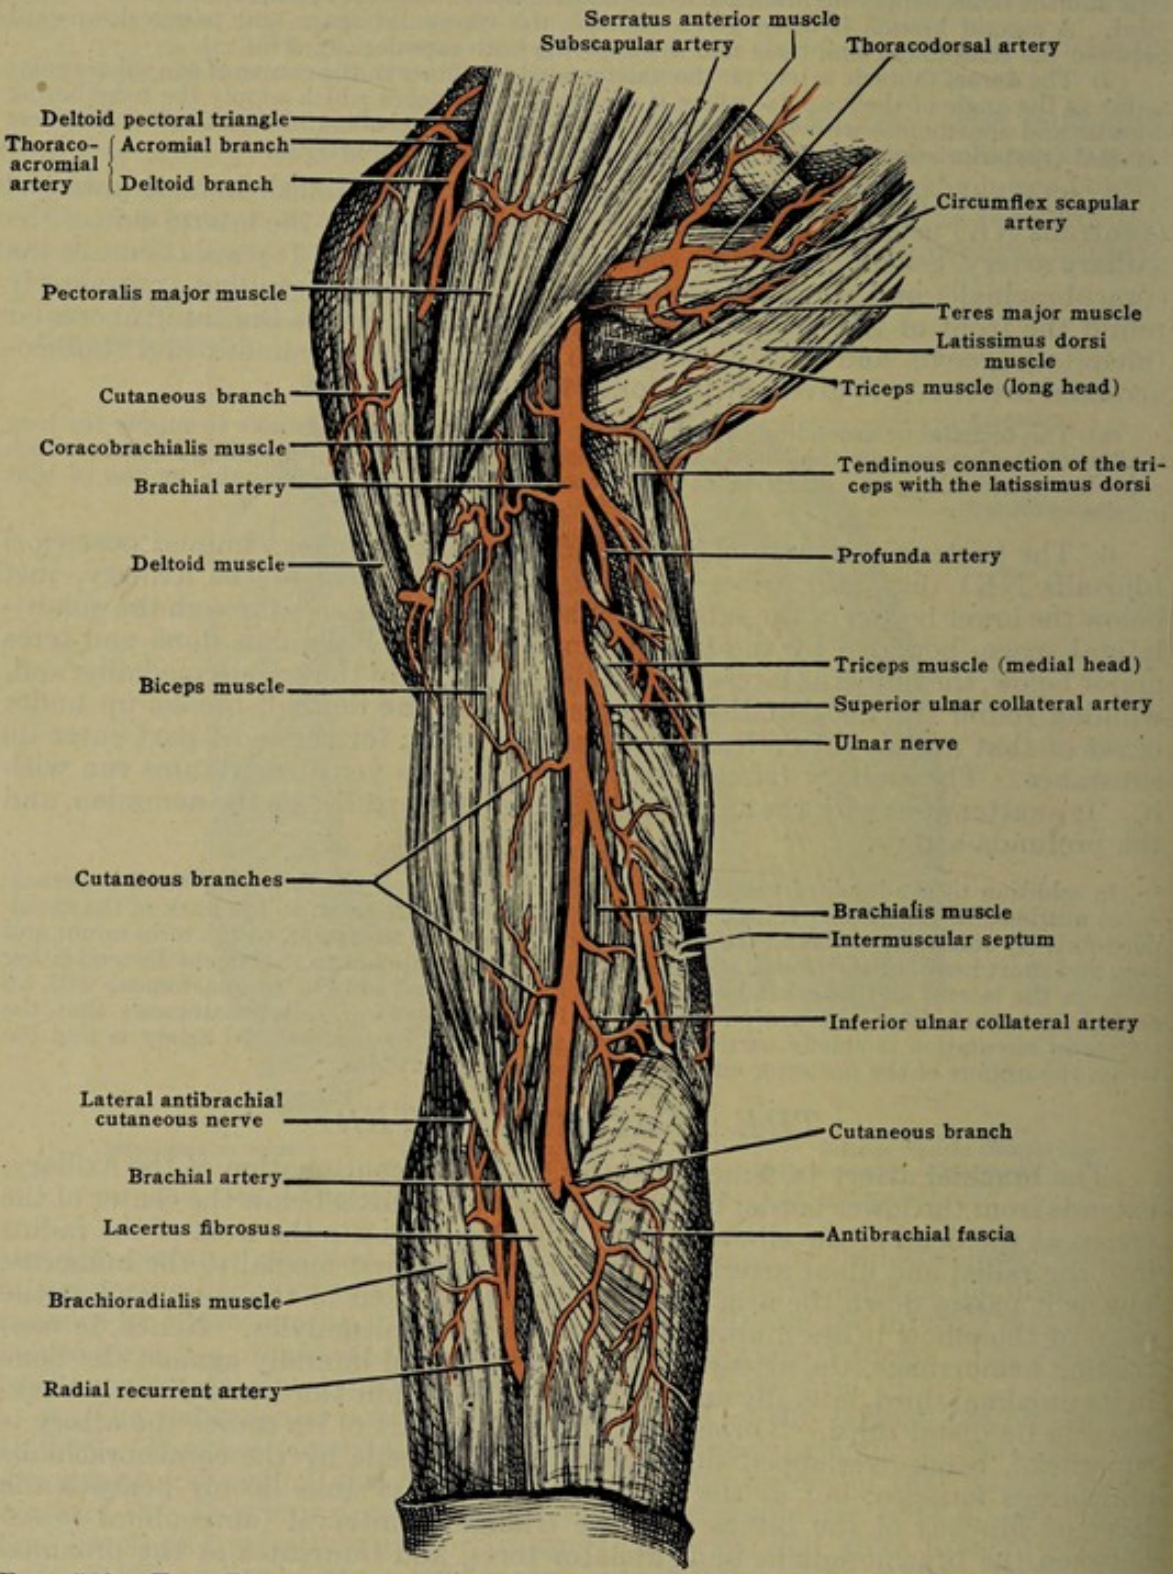

FIG. 546.—THE BRACHIAL ARTERY. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

Laterally the brachial artery is overlapped by the coracobrachialis above, and the muscular belly of the biceps below. The median nerve is in close contact with the lateral side of the artery in the upper third of its course, but in the middle third crosses the artery obliquely to gain the medial side. The tendon of the biceps lies laterally to the artery in its lower portion.

Medial to the artery in the upper part of its course are the medial antibrachial (internal) cutaneous and the ulnar nerves; the latter nerve, however, leaves the artery about the origin of the ulnar collateral (inferior profunda) branch, to pass, with that vessel, to the medial epicondyle. Lower down, the medial antibrachial cutaneous nerve also leaves the artery, by piercing the deep fascia. The median nerve is in close contact with the medial side of the

artery in its lower third and at the bend of the elbow. The basilic vein is superficial to it, and a little to its medial side in the greater part of its course, but separated from it by the deep fascia. The brachial artery is accompanied by two or more venæ comitantes.

In **ligature of the artery** here the line extends from the midaxillary region above, prolonged to the center of the front of the elbow. The only structures seen should be the medial edge of the biceps, the basilic vein, and the median nerve. Fig. 548 shows **collateral circulation** after ligature of the brachial, according as the vessel is tied above or below the profunda brachii, or below the superior ulnar collateral.

Branches of the Brachial Artery

The **branches of the brachial artery** are: (1) The profunda brachii; (2) the nutrient artery to the humerus; (3) the superior ulnar collateral (inferior profunda); (4) the inferior ulnar collateral (anastomotica magna); and (5) the terminal branches—the radial and ulnar arteries. The various anastomoses of the brachial artery are shown in fig. 548.

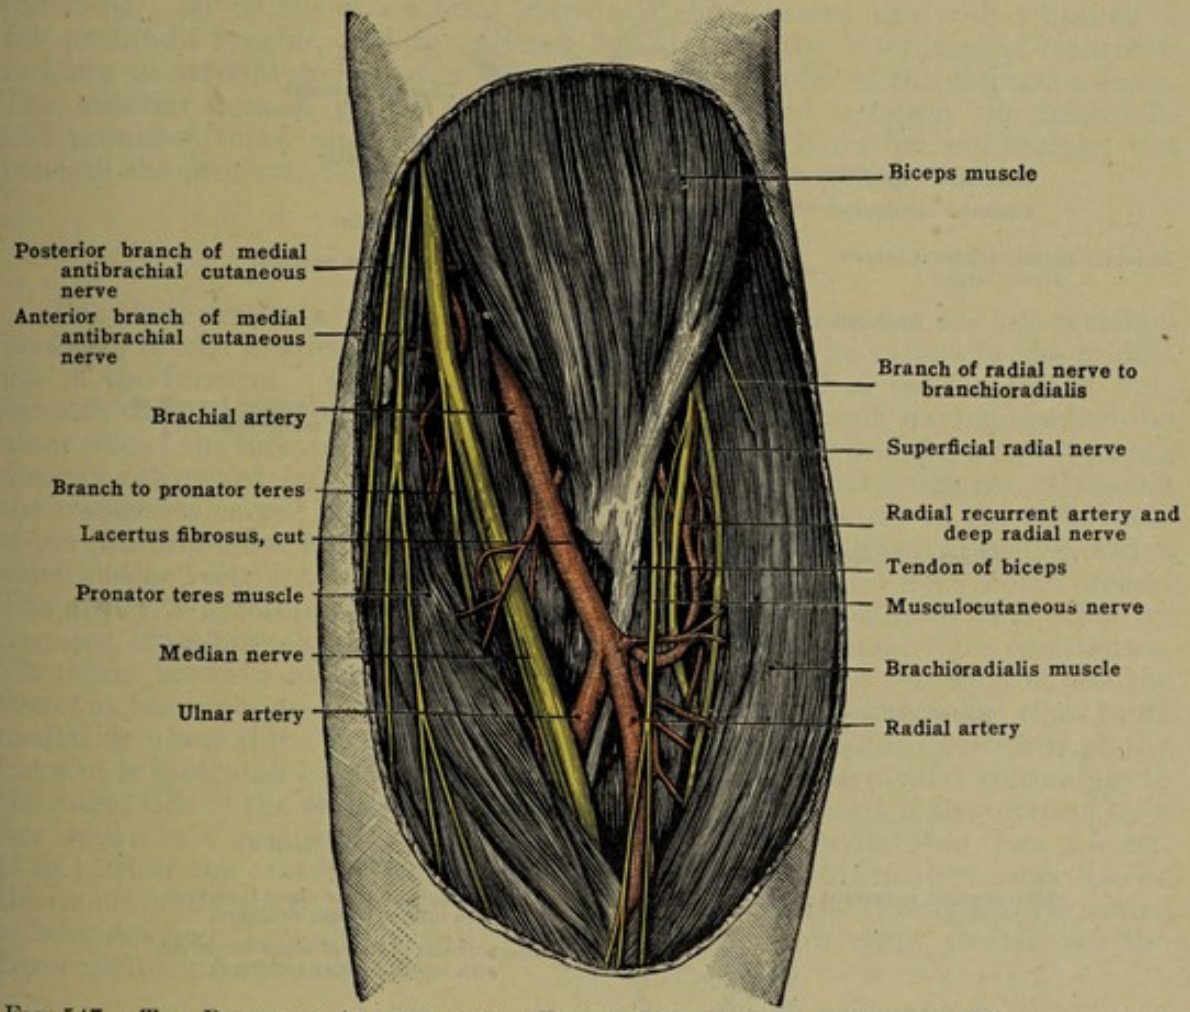

Fig. 547.—The Brachial Artery at the Elbow, Left Side, Front View. (From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)

(1) The Profunda Artery

The **profunda brachii** (superior profunda) is the largest branch of the brachial. It arises from the medial and posterior aspect of the artery, a little below the inferior border of the tendon of the teres major. It at first lies to the medial side of the brachial, but soon passes behind that vessel, and, sinking between the medial and long heads of the triceps with the radial (musculospiral) nerve. Having given origin to the medial collateral artery, the remainder of the vessel, the radial collateral artery, follows the radial nerve, lying between the bone and the lateral head of the triceps. On reaching the lateral supracondyloid ridge of the humerus it perforates the lateral intermuscular septum, and, continuing forward between the brachioradialis and brachialis to the front of the lateral epicondyle, ends by anastomosing with the radial recurrent artery. Before perforating the septum it sends a branch distally to anastomose with the dorsal interosseous recurrent and with the inferior ulnar collateral (figs. 550, 552).

It gives off the following branches:

(*a*) The **deltoid** branch [r. deltoideus] which may, however, arise from the brachial itself or from the superior ulnar collateral. It runs across the anterior surface of the humerus, under cover of the coracobrachialis and biceps, and supplies the brachialis and deltoid.

(*b*) The **medial collateral** artery [a. collateralis media] runs in the substance of the medial head of the triceps as far as the elbow, where it often terminates in the articular rete.

(*c*) The **radial collateral** artery [a. collateralis radialis] is described above.

(*d*) A **nutrient humeral** artery [a. nutritia humeri], usually accessory to a larger one from the brachial itself, enters a canal above and to the medial side of the sulcus for the radial nerve.

(2) The Nutrient Humeral Artery

The **nutrient humeral** artery [a. nutritia humeri] arises near the origin of the superior ulnar collateral or, occasionally, from that artery. It traverses the brachialis muscle and enters a foramen usually just beyond the middle of the bone, immediately anterior to the proximal end of the medial epicondylic ridge.

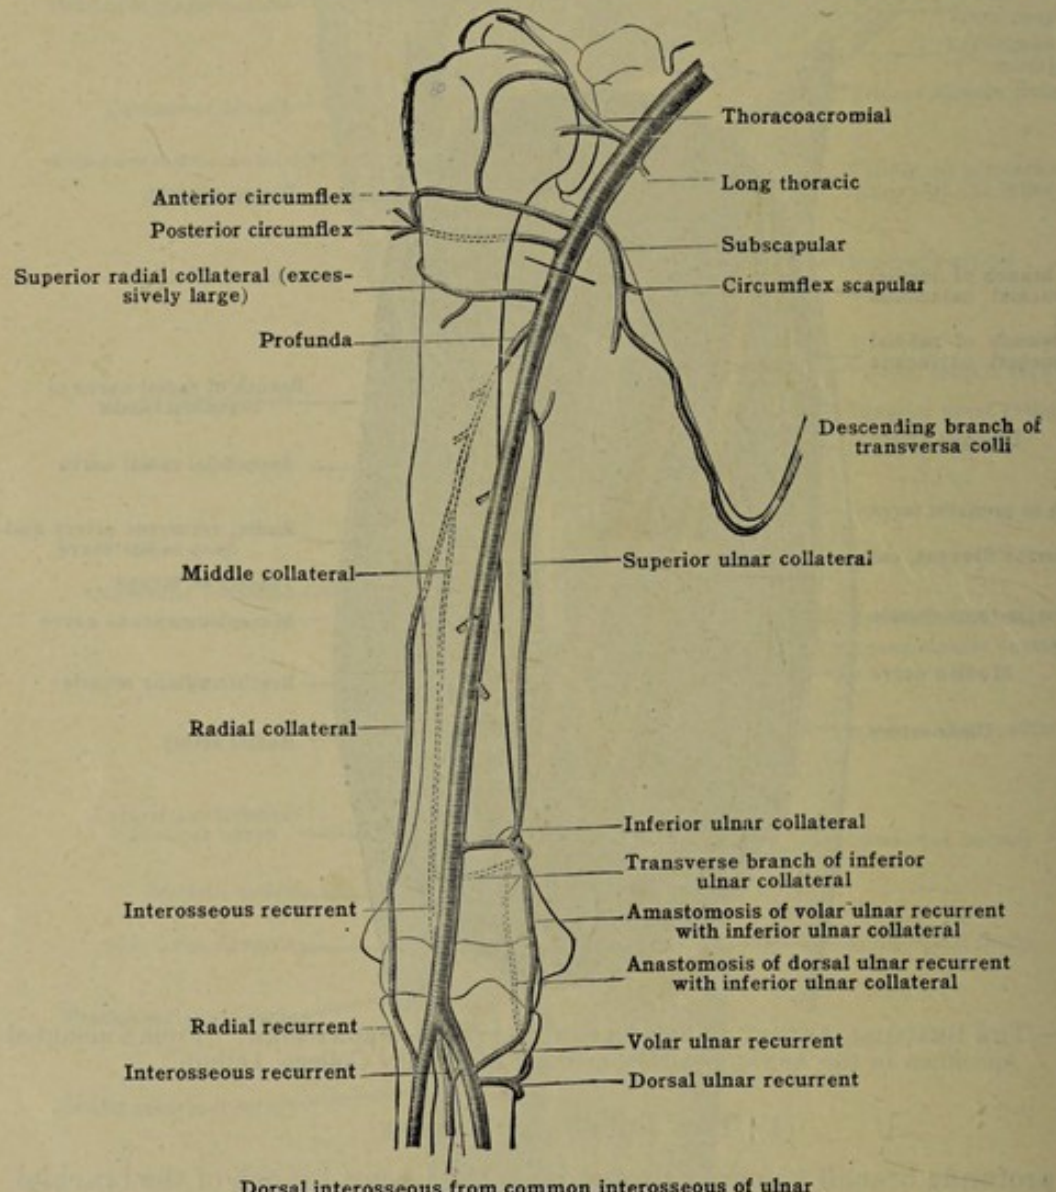

Fig. 548.—Diagram of the Anastomoses of the Brachial Artery. (MacCormac and Anderson.)

(3) The Superior Ulnar Collateral Artery.

The **superior ulnar collateral** artery [a. collateralis ulnaris superior] (proximalis NK) arises from the medial side of the brachial, usually about the level of the insertion of the coracobrachialis, sometimes from a trunk common to it and to the profunda brachii. It passes with the ulnar nerve medially and downward through the medial intermuscular septum, and then along the medial head of the triceps to the back of the medial epicondyle, where, under cover of the deep fascia and the origin of the flexor carpi ulnaris from the olecranon and medial epicondyle, it anastomoses with the inferior ulnar collateral and with the dorsal

ulnar recurrent. It frequently supplies the nutrient artery to the humerus. It gives branches to the triceps, to the elbow-joint, and a branch which passes in front of the medial epicondyle to anastomose with the volar ulnar recurrent and the inferior ulnar collateral.

(4) The Inferior Ulnar Collateral Artery

The **inferior ulnar collateral** artery [a. collateralis ulnaris inferior] (distalis NK) or anastomotica magna arises from the medial side of the brachial, about 5 cm. (2 in.) above its bifurcation into the radial and ulnar arteries, and, running medially and downward across the brachialis, divides into two branches, a posterior and an anterior. The **posterior** pierces the medial intermuscular septum, winds round the medial supracondylar ridge of the humerus, and pierces the triceps, between which and the bone it anastomoses with the dorsal ulnar recurrent. By means of a lateral branch, it anastomoses also with a branch of the profunda brachii, and to a lesser extent with the interosseous recurrent, forming an arterial arch or rete around the upper border of the olecranon fossa. The **anterior** branch passes medially and downward between the brachialis and pronator teres, and anastomoses in front of the medial epicondyle, but beneath the pronator teres, with the volar ulnar recurrent (fig. 550).

THE ULNAR ARTERY

The **ulnar** artery [a. ulnaris] (figs. 549 and 552), the larger of the two terminal branches of the brachial, begins opposite the neck of the radius in the middle line of the forearm. Thence through the proximal half of the forearm it runs beneath the pronator teres and superficial flexor muscles, and, having reached the ulnar side of the forearm about midway between the elbow and the wrist, it passes directly downward, being merely overlapped by the flexor carpi ulnaris. Crossing the transverse carpal (anterior annular) ligament immediately to the radial side of the pisiform bone, it enters the palm, where it divides into two branches, which enter respectively into the formation of the superficial and deep volar arches. The artery is accompanied by two veins, which anastomose with each other by frequent cross-branches, and usually terminate in the brachial venæ comitantes. The ulnar nerve is at first some distance from the artery, but approaches the vessel at the junction of its proximal and middle thirds, and then lies close to its medial or ulnar side. The course of the artery in the distal two-thirds of the forearm is indicated by a line drawn from the front of the medial epicondyle to the radial side of the pisiform bone; and in the proximal third of the forearm by a line drawn in a gentle curve with its convexity to the medial side from 2.5 cm. (1 in.) below the center of the bend of the elbow to a point in the former line at the junction of its proximal and middle thirds. The artery throughout its course is best reached through the interval between the flexor carpi ulnaris and the flexor digitorum sublimis.

The relations of the artery will be given in detail in the forearm, and in the palm of the hand. The **relations in the forearm** are:

In front.—In the proximal half of the forearm the ulnar artery is deeply placed beneath the pronator teres, the flexor carpi radialis, the palmaris longus, and the flexor digitorum sublimis. In the distal half it is comparatively superficial, being merely overlapped above by the tendon of the flexor carpi ulnaris, while the last inch or so of the vessel is only covered as a rule by the skin and superficial and deep fasciæ. As the artery lies beneath the pronator teres, it is crossed from the medial to the lateral side by the median nerve, the deep head of origin of the muscle intervening, when present. The distal part of the artery is crossed by the palmar cutaneous branch of the ulnar nerve. In **ligature of the artery** in the middle of the forearm, the white line and sulcus between the flexor carpi ulnaris and the sublimis must be identified. A small muscular branch will often lead down to the artery.

Behind.—For about 2.5 cm. (1 in.) of its course the artery lies upon the brachialis; but thence, as far as the transverse carpal (anterior annular) ligament, upon the flexor digitorum profundus, which separates it above from the interosseous membrane and bone, and at the wrist from the pronator quadratus. The artery is bound down to the flexor digitorum profundus by bands of fascia. To the **lateral side** in the distal two-thirds of its course is the flexor digitorum sublimis. To the **medial side** in the distal two-thirds is the flexor carpi ulnaris, the guide to the vessel. The ulnar nerve, as it enters the forearm from behind the medial epicondyle, is at first some distance from the artery, being separated from it in its proximal third by the flexor digitorum sublimis; but in its distal two-thirds is in close contact with the vessel on its ulnar side.

The **branches of the ulnar artery in the forearm** are: (1) the ulnar recurrent arteries; (2) the common interosseous; (3) muscular; (4) dorsal ulnar carpal; (5) volar ulnar carpal.

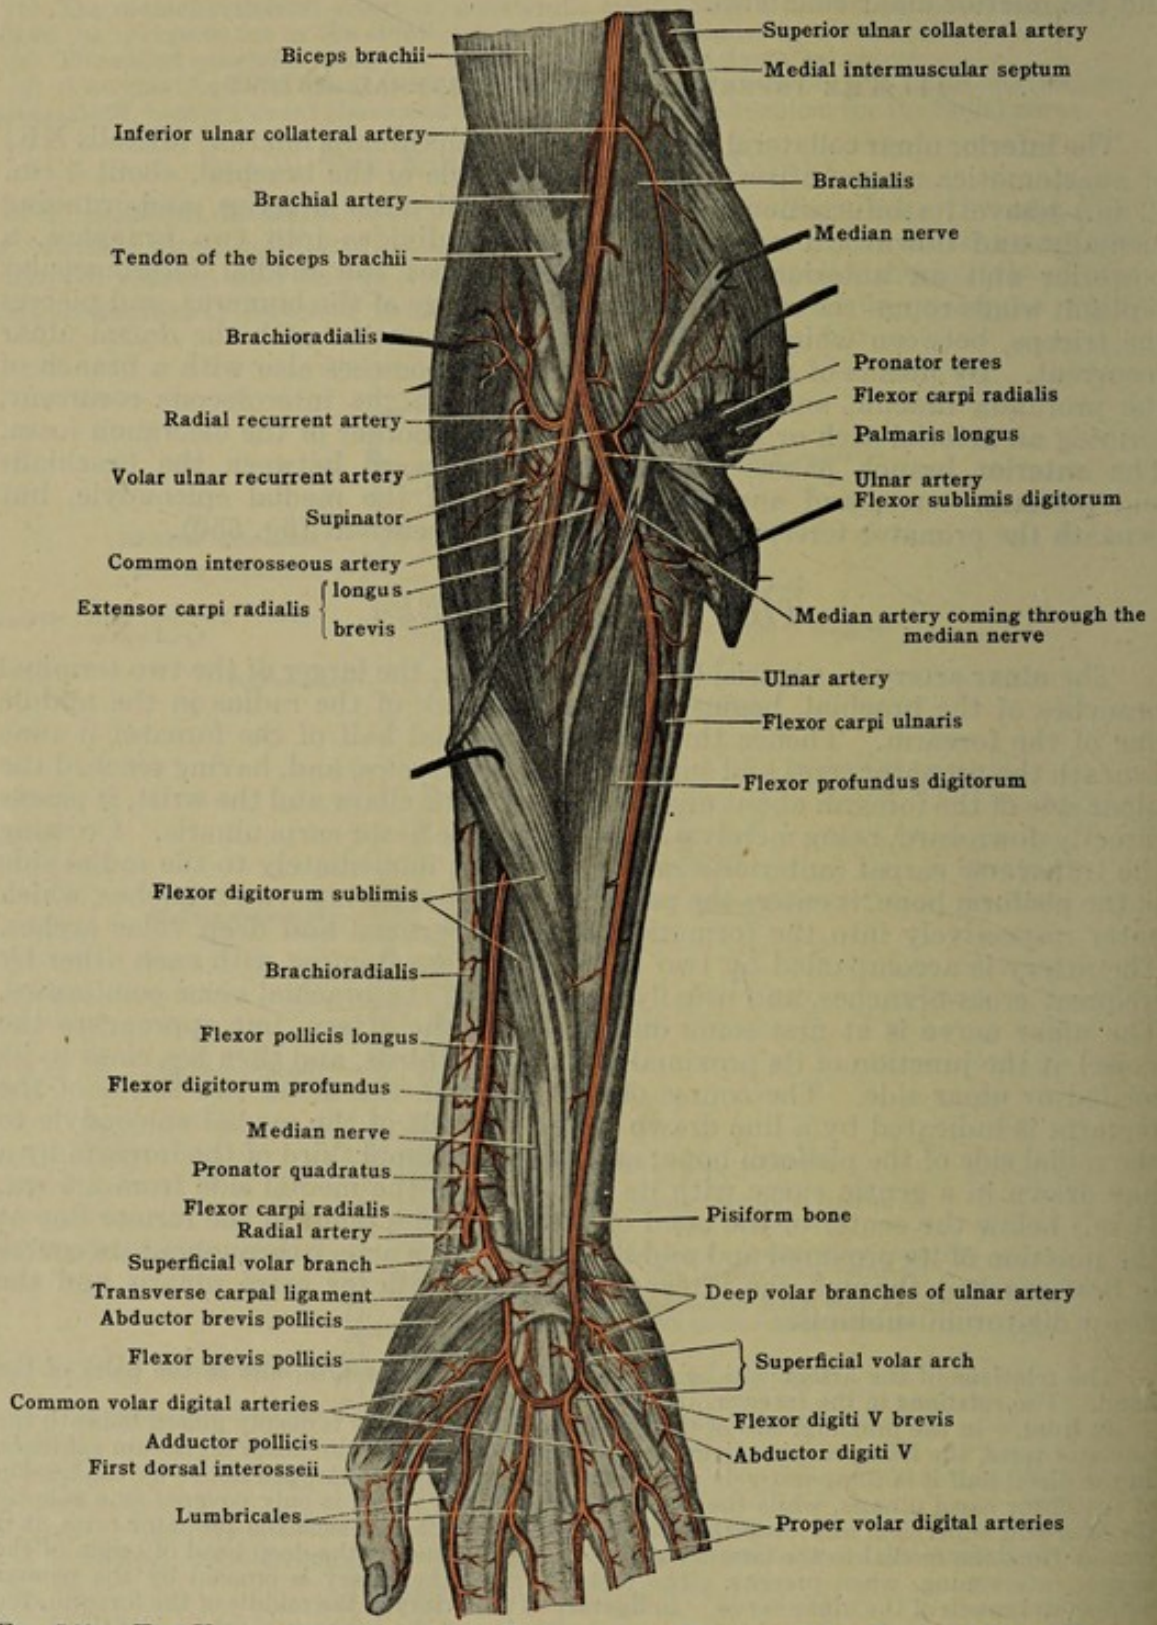

FIG. 549.—THE VOLAR ARTERIES OF THE FOREARM AND HAND. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

1. The **ulnar recurrent** arteries [aa. recurrentes ulnares] are two, the volar, and dorsal. The *volar* is a small branch which arises from the medial side of the ulnar artery, separately or in common with the dorsal ulnar recurrent. Running between the lateral edge of the pronator teres and the brachialis, it anastomoses in front of the medial epicondyle with the inferior and superior ulnar collaterals. It supplies branches to the muscles between which it runs, and to the skin. The *dorsal*, larger than the volar, comes off from the medial side of the ulnar artery, either a little beyond the latter branch, or in common with it, and, passing between the flexores digitorum sublimis and profundus, reaches the back of the medial epicondyle, where it lies with the ulnar nerve between the two heads of origin of the flexor carpi ulnaris. It supplies the

contiguous muscles, the elbow-joint and the ulnar nerve, and anastomoses with the inferior and superior ulnar collaterals, and with the interosseous recurrent, forming the so-called *rete olecrani*.

2. The **common interosseous** artery [a. interossea communis] is a short thick trunk 1.2 cm. (½ in.) or so in length, which comes off from the lateral and dorsal aspect of the ulnar artery about 2.5 cm. (1 in.) from its origin, and just before that artery is crossed by the median nerve. It passes backward and downward between the flexor pollicis longus and the flexor digitorum profundus, toward the triangular interval bounded by the upper border of the interosseous membrane, the oblique ligament, and the lateral border of the ulna, where it divides into the volar and dorsal interosseous arteries.

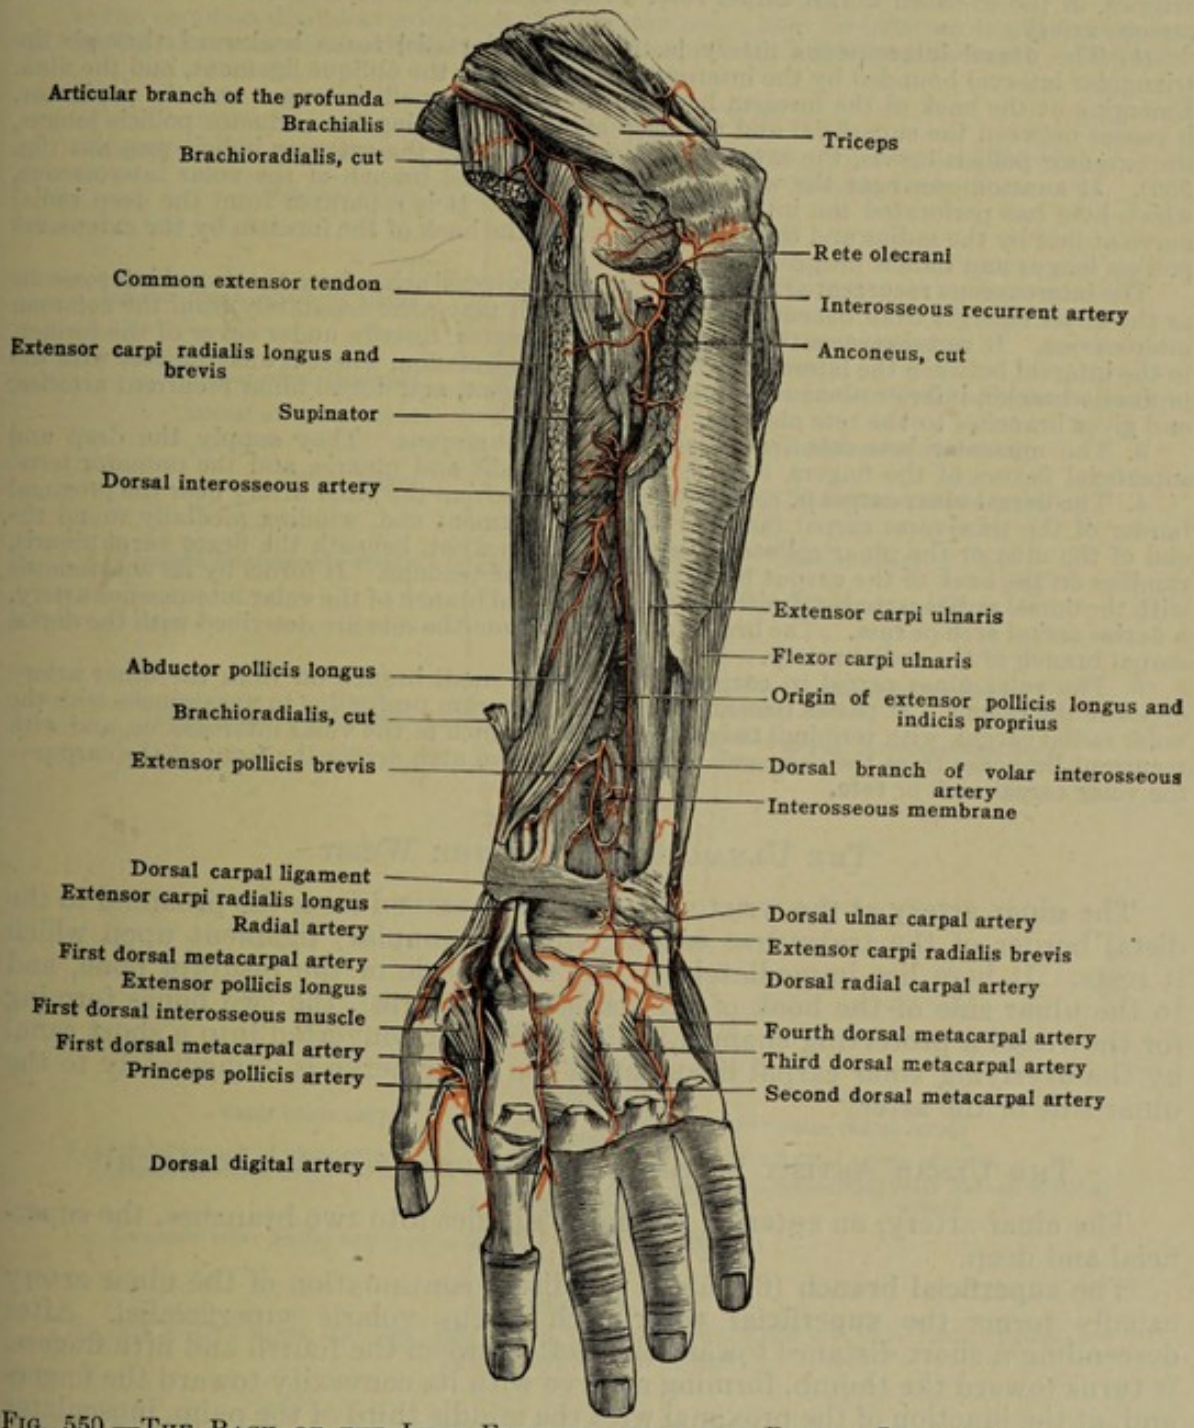

FIG. 550.—THE BACK OF THE LEFT FOREARM, WITH THE DORSAL INTEROSSEOUS ARTERY AND BRANCHES OF THE RADIAL AT THE BACK OF THE WRIST.
(From a dissection in the Hunterian Museum.)

(*a*) The **volar interosseous** artery [a. interossea volaris] passes distally in front of the interosseous membrane. It lies under cover of the overlapping edges of the flexor digitorum profundus and flexor pollicis longus, to both of which muscles it supplies branches. At the proximal border of the pronator quadratus it divides into two branches, the anterior and the posterior terminal (fig. 551).

The volar interosseous artery is accompanied by two veins and by the deep branch of the median nerve which lies to its radial side. The artery is bound down to the interosseous membrane by aponeurotic fibers.

The **branches of the volar interosseous artery** are: (i) The **median** artery [a. mediana] is a long slender vessel which arises from the proximal part of the artery. It passes forward between the flexor digitorum profundus and the flexor pollicis longus to the median nerve, with

which it descends beneath the transverse carpal (anterior annular) ligament into the palm, and when of large size sometimes enters into the formation of the superficial volar arch. This artery may arise from the common interosseous. (ii) The **nutrient arteries** of the radius and ulna. (iii) The **volar terminal** division of the volar interosseous artery passes behind the pronator quadratus and in front of the interosseous membrane, and anastomoses with the volar carpal branches of the radial and ulnar arteries, and with the recurrent branches from the deep volar arch in the so-called **volar carpal rete.** (iv) The **dorsal terminal,** the larger division, pierces the interosseous membrane, and continues under cover of the extensor muscles to the back of the wrist, where it ends by anastomosing with the dorsal carpal branches of the radial and ulnar arteries, in the so-called **dorsal carpal rete.** This branch anastomoses with the dorsal interosseous artery.

(*b*) The **dorsal interosseous** artery [a. interossea dorsalis] turns backward through the triangular interval bounded by the interosseous membrane, the oblique ligament, and the ulna. Emerging at the back of the forearm between the abductor pollicis longus and the supinator, it passes between the superficial and the deep extensors, crossing the abductor pollicis longus, the extensor pollicis brevis, the extensor pollicis longus, and the extensor indicis proprius (fig. 550). It anastomoses near the wrist joint with the dorsal branch of the volar interosseous, which here has perforated the interosseous membrane. It is separated from the deep radial nerve at first by the radius and the supinator, and on the back of the forearm by the extensores pollicis longus and indicis proprius.

The **interosseous recurrent** artery [a. interossea recurrens] arises from the dorsal interosseous as the latter emerges from beneath the supinator, or it may arise separately from the common interosseous. It runs between the anconeus and supinator, usually under cover of the former, to the interval between the lateral epicondyle and the olecranon, where it anastomoses with the profunda brachii, inferior ulnar collateral, radial recurrent, and dorsal ulnar recurrent arteries, and gives branches to the rete olecrani.

3. The **muscular** branches [rr. musculares] are numerous. They supply the deep and superficial flexors of the fingers, the flexor carpi radialis and ulnaris, and the pronator teres.

4. The **dorsal ulnar carpal** [r. carpeus dorsalis] arises from the ulnar artery near the proximal border of the transverse carpal (anterior annular) ligament and, winding medially round the end of the ulna or the ulnar collateral ligament of the wrist, beneath the flexor carpi ulnaris, ramifies on the back of the carpus beneath the extensor tendons. It forms by its anastomosis with the dorsal radial carpal and with the dorsal terminal branch of the volar interosseous artery, a **dorsal carpal arch** or **rete.** The branches given off from the rete are described with the dorsal carpal branch of the radial artery.

5. The **volar ulnar carpal** [r. carpeus volaris] is a small branch off from the ulnar artery opposite the carpus. It passes beneath the flexor digitorum profundus to anastomose with the volar radial carpal, with terminal twigs of the volar branch of the volar interosseous, and with recurrent branches from the deep volar arch, forming an arch across the front of the carpus—the **volar carpal arch** or **rete.**

The Ulnar Artery at the Wrist

The **ulnar artery at the wrist** may be said to extend from the proximal to the distal border of the transverse carpal (anterior annular) ligament upon which it rests. It here lies immediately to the radial side of the pisiform bone, and to the ulnar side of the hook of the hamate (unciform), the two bones forming for the vessel a protecting channel, which is further converted into a short canal by the overlying volar carpal ligament. The ulnar nerve is immediately to the ulnar side of the artery.

The Ulnar Artery in the Palm (Superficial Volar Arch)

The ulnar artery, on entering the palm, divides into two branches, the superficial and deep.

The **superficial branch** (fig. 550), the direct continuation of the ulnar artery usually forms the **superficial volar arch** [arcus volaris superficialis]. After descending a short distance toward the cleft between the fourth and fifth fingers, it turns toward the thumb, forming a curve with its convexity toward the fingers and, at the junction of the proximal with the middle third of the palm, inosculates with the superficial volar branch of the radial artery to complete the arch. The arch is completed in some cases, wholly or in part by the volar radial artery of the index. A line drawn transversely across the palm on a level with the metacarpophalangeal joint of the thumb will roughly indicate the situation of the arch.

Relations.—In front, in addition to the skin and superficial fascia, the vessel is crossed successively, by the palmaris brevis, the palmar branch of the ulnar nerve, the palmar aponeurosis and the palmar branch of the median nerve. **Behind,** it rests successively upon the short muscles of the little finger, the digital branches of the ulnar nerve, the flexor tendons, and the digital branches of the median nerve.

The **branches of the superficial volar arch.** In addition to small muscular and cutaneous branches the superficial volar supplies:

The **common digital arteries** [aa. digitales volares communes]. These, usually three in number, arise from the convexity of the superficial arch and, running downward through the palm, join the three corresponding volar metacarpal arteries to form short trunks which give the volar **digital arteries proper** [aa. digitales volares propriæ] to the radial side of the little finger and to both sides of the ring and middle fingers, and the ulnar side of the index finger. The radial side of the index finger is supplied by the a. volaris radialis indicis.

The proper digital artery for the ulnar side of the little finger passes distally over the hypothenar muscles and thence along the medial margin of the little finger. The remaining arteries pass distally in the three ulnar intermetacarpal spaces to within about 6 mm. (¼ in.) of the clefts between the fingers.

As the common digital arteries pass through the palm, they lie between the flexor tendons, on the digital nerves and lumbrical muscles, and beneath the palmar aponeurosis. Just before

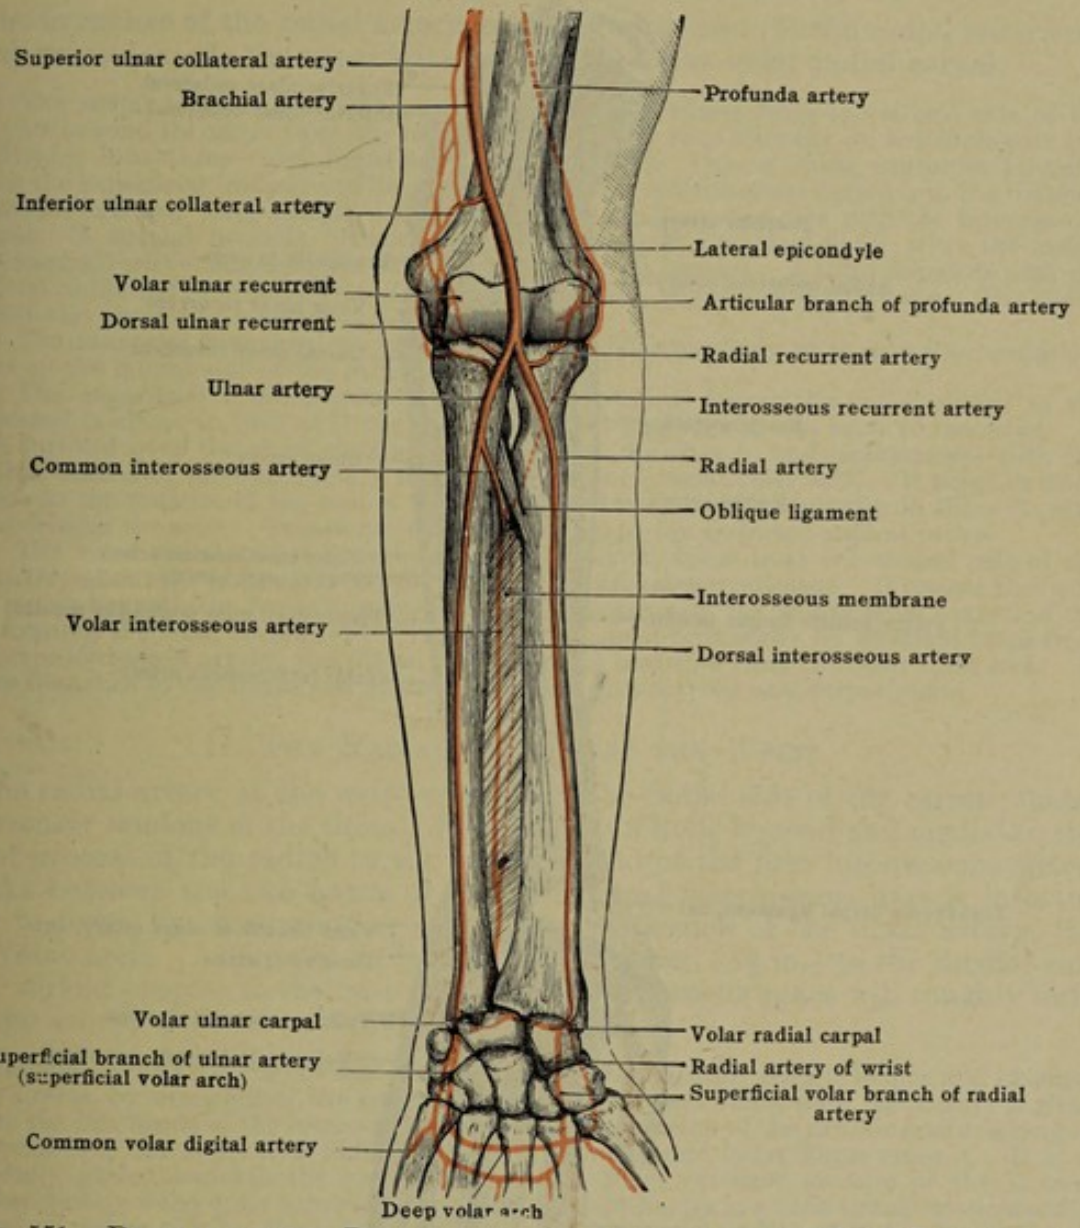

FIG. 551.—DIAGRAM OF THE RELATION OF THE ARTERIES OF THE LEFT FOREARM TO THE BONES. (Walsham.)

uniting with the volar metacarpal branches from the deep volar arch, they pass under the transverse fasciculi and receive the volar perforating branches from the dorsal metacarpal vessels (fig. 553). On the sides of the fingers the proper digital arteries lie between the palmar and dorsal digital nerves. They anastomose by small branches, forming an arch across the front of the bones on the proximal side of each interphalangeal joint. They supply the flexor tendons and the integument, and terminate in a plexiform manner beneath the pulp of the finger and around the matrix of the nail. A dorsal digital branch is given off to the back of the fingers about the level of the middle of the first phalanx, and a second but smaller dorsal digital branch about the level of the middle of the second phalanx.

The **deep branch** of the ulnar artery [ramus volaris profundus], also called the communicating artery, sinks deeply into the palm between the abductor and flexor quinti digiti brevis, and joins the radial to complete the deep volar arch. (See RADIAL ARTERY.)

THE RADIAL ARTERY

The **radial** artery—the smaller of the two arteries into which the brachial divides—appears as the direct continuation of the brachial. It runs, at first curving laterally, along the radial side of the forearm as far as the styloid process, then, curving over the radial collateral ligament and the lateral and back part of the wrist, enters the palm between the bases of the first and second metacarpal bones, and ends by anastomosing with the deep branch of the ulnar to form the deep volar arch. Hence the artery is divisible into three parts: that in the

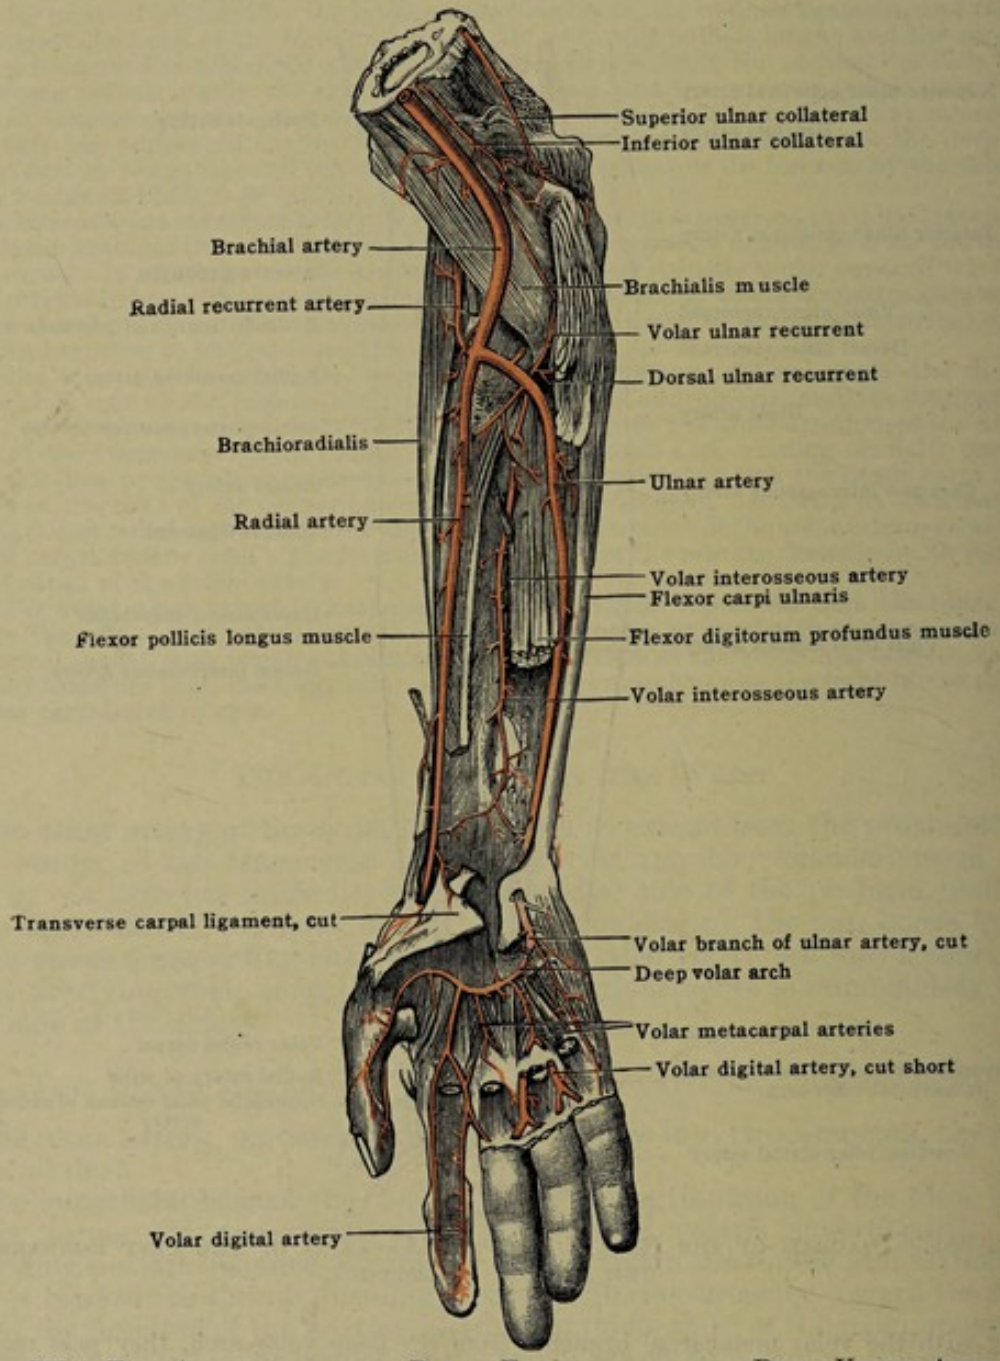

FIG. 552.—THE ARTERIES OF THE RIGHT FOREARM AND THE DEEP VOLAR ARCH.

forearm, that at the wrist, and that in the palm of the hand. The course of the artery is indicated by a line drawn from a point 2.5 cm. (1 in.) below the center of the elbow to a point situated just medial to the styloid process of the radius.

1. THE RADIAL ARTERY IN THE FOREARM

In its course through the forearm (fig. 552) the radial artery is found in the most lateral of the intermuscular spaces, the radial sulcus, and for exposure, it is necessary to divide only the skin, superficial and deep fascia and, in the upper third of the forearm, to separate the brachioradialis from the pronator teres. There are two venæ comitantes.

Relations.—**In front,** the artery is at first overlapped by the brachioradialis, but for the rest of its course it is merely covered by the skin, superficial and deep fasciæ, by some cutaneous veins, and by cutaneous branches of the musculocutaneous nerve.

Behind, it lies successively on the tendon of the biceps, the supinator, from which it is separated by a layer of fat, on the insertion of the pronator teres, the radial origin of the flexor digitorum sublimis, the flexor pollicis longus, the pronator quadratus, and the volar surface of the distal end of the radius. It is in this last situation, where the artery lies upon the bone, that the pulse is usually felt.

On its **lateral side** it has, throughout the whole of its course, the brachioradialis muscle and tendon and, in its middle third, the superficial radial nerve. In its distal third the superficial radial nerve is to its lateral side, but separated from it by the brachioradialis and fascia.

On its **medial side,** in the proximal third is the pronator teres, and in the distal third the tendon of the flexor carpi radialis. It is accompanied by venæ comitantes.

The **branches of the radial artery in the forearm** are: (1) the radial recurrent; (2) the muscular; (3) the superficial volar and (4) the volar radial carpal.

(1) The **radial recurrent** [a. recurrens radialis] usually arises from the lateral side of the radial just beyond its origin from the brachial. It at first runs laterally on the supinator and then divides into three chief branches (figs. 549, 551). One of these continues laterally between the superficial (radial) and deep radial (posterior interosseous) nerves into the brachioradialis and extensor carpi radialis longus and brevis, and anastomoses with the interosseous recurrent. A second ascends between the brachialis and brachioradialis, with the radial (musculospiral) nerve, and anastomoses with the profunda brachii. A third descends with the superficial radial nerve under cover of the brachioradialis, supplying that muscle. The radial recurrent also gives off branches to the elbow-joint.

(2) The **muscular branches** [rr. musculares] come off irregularly to supply the contiguous muscles on the lateral side of the forearm.

(3) The **superficial volar** branch [r. volaris superficialis] leaves the radial artery as the latter vessel is about to turn over the radial collateral ligament to the back of the wrist. It courses forward over the short muscles of the ball of the thumb, and anastomoses with the superficial branch of the ulnar artery to complete the superficial volar arch. It supplies small branches to the muscles of the ball of the thumb, and frequently terminates in these muscles without joining the arch. Occasionally it passes beneath the abductor pollicis brevis.

(4) The **volar radial carpal** branch [r. carpeus volaris] arises from the medial side of the radial artery about the level of the distal border of the pronator quadratus. It crosses the front of the radius beneath the flexor muscles, and anastomoses with the volar carpal branch of the ulnar, forming the volar carpal rete. This plexus is joined proximally by terminal twigs from the volar interosseous artery, and distally by recurrent branches from the deep volar arch. It supplies branches to the distal end of the radius, and to the wrist and carpal joints.

II. The Radial Artery at the Wrist

The radial artery at the wrist winds over the radial side of the carpus, under the extensor tendons of the thumb, from a point a little beyond and medial to the styloid process of the radius to the proximal end of the first interosseous space. It sinks between the two heads of the first dorsal interosseous muscle into the palm, to form, by anastomosing with the deep branch of the ulnar artery, the deep volar arch. A line drawn from a point 1.2 cm. (½ in.) to the medial side of the styloid process to the base of the first interosseous space will roughly indicate the course of the artery (fig. 550).

Relations.—The artery is covered successively by the abductor pollicis longus and extensor pollicis brevis, by branches of the superficial radial nerve and veins, and, just before it sinks between the two heads of the interosseous muscle, by the tendon of the extensor pollicis longus. The branches of the superficial radial nerve to the thumb and index finger cross it. It is at first deeply placed beneath the long abductor and short extensor muscles of the thumb; but subsequently it lies quite superficial, and can be felt pulsating in a little triangular depression bounded on either side by the extensores pollicis longus and brevis, and above by the lower end of the radius. The artery lies successively on the radial collateral ligament of the wrist, on the navicular (scaphoid), the greater multangular (trapezium), the base of the first metacarpal bone, and on the dorsal ligaments uniting these bones. It has usually with it two companion veins, and a few branches of the musculocutaneous nerve.

The **branches of the radial artery at the wrist** are: (1) The dorsal radial carpal; (2) the first dorsal metacarpal.

(1) The **dorsal radial carpal** branch [r. carpeus dorsalis] arises from the radial as the latter vessel passes under the abductor pollicis longus, and runs medially beneath the extensor carpi radialis longus and brevis, and the extensor pollicis longus, across the dorsal surface of the carpus, to anastomose with the dorsal ulnar carpal and with the terminal twigs of the posterior branch of the volar interosseous artery. This anastomosis is called the **dorsal carpal rete** [rete carpi dorsale]. From this rete are given off the second, third, and fourth **dorsal metacarpal arteries** to the second, third, and fourth intermetacarpal spaces respectively. These vessels run distally on the dorsal interosseous muscles as far as the flexure of the fingers, and there divide into two **dorsal digital** branches [aa. digitales dorsales], which run along the sides of the dorsal aspect of the contiguous fingers. Between the bases of the metacarpal bones, the

dorsal metacarpal arteries anastomose with the **perforating branches of the deep volar arch.** Distally they are connected by **perforating** branches with the junction of the volar metacarpal and common digital arteries of the corresponding spaces. The proper dorsal digital arteries are usually small, the fingers being supplied largely by the volar proper digitals (fig. 553).

(2) The **first dorsal metacarpal** (fig. 550) is given off by the radial shortly before it passes between the two heads of the first dorsal interosseous muscle. It divides into two branches which supply the dorsal surface of the thumb and the radial side of the dorsal surface of the index-finger.

III. The Radial Artery in the Palm (Deep Volar Arch)

The radial artery enters the palm between the first and second metacarpal bones at the base of the first interosseous space, by passing between the two

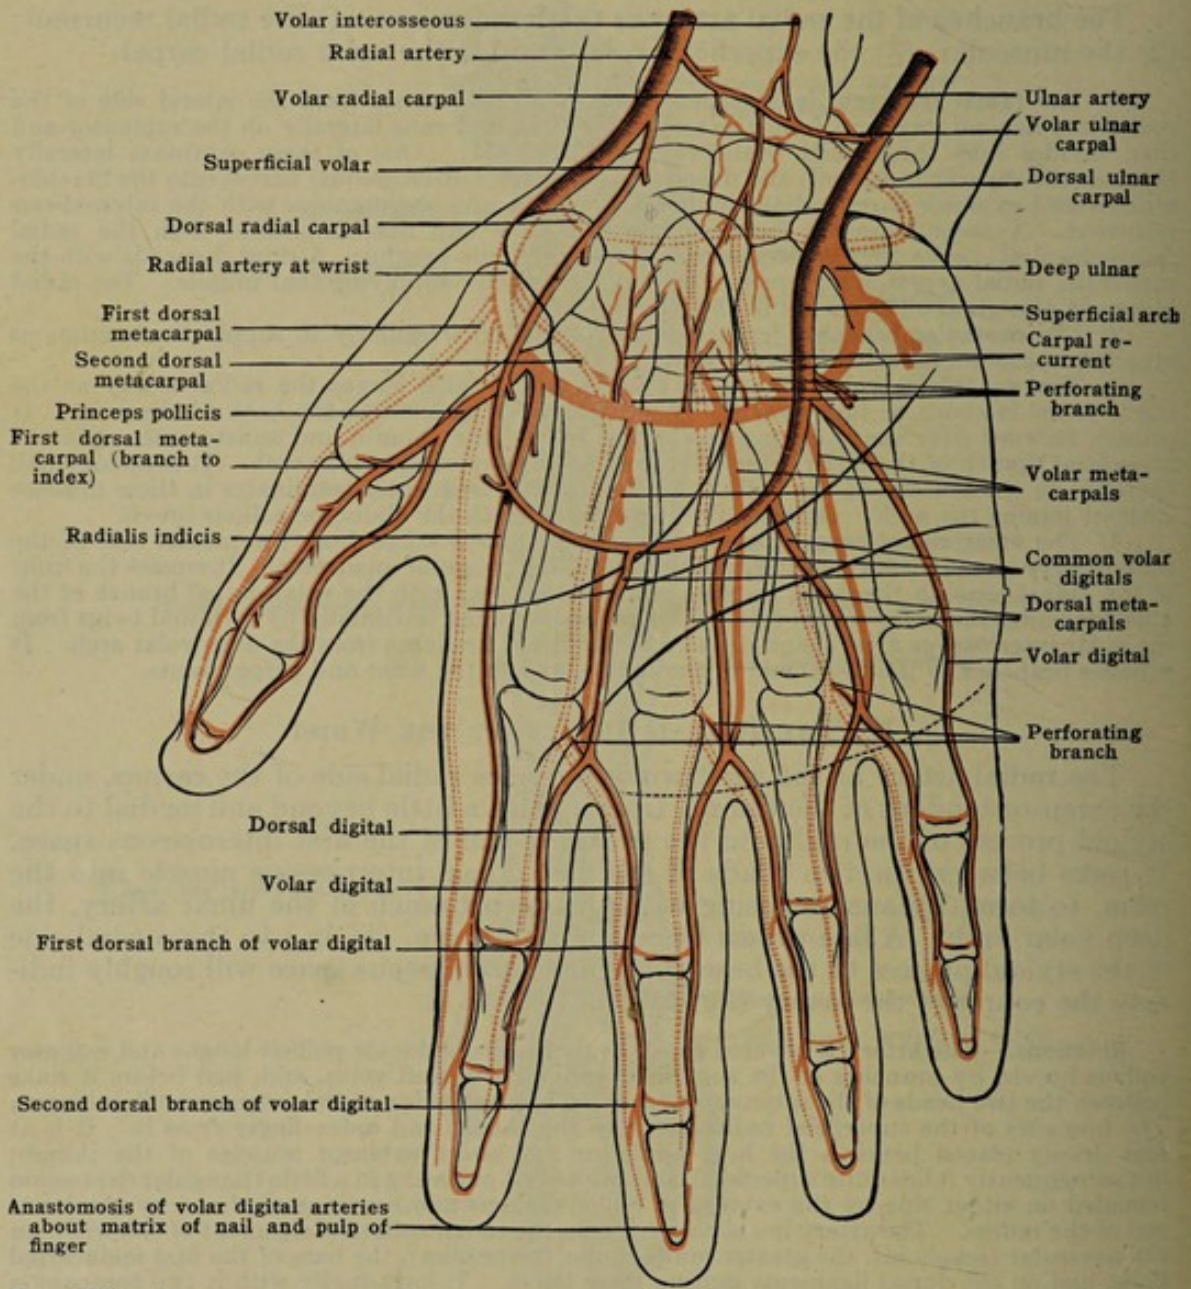

Fig. 553.—Anastomoses and Distribution of the Arteries of the Hand. (Walsham.)

heads of the first dorsal interosseous muscle. It then runs medially between the transverse and oblique heads of the adductor pollicis muscle and continuing its course, with a slight convexity forward, across the base of the metacarpal bones and interosseous muscles, joins the deep branch of the ulnar, forming the **deep volar arch** [arcus volaris profundus]. The arch may be said to extend from the first interosseous space to the base of the metacarpal bone of the little finger, and is a finger's breadth nearer the wrist than the superficial arch. It is covered by the superficial and deep flexor tendons, by the superficial head of the flexor pollicis brevis, and by part of the flexor quinti digiti brevis. It is accompanied by the deep branch of the ulnar nerve, and two small venæ comitantes (figs. 552, 553).

The **branches of the deep volar arch** are: (1) The princeps pollicis; (2) the volaris indicis radialis; (5) the volar metacarpals (three in number); (4) the recurrent carpal; (3) the dorsal perforating.

(1) The **arteria princeps pollicis** arises from the radial artery after it has entered the palm between the two heads of the first dorsal interosseous muscle. It passes downward between the adductor pollicis transversus and the first dorsal interosseous muscle, parallel with the metacarpal bone, and between the two portions of the flexor pollicis brevis under cover of the flexor pollicis longus. Opposite the metacarpophalangeal joint it usually divides into two branches, one of which is distributed to each side of the volar aspect of the thumb. These vessels anastomose with each other at the end of the thumb, like the other digital arteries.

(2) The **arteria volaris indicis radialis** comes off from the radial artery a little beyond the princeps pollicis, or as a common trunk with it, and passes forward between the first dorsal interosseous and adductor pollicis transversus, parallel with the radial side of the second metacarpal bone. After emerging from beneath the adductor pollicis transversus it continues along the radial side of the volar aspect of the index-finger, anastomosing with the digital artery on the opposite side of the finger in a way similar to that of the other digital arteries. It frequently communicates, at the lower border of the adductor pollicis, with the superficial volar arch, which it may complete, in the absence of the superficial volar artery. It gives off a dorsal branch, which anastomoses with the branch from the first dorsal metacarpal to the index-finger.

(3) The **volar metacarpal** arteries [aa. metacarpeæ volares], three in number, come from the convexity of the deep arch, and, running in the second, third, and fourth interosseous spaces on the interosseous muscles, terminate near the cleft of the fingers by anastomosing with the digital arteries from the superficial arch. These vessels supply the interosseous muscles and the bones, and the second, third, and fourth lumbricales.

(4) The **recurrent branches** come from the concavity of the arch, and consist of two or three small vessels which run toward the wrist, and anastomose with the volar branch of the volar interosseous, and the volar radial and ulnar carpal arteries.

(5) The **perforating** branches [rr. perforantes], which are usually three in number, pass from the arch directly through the second, third, and fourth interosseous spaces between the two heads of the corresponding dorsal interosseous muscle, and join the second, third, and fourth dorsal metacarpal arteries respectively.

THE THORACIC AORTA

The **thoracic aorta** [aorta thoracalis] (fig. 554) is the thoracic portion of the aorta descendens. It extends from the termination of the aortic arch at the lower border of the body of the fourth thoracic vertebra to the lower border of the body of the twelfth thoracic vertebra, where it passes between the medial crura of the diaphragm, and is thence continued under the name of the abdominal aorta. It is at first situated a little to the left of the vertebral column, but as it descends, approaches the front of the column, at the same time following its backward curve, and at the diaphragm is almost in the middle line. It lies in the posterior mediastinum, having the esophagus at first a little to the right of it, then in front, and finally (near the lower end of the esophagus) a little to the left side.

Relations.—In front the descending aorta is crossed from above downward by the root of the left lung, by the esophagus, which separates it from the pericardium and heart, and by the diaphragm. **Behind,** it lies upon the lower seven thoracic vertebræ, and is crossed obliquely opposite the seventh or eighth thoracic vertebra by the vena hemiazygos (azygos minor) and opposite the fifth or sixth vertebra by the accessory hemiazygos vein, or by one or more of the intercostal veins. On the **right side** it has, above, the esophagus and vertebral column; lower down the right pleura and lung. The vena azygos and thoracic duct also lie to the right, but on a somewhat posterior plane. On the **left side** it has the left lung and pleura above, and the esophagus below. The vena hemiazygos and the accessory hemiazygos vein are also to the left, but on a posterior plane.

Branches of the Thoracic Aorta

The **branches of the thoracic aorta** may be divided into (*A*) the visceral and (*B*) the parietal. The **visceral** are: (1) The pericardiac; (2) the bronchial; and (3) the esophageal. The **parietal** are: (1) The intercostal; (2) the superior phrenic; and (3) the arteria aberrans.

A. Visceral Branches

(1) The **pericardiac** branches [rr. pericardiaci]—two or three small branches, irregular in their origin, course, and distribution—pass to the posterior surface of the pericardium to supply that structure, and anastomose with the other **pericardiac** branches. They give small twigs to the posterior mediastinal glands.

(2) The **bronchial** arteries [aa. bronchiales] supply the bronchi and the lung substance. They vary considerably in their origin, course, and distribution; they are usually three in number—one on the right side, and two on the left.

(*a*) The **right bronchial** generally arises either from the first right aortic intercostal, or as a common trunk with the left upper bronchial from the front of the aorta just below the level of the bifurcation of the trachea. It passes laterally on the back of the right bronchus, and is distributed to the bronchi and lung substance. (*b*) The **left upper bronchial** arises from the front of the aorta just below the bifurcation of the trachea, or as a common trunk with the right bronchial. (*c*) The **left lower bronchial** arises from the front of the aorta just below the level

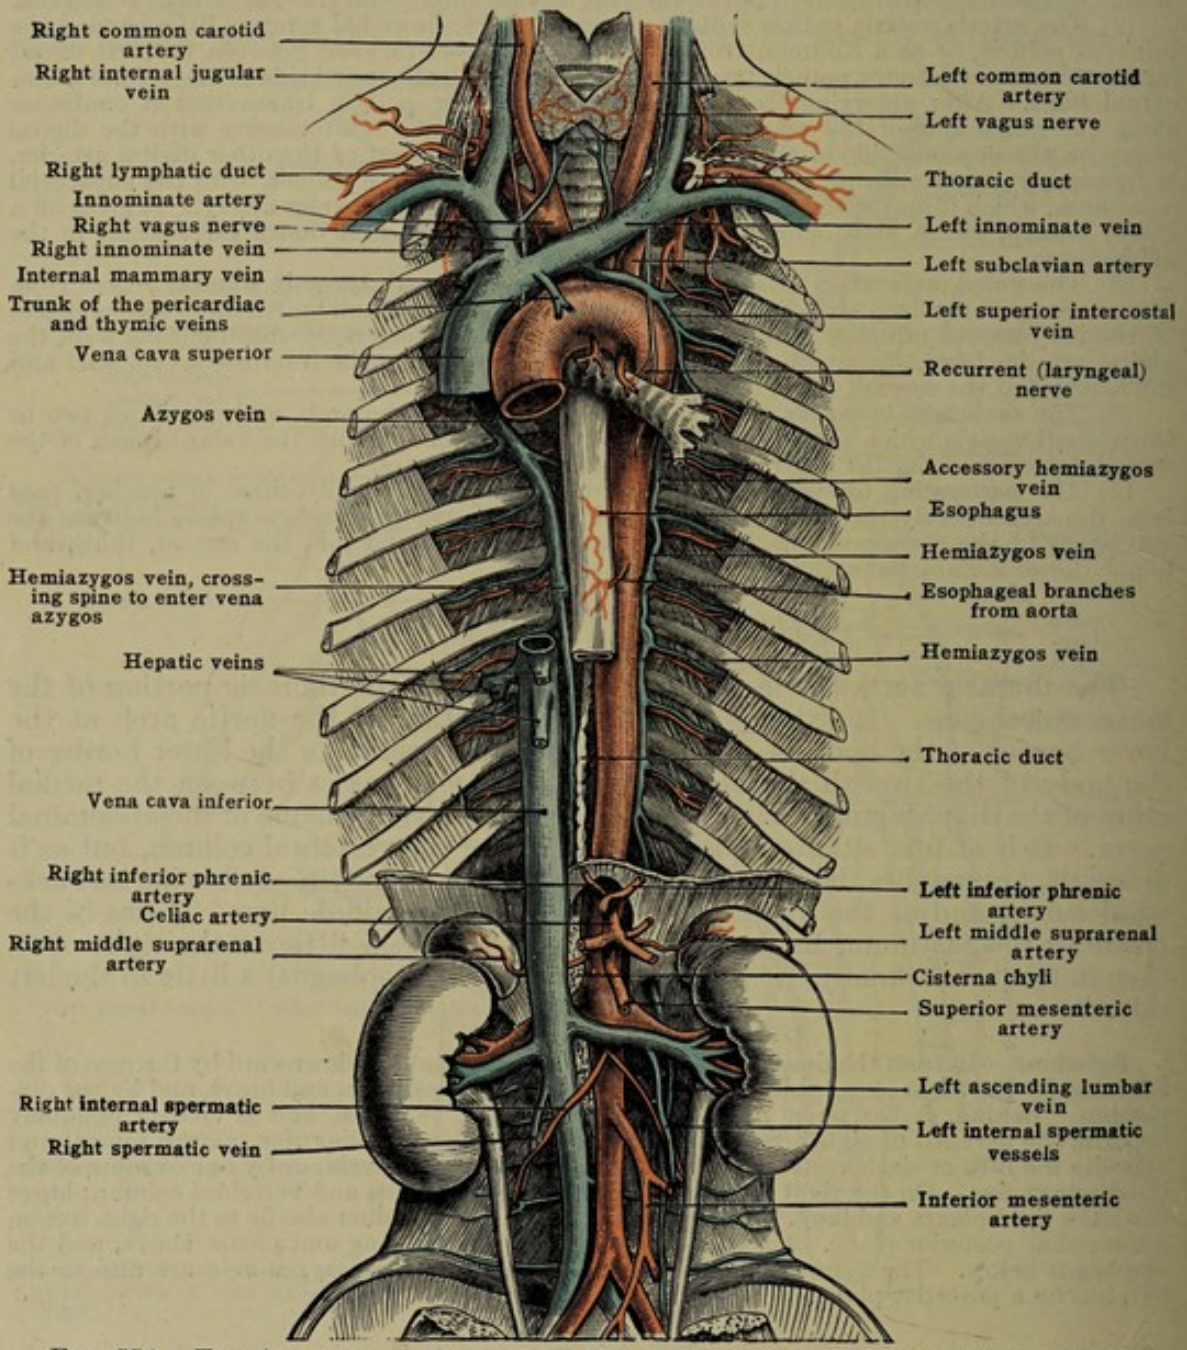

FIG. 554.—THE ARCH OF THE AORTA, THE THORACIC AORTA, AND THE ABDOMINAL AORTA, WITH THE VENA CAVA SUPERIOR AND INFERIOR AND THE INNOMINATE AND AZYGOS VEINS.

of the left bronchus. Like the corresponding artery on the right side, the left bronchial arteries run laterally on the left bronchus and, after dividing and subdividing on the back of the bronchi, supply the bronchi themselves and the lung substance. Small twigs are given from the bronchial arteries to the bronchial glands and to the esophagus.

(3) The **esophageal** arteries [aa. œsophageæ], four or sometimes five in number, arise at intervals from the front of the descending thoracic aorta, the first coming off just below the left lower bronchial. They usually increase in size from above downward, the upper arising toward the right side of the aorta, the lower more toward the left side. They pass forward to the esophagus, supplying that tube and anastomosing with each other and with the descending esophageal

branches of the inferior thyroid above, and with the ascending esophageal branches of the phrenic and gastric arteries below, thus forming a chain of anastomoses along the whole length of the tube.

B. Parietal Branches

(1) **The intercostal** arteries [aa. intercostales], usually ten in number on each side, supply the lower intercostal spaces, the two upper spaces (occasionally the first only) being supplied from the costocervical trunk of the subclavian artery. The lowest artery accompanies the twelfth thoracic nerve below the last rib and is therefore called the **subcostal artery.** Its distribution is similar to that of the lumbar arteries (p. 664) except that it commonly crosses the anterior surface, rather than the posterior, of the quadratus lumborum.

The intercostals arise in pairs from the back part of the aorta, and turning, the one to the right and the other to the left, wind backward over the front and sides of the vertebral bodies to reach the intercostal spaces. In fetal life these arteries run almost transversely, or even with a slight downward inclination, to the

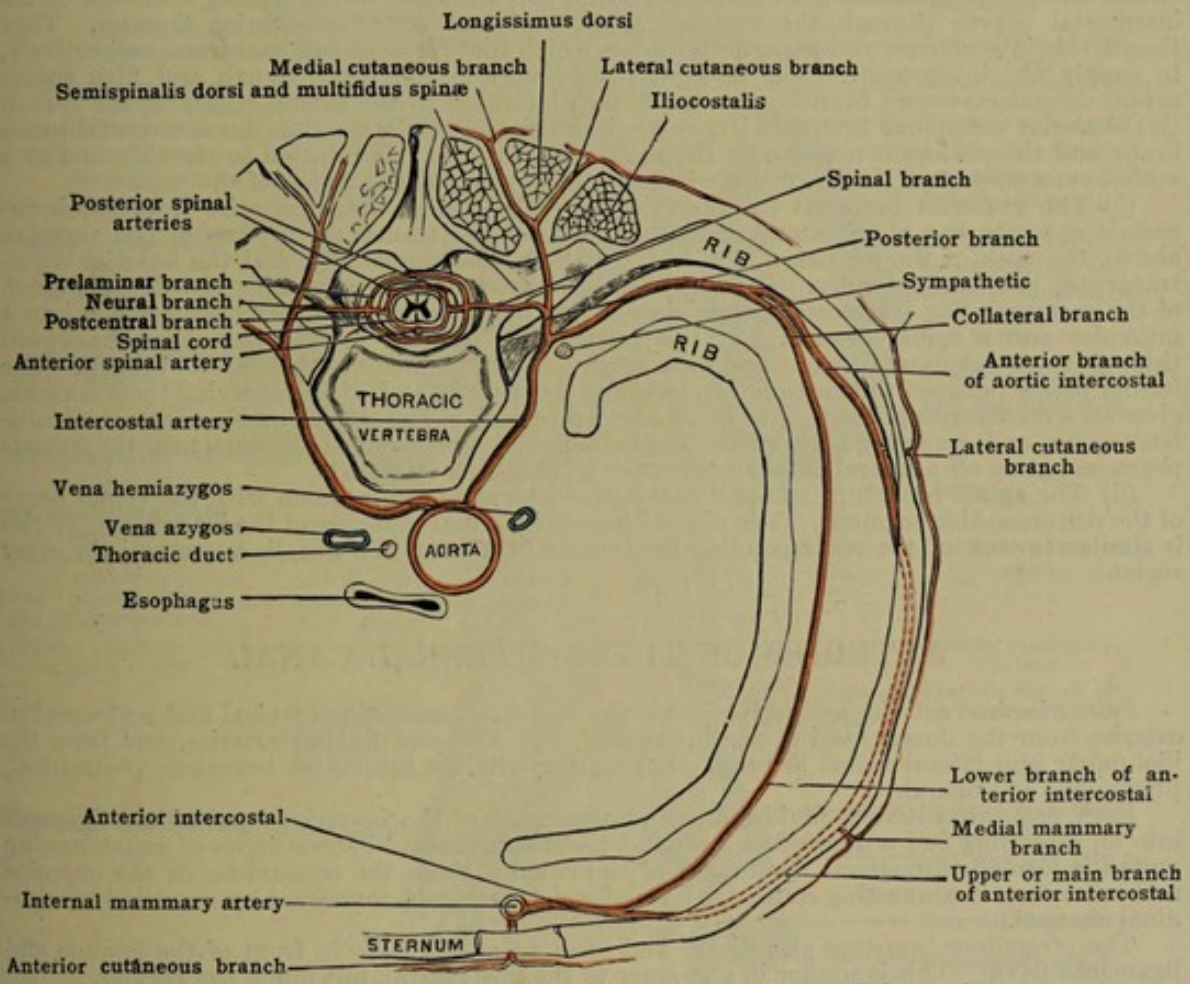

Fig. 555.—Scheme of Intercostal Artery. (Walsham.)

intercostal spaces; but after the first year, in consequence of the disproportionate growth of the aorta and vertebral column, the upper intercostals have to ascend to reach their respective spaces.

The arteries in their course around the vertebræ differ on the two sides of the body. On the **right side** they—and especially the upper, in consequence of the aorta lying a little to the left side of the spine in the upper part of its course—are longer than the left. They wind over the front and right side of the vertebræ, being crossed by the thoracic duct and vena azygos (major), and covered by the right pleura and lung. The upper are also crossed by the esophagus. They give small branches to the bodies of the vertebræ and anterior longitudinal ligament. On the **left side,** as the intercostals wind around the sides of the bodies of the vertebræ, the lower ones are crossed by the vena hemiazygos (azygos minor), the two upper by the left superior intercostal vein, and the two next by the accessory hemiazygos, when this is present. They are all covered by the left pleura and lung (figs. 554, 555).

The **branches of the intercostal arteries** are: (a) anterior, (b) posterior.

(*a*) The **anterior** branches [rr. anteriores] at first cross the intercostal space obliquely, in consequence of the downward direction of the ribs, toward the angle of the rib above, and thence

are continued forward in the costal groove. They anastomose with the superior branches of the anterior intercostal branches of the internal mammary in the upper spaces, and of the musculophrenic in the lower spaces. They lie at first on the external intercostal muscles, being covered in front by the pleura and lung, the posterior intercostal membranes and the subcostal muscles. Opposite the heads of the ribs they are crossed by the sympathetic nerve. At the angle of the ribs they pass under cover of the internal intercostal muscles, and thence to their termination lie between the two intercostal muscles. They are accompanied by a nerve and a vein, the vein lying above and the nerve below; except in the upper spaces, where the artery, having to ascend to reach the space, at first lies below the nerve which runs more horizontally. The uppermost branch anastomoses with the superior intercostal artery, and at times supplies almost entirely the second intercostal space. The arteries to the tenth and eleventh spaces on reaching the end of the costal cartilages pass between the abdominal muscles, and anastomose with the inferior epigastric and lateral epigastric arteries from the external iliac, and with the lumbar arteries from the abdominal aorta. The artery beneath the twelfth rib anastomoses with the lumbar arteries and with branches of the deep circumflex iliac.

Each anterior branch gives off the following: (i) The **collateral** branch which comes off near the angle of the rib and runs forward, between the external and internal intercostals, along the upper border of the lower rib enclosing the space. It is smaller than the main anterior branch and anastomoses with the lower anterior intercostal in each space. (ii) **Muscular** branches [rr. musculares] supply the intercostal, pectoral and abdominal muscles. (iii) The **lateral cutaneous** branches [rr. cutanei laterales] run with the corresponding branches of the intercostal nerves through the external intercostal and serratus anterior muscles. They then divide into *anterior* and *posterior* branches which turn forward and backward, respectively, to supply the integument. The anterior branches from the third, fourth and fifth spaces supply *lateral mammary* branches [rr. mammarii laterales] to the lateral region of the breast. (iv) **Anterior cutaneous** branches [rr. cutanei anteriores] pierce the anterior intercostal membrane and the pectoralis major near the sternum. They are distributed to the skin and give *medial mammary* branches [rr. mammarii mediales] to the medial region of the breast.

(*b*) **The posterior** branches [rr. posteriores].—These large branches arise from the intercostals opposite the quadrilateral space bounded by the transverse process of the vertebra above, the neck of the rib below, the body of the vertebra medially, and the anterior costotransverse ligament laterally. Passing backward toward this space with the dorsal branch of the corresponding intercostal nerve, they divide opposite the intervertebral foramen into a muscular and a spinal branch. (i) The **muscular** branch [r. muscularis] passes backward through the quadrilateral space, and soon subdivides into a medial and a lateral branch. The former passes between the longissimus dorsi and iliocostalis, and, after supplying these muscles, gives off a **medial cutaneous** branch [r. cutaneus medialis]. The latter branch pierces the multifidus spinæ, and, emerging between the longissimus dorsi and semispinalis dorsi near the spinous processes, gives off a **lateral cutaneous** branch [r. cutaneus lateralis].

(ii) The **spinal** branch [r. spinalis] enters the intervertebral foramen with the spinal nerve of the corresponding segment. The disposition of the spinal branches of the intercostal arteries is similar to that of the corresponding branches which enter the canalis vertebralis in other regions.

ARTERIES OF THE VERTEBRAL CANAL

Pairs of spinal arteries are derived from the vertebral, ascending cervical and costocervical arteries from the dorsal rami of the intercostal (fig. 555) and lumbar arteries, and from the iliolumbar and lateral sacral arteries. Each artery divides into three branches, postcentral, prelaminar and neural.

Each *postcentral* branch divides on the lateral part of the posterior longitudinal ligament into an ascending and a descending branch by which means a bilateral series of anastomosing arches is formed throughout the length of the canal. From the concavities of the opposite arches transverse connecting stems are formed which are again connected by a median longitudinal channel.

The *prelaminar* branches also divide and form an anastomosis in front of the laminæ and ligamenta flava. This is similar in character to the postcentral, but much less regular.

The *neural* branches enter the dura mater and are usually small and end by supplying the nerve roots. A variable number of these (5–10 on a side) are larger than the others and reinforce the longitudinal anterior and posterior spinal arteries given off from the vertebrals within the cranium. (For arteries of the spinal cord, see Section VIII.)

(2) The **superior phrenic** arteries [aa. phrenicæ superiores], are small twigs coming off from the thoracic aorta immediately above the diaphragm. They are distributed to the vertebral portion of the diaphragm on its upper surface.

(3) The **arteria aberrans** is a small twig which, arising from the thoracic aorta near the right bronchial artery, passes upward and to the right behind the esophagus and trachea, and is occasionally found to anastomose on the esophagus with an arteria aberrans from the right subclavian, costocervical or superior intercostal artery (see p. 633). It is regarded as the remains of the right aortic dorsal stem (fig. 543).

(4) The **mediastinal** branches [rr. mediastinales], numerous, but small, are distributed to the pleura, and the vessels, nerves and lymph-nodes of the posterior mediastinum.

THE ABDOMINAL AORTA

The **abdominal aorta** [aorta abdominalis] (fig. 556), the abdominal portion of the descending aorta, begins at the aortic opening in the diaphragm opposite the lower border of the twelfth thoracic vertebra, and ends usually opposite the body of the fourth lumbar vertebra by dividing into the right and left common iliac arteries. It is at first centrally placed between the medial crura of the diaphragm, but as it descends it deviates a little to the left side.

The place at which the aorta bifurcates may be somewhat roughly indicated on the surface of the abdomen by a point about 2.5 cm. (1 in.) below and a little to the left of the umbilicus. The level of its bifurcation may be more accurately determined by drawing a straight line between the highest points of the iliac crests.

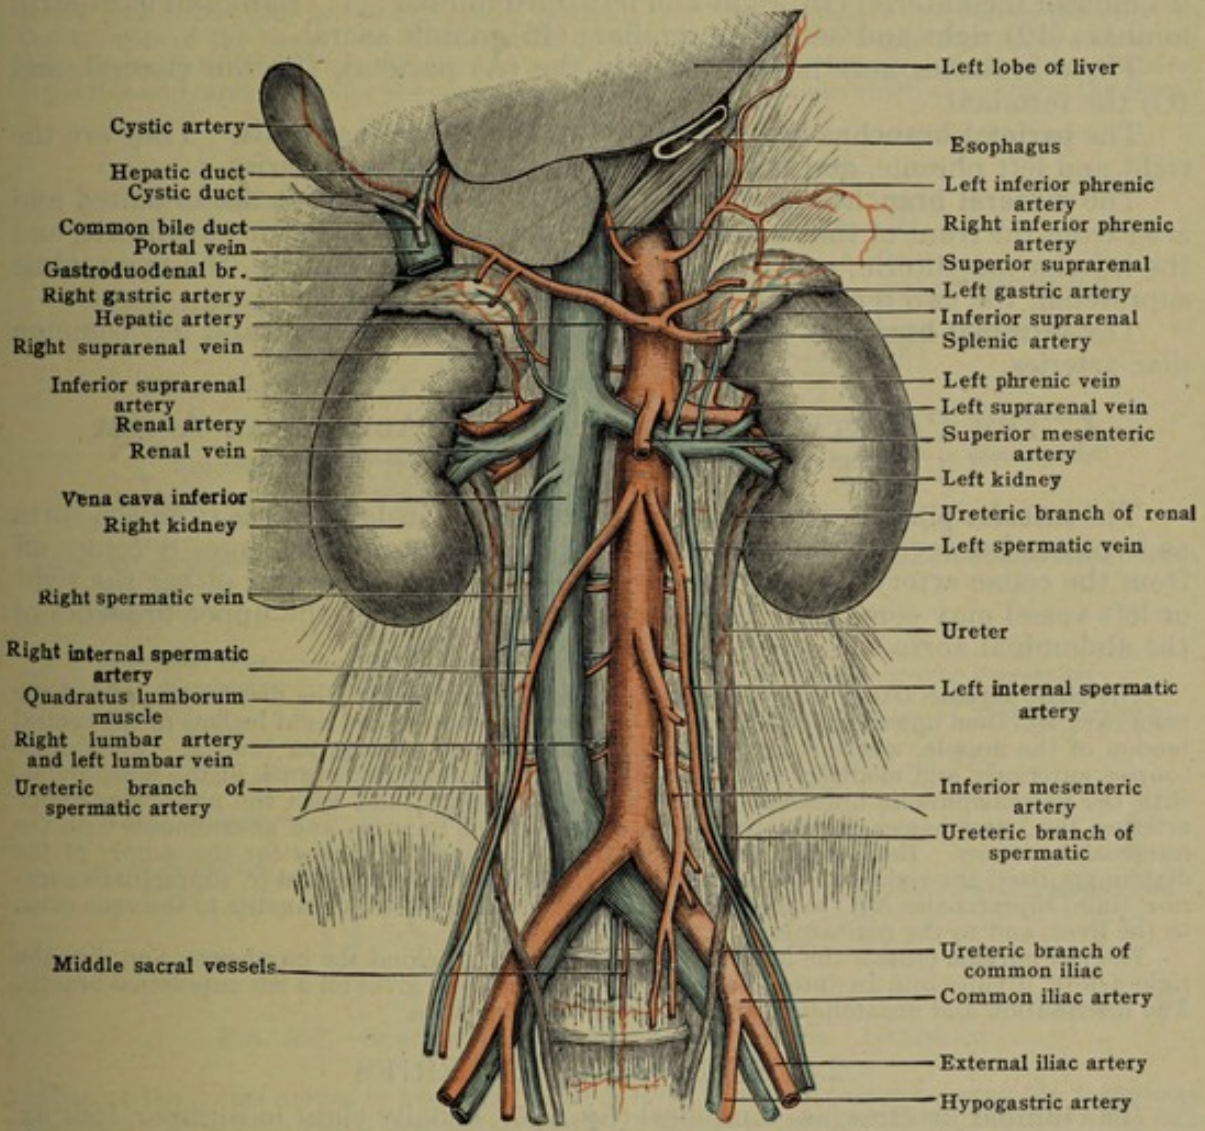

FIG. 556.—THE ABDOMINAL AORTA AND ITS BRANCHES, WITH THE VENA CAVA INFERIOR AND ITS TRIBUTARIES.

Relations.—In front, the aorta is successively crossed from above downward by the left lobe of the liver, the celiac (solar) plexus, the lesser omentum, the termination of the esophagus in the stomach, the ascending layer of the transverse mesocolon, the splenic vein or commencement of the portal vein, the pancreas, the left renal vein, the third portion of the duodenum, the mesentery, the aortic plexus of the sympathetic nerve, the internal spermatic or ovarian arteries, the inferior mesenteric artery, the median lumbar lymphatic nodes and lymphatic vessels, and the small intestines. Of these structures the celiac (solar) plexus, the aortic plexus, the splenic vein or the commencement of the portal vein, the pancreas, the left renal vein, the duodenum, the lymphatics, the spermatic or ovarian arteries, and the peritoneal reflexions are in direct contact with the aorta.

Behind, the aorta lies upon the bodies of the lumbar vertebræ and intervening intervertebral cartilages, the anterior longitudinal ligament, the origin of the left medial crus of the diaphragm, and the left lumbar veins.

On the **right side** from above downward are the right medial and intermediate crura of the diaphragm, the great splanchnic nerve, the caudate lobe of the liver, the cisterna chyli and beginning of the thoracic duct (the two latter structures are on a posterior plane), the right celiac (semilunar) ganglion, and the inferior vena cava. Inferiorly, the vena cava is in contact

with the aorta, and on a somewhat posterior plane. Superiorly, the vena cava is separated from the aorta by the right medial and intermediate crura of the diaphragm, and the caval opening of the diaphragm is on a plane anterior to the aortic.

On the **left side** are the left medial and intermediate crura of the diaphragm, the left splanchnic nerve, and the left celiac (semilunar) ganglion. The pancreas is also in contact with the aorta on the left side, and the small intestines are separated from it only by peritoneum.

Branches of the Abdominal Aorta

The **branches of the abdominal aorta** usually arise in the following order from above downward (figs. 556, 557):

(1) Right and left inferior phrenic; (2) celiac; (3) right and left middle suprarenal; (4) right and left first lumbar; (5) superior mesenteric; (6) right and left renal; (7) right and left internal spermatic; (8) right and left second lumbar; (9) inferior mesenteric; (10) right and left third lumbar; (11) right and left fourth lumbar; (12) right and left common iliac; (13) middle sacral.

These branches may be divided into the (A) parietal, (B) the visceral, and (C) the terminal.

The **parietal branches** are distributed to the abdominal walls. They are the right and left phrenic, and the four right and left lumbar arteries.

The **visceral branches** supply the viscera. Three of these are unpaired and arise from the front of the aorta, namely, the celiac, the superior mesenteric, and the inferior mesenteric; and three are given off in pairs, namely, the two middle suprarenal, the two renal, and the two spermatic arteries.

The **terminal branches** are the middle sacral and the right and left common iliac arteries.

A. The Parietal Branches of the Abdominal Aorta

1. THE INFERIOR PHRENIC ARTERIES

The **inferior phrenic** artery [a. phrenica inferior] usually arises from the aorta as it passes between the medial crura of the diaphragm. At times it comes off from the celiac artery; or when it arises as two separate vessels, either the right or left vessel may come from this artery, or from other of the upper branches of the abdominal aorta.

The **right phrenic** artery (fig. 556) passes over the right crus of the diaphragm behind the vena cava and then upward and to the right between the central and right leaflets of the central tendon of the muscle, where it divides into an **anterior** and a **posterior** branch. The former courses anteriorly and medially and anastomoses with the anterior branch of the left phrenic, with the musculophrenic branches of the internal mammary, and with the pericardiophrenic arteries; the latter passes posteriorly and laterally toward the ribs, and anastomoses with the intercostal arteries. Besides the two terminal branches and branches for the supply of the diaphragm itself the right phrenic gives off the **right superior suprarenal** [r. suprarenalis superior] (rami suprarenales NK) to the right suprarenal gland, as well as branches to the vena cava, to the liver, and to the pericardium.

The **left phrenic** crosses the left crus of the diaphragm behind the esophagus, and, like the right artery, divides into an anterior and posterior branch and gives off a left suprarenal branch. The distribution and anastomoses are similar on the two sides.

2. THE LUMBAR ARTERIES

The **lumbar** arteries [aa. lumbales] (fig. 556), usually eight in number, four on each side, come in pairs from the posterior aspect of the abdominal aorta, opposite the bodies of the four upper lumbar vertebræ. A fifth pair of lumbar arteries, generally of small size, frequently arises from the middle sacral artery opposite the fifth lumbar vertebra. The lumbar arteries, which are rather longer on the right than on the left side, in consequence of the aorta lying a little to the left of the median line, wind more or less transversely around the bodies of the vertebræ to the spaces between the transverse processes, where each gives a dorsal branch, and then, coursing forward between the abdominal muscles, terminates, by anastomosing with the other arteries of the abdominal wall.

Relations.—As they wind around the bodies of the vertebræ they pass beneath the sympathetic trunk, and the upper two beneath the medial and intermediate crura of the diaphragm. The right arteries also pass beneath the vena cava inferior, and the two upper on that side beneath the cisterna chyli. The arteries on both sides then dip beneath the tendinous arch thrown across the sides of the bodies of the vertebræ by the psoas, and continue beneath this muscle until they arrive at the interval between the transverse processes of the vertebræ and the medial edge of the quadratus lumborum. While under cover of the psoas they are accompanied by rami communicantes of the sympathetic and by the lumbar veins. A little anterior

to the transverse processes they are crossed by branches of the lumbar plexus of nerves, and here usually cross in front of the ascending lumbar vein. They now pass behind the quadratus lumborum, with the exception sometimes of the fourth, which may pass in front of the muscle. At the lateral edge of the quadratus they run between the transversus and the internal oblique, and then, after perforating the internal oblique, between the internal and external oblique. Finally, much diminished in size, they enter the rectus, and give off one or more anterior cutaneous branches, which accompany the branches of thoracic and the iliohypogastric nerves to the skin. They anastomose with the lower intercostal, iliolumbar, deep circumflex iliac, and inferior epigastric arteries.

The **branches of the lumbar arteries** are:

(*a*) **Vertebral** branches which supply the bodies of the vertebræ and their ligaments.

(*b*) **Muscular** branches to the psoas, quadratus lumborum, and to the oblique muscles of the abdomen.

(*c*) The **dorsal** branch [r. dorsalis]. This is of large size, and passes backward in company with the dorsal branch of the corresponding lumbar nerve between the transverse processes above and below, the intertransversalis medially and the quadratus lumborum laterally, to the muscles of the back. On reaching the interval between the longissimus dorsi and multifidus spinæ, it divides into a lateral and a medial branch. The former ends in the multifidus, the latter and larger supplies the sacrospinalis, and gives branches which accompany the termi-

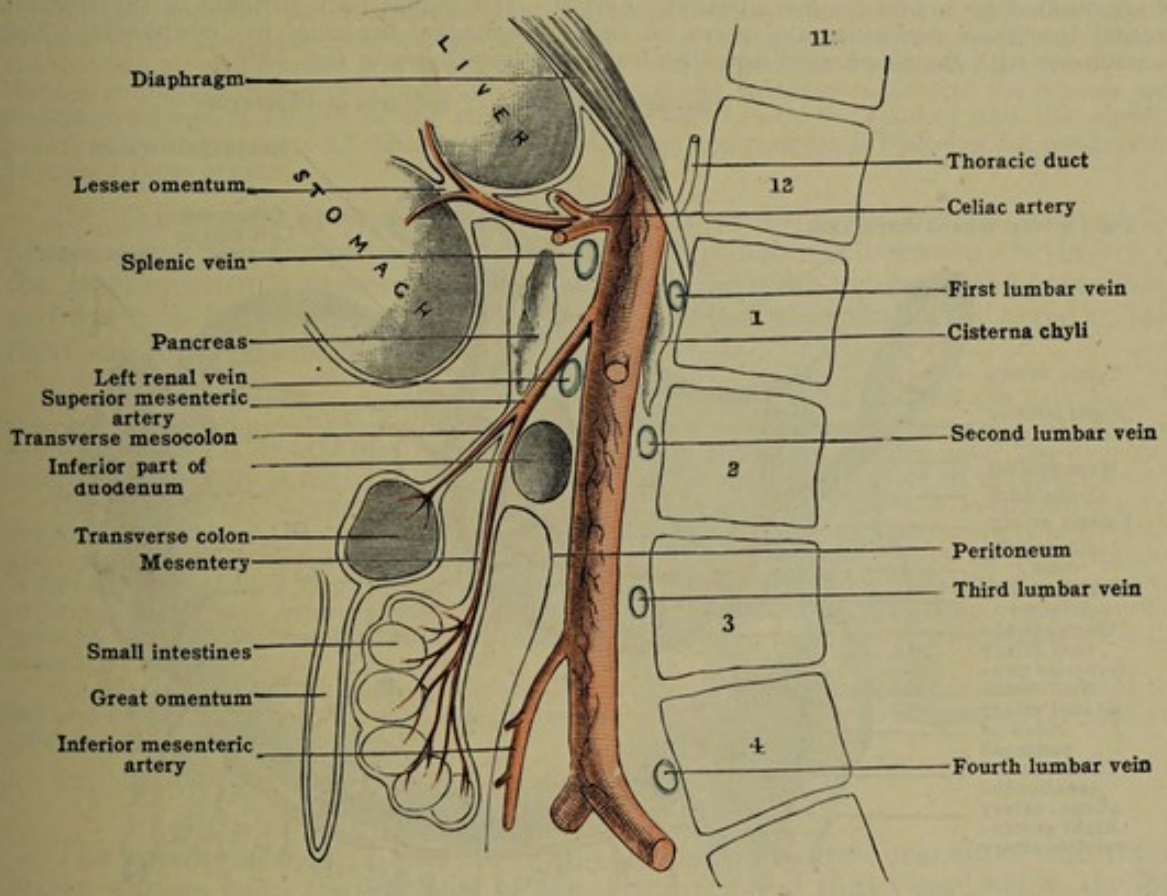

FIG. 557.—SCHEME OF THE ABDOMINAL AORTA. (Walsham.)

nation of the dorsal nerves to the skin. Just before the artery passes between the transverse processes it gives off a **spinal** branch [r. spinalis], which accompanies the lumbar nerve through the intervertebral foramen into the vertebral canal (see p. 662).

(*d*) **Renal** branches of small size pass forward in front of the quadratus lumborum to the capsule of the kidney. They anastomose with the renal artery. A communication is thus established between the renal arteries and the arteries supplying the lumbar region.

B. THE VISCERAL BRANCHES OF THE ABDOMINAL AORTA

THE CELIAC ARTERY

The **celiac** artery [a. cœliaca] or **celiac axis,** is a short thick trunk arising from the front of the aorta between the medial crura of the diaphragm a little below the aortic opening. It passes horizontally forward above the upper margin of the pancreas for about half an inch, and then breaks up into three branches for the supply of the stomach, duodenum, spleen, pancreas, liver, and gall-bladder (fig. 558).

Relations.—**In front** is the lesser omentum; **behind,** the aorta; **above,** the left lobe of the liver; **below,** the pancreas; to the **right,** the right celiac (semilunar) ganglion and caudate lobe of the liver; to the **left,** the left celiac (semilunar) ganglion and the cardiac end of the stomach. It is closely surrounded by the dense celiac (solar) plexus of sympathetic nerves.

The **branches of the celiac artery** are: (1) the left gastric, (2) the hepatic, and (3) the splenic arteries.

1. The Left Gastric Artery

The **left gastric** [a. gastric sinistra] (fig. 558), the smallest of the three branches of the celiac artery, courses at first upward and to the left toward the cardiac end of the stomach, where it turns sharply round, and then, following the lesser curvature of the stomach, descends from left to right toward the pylorus. It anastomoses with the right gastric branch of the hepatic artery, which has proceeded from the opposite direction, the two branches thus forming a continuous arterial arch corresponding to the lesser curvature of the stomach.

The artery at first lies behind the posterior layer of the omental bursa of peritoneum and then curves forward around the left side of the superior recess. In so doing, it raises a crescentic ridge of peritoneum, the left gastro-pancreatic fold. Reaching the area uncovered by peritoneum near the cardiac end of the stomach it passes, between the layers of the lesser omentum, in which it then runs to its terminal anastomosis with the right gastric artery. It is surrounded by a plexus of sympathetic nerves. It supplies both surfaces of the stomach around the lesser curvature and gives off small **esophageal** branches [rr. œsophagei] which anastomose with the esophageal branches from the thoracic aorta (fig. 558).

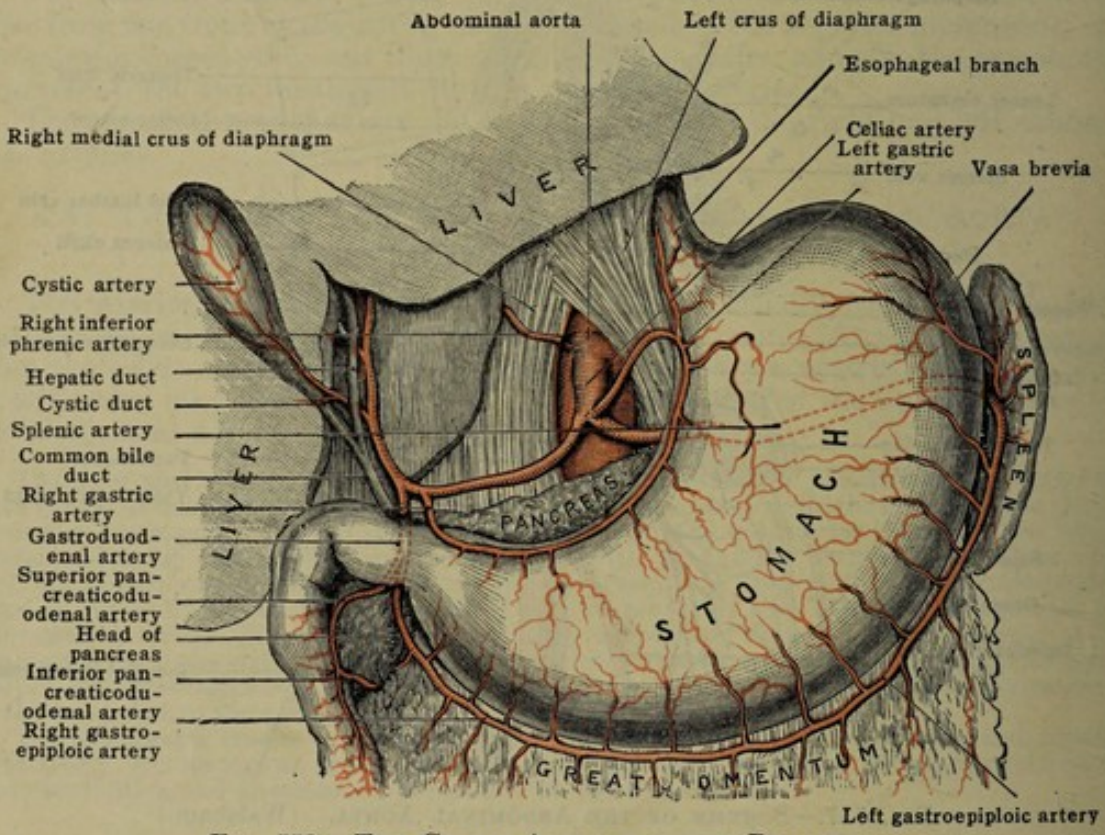

Fig. 558.—The Celiac Artery and its Branches.

2. The Hepatic Artery

The **hepatic artery** [a. hepatica] (a. hepatica communis NK) is the largest branch of the celiac artery in the fetus, but intermediate in the adult between the left gastric and the splenic. It arises on the right side of the celiac artery, and, winding upward and to the right to the porta (portal fissure) of the liver, there breaks up into two chief branches for the supply of the right and left lobes of that organ. It at first courses forward and to the right along the upper border of the head of the pancreas, behind the posterior layer of the peritoneal omental bursa, to the upper margin of the duodenum, where it passes forward in the right gastro-pancreatic fold, which limits the superior recess of the bursa on the right. It then runs between the two layers of the lesser omentum, and ascends along with the hepatic duct which lies to its right, and with the portal vein which lies behind it (figs. 556, 558).

The **branches of the hepatic artery** are: (1) the right gastric; (2) the gastroduodenal; (3) the hepatic proper.

(1) The **right gastric** artery [a. gastrica dextra] arises from the hepatic as the latter vessel enters the lesser omentum, and, descending to the pylorus, there

turns to the left, and, ascending from right to left, anastomoses along the lesser curvature of the stomach, as already mentioned, with the left gastric artery, which descends from the opposite direction.

(2) The **gastroduodenal** artery [a. gastroduodenalis] arises from the hepatic a little beyond the right gastric. It descends behind the first part of the duodenum to the lower border of the pylorus, where it divides into the **right gastroepiploic** and the **superior pancreaticoduodenal.** It varies from 1.2 to 2.5 cm. (½ to 1 in.) in length.

(*a*) The **right gastroepiploic** artery [a. gastroepiploica dextra] passes from right to left along the greater curvature of the stomach between the layers of the great omentum, and anastomoses with the left gastroepiploic branch of the splenic. From this anastomotic arch are given off: (i) **Ascending** or **gastric** branches, which supply the anterior and posterior surfaces of the stomach, and anastomose with the descending gastric branches of the arteries along the lesser curvature. (ii) **Epiploic** [rr. epiploici] or **omental branches**—long slender vessels which descend between the two anterior layers of the great omentum, and then, looping upward, anastomose with similar slender branches given off from the middle and left colic, and passing down in like manner between the posterior layers of the great omentum.

(*b*) The **superior pancreaticoduodenal** [a. pancreaticoduodenalis superior]—the smaller division of the gastroduodenal—arises from that vessel as it passes behind the first portion of the duodenum, and courses downward behind the peritoneum, in the anterior groove between the descending portion of the duodenum and the pancreas, to anastomose with the inferior pancreaticoduodenal, a branch of the superior mesenteric. Both the inferior and the superior pancreaticoduodenal give off **duodenal** [rr. duodenales] and **pancreatic** branches [rr. pancreatici] to supply these organs.

(3) The **hepatic artery proper** [a. hepatica propria] is the continuation of the hepatic after the gastroduodenal has arisen. It ascends between the layers of the lesser omentum, preserving the relations of the main artery to the portal vein and common bile (and hepatic) duct, and divides, near the porta hepatis, into **right** and **left** branches.

(*a*) The **right branch** [r. dexter], given off at the porta (portal fissure) of the liver, runs to the right either behind the hepatic and cystic ducts, or between these structures. At the right end of the porta it divides into branches, which again subdivide as they enter the liver substance for the supply of the right lobe. As it crosses the cystic duct it gives off the cystic artery.

The **cystic** artery [a. cystica] (a. vesicæ felleæ NK) courses forward and downward through the angle formed by the union of the hepatic and cystic ducts, and just before it reaches the gall-bladder divides into a superficial and deep branch. The former breaks up into a number of small vessels, which ramify over the free surface of the gall-bladder beneath the peritoneal covering, and furnish branches to the muscular and mucous coats. The deep branch ramifies between the gall-bladder and the liver-substance, supplying each, and anastomosing with the superficial branch.

(*b*) The **left** branch [r. sinister], the smaller division of the hepatic artery, runs toward the left end of the porta hepatis, and, after giving off a distinct branch to the caudate (Spigelian) lobe, enters the left lobe of the liver.

3. The Splenic Artery

The **splenic** artery [a. lienalis] (fig. 558)—the largest branch of the celiac artery—arises from the left side of the termination of that vessel below the left gastric, and passes along the upper border of the pancreas in a tortuous manner to the spleen. It at first lies behind the posterior wall of the bursa omentalis, but on nearing the spleen enters the phrenolienal (lienorenal) ligament, and there breaks up into numerous branches, which enter the hilus and supply the organ. It crosses in front of the left crus of the diaphragm and the upper end of the left kidney and is placed above the splenic vein.

The **branches of the splenic artery** are: (*a*) The pancreatic; (*b*) the left gastroepiploic; (*c*) the vasa brevia; and (*d*) the terminal.

(*a*) The **pancreatic** branches (rr. pancreatici) arise from the splenic at varying intervals as that vessel courses along the upper margin of the pancreas and enter to supply the organ. One larger branch usually arises from the splenic about the junction of its middle with its left third. Entering the pancreas obliquely, it runs from left to right, commonly above, and a little behind, the pancreatic duct, which it supplies together with the substance of the organ.

(*b*) The **left gastroepiploic** [a. gastroepiploica sinistra] arises from the splenic near the greater curvature and below the fundus of the stomach and, passing between the anterior layers of the great omentum, descends along the greater curvature of the stomach from left to right, and anastomoses with the right gastroepiploic. Like that vessel, it gives off **ascending** or **gastric** branches to the anterior and posterior surfaces of the stomach respectively, and long slender **descending epiploic** or **omental** branches to the great omentum which anastomose with like branches from the right and left colic arteries.

(*c*) The **vasa brevia** [aa. gastricæ breves] come off from the splenic just before it divides into its terminal branches, or from some of the terminal branches themselves. Passing from

between the folds of the phrenolienal ligament into those of the gastrolienal, they reach the fundus of the stomach, where, ramifying over its anterior and posterior surfaces, they anastomose with the left gastric and left gastroepiploic arteries.

(*d*) The **splenic** or **terminal** branches, five to eight or more in number, are given off from the splenic as it lies in the phrenolienal ligament, and, entering the spleen at the hilum, are distributed as noted in the description of that organ.

THE SUPERIOR MESENTERIC ARTERY

The **superior mesenteric artery** [a. mesenterica superior] arises from the front of the aorta a little below the celiac, which it nearly equals in size; sometimes the two vessels arise by a common trunk. Lying at first behind the pancreas and splenic vein, it soon passes forward between the lower border of the pancreas and the upper border of the inferior portion of the duodenum. It here gives its middle colic branch and, crossing the inferior part of the duodenum, it enters the mesentery, in which it runs in the form of a curve with its convexity to the left, to the cecum, where it anastomoses with its ileocolic branch. Its vein lies to its right side above, having previously crossed obliquely in front of the artery from the left. It is surrounded by the mesenteric plexus of nerves. The uncinate process of the head of the pancreas dips in behind the vessel.

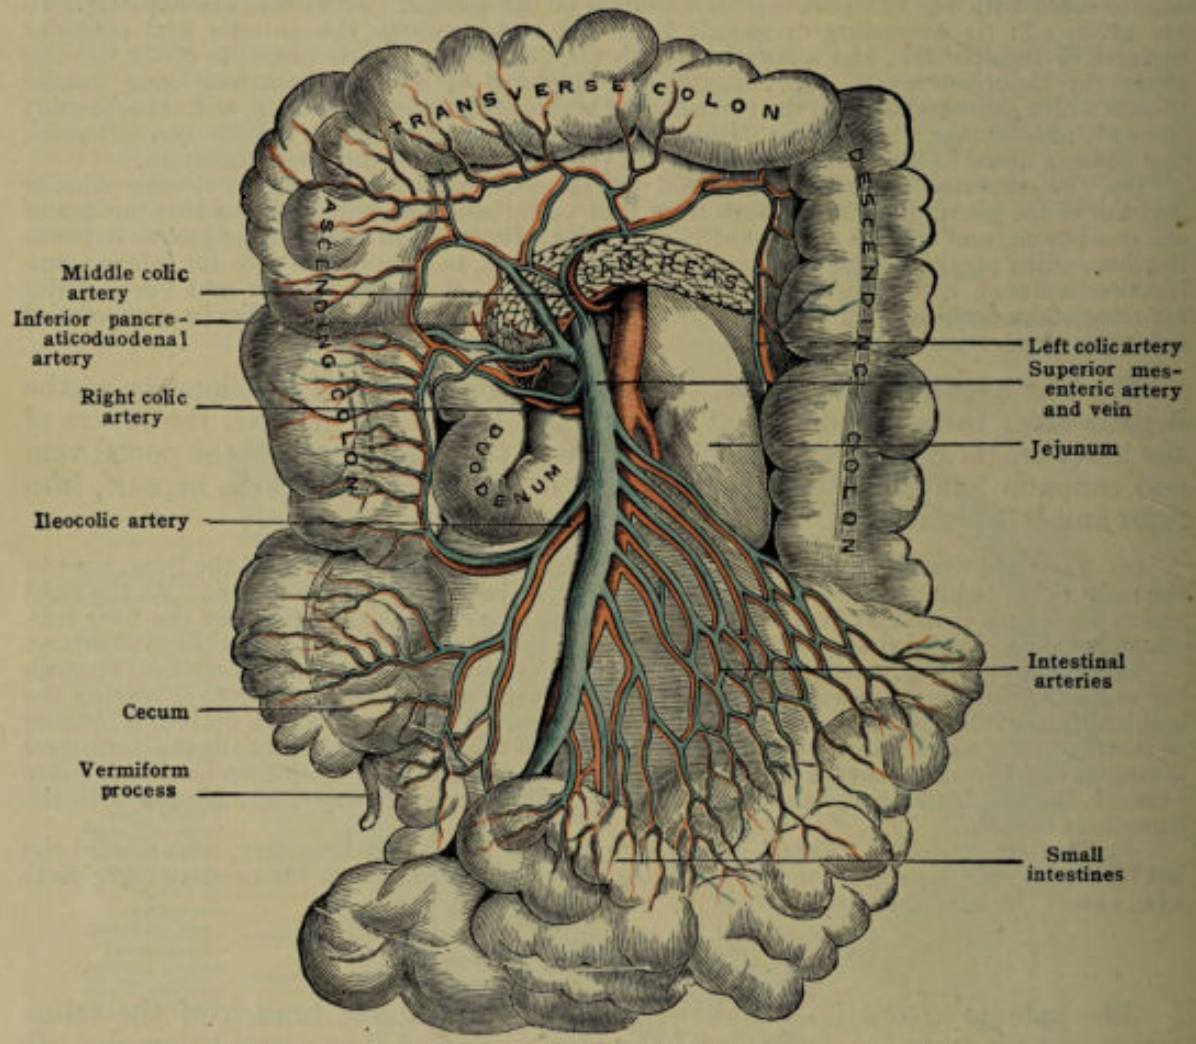

FIG. 559.—THE SUPERIOR MESENTERIC ARTERY AND VEIN.
(The colon is turned up, and the small intestines are drawn over to the left side.)

The **branches of the superior mesenteric** are: (1) the inferior pancreaticoduodenal; (2) the intestinal arteries; (3) the ileocolic; (4) the right colic; and (5) the middle colic (fig. 559).

(1) The **inferior pancreaticoduodenal** [a. pancreaticoduodenalis inferior] artery arises either from the superior mesenteric as that vessel emerges from the contiguous margins of the pancreas and inferior part of the duodenum or from its first intestinal branch. Crossing behind the superior mesenteric vein, it courses upward and to the right between the head of the pancreas and the duodenum, and beneath the ascending layer of the transverse mesocolon, to anastomose with the superior pancreaticoduodenal artery.

(2) The **intestinal** arteries [aa. intestinales] arise from the convex side of the superior mesenteric both before and after it enters the mesentery. Varying from twelve to sixteen in number,

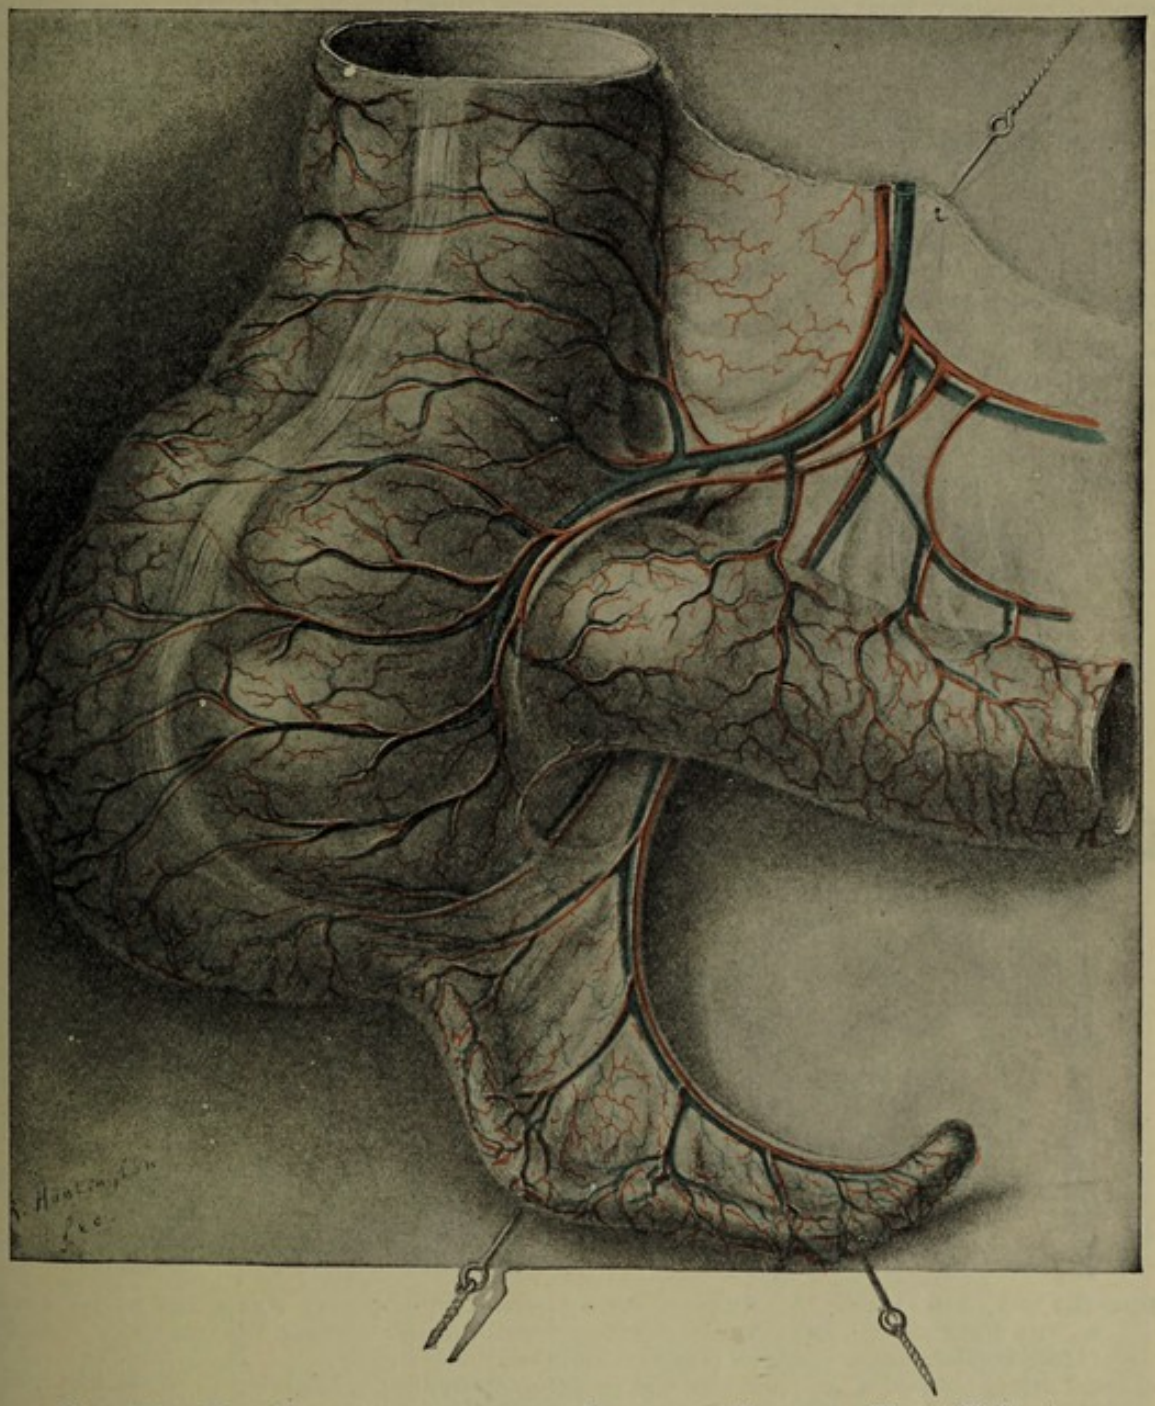

FIG. 560.—THE BLOOD-VESSELS OF THE ILEOCECAL REGION. (From Kelley.)

(Arteries red, veins blue.) The peritoneal covering is removed so as to show the vessels more clearly. Above and to the right are seen the cut ends of the ileocolic artery and vein. This artery gives off a branch to the ascending colon and a posterior and anterior cecal artery, the latter descending through the ileocolic fold. A short anastomosis connects the ileocolic with the mesenteric. The artery of the vermiform process (appendix) is seen to arise from the posterior cecal artery, 2 cm. above the ileum. It passes behind the ileum in the free border of the mesoappendix and gives off five branches (long appendices have 8–12, short appendices, 2–3), which traverse the mesoappendix at fairly regular intervals in the direction of the hilus of the appendix, where they divide into anterior and posterior branches. The branches in the mesoappendix are sometimes seen to anastomose, forming loops of varying size. The terminal branch curves around the tip. The cecoappendicular junction is supplied by a separate branch arising likewise from the posterior ileocecal trunk. This branch may or may not anastomose with the proximal appendicular twig and while in some cases it supplies only the cecum, in others, as in the present case, it sends a few delicate branches into the appendix. At the place where this cecoappendicular artery crosses the ileocecal fold it is seen to give off a delicate recurrent twig to this structure. Throughout their entire course the arteries are accompanied by veins.

they radiate in the mesentery, where each divides into two branches, which inosculate with similar branches given off from the branch above and below. From the primary loops thus formed, secondary loops are derived in like manner, and from these tertiary, and at times quaternary, or even quinary loops. From the ultimate loops terminal **jejunal and ileac** branches [aa. jejunales et ileæ] pass on to the muscular coat of the gut. These terminal vessels bifurcate, the two branches encircling the intestine, and thus forming with those above and below a series of vascular rings surrounding the small intestine throughout its whole length. The first intestinal artery anastomoses with the pancreaticoduodenal artery, and the last (the continuation of the main artery) with the ileocolic. The branches of the superior mesenteric in their course to the intestine also supply the mesentery and the mesenteric glands.

(3) The **ileocolic** artery [a. ileocolica] arises just before the superior mesenteric enters the mesentery and descends behind the peritoneum toward the cecum. Here it divides into a colic branch which tracks upward beneath the peritoneum to anastomose with the descending branch of the right colic; and into an iliac branch which passes between the layers of the mesentery and anastomoses with the termination of the superior mesenteric artery. Near the site of division the ileocolic gives off anterior and posterior cecal branches. From the latter of these arises a cecoappendicular artery, to the cecum and root of the vermiform process, and a main **appendicular** artery [a. appendicularis] (fig. 560).

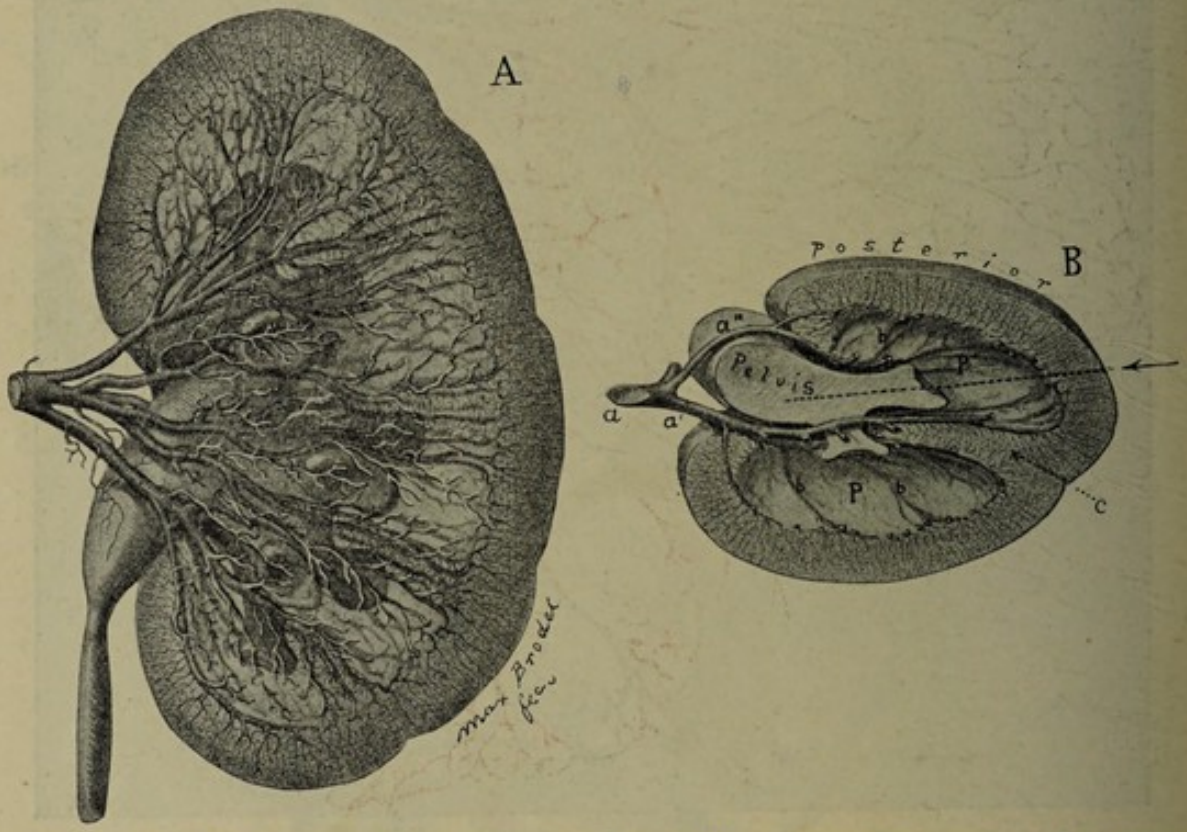

FIG. 561.—A. THE RENAL ARTERY AND THE DISTRIBUTION OF ITS BRANCHES IN RELATION TO THE PELVIS. B. TRANSVERSE SECTION THROUGH THE MIDDLE OF THE SAME KIDNEY. (After Brödel, Johns Hopkins Hospital Bulletin.)

a, renal artery; *a'* and *a''*, its anterior and posterior branches; *b*, branches to pyramids; *c*, line of division between anterior and posterior pyramids. The arrow and dotted line indicate the line of separation between the terminals of the anterior and posterior branches.

(4) The **right colic** [a. colica dextra]—sometimes given off as a common trunk either with the middle colic or with the ileocolic—passes to the right behind the peritoneum to the back of the ascending colon, where it divides into an ascending branch, which enters the mesocolon to anastomose with the descending branch of the middle colic, and a descending branch which anastomoses behind the peritoneum with the ascending or colic branch of the ileocolic.

(5) The **middle colic** [a. colica media], arising from the concavity of the superior mesenteric a little below the pancreas, enters the transverse mesocolon, and divides into two branches—one of which passes to the left and anastomoses with the ascending branch of the left colic; the other, winding downward and to the right, anastomoses with the ascending branch of the right colic.

THE RENAL ARTERIES

The **renal** arteries [aa. renales] come off one on each side of the abdominal aorta, a little below the superior mesenteric and first lumbar arteries, on a level with the first lumbar vertebra. They pass laterally across the intermediate crura of the diaphragm to the kidneys, the right being on a slightly lower plane and somewhat longer than the left, and passing behind the vena cava inferior. In front of each is the corresponding renal vein, and behind, at the hilus of the kidney,

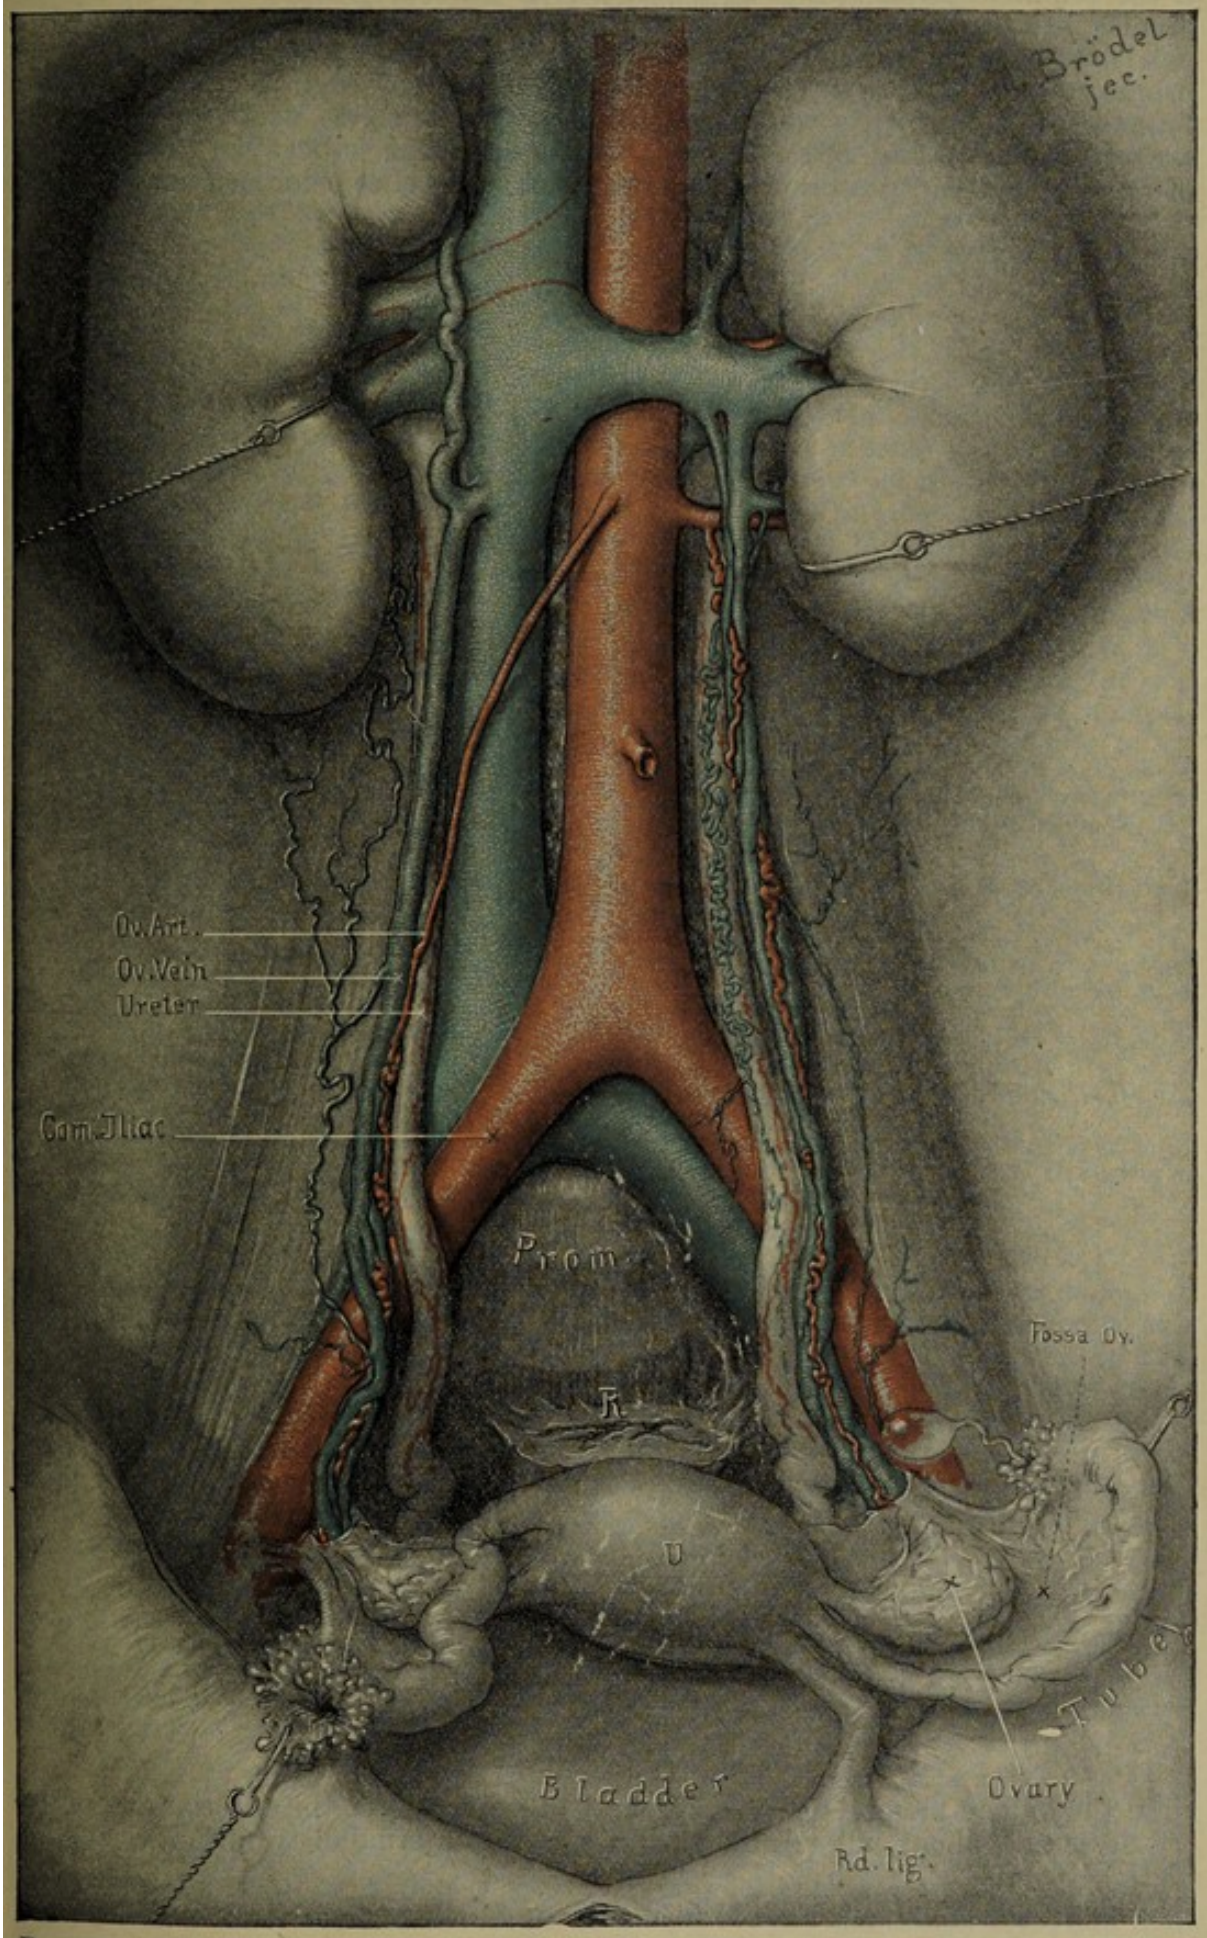

FIG. 562.—THE VASCULAR TRUNKS OF THE LOWER ABDOMEN. (From Kelley, by Brödel.)

is the commencement of the ureter. Each artery as it enters the hilus usually divides into three main stems, one of which passes toward the upper part of the pelvis, a second to its middle portion, and a third to its lower. Each of these primary stems then divides so that there result from seven to nine secondary branches, the majority of which pass anteriorly to the pelvis, while the remainder are posterior to it (fig. 561). No anastomoses take place between the branches of the anterior and posterior secondary stems and hence a longitudinal incision

FIG. 563.—THE OVARIAN VESSELS. (After Clark.)

into the kidney along its curved border, half way between the anterior and posterior calices, will cut only terminal arteries. (For internal distribution see Section XII.)

The **branches of the renal arteries** are:

(1) The **inferior suprarenal** [a. suprarenalis inferior] (rami suprarenales NK) which ascends to the suprarenal body.
(2) The **capsular** or **perirenal** branches to the capsule of the kidney and perirenal fat.
(3) The **ureteral** branch to the upper end of the ureter.

THE MIDDLE SUPRARENAL ARTERIES

The **middle suprarenal** artery [a. suprarenalis media] (a. suprarenalis NK) comes off, one on each side from the aorta, just above the first lumbar artery, and passes laterally to the suprarenal body, across the crura of the diaphragm a little above the renal arteries. In the fetus they are as large as the renals, but in the adult they are much smaller. They anastomose with the superior and inferior suprarenal arteries from the inferior phrenic and renal arteries respectively. For the distribution of the suprarenal vessels within the suprarenal bodies, see Section XIII.

THE INTERNAL SPERMATIC ARTERIES

The **internal spermatic** arteries [a. spermatica interna] (figs. 556, 618), right and left, come off from the front of the abdominal aorta. They diverge from each other as they descend over the aorta and psoas muscle to the abdominal inguinal (internal abdominal) ring, where they are joined by the ductus deferens and, passing with it through the inguinal canal and out of the subcutaneous inguinal (external abdominal) ring, run downward into the scrotum in a tortuous course to the testes. They terminate in branches to the epididymis and testis. Within the abdomen they lie beneath the peritoneum, and cross in their descent over the ureters and distal ends of the external iliac arteries; the right being superficial to the vena cava, and behind the termination of the ileum; and the left beneath the sigmoid colon. In the inguinal canal and in the scrotum the spermatic veins lie in front of the artery, and the ductus deferens lies behind it.

In the fetus these vessels pass in a transversely lateral direction to the testis, which in early fetal life lies in the loin in front of the kidney; but as the testes descend to the scrotum, the vessels become elongated, and are drawn with the testis into the scrotum.

The **branches of the internal spermatic artery** are: (1) ureteral; (2) cremasteric; (3) epididymal; and (4) testicular.

(1) The **ureteral** are small branches given off to the ureter as the spermatic artery crosses it. They anastomose with the other ureteral branches derived from the renal, common iliac, and vesical arteries, and also supply the adjacent retroperitoneal tissue.

(2) The **cremasteric** are small branches given off to the cremaster muscle; they anastomose with the external spermatic branch of the inferior epigastric.

(3) The **epididymal** arteries are distributed to the epididymis, and anastomose with the deferential artery.

(4) The **testicular** arteries [aa. testiculares] are the terminal branches of the spermatic; they perforate the tunica albuginea posteriorly, and are distributed to the body of the organ as described in the section on the TESTIS.

THE OVARIAN ARTERIES

The **ovarian** arteries [aa. ovaricæ] (figs. 562, 563, 571) are the homologs of the internal spermatic arteries in the male, and correspond in their relations in the upper part of their course. They diverge somewhat less, however, and, on reaching the level of the common iliac artery, turn medialward over that vessel and descend tortuously into the pelvis on each side between the folds of the suspensory ligament of the ovaries. Continuing between the layers of the broad ligament of the uterus, the ovarian artery lies below the Fallopian tube and inosculates with the uterine artery forming an arch (fig. 571) from which the ovary and uterine tube are supplied (see Uterine artery, p. 683).

The **ureteral** branches are distributed, as in the male, to the ureter, which is crossed by the ovarian artery as it descends toward the pelvis (shown in fig. 562).

Like the spermatic, the ovarian arteries in the fetus come off at right angles to the aorta, and pass transversely lateralward to the ovaries, which are formed, as are the testes, in the right and left loin in front of the kidneys. They elongate as the ovaries descend into the pelvis. During pregnancy these arteries undergo great enlargement.

THE INFERIOR MESENTERIC ARTERY

The **inferior mesenteric** artery [a. mesenterica inferior], smaller than the superior, arises from the front of the abdominal aorta about 3.7 cm. (1½ in.) above the bifurcation of that vessel. It runs obliquely downward and to the left, behind the peritoneum, across the lower part of the abdominal aorta and then over the left psoas muscle and left common iliac artery. It descends into the pelvis between the layers of the sigmoid mesocolon, and terminates on the rectum as in the superior hemorrhoidal artery. It supplies the lower half of the large

intestine. Its vein lies at first close to the left side, but soon passes upward on the psoas, away from the artery, to end in the splenic vein (fig. 564).

The **branches of the inferior mesenteric** are: (1) the left colic; (2) the sigmoid; and (3) the superior hemorrhoidal.

(1) The **left colic** artery [a. colica sinistra] runs transversely to the left, beneath the peritoneum, and divides into two branches, one of which ascends and, entering the transverse mesocolon, passes to the right, to anastomose with the middle colic. The other descends, and, entering the sigmoid mesocolon anastomoses with the ascending branch of the sigmoid artery.

The distribution of the branches of the left colic and of the sigmoid artery to the colon is similar to that of the colic branches of the superior mesenteric, and does not require a separate description.

(2) The **sigmoid arteries** [aa. sigmoideæ] run downward and to the left over the psoas muscle and, entering the sigmoid mesocolon, are distributed to the iliac and anastomose with the left colic and the lower with the superior hemorrhoidal. The distribution of the branches of the left colic and of the sigmoid arteries to the colon is similar to that of the colic branches of the superior mesenteric, and does not require a separate description. (See p. 670.)

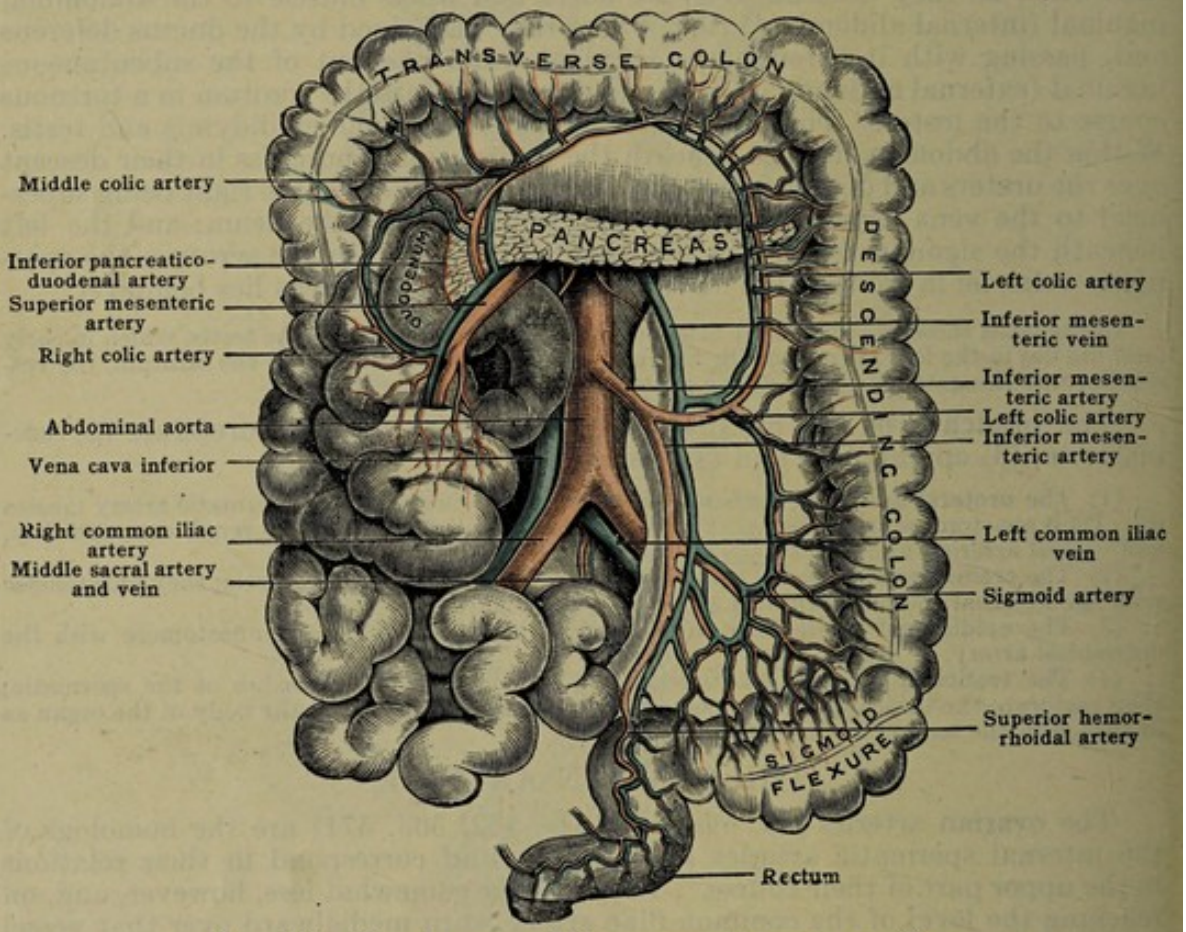

FIG. 564.—THE INFERIOR MESENTERIC ARTERY AND VEIN.
(The colon is turned up, and the small intestines are drawn to the right side.)

(3) The **superior hemorrhoidal** artery [a. hæmorrhoidalis superior] (a. rectalis cranialis NK) (fig. 564) is the continued trunk of the inferior mesenteric. It descends into the pelvis, behind the rectum, between the layers of the sigmoid mesocolon. It bifurcates about 18 cm. (7.2 in.) from its origin and the two branches redivide several times finally forming an arcade parallel with the gut, continuous with that formed by the sigmoid arteries. Offshoots, reaching the muscularis again divide, and the branches, piercing the muscular coat, descend between that coat and the mucous membrane, forming with each other, and with the middle hemorrhoidal arteries—derived from the hypogastric (internal iliac)—a series of small vessels, running longitudinally to the rectum, and parallel with each other as far as the level of the internal sphincter, where, by their anastomosis, they form a series of loops around the lower part of the rectum.

C. THE TERMINAL BRANCHES OF THE ABDOMINAL AORTA

THE MIDDLE SACRAL ARTERY

The **middle sacral** artery [a. sacralis media] (aorta caudalis NK) extends from the bifurcation of the aorta to the tip of the coccyx. As it passes downward into the pelvis, it runs behind the left common iliac vein, the hypogastric plexus of the sympathetic nerve, and the peritoneum. It lies successively upon the intervertebral disk between the fourth and fifth lumbar vertebræ, the fifth

lumbar vertebra, the intervertebral disk between that vertebra and the sacrum, and lower down upon the anterior surface of the sacrum and coccyx. Along the course of the middle sacral artery are some scattered nodules forming the *glomus coccygeum* (see fig. 1166).

(1) The **lowest lumbar** artery [a. lumbalis ima] runs laterally beneath the common iliac artery and vein; and, after giving off a dorsal branch, ramifies over the lateral part of the sacrum, and ends in the iliacus muscle by anastomosing with the circumflex iliac artery. The **dorsal branch** passes to the back between the last lumbar vertebra and the sacrum and ramifies in the gluteus maximus, anastomosing with the lumbar arteries above, and the superior gluteal artery below.

(2) **Lateral sacral** branches, are usually four in number. They are serially homologous with the intercostal and lumbar arteries given off by the aorta. They run laterally, and anastomose with the lateral sacral branches of the hypogastric (internal iliac) artery. They give off small spinal branches, which pass through the sacral foramina, and supply the sacral canal and back of the sacrum.

(3) **Rectal** or **hemorrhoidal** branches pass forward beneath the peritoneum or in the sigmoid mesocolon to the rectum, which they help to supply, and anastomose with the other hemorrhoidal or rectal arteries.

THE COMMON ILIAC ARTERIES

The **common iliac** arteries [aa. iliacæ communes] arise opposite the left side of the middle of the body of the fourth lumbar vertebra, at the bifurcation of the abdominal aorta, and, diverging from each other in the male at about an angle of 60°, and in the female at an angle of 68°, terminate opposite the lumbosacral articulation by bifurcating into the external iliac, which is continued along the brim of the pelvis to the lower limb, and into the hypogastric (internal iliac), which descends into the pelvis minor (fig. 565). The relations differ slightly on the two sides, which may be considered separately.

The Right Common Iliac Artery

The **right common iliac** artery (fig. 565) measures about 5 cm. (2 in.) in length, and is rather longer than the left, in consequence of the aorta bifurcating a little to the left of the median line.

Relations.—**In front** it is covered by the peritoneum, and is crossed by the right ureter a little before its bifurcation, by the ovarian artery in the female, by the termination of the ileum by the terminal branches of the superior mesenteric artery, and by branches of the sympathetic nerve descending to the hypogastric plexus.

Behind, it lies on the right common iliac vein, the end of the left common iliac vein, and the commencement of the vena cava inferior which separate it from the fourth and fifth lumbar vertebræ and their intervening disks, the psoas muscle, and the sympathetic nerve trunk. Still deeper in the groove between the fifth vertebra and the psoas are the lumbosacral trunk the obturator nerve, and the iliolumbar artery.

To the **right side** are the beginning of the vena cava inferior, the end of the right common iliac vein, and the psoas muscle. The muscle, however, is separated from the upper part of the artery by the vena cava inferior.

To the **left side** are the right common iliac vein, the termination of the left common iliac vein, and the hypogastric plexus.

The Left Common Iliac Artery

The **left common iliac** artery, 4 cm. (1.6 in.) in length, is a little shorter and thicker than the right.

Relations.—**In front** it is covered by the peritoneum and is crossed by the ureter, the ovarian artery in the female, branches of the sympathetic nerve descending to the hypogastric plexus, the termination of the inferior mesenteric artery, the sigmoid colon, and the sigmoid mesocolon.

Behind are the lower border of the body of the fourth lumbar vertebra, the disk between the fourth and fifth lumbar vertebra, the body of the fifth lumbar vertebra, and the disk between it and the sacrum. Crossing deeply behind the artery between the fifth lumbar vertebra and the psoas, are the obturator nerve, the lumbosacral trunk, and the iliolumbar artery.

To the **left side** is the psoas muscle.

To the **right side** are the left common iliac vein, the hypogastric plexus, and the middle sacral artery.

Collateral Circulation

The **collateral circulation** after obstruction or ligature of the common iliac artery is carried on chiefly (fig. 574) by the anastomosis of the middle sacral with the lateral sacral; the internal mammary with the epigastric; the lumbar arteries of the aorta with the iliolumbar and deep circumflex iliac; the pubic branch of the epigastric with the pubic branch of the obturator; the posterior branches of the sacral arteries with the superior gluteal (gluteal); the superior hemorrhoidal from the inferior mesenteric, with the hemorrhoidal branches of the hypogastric (in-

ternal iliac) and pudic; the ovarian arteries from the aorta with the uterine branches of the hypogastric (internal iliac); and by the anastomosis across the middle line of the pubic branch of the obturator with the like vessel of the opposite side; the lateral sacral with the opposite lateral sacral; and the vesical, hemorrhoidal, uterine, and vaginal branches of the hypogastric with the corresponding branches of the opposite hypogastric (internal iliac).

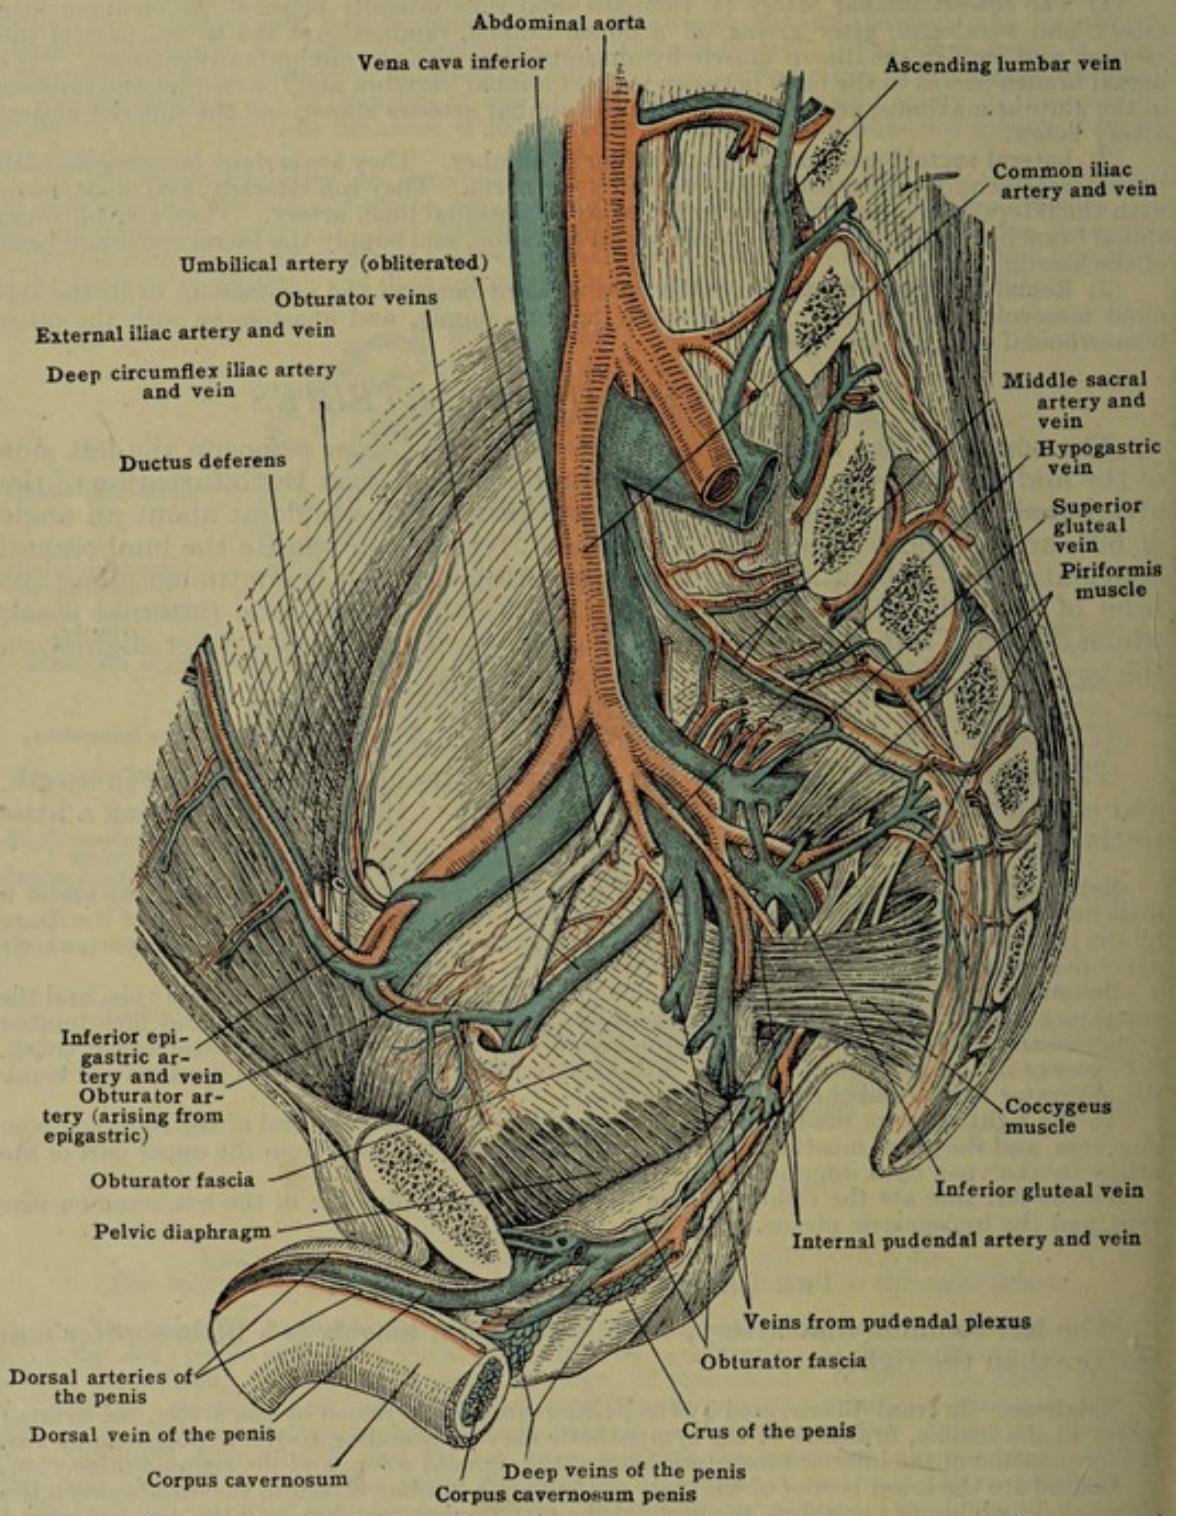

FIG. 565.—BLOOD-VESSELS OF THE MALE PELVIS. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

BRANCHES OF THE COMMON ILIAC ARTERY

The **branches of the common iliac artery** (fig. 565) are:—(1) The hypogastric (internal iliac); and (2) the external iliac.

A few small, unimportant branches are distributed to the peritoneum and subperitoneal fat. They anastomose with vessels given off from the lumbar, inferior phrenic, and renal arteries, forming a subperitoneal arterial anastomosis. The ureter as it crosses the artery receives small twigs which anastomose with the ureteral arteries given off from the internal spermatic above, and with those derived from the vesical arteries below.

THE HYPOGASTRIC ARTERY

The **internal iliac** or **hypogastric** artery [a. hypogastrica] (a. ilica interna NK) (figs. 565, 566), arises at the bifurcation of the common iliac opposite the lumbosacral articulation. It descends into the pelvis minor medially to the common iliac and external iliac veins, and arches forward to become continuous with the lateral umbilical ligament.

In the fetus the hypogastric artery is larger than the external iliac; for through it the fetal blood is returned to the placenta. The common iliac-hypogastric trunk replaces the proximal part of the original umbilical branch of the aorta, which disappears at an early stage of develop-

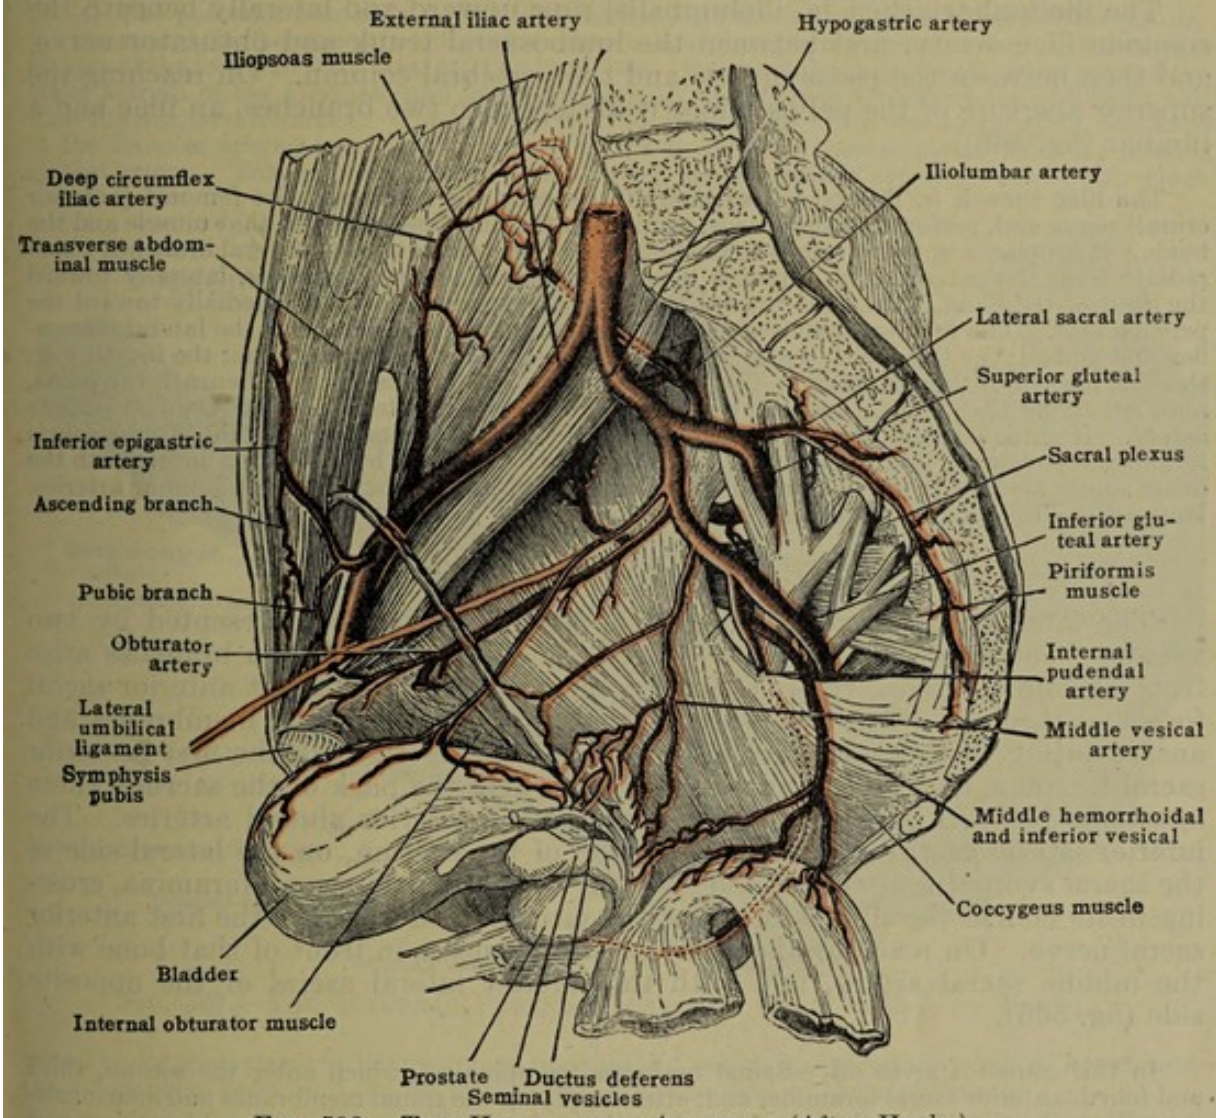

FIG. 566.—THE HYPOGASTRIC ARTERY. (After Henle.)

ment. The larger part of the remainder of the umbilical artery is reduced, shortly after birth, to an impervious cord, the lateral umbilical ligament.

Relations.—Laterally, the hypogastric artery rests on the common iliac vein and the termination of the external iliac vein, which separate it from the medial margin of the psoas muscle, and the obturator nerve. **Behind** it rests on the hypogastric vein. **In front,** it is covered by the peritoneum, and is crossed by the ureter.

The **branches of the hypogastric artery** may be divided into parietal and visceral sets. The **parietal** branches are: (1) the iliolumbar; (2) the lateral sacral; (3) the obturator; (4) the internal pudendal and (5) the gluteal arteries.

The **visceral** branches are: (1) the umbilical; (2) the inferior vesical; (3) the deferential; (4) the middle hemorrhoidal; and (5) the uterine.

The branching of the hypogastric artery is subject to great variation. While some branches take direct origin from the artery, many arise indirectly from it, being associated with others by means of a common trunk of origin. The studies of Adachi, Jastschinski, Lipschitz and others show that the large parietal branches, the superior gluteal, the inferior gluteal and the internal pudendal arise in that order, although the origin of any two or all of them may be united by a common trunk of origin. The so-called anterior division of the artery (formed to a large extent by a trunk common to the origin of the inferior gluteal and internal pudendal arteries) may therefore not exist at all; nor may the posterior division (formed by the superior

gluteal associated only with the iliolumbar and lateral sacral arteries). The obturator may arise separately from the hypogastric or in common with one or both of the gluteal arteries. The iliolumbar and lateral sacral arteries are most commonly associated with the superior gluteal. Of the visceral branches, the superior vesical is almost invariably the last direct branch of the hypogastric. The others vary greatly as to site of origin. The uterine seems most frequently to be a direct branch of the artery, from which the inferior vesical and deferential often arise by a common trunk. The middle hemorrhoidal is often associated in origin with the inferior gluteal.

Parietal Branches of the Hypogastric Artery

1. THE ILIOLUMBAR ARTERY

The **iliolumbar** artery [a. iliolumbalis] runs upward and laterally beneath the common iliac artery, first between the lumbosacral trunk and obturator nerve, and then between the psoas muscle and the vertebral column. On reaching the superior aperture of the pelvis minor it divides into two branches, an iliac and a lumbar (fig. 566).

The **iliac** branch [r. iliacus] passes laterally beneath the psoas and the femoral (anterior crural) nerve and, perforating the iliacus, ramifies in the iliac fossa between that muscle and the bone. It supplies a nutrient artery to the bone, and then breaks up into several branches which radiate from the parent trunk, upward toward the sacroiliac synchondrosis, laterally toward the crest of the ilium, downward toward the anterior superior spine, and medially toward the pelvis minor. The first anastomoses with the last lumbar; the second with the lateral circumflex and gluteal; the third with the deep circumflex iliac from the external iliac; the fourth with the iliac branch of the obturator. The **lumbar** branch [r. lumbalis] ascends beneath the psoas, and, supplying that muscle and the quadratus lumborum, anastomoses with the last lumbar artery. It sends a **spinal** branch (r. spinalis) into the vertebral canal through the intervertebral foramen between the last lumbar vertebra and the sacrum; this branch anastomoses with the other spinal arteries. The iliolumbar artery is serially homologous with the lumbar arteries. Hence the similarity in its course and distribution.

2. THE LATERAL SACRAL ARTERIES

The **lateral sacral** artery [a. sacralis lateralis] may be represented by two vessels. The **superior** artery (or branch, in cases in which two branches arise from a common stem), runs downward and medially to the first anterior sacral foramen, through which it passes. After supplying the spinal membranes and anastomosing with the other spinal arteries, it passes through the first posterior sacral foramen, and is distributed to the skin over the back of the sacrum, there anastomosing with branches of the superior and inferior gluteal arteries. The **inferior lateral sacral** descends on the side of the sacrum, on the lateral side of the sacral sympathetic trunk, and medially to the anterior sacral foramina, crossing in its course the slips of origin of the piriformis muscle and the first anterior sacral nerve. On reaching the coccyx it anastomoses in front of that bone with the middle sacral artery, and with the inferior lateral sacral of the opposite side (fig. 566).

In this course it gives off:—**Spinal** branches [rr. spinales], which enter the second, third and fourth anterior sacral foramina, and, after supplying the spinal membranes and anastomosing with each other, leave the spinal canal by the corresponding posterior sacral foramina, and are distributed to the muscle and skin over the back of the sacrum; and **rectal** branches which run forward to the rectum.

At times the lateral sacral arteries are very small, the spinal branches then coming chiefly from the middle sacral. The anastomosing branches between the lateral sacral and middle sacral are regarded as sacral segmental arteries serially homologous with the lumbar and intercostal arteries.

3. THE OBTURATOR ARTERY

The **obturator** artery [a. obturatoria] (fig. 566), sometimes arises from the inferior epigastric (fig. 565) or from the external iliac artery (see p. 686). It runs forward and downward a little below the brim of the pelvis, having the obturator nerve above and the obturator vein below. It here lies between the peritoneum and the endopelvic fascia, but later it passes through the obturator canal, the aperture in the upper part of the obturator membrane. In this course it is crossed by the ductus deferens. On emerging from the obturator canal the artery divides into two branches, anterior and posterior, which wind around the margin of the obturator foramen beneath the obturator externus muscle.

The **branches of the obturator artery** are: (1) the iliac or nutrient branch; (2) the pubic branch; (3) the anterior, and (4) the posterior terminal branches.

(1) The **iliac or nutrient** branch ascends to the iliac fossa, passing between the iliacus muscle and the bone. It supplies a nutrient vessel to the ilium, and anastomoses with the medial branch of the iliac division of the iliolumbar artery.

(2) The **pubic** branch [r. pubicus] comes off from the obturator as that vessel is leaving the pelvis by the obturator canal. It runs upward and medially behind the pubis, anastomosing with its fellow of the opposite side of the body, and with the pubic branch of the inferior epigastric artery. One of the anastomosing channels between the pubic branch of the obturator and pubic branch of the inferior epigastric arteries is sometimes of large size (fig. 566), a fact of surgical interest in that the enlarged vessel may then run around the medial side of the femoral ring (p. 686; fig. 1019).

(3) The **anterior** branch [r. anterior] (medialis NK) runs around the medial margin of the obturator foramen, and anastomoses with the posterior branch and with the medial circumflex artery. It supplies branches to the obturator and adductor muscles.

(4) The **posterior** branch [r. posterior] (lateralis NK) skirts the lateral margin of the obturator foramen, lying between the obturator externus and the obturator membrane. At the lower margin of the foramen it divides into two branches. One branch continues its course around the lower margin of the foramen, and anastomoses with the anterior branch of the obturator and with the medial circumflex. The other branch turns laterally below the acetabulum, and ends in the muscles arising from the tuberosity of the ischium. It anastomoses with the inferior gluteal artery. This branch gives off a small twig, the **acetabular** artery [a. acetabuli], which

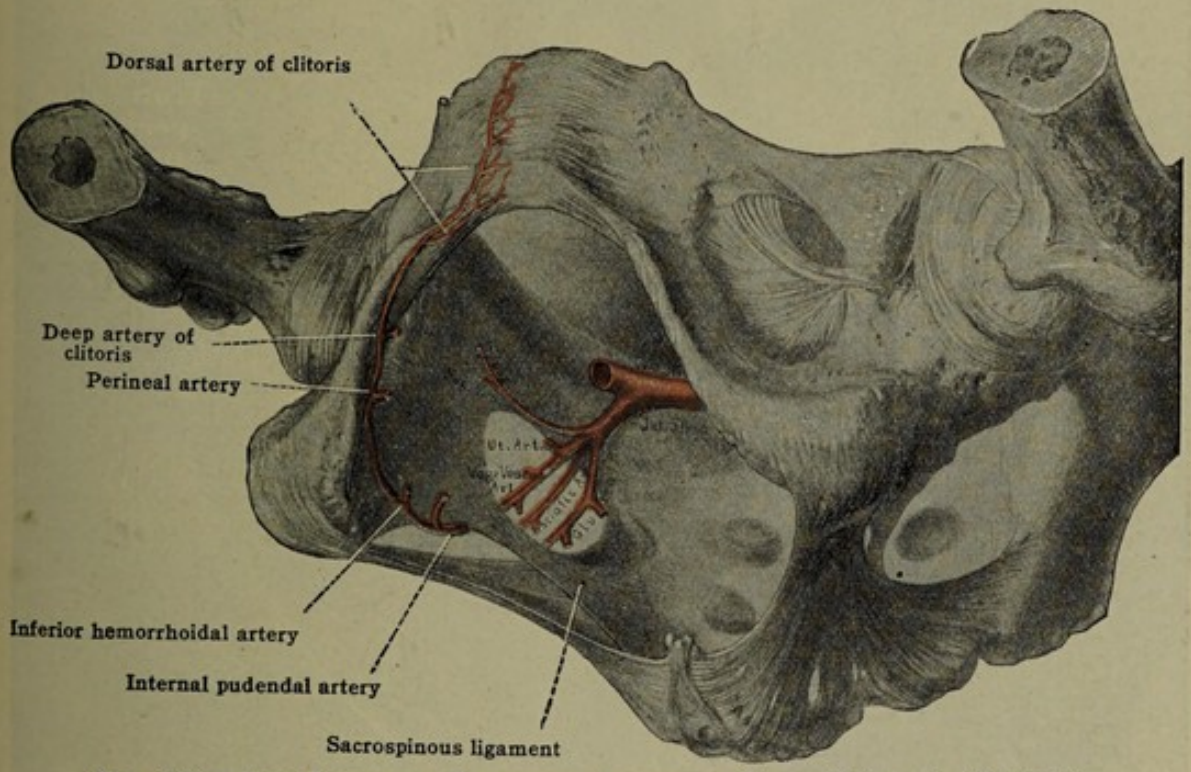

FIG. 567.—THE INTERNAL PUDENDAL ARTERY. (From Kelley, by Brödel.)

passes under the transverse ligament into the hip-joint, where it supplies the synovial membrane, the ligamentum teres, and the fat in the fossa at the bottom of the acetabulum.

4. THE INTERNAL PUDENDAL ARTERY

The **internal pudendal** (pudic) artery [a. pudenda interna] (figs. 567, 568, 569) arises opposite the piriformis muscle and accompanies the inferior gluteal downward to the lower border of the great sciatic foramen. It leaves the pelvis between the piriformis and coccygeus and winds over the ischial spine to enter the ischiorectal fossa through the small sciatic foramen. Running forward in the ischiorectal fossa, in a canal in the obturator fascia, it ends by dividing into the **perineal artery** and the **artery of the penis** (or clitoris).

Relations.—*Within the pelvis*, the artery lies anteriorly to the piriformis muscle and the sacral plexus of nerves, and laterally to the inferior gluteal artery. It passes between the piriformis and coccygeus, with the gluteal artery and pudendal nerve on the medial side, and the nerve to the obturator internus upon the lateral. The sciatic and posterior femoral cutaneous (lesser sciatic) nerves lie still more laterally. *On the ischial spine* the artery retains its relations to the pudendal nerve (which often divides in this situation into its two terminal branches) and the nerve to the obturator internus. It is accompanied by venæ comitantes and covered by the gluteus maximus muscle. *In the ischiorectal fossa* the artery is placed on the lateral wall about 3.5 cm. (1½ in.) above the tuberosity of the ischium. It is accompanied in a canal in the obturator fascia (*Alcock's canal*) by the dorsal nerve of the penis and the perineal nerve, which are respectively above and below the artery.

The **branches of the internal pudendal artery** are:—(1) Small branches to the gluteal region; (2) the inferior hemorrhoidal arteries; and the terminal branches, (3) perineal; and (4) artery of the penis or clitoris.

(1) The **branches of the gluteal region** are:—(*a*) twigs to the gluteus maximus; (*b*) branches accompanying the nerve to the obturator internus; (*c*) a sacral branch which pierces the sacrotuberous ligament and anastomoses with the inferior gluteal artery.

(2) The **inferior hemorrhoidal** artery [a. hæmorrhoidalis inferior] (a. analis NK) (figs. 567, 568) arises at the posterior part of the ischiorectal fossa and, perforating the obturator fascia, at once breaks up into several branches. These, running medially toward the anus, traverse the ischiorectal fat and supply the fascia, skin and the levator ani and external sphincter muscles. The inferior hemorrhoidal branches anastomose with those from the middle and superior hemorrhoidal, and from the gluteal and perineal arteries.

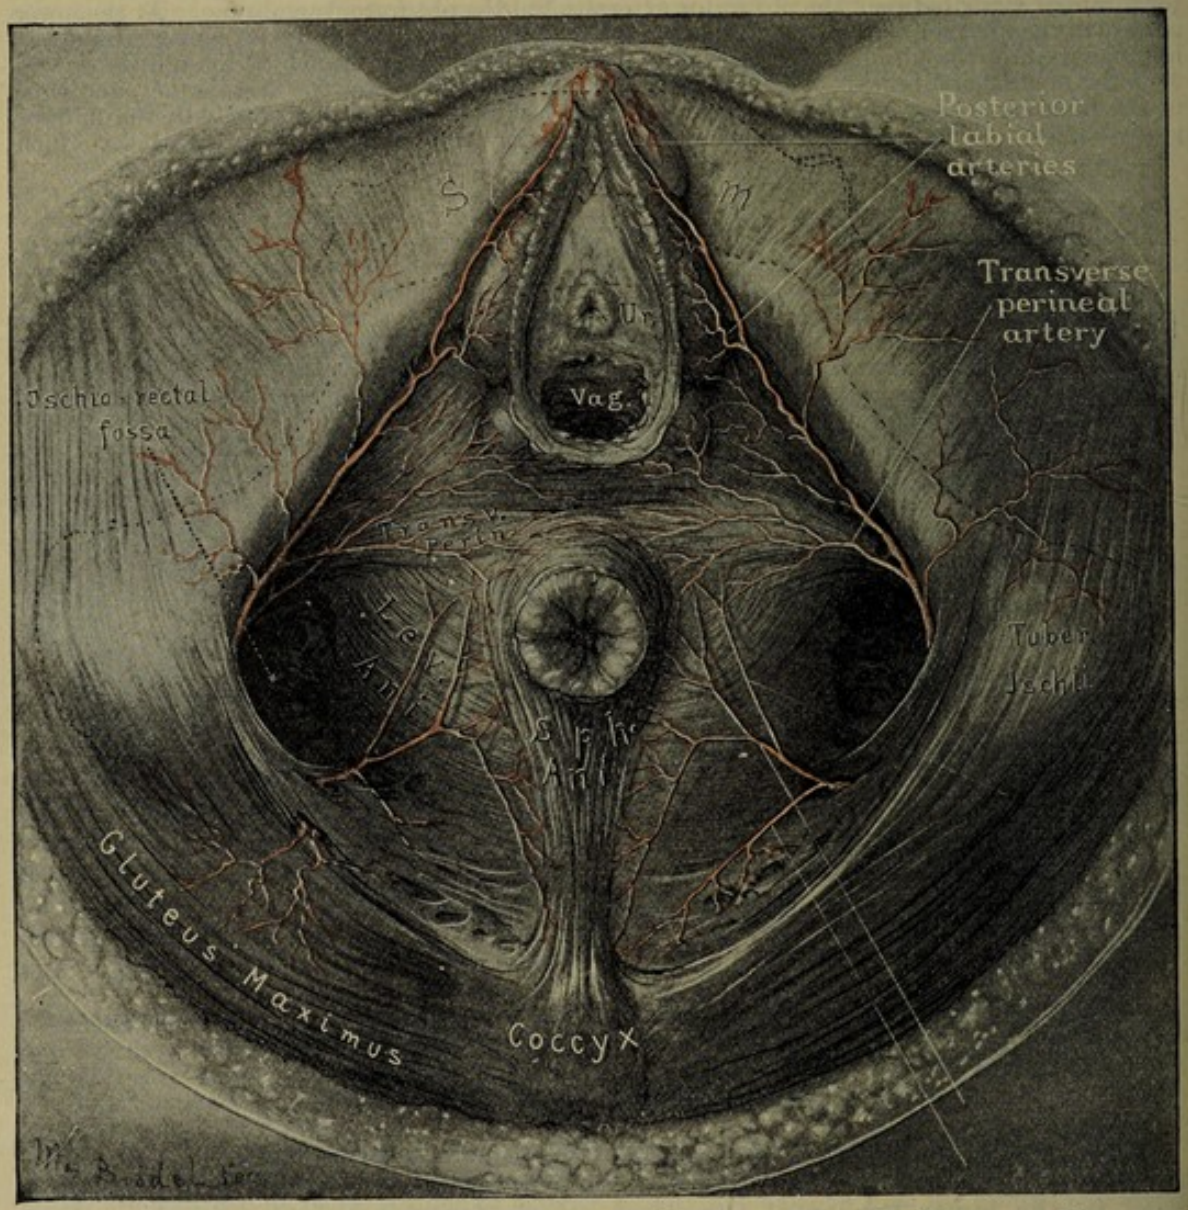

FIG. 568.—THE PERINEAL AND HEMORRHOIDAL BRANCHES OF THE INTERNAL PUDENDAL ARTERIES. (From Kelley, by Brödel.)

(3) The **perineal** artery [a. perinei] (figs. 567, 568), one of the terminal arteries of the internal pudendal, arises at the anterior part of the ischiorectal fossa. It pierces the base of the urogenital diaphragm (triangular ligament), and enters the space deep to Colles's fascia. Here it runs forward between the ischiocavernosus and bulbocavernosus muscles to the scrotum or labium majus and divides into numerous terminal branches. Immediately after piercing the diaphragm, the perineal artery gives off a constant **transverse perineal** branch which runs toward the median line along the superficial transverse perineal muscle. The terminal branches of the perineal are the **posterior scrotal or labial** arteries [aa. scrotales, or labiales posteriores] which ramify on the scrotum or labia majora (according to sex) and anastomose with external pudendal arteries.

(4) The **artery of the penis, or clitoris** [a. penis; a. clitoridis] (figs. 567, 569) pierces the posterior border of the urogenital diaphragm and runs forward between the layers of the diaphragm with the dorsal nerve of the penis along the inferior ramus of the pubis. It traverses the fibers of the deep transverse perineal muscle and of the sphincter of the membranous urethra and ends by dividing into deep and dorsal arteries of the penis, or clitoris, according to sex.

The **branches of the artery of the penis (or clitoris)** are:—(*a*) The artery to the bulb; (*b*) the urethral artery; (*c*) the deep artery, and (*d*) dorsal artery of the penis or clitoris.

(*a*) The **artery of the bulb** [a. bulbi urethræ; a. vestibuli vaginæ] takes a medial direction through the fibers of the m. transversus perinei profundus. It then pierces the inferior fascia of the urogenital diaphragm to reach the bulb, the erectile tissue of which it supplies, in either sex. This vessel also supplies branches to the bulbourethral gland (Cowper's) in the male, or the greater vestibular (Bartholin's) gland in the female.

(*b*) The **urethral** artery [a. urethralis] is a small branch which passes into the corpus cavernosum urethræ (corpus spongiosum) and anastomoses with branches from the artery of the bulb.

(*c*) The **deep artery of the penis or clitoris** [a. profunda penis; a. profunda clitoridis], larger in the male sex, pierces the inferior layer of the urogenital diaphragm near the inferior ramus of the pubis. It enters the crus of the penis (fig. 569) or clitoris, and is distributed in the corpus cavernosum penis.

(*d*) The **dorsal artery of the penis or clitoris** [a. dorsalis penis; a. dorsalis clitoridis] (figs. 567–569), perforates the inferior fascia of the urogenital diaphragm near its apex. The dorsal nerve lies on the lateral side of the artery and joins the dorsal vein (which lies between the

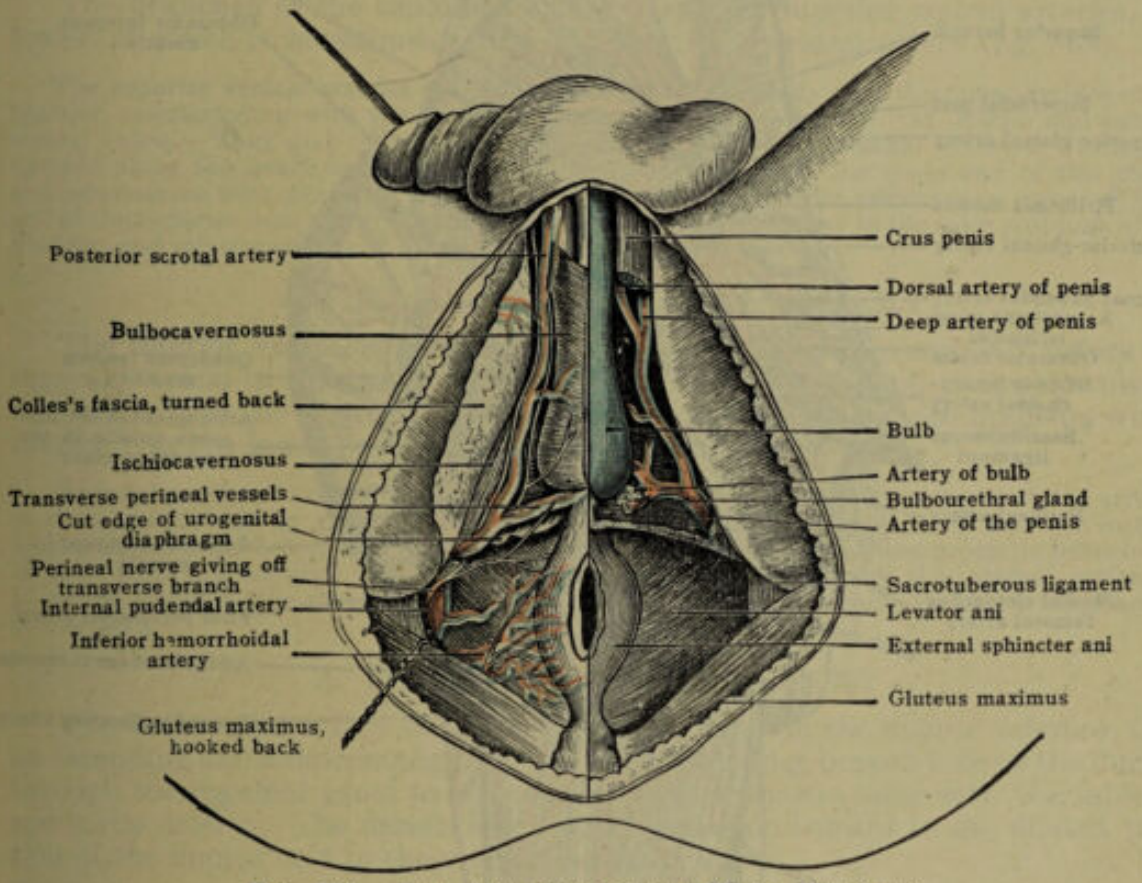

FIG. 569.—THE ARTERIES OF THE MALE PERINEUM.

arteries of either side) on the dorsum of the penis or clitoris. The artery is much larger in the male than the female; in either sex it supplies the glans, corona, and prepuce and anastomoses with the external pudendal artery.

5. THE GLUTEAL ARTERIES

There are two gluteal arteries, the **superior** and **inferior** (fig. 570). The **superior gluteal** artery [a. glutea superior], comes off as a short trunk from the lateral and back part of the hypogastric associated in origin with the iliolumbar and lateral sacral and sometimes with the interior gluteal or with the inferior gluteal and the internal pudendal. Passing backward between the first sacral nerve and the lumbosacral trunk through an osseo-tendinous arch formed by the margin of the bone and the upper edge of the endopelvic fascia, it leaves the pelvis through the great sciatic foramen above the piriformis muscle in company with its vein and the superior gluteal nerve. At its exit posteriorly from the great sciatic foramen it lies under cover of the gluteus maximus and beneath the superior gluteal vein, and in front of the superior gluteal nerve. It here breaks up into two chief parts, the superficial and deep. Its emergence from the pelvis is indicated on the surface by a point situated at the junction of the posterior with the middle third of a line drawn from the anterior superior to the posterior inferior spine of the ilium.

The **branches of the superior gluteal artery** are:—

(*a*) **Within the pelvis,** branches are distributed to the obturator internus, the piriformis, the levator ani, the coccygeus, and the pelvic bones.

(*b*) **External to the pelvis,** the artery divides into a superficial and deep part, the latter again subdividing into a superior and an inferior branch.

The superficial part of the superior gluteal artery breaks up at once into a number of large vessels for the supply of the upper portion of the gluteus maximus, some of them piercing the muscle and supplying the skin over it, and anastomosing with the posterior branches of the lateral sacral arteries; one of larger size, emerging from the muscle near the iliac crest, anasto-

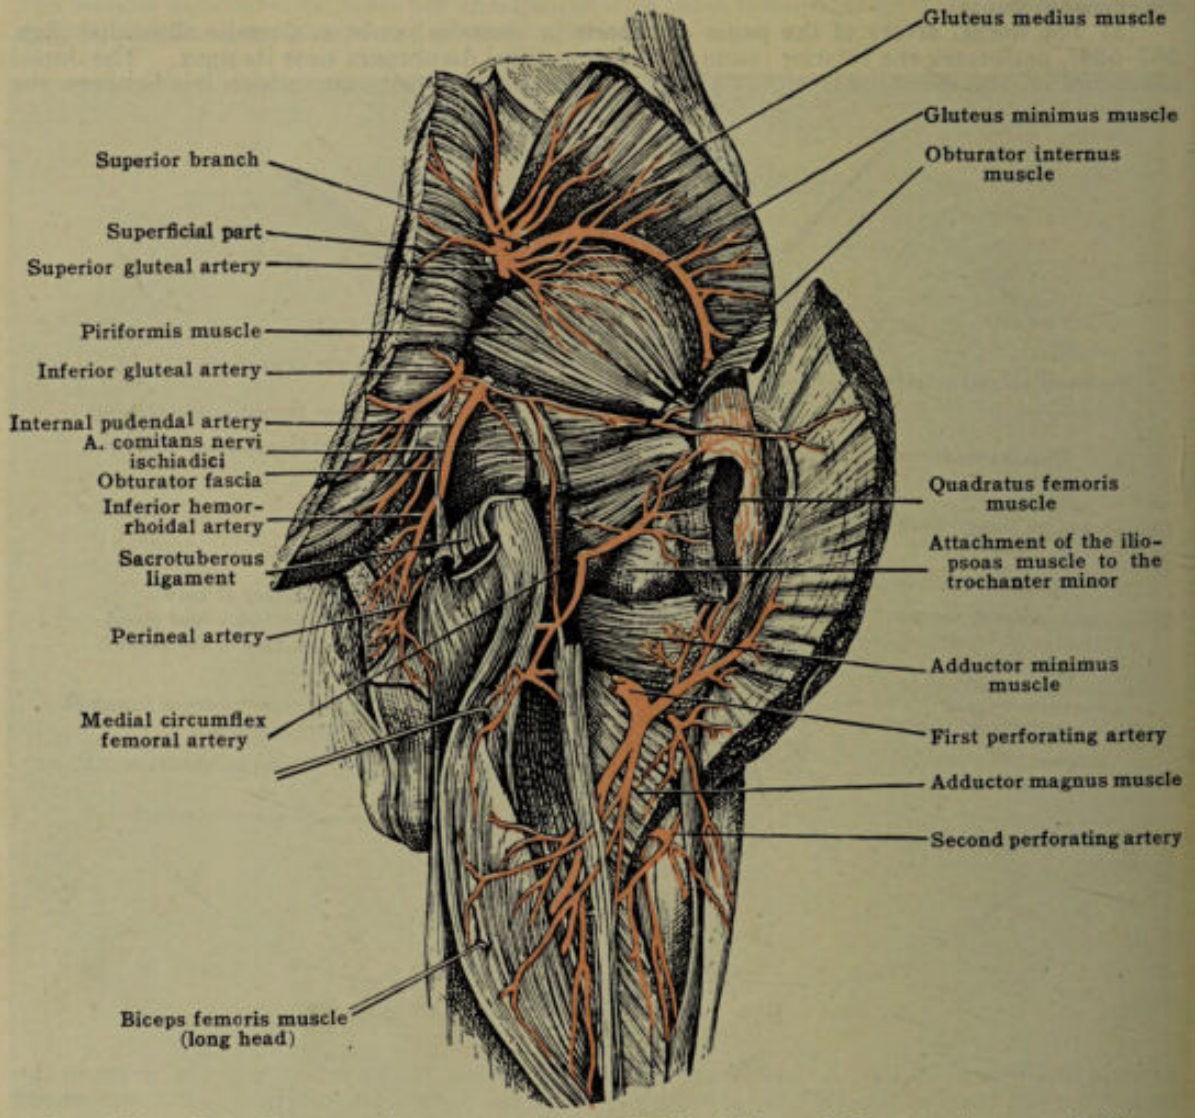

FIG. 570.—THE GLUTEAL ARTERIES. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

moses with the deep circumflex iliac artery. The lower branches to the muscle anastomose with branches of the inferior gluteal (sciatic).

(ii) The deep part of the artery subdivides into two branches. The **superior branch** [r. superior] skirts along the line of origin of the gluteus minimus (fig. 570), between the gluteus medius and the bone, and, emerging in front from beneath these muscles under cover of the tensor fasciæ latæ, anastomoses with the ascending branch of the lateral circumflex and the deep circumflex iliac arteries. The **inferior branch** [r. inferior] passes forward between the gluteus medius and minimus, accompanied by the branch to the tensor fasciæ latæ of the inferior division of the superior gluteal nerve, toward the greater trochanter, where it anastomoses with the ascending branch of the lateral circumflex. It supplies branches to the contiguous muscles and to the hip-joint. The inferior branch before its division gives off the external nutrient artery of the ilium.

The **inferior gluteal** artery [a. glutea inferior], leaves the pelvis below the piriformis muscle, and immediately breaks up into a number of diverging branches. The largest enter the gluteus maximus muscle, where they anastomose with the superior gluteal branches. Others pass to the hip-joint, and the deep muscles around it; a third group passes downward to the hamstring muscles and anastomoses with the medial and lateral circumflex and first perforating; a fourth

slender branch, the **sciatic** artery [a. comitans n. ischiadici], accompanies the sciatic nerve (fig. 570).

Visceral Branches of the Hypogastric Artery

1. THE UMBILICAL ARTERY

The **umbilical** artery in the fetus is the continuation of the hypogastric. Passing forward along the side of the pelvis, it runs beneath the lateral reflection of peritoneum from the bladder, where, after giving off one or more vesical branches, it ceases to be pervious and passes on to the upper part of the bladder. Thence it ascends in the lateral umbilical fold, as a fibrous cord [ligamentum umbilicale laterale] (chorda umbilicalis lateralis NK), to the umbilicus, where it is joined by its fellow of the opposite side. As it lies upon the bladder it is crossed by the ductus deferens.

The **branches of the umbilical artery** are:—(1) Superior vesical arteries, the lowest of which is sometimes called (2) the middle vesical artery (fig. 566).

The **superior vesical** arteries [aa. vesicales superiores] ramify over the upper surface of the bladder, anastomosing with the artery of the opposite side and with the middle and inferior vesical below. They give off the following branches:—(*a*) The **urachal** branches which pass upward along the urachus. (*b*) The **ureteric** branches pass to the lower end of the ureter, and anastomose with the other ureteric arteries. (*c*) The **middle vesical** may come off from one of the superior vesicals or from the umbilical. It is distributed to the sides and base of the bladder, and anastomoses with the other vesical arteries.

2. THE INFERIOR VESICAL ARTERY

The **inferior vesical** artery [a. vesicalis inferior] arises commonly before the superior vesical in common with the deferential (fig. 566), and passes downward and medially to the fundus of the bladder, where it breaks up into branches which ramify over the lower part of the viscus.

It gives branches to the prostate, which supply that organ and anastomose with the arteries of the opposite side by passing through the prostatic plexus of veins, and with the inferior hemorrhoidal branches of the internal pudendal. At times one of these prostatic branches is of large size, and supplies certain of the parts normally supplied by the internal pudendal. It is then known as the **accessory pudendal** and most commonly terminates as the dorsal artery of the penis.

3. THE DEFERENTIAL ARTERY

The **deferential** artery [a. deferentialis] divides, on the ductus deferens, into an ascending and a descending branch. The ascending branch follows the ductus through the inguinal canal to the testis, where it anastomoses with the internal spermatic artery. The descending branch passes downward to the dilated portion of the ductus and to the vesiculæ seminales.

4. THE MIDDLE HEMORRHOIDAL ARTERY

The **middle hemorrhoidal** artery [a. haemorrhoidalis media] (a. rectalis caudalis NK) (fig. 566), variable in origin, most usually arises in common with the internal pudendal. It runs medially to the side of the middle portion of the rectum, dividing into branches which anastomose above with the superior hemorrhoidal derived from the inferior mesenteric, and below with the inferior hemorrhoidal derived from branches of the internal pudendal. Its corresponding vein terminates in the inferior mesenteric vein. In the female it also sends branches to the vagina.

5. THE UTERINE ARTERY

The **uterine** artery [a. uterina] (fig. 571), runs downward and medially through the pelvic connective tissue, crossing the ureter about 12 mm. (½ in.) from the cervix uteri. It then ascends in the parametrium between the layers of the broad ligament at the side of the uterus in a coiled and tortuous manner, and, after giving off a number of tortuous branches which ramify horizontally over the front and back of the uterus, inosculates with the ovarian artery to complete an arch from which the following branches arise:

(1) **Cervical.**—This branch arises from the uterine artery as it crosses the ureter to turn upward on to the uterus. It is directed medially, and divides into three or four branches which pass on to the cervix; one branch anastomosing with its fellow of the opposite side in front and

behind the neck, forming the so-called coronary artery of the cervix. (2) The **tubal** branch [r. tubarius] courses along the lower surface of the tuba uterina (Fallopian tube) as far as fimbriated extremity, and may also send a branch to the ligamentum teres. (3) The **ovarian** branch [r. ovarii] runs along the attached border of the ovary, sending branches to that structure. (4) The **ligamentous** branch is distributed to the round ligament, passing with that structure through the inguinal canal; it anastomoses with the superficial external pudendal artery. (5) The **vaginal** artery [a. vaginalis] is usually a branch of the uterine, and corresponds

FIG. 571.—OVARIAN AND UTERINE AND VAGINAL ARTERIES. (From Kelly, by Brödel.)

to the inferior vesical artery of the male. It passes medially, behind the ureter, to the upper part of the vagina, and sends numerous branches to that structure and also some to the posterior part of the fundus of the bladder.

The branches to the vagina tend to anastomose with one another and with the cervical branch of the uterine, to form a more or less perfect vertical stem in the median line of the vagina, both back and front. This stem is sometimes termed the **azygos artery of the vagina.** Branches also pass to the vagina from the middle hemorrhoidal artery.

THE EXTERNAL ILIAC ARTERY

The **external iliac** artery [a. iliaca externa]—the larger in the adult of the two vessels into which the common iliac divides opposite the lumbosacral articulation

(fig. 565)—extends along the superior aperture of the pelvis minor, lying upon the medial border of the psoas muscle. At the lower margin of the inguinal ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, it passes into the thigh, and takes the name of the femoral.

It measures 8.5 to 10 cm. (3½ to 4 in.) in length. The course of the vessel is indicated by a line drawn from 2.5 cm. (1 in.) below and a little to the left of the umbilicus to a point midway between the symphysis pubis and the anterior superior spine of the ilium. If this line is divided into thirds, the lower two-thirds of it will indicate the situation of the external iliac, and the upper third that of the common iliac. The external iliac vein, the continuation upward of the femoral vein from the thigh, lies to the medial side of the artery but on a slightly deeper plane, and, just before its termination, extends a little behind the artery on the right side.

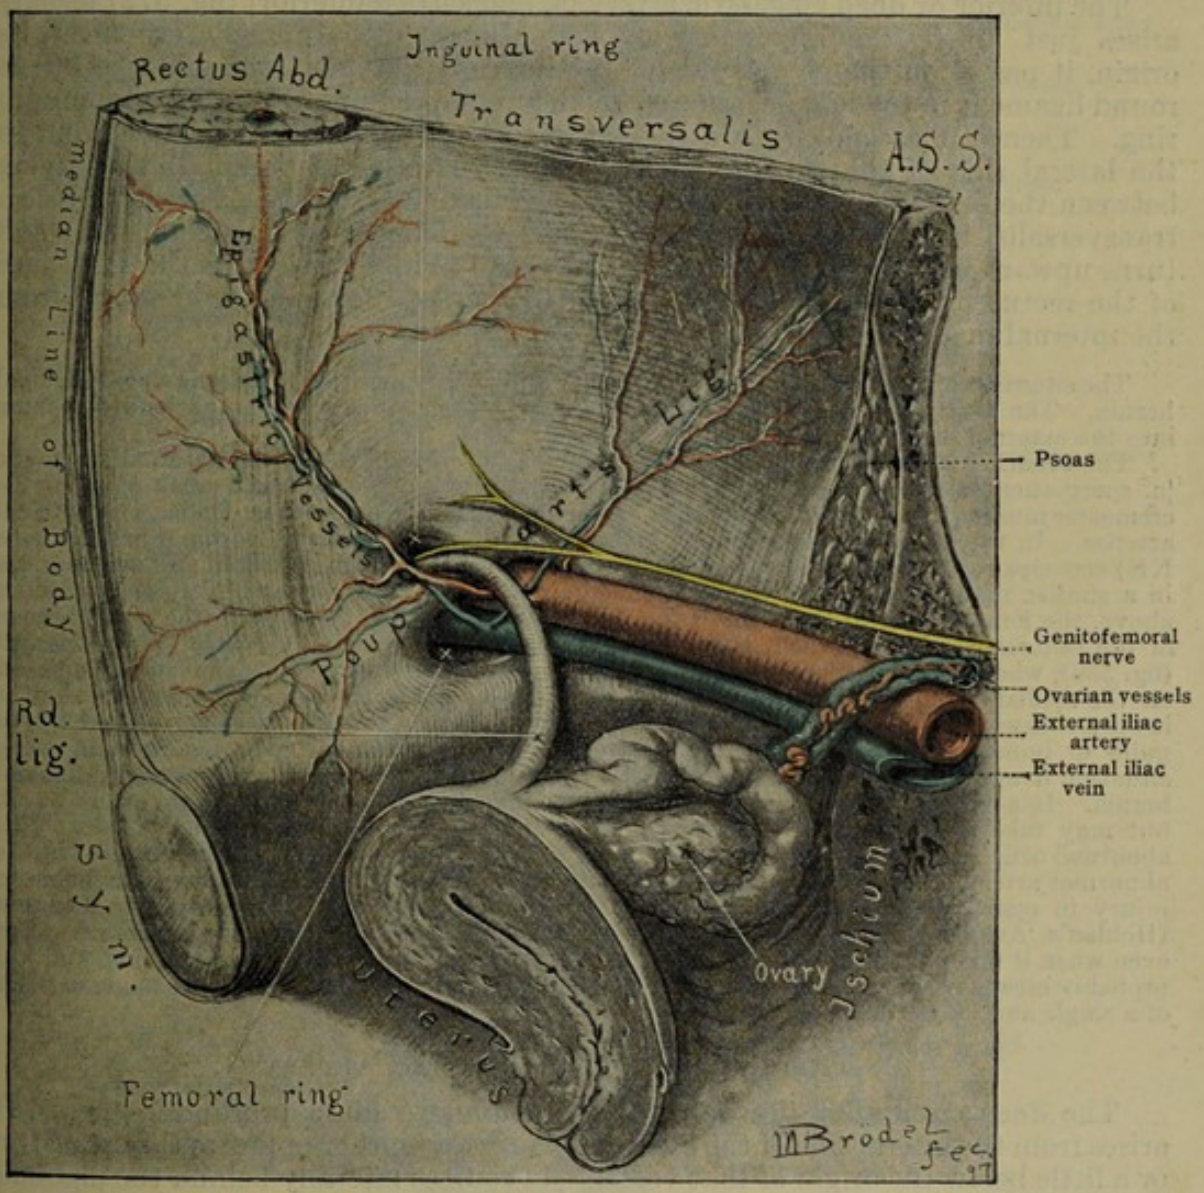

FIG. 572.—THE INFERIOR (DEEP) EPIGASTRIC ARTERY. (From Kelley, by Brödel.)

Relations.—In front, the artery together with the vein is covered by the parietal peritoneum descending from the abdomen into the pelvis, and by a layer of condensed subperitoneal tissue (Abernethy's fascia). It is crossed by the termination of the ileum on the right side, and by the sigmoid colon on the left. The external spermatic (genital) branch of the genitofemoral (genitocrural) nerve runs obliquely over its lower third, and just before its termination it is crossed transversely by the deep circumflex iliac vein. The internal spermatic or ovarian vessels lie for a short distance on the lower part of the artery, and the ductus deferens in the male curves over it to descend to the pelvis. It is sometimes crossed at its origin by the ureter. The external iliac lymphatic nodes lie along the course of the artery. The commencement of its inferior epigastric branch is also in front.

Behind.—The artery at first lies partly upon its own vein; lower down upon the medial border of the psoas; just before it passes through the lacuna vasorum, beneath the inguinal ligament, it lies upon the tendon of the psoas. The iliac fascia is also behind it.

To its **medial side** are the external iliac vein, the peritoneum, and the ductus deferens in the male, or the ovarian vessels in the female.

To its **lateral side** are the psoas muscle and the iliac fascia.

The **collateral circulation** is carried on (fig. 574) when the external iliac is tied, by the anastomosis of the iliolumbar and lumbar arteries with the circumflex iliac; the internal mammary with the inferior epigastric; the obturator with the medial circumflex; the inferior gluteal with the medial circumflex and superior perforating; the gluteal with the lateral circumflex; the arteria comitans nervi ischiadici from the inferior gluteal, with the perforating branches of the profunda; the external pudenal with the internal pudendal; the pubic branch of the obturator with the pubic branch of the inferior epigastric.

The **branches of the external iliac artery** are:—(1) The inferior epigastric; (2) the deep circumflex iliac; and (3) several small and insignificant twigs to the neighboring psoas muscle and lymphatic glands.

(1) The Inferior Epigastric Artery

The **inferior** or **deep epigastric** artery [a. epigastrica inferior] (fig. 572) usually arises just above the inguinal (Poupart's) ligament. Immediately after its origin, it passes on the medial side of the ductus deferens in the male, or of the round ligament in the female, and to the abdominal inguinal (internal abdominal) ring. Thence it ascends with a slightly medial direction passing above and to the lateral side of the subcutaneous inguinal (external abdominal) ring, lying between the fascia transversalis and the peritoneum. Having pierced the fascia transversalis, it passes in front of the linea semicircularis (Douglas' fold) and turns upward between the rectus and its sheath. Finally, it enters the substance of the rectus muscle, and anastomoses with the superior epigastric artery from the internal mammary.

The situation of the artery should be borne in mind in the operation for strangulated inguinal hernia. The artery is accompanied by two veins which end in a single trunk before opening into the external iliac vein.

The **branches of the inferior epigastric** are small and include:—(*a*) The **external spermatic** [a. spermatica externa], which runs with the ductus through the inguinal canal, supplies the cremaster muscle, and anastomoses with the internal spermatic, external pudendal, and perineal arteries. In the female a corresponding artery [**a. lig. teretis uteri**] (a. chordæ uteroinguinalis NK) accompanies the round ligament of the uterus through the inguinal canal and anastomoses in a similar manner. (*b*) **The pubic** branch [r. pubicus], which passes below, or sometimes above, the femoral ring to the back of the pubis, where it anastomoses with the pubic branch of the obturator. This branch, though usually small, is occasionally considerably enlarged (fig. 536), when its exact course becomes of great interest to the surgeon. Thus it may descend on the medial side of the femoral vein, and therefore lateral to the side of the femoral ring, or it may course medially in front of the femoral ring and turn downward either behind the os pubis or immediately behind the free edge of the lacunar (Gimbernat's) ligament, in which situation it would be exposed to injury in the operation for the relief of a strangulated femoral hernia. In such cases the obturator may not be connected with the hypogastric artery at all, but may take origin entirely from the external iliac or from the inferior epigastric. This abnormal origin of the obturator is said to occur once in every three and a half subjects but the abnormal artery courses around the medial side of the ring—in which situation it is liable to injury in operation for femoral hernia—in exceptional cases only. According to Langton (Holden's 'Anatomy'), the chances are about seventy to one against this occurrence. But even when it takes the abnormal course it lies 3 mm. or so from the margin of the ring, and will probably escape injury in the division of the stricture if several short notches are made in place of a single and longer incision.

(2) The Deep Circumflex Iliac Artery

The **deep circumflex iliac** artery [a. circumflexa ilium profunda], (fig. 573) arises from the lateral side of the external iliac artery either opposite the epigastric or a little below the origin of that vessel. It courses laterally behind the inguinal (Poupart's) ligament, lying between the fascia transversalis and the peritoneum, or in a fibrous canal formed by the union of the fascia transversalis with the iliac fascia. Near the anterior superior spine of the ilium, it perforates the transversus, and then courses between that muscle and the internal oblique, along and a little above the crest of the ilium. It finally runs backward to anastomose with the iliolumbar artery. It is accompanied by two veins. These unite into one trunk, which then crosses the external iliac artery to join the external iliac vein.

The **branches of the deep circumflex iliac artery** are as follows:—(*a*) **Muscular** branchse which supply the psoas, iliacus, sartorius, tensor fasciæ latæ, and the oblique and transverse muscles of the abdomen. One of these branches, larger than the rest, is the *a. epigastriae lateralis* (Führer) or '*la branche ascendante*' of French anatomists, who regard this as one of the terminal divisions of the artery ('la branche transversale' being the other). This branch

arises about 2.5 cm. (1 in.) medially to the anterior superior spine of the ilium. It ascends between the transversus muscle and the internal oblique and is important to the surgeon, as it indicates the intermuscular plane between the two muscles. (*b*) **Cutaneous** branches, which supply the skin over the course of the vessel, and anastomose with the superficial circumflex iliac, the superior gluteal, and the ascending branch of the lateral circumflex.

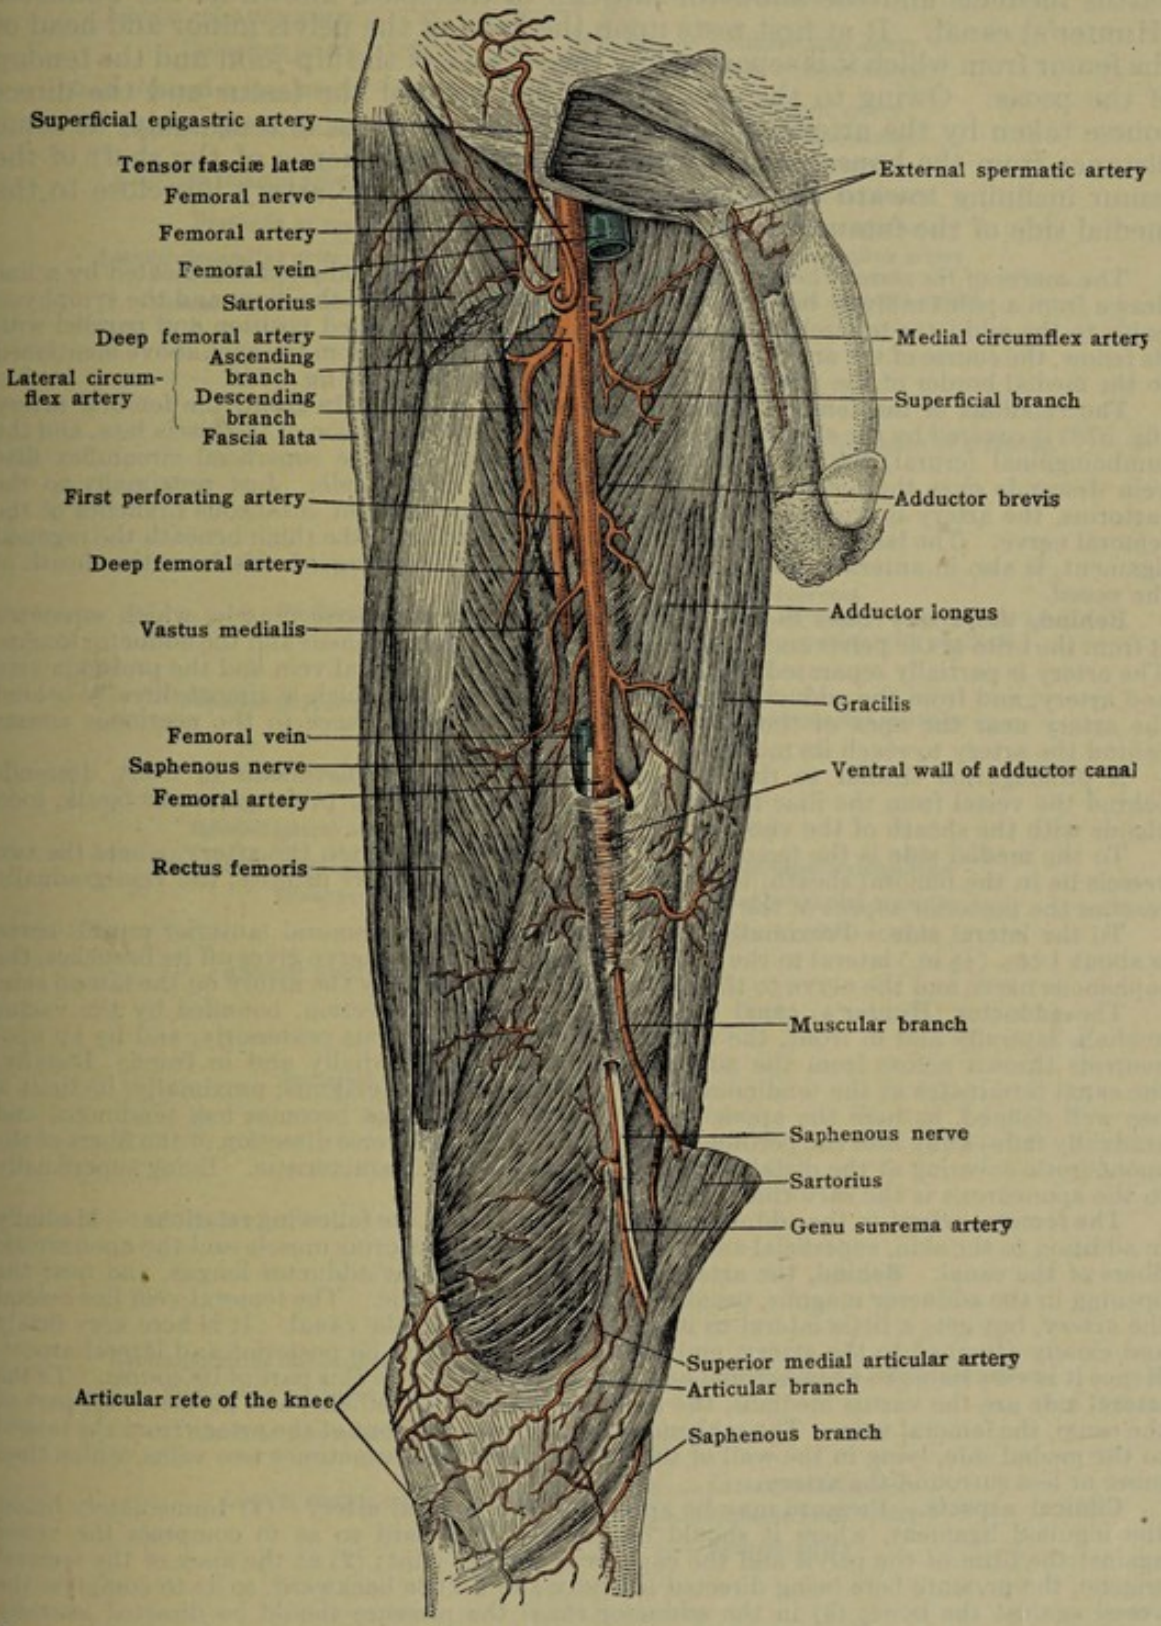

FIG. 573.—THE FEMORAL ARTERY. (After Toldt, 'Atlas of Human Anatomy', The Macmillian Company.)

THE FEMORAL ARTERY

The **femoral** artery (fig. 573) is the continuation of the external iliac, and extends from the lower border of the inguinal (Poupart's) ligament, down the anterior and medial aspect of the thigh, to the tendinous opening in the adductor magnus, through which it passes into the popliteal space, and is then known as the popliteal. The femoral artery is at first quite superficial, being covered only by

the skin, and superficial and deep fascia; but after passing about 13 cm. (5 in.) downward through the space known as the femoral trigone (Scarpa's triangle), it sinks at the apex of that triangle beneath the sartorius muscle. Thence to its termination it continues beneath the sartorius, coursing deeply between the vastus medialis and the adductor muscles in the space known as the adductor (Hunter's) canal. It at first rests upon the brim of the pelvis minor and head of the femur from which it is separated by the capsule of the hip-joint and the tendon of the psoas. Owing to the obliquity of the neck of the femur and the direct course taken by the artery, the latter lies lower down on muscles only, at some distance from the bone. At its termination, in consequence of the shaft of the femur inclining toward the middle line of the body, the artery lies close to the medial side of the femur.

The *course of the vessel* when the thigh is slightly flexed and abducted is indicated by a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle. When the thigh is in the extended position and parallel with its fellow, the course of the artery will correspond to a line drawn from the spot above mentioned to the medial border of the patella. Its *anastomoses* are shown in fig. 574.

The relations of the femoral artery in the femoral trigone.—In front, the femoral artery (fig. 573) is covered by the skin, the superficial fascia, the iliac portion of the fascia lata, and the lumboinguinal (crural) branch of the genitofemoral nerve. The superficial circumflex iliac vein descends over the artery from the lateral to the medial side. Just proximally to the sartorius, the artery is crossed by the most medial of the anterior cutaneous branches of the femoral nerve. The fascia transversalis, which is continued into the thigh beneath the inguinal ligament, is also in anterior relation, but it soon becomes indistinguishable from the sheath of the vessel.

Behind, the artery rests in turn upon the tendon of the psoas muscle, which separates it from the brim of the pelvis and capsule of the hip-joint, the pectineus and the adductor longus. The artery is partially separated from the pectineus by the femoral vein and the profunda vein and artery, and from the adductor longus by the femoral vein which is almost directly behind the artery near the apex of the femoral trigone. The small nerve to the pectineus crosses behind the artery to reach its medial side.

A prolongation similar to that derived from the fascia transversalis in front, descends behind the vessel from the iliac fascia; but this, like the anterior prolongation or fascia, soon blends with the sheath of the vessels.

To the **medial side** is the femoral vein. This is separated from the artery, where the two vessels lie in the femoral sheath, by a thin fascial septum. More distally, the vein gradually reaches the posterior aspect of the artery.

To the **lateral side.**—Proximally, the common stem of the femoral (anterior crural) nerve is about 1 cm. (⅓ in.) lateral to the artery. When the femoral nerve gives off its branches, the saphenous nerve and the nerve to the vastus medialis accompany the artery on the lateral side.

The **adductor (Hunter's) canal** (fig. 573) is triangular in section, bounded by the vastus medialis laterally and in front, the adductors longus and magnus posteriorly, and by an aponeurosis thrown across from the adductors to the vastus medially and in front. Distally, the canal terminates at the tendinous opening in the adductor magnus; proximally, its limit is less well defined, as here the aponeurosis between the muscles becomes less tendinous, and gradually fades away into the perimuscular fascia. The transverse direction of the fibers of the aponeurotic covering at the distal two-thirds of the canal is characteristic. Lying superficially to the aponeurosis is the sartorius muscle.

The femoral artery, in the adductor (Hunter's) canal, has the **following relations:—Medially** in addition to the skin, superficial and deep fascia, are the sartorius muscle and the aponeurotic fibers of the canal. **Behind,** the artery is in contact with the adductor longus, and near the opening in the adductor magnus, usually with the latter muscle. The femoral vein lies behind the artery, but gets a little lateral to it at the distal part of the canal. It is here very firmly and closely attached to the artery, embracing it as it were on its posterior and lateral aspect. Hence it is very liable to be punctured on ligaturing the artery in this part of its course. To the **lateral side** are the vastus medialis, the nerve to the vastus medialis, and at the distal part of the canal, the femoral vein. The saphenous nerve crosses in front of the artery from the lateral to the medial side, lying in the wall of the canal. There are sometimes two veins, which then more or less surround the artery.

Clinical aspects.—Pressure may be applied to the femoral artery—(1) Immediately below the inguinal ligament, where it should be directed backward so as to compress the vessel against the brim of the pelvis and the capsule of the hip-joint; (2) at the apex of the femoral trigone, the pressure here being directed laterally and a little backward, so as to compress the vessel against the bone; (3) in the adductor canal the pressure should be directed laterally with the same object. Care must be taken, especially above, to avoid the vein, which lies very close to the artery, and also the femoral nerve, which enters the thigh about 1.2 cm. (½ in.) lateral to the artery, and at once breaks up into its branches, superficial and deep.

In ligature of the femoral in the femoral trigone the incision should be about 7.5 cm. (3 in.) long, in the line of the artery, and begins about 7.5 cm. (3 in.) below the inguinal ligament, and runs over the apex of the triangle. The femur is flexed slightly, abducted and rotated laterally. The fascia lata being divided, the sartorius, readily recognized by its direction, is drawn laterally. The closely subjacent sheath must be opened on its lateral side. Structures that may be seen are a vein joining the great saphenous, the anterior cutaneous and saphenous nerves, and the nerve to the vastus medialis. The **collateral circulation** (fig. 574) is mainly through the following channels:—(1) The lateral and medial circumflex above, with the genu suprema and

lower muscular branches of the femoral, and the articular of the popliteal. (2) The perforating branches of the profunda above, with the vessels below first given. (3) The a. comitans nervi ischiadici with the articular of the popliteal. Ligature of the femoral artery and vein results in gangrene in 36 to 39 per cent. of cases (Kagiyama).

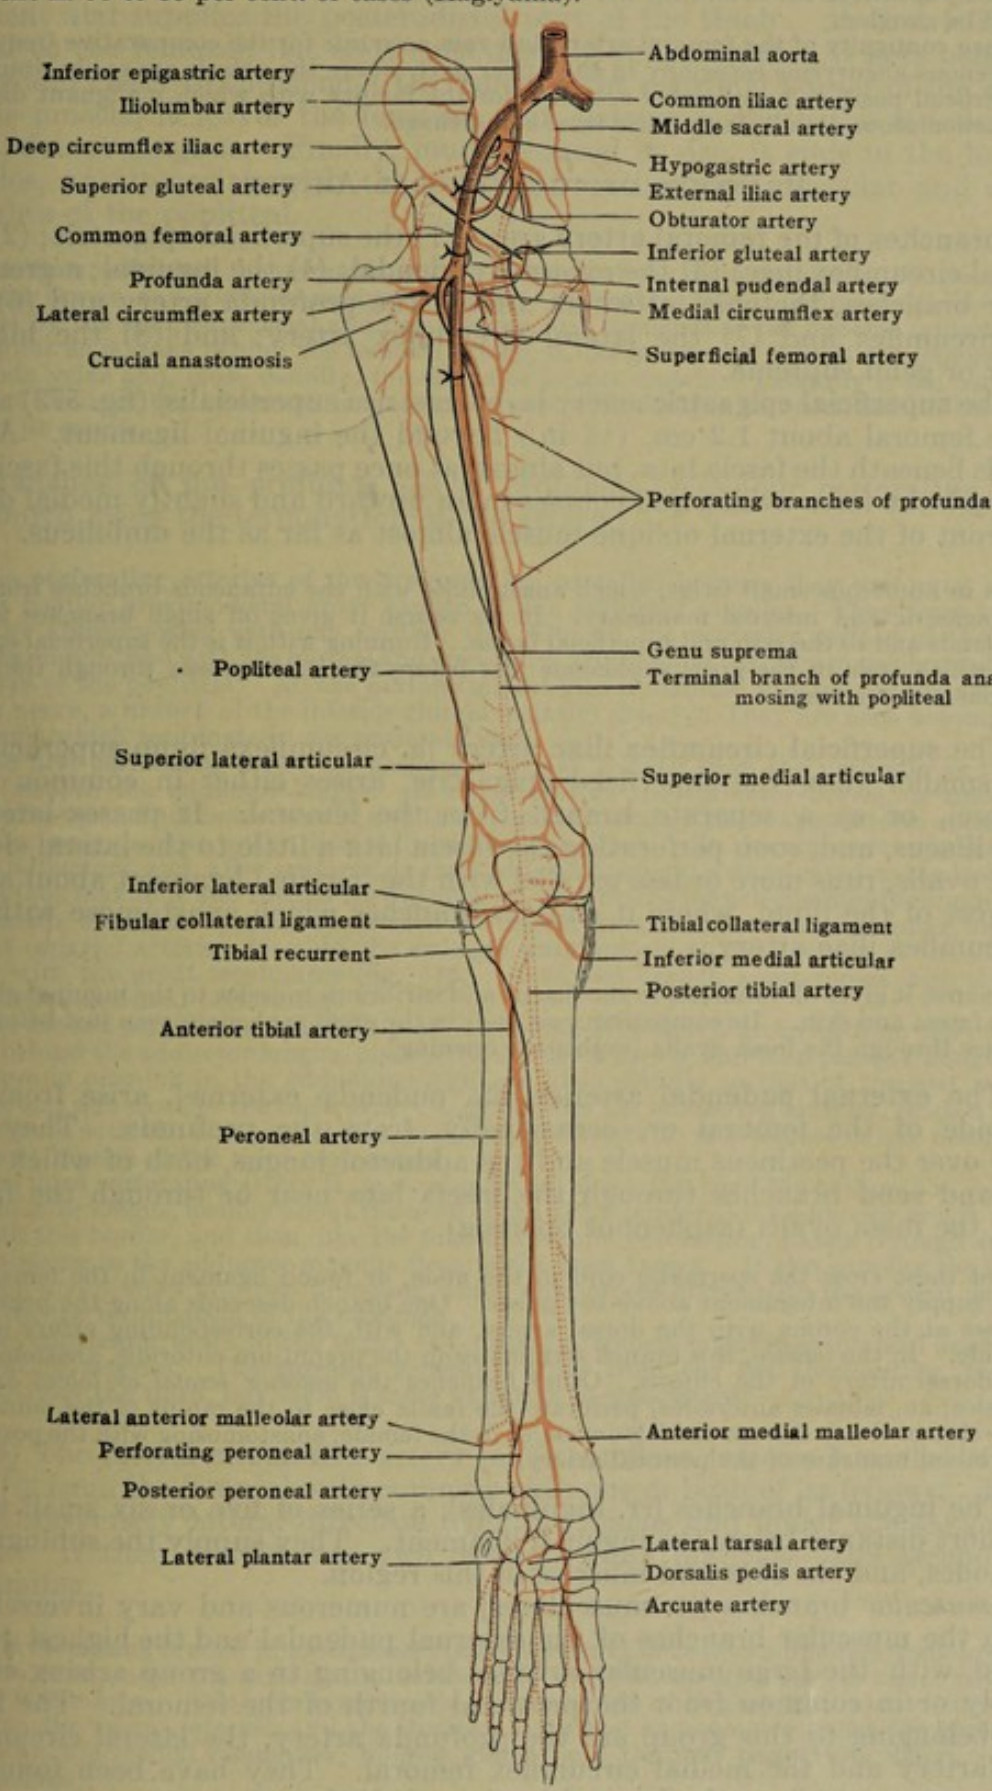

FIG. 574.—TO SHOW THE ANASTOMOSES OF THE ARTERIES OF THE LOWER EXTREMITY. (After Smith and Walsham.)

In ligature of the femoral artery in Hunter's canal, the line of the incision, in the middle third of the thigh, must exactly follow that of the vessel. It is frequently made too lateral, exposing the vastus medialis. Branches of the saphenous vein being removed, the fascia lata is slit up and the sartorius identified by its fibers descending medially. Those of the vastus

medialis are less oblique and are directed downward and laterally. The sartorius having been drawn to the medial side, usually, the aponeurotic roof of the canal is opened, and the femoral artery identified. The vein, here posterior and to the lateral side, is closely connected to the artery. The saphenous nerve and the nerve to the vastus medialis are superficial to the vessels and should be avoided.

The close contiguity of the femoral artery and vein accounts for the comparative frequency of arteriovenous aneurysms especially in the upper part, where the vessels are easily wounded. Their superficial position here further accounts for the facility with which malignant disease, e. g., epitheliomatous glands, may cause fatal hemorrhage.

Branches of the Femoral Artery

The **branches of the femoral artery** are:—(1) the superficial epigastric; (2) the superficial circumflex iliac; (3) the external pudendal; (4) the inguinal; a group of muscular branches, the chief of which are (5) the profunda artery and (6) the medial circumflex and (7) the lateral circumflex artery; and (8) the highest genicular or genu suprema.

(1) The **superficial epigastric** artery [a. epigastrica superficialis] (fig. 573) arises from the femoral about 1.2 cm. (½ in.) beyond the inguinal ligament. At its origin it is beneath the fascia lata, but almost at once passes through this fascia, or else through the fossa ovalis, and courses in an upward and slightly medial direction in front of the external oblique muscle almost as far as the umbilicus.

It ends in numerous small twigs, which anastomose with the cutaneous branches from the inferior epigastric and internal mammary. In its course it gives off small branches to the inguinal glands and to the skin and superficial fascia. Running with it is the superficial epigastric vein, which ends in the great saphenous just before the latter passes through the fossa ovalis (saphenous opening).

(2) The **superficial circumflex iliac** artery [a. circumflexa ilium superficialis], usually smaller than the superficial epigastric, arises either in common with that vessel, or as a separate branch from the femoral. It passes laterally over the iliacus, and, soon perforating the fascia lata a little to the lateral side of the fossa ovalis, runs more or less parallel with the inguinal ligament about as far as the crest of the ilium, where it ends in branches which anastomose with the deep circumflex iliac artery.

In its course it gives off branches to the iliacus and sartorious muscles to the inguinal glands, and to the fascia and skin. Its companion vein ends in the great saphenous vein just before the latter passes through the fossa ovalis (saphenous opening).

(3) The **external pudendal** arteries [aa. pudendæ externæ], arise from the medial side of the femoral or, occasionally, from the profunda. They run medially over the pectineus muscle and the adductor longus, both of which then supply, and send branches through the fascia lata near or through the fascia covering the fossa ovalis (saphenous opening).

Some of these cross the spermatic cord in the male, or round ligament in the female, to reach and supply the integument above the pubes. One branch descends along the penis and anastomoses at the corona with the dorsal artery, and with the corresponding artery of the opposite side. In the female, this branch terminates in the preputium clitoridis, anastomosing with the dorsal artery of the clitoris. Other branches the *anterior scrotal or labial arteries* [aa. scrotales; aa. labiales anteriores] perforate the fascia close to the ramus of the pubis and supply the skin of the *scrotum* or the *labium majus* in the female, anastomosing with the posterior scrotal or labial branches of the perineal artery.

(4) The **inguinal** branches [rr. inguinales], a series of five or six small twigs arise a short distance below the inguinal ligament. They supply the subinguinal lymph-nodes, and the skin and muscles in this region.

The *muscular* branches [rr. musculares] are numerous and vary inversely in size with the muscular branches of the external pudendal and the highest genicular, and with the large muscular arteries belonging to a group arising either separately or in common from the proximal fourth of the femoral. The large arteries belonging to this group are the profunda artery, the lateral circumflex femoral artery and the medial circumflex femoral. They have been found to take common origin from the femoral in about half the cases.

The usual text-book description is applicable to such an arrangement, but not the numerous cases in which one or more of these vessels arises separately from the femoral. Winslow avoided a too rigid method of describing the ways in which these arteries may arise, by saying that any two or all of them may take origin from the femoral by means of a common trunk of origin. As providing the plasticity demanded by the situation, this method is followed here.

(5) The **profunda** artery [a. profunda femoris] (figs. 573, 574) is the largest muscular artery of the thigh. It is usually given off from the back and lateral part of the common femoral, about 4 cm. (1½ in.) beyond the inguinal (Poupart's) ligament and supplies the posterodistal part of the thigh. At first it is a little lateral to the femoral, but as it runs distally and backward it gets behind that artery and closer to the bone. On reaching the proximal border of the adductor longus muscle, it leaves the femoral, and, passing beneath the muscle, pierces the abductor magnus. Finally, much reduced in size, it ends in the hamstring muscles, anastomosing with the third perforating and muscular and articular branches of the popliteal.

Relations.—Behind, the profunda artery lies successively upon the iliacus, the pectineus, the adductor brevis, and adductor magnus muscles. **In front,** at first it is superficial, being merely covered by the skin, superficial and deep fasciæ, and branches of the femoral (anterior crural) nerve; but as it sinks behind the femoral artery, it has in front of it both the femoral and the profunda veins and, more distally, the adductor longus muscle. **Laterally** is the femur at the angle of union of the adductors longus and brevis. **Medially** is the pectineus in the proximal part of its course.

Branches of the profunda.—The profunda gives four perforating arteries, the fourth being the termination of the artery.

The **perforating arteries of the profunda** are so called because they perforate, in a more or less regular proximodistal order certain of the adductor muscles. They form a series of loops by anastomosing with one another (fig. 570) on the posterior surface of the adductor magnus muscle, and with the gluteal and circumflex arteries and with the muscular and genicular branches of the popliteal. All the perforating arteries contribute to reinforce the artery of the sciatic nerve, a branch of the inferior gluteal (sciatic) artery. They are each accompanied by two veins which terminate in the profunda vein.

The **first perforating** artery [a. perforans prima] is given from the profunda as that vessel sinks beneath the adductor longus. It either pierces the adductor brevis, or runs between the pectineus and adductor brevis, and then passes through a small aponeurotic opening in the adductor magnus close to the medial lip of the linea aspera. In this course it supplies branches to the adductors, and, after perforating the adductor magnus, is distributed to the lower part of the gluteus maximus and the hamstring muscles, a recurrent branch commonly running beneath the gluteus maximus to anastomose with the lateral circumflex, medial circumflex, and inferior gluteal (sciatic) arteries, forming the **cruciate anastomosis** at the junction of the neck of the femur with the great trochanter (fig. 570). A second branch anastomoses with a recurrent branch of the second perforating.

The **second perforating** artery [a. perforans secunda] which is given off from the profunda as it lies behind the adductor longus, pierces the adductor brevis, and then passes through a second aponeurotic opening in the adductor magnus a little distally to that of the first perforating artery, and also close to the linea aspera. It supplies the hamstring muscles, sends a branch to anastomose with the first perforating, and another branch to anastomose in like manner with a recurrent branch of the third perforating.

The **third perforating** artery [a. perforans tertia] also arises from the profunda as it lies under the adductor longus, usually about the level of the distal border of the adductor brevis. It turns beneath this border, and then, like the first and second perforating, passes through an aponeurotic opening in the adductor magnus close to the linea aspera. It also supplies the hamstring muscles, and divides into two branches, which anastomose above with the second perforating, and with the termination of the profunda.

Two **nutrient** arteries to the femur [aa. nutritiæ femoris superior et inferior] arise from the perforating arteries. The superior generally arises from the first perforating, the inferior usually from the third, but there is some variation in this regard.

(6) The **lateral circumflex** artery [a. circumflexa femoris lateralis] may arise directly from the femoral or in common with one or both of its fellows. It passes in a transversely lateral direction over the iliacus and under the sartorius and rectus. It then divides into two or more chief branches—the ascending and descending.

The **ascending** branch [r. ascendens] breaks almost at once into numerous branches, some of which ascend under the sartorius to anastomose with the superior gluteal under cover of the tensor fasciæ latæ. One large branch—the r. transversus of English text-books—runs laterally between the vastus lateralis and the iliotibial tract and anastomoses under the gluteus maximus with the medial circumflex, inferior gluteal and the first perforating artery (cruciform anastomosis).

The **descending** branch [r. descendens] runs with the nerve to the vastus lateralis muscle beneath the rectus and on the vasti intermedius and lateralis. It sends branches to the knee joint which anastomose with the supreme genicular and with the genicular branches of the popliteal artery. The descending branch of the lateral circumflex is developed separately from the trunk and ascending branch of the artery. Although they are usually combined in the adult, as described above, they may arise from different parts of the femoral, either alone or in common with the one or more of the other elements of the group.

(7) The **medial circumflex** artery [a. circumflexa femoris medialis] may arise from the femoral directly, or in combination with the lateral circumflex or the profunda. It passes medially over the iliacus and psoas and then turns backwards, as the **deep** branch [r. profundus], between the latter muscle and the pectineus. Continuing above the adductor brevis and the obturator externus, it enters the gluteal region between the quadratus femoris and the adductor magnus, covered by the gluteus maximus.

Before leaving the femoral trigone it gives a **superficial** branch [r. superficialis] to the pectineus, adductor longus, adductor brevis and the proximal part of the gracilis, which varies inversely in size with the external pudendal arteries and may replace them. The deep branch gives an **acetabular** branch [r. acetabuli] to the acetabulum and an ascending branch along the tendon of the obturator externus, which anastomoses with the obturator artery and with the inferior gluteal in the trochanteric fossa. The remainder of the deep branch, formerly described

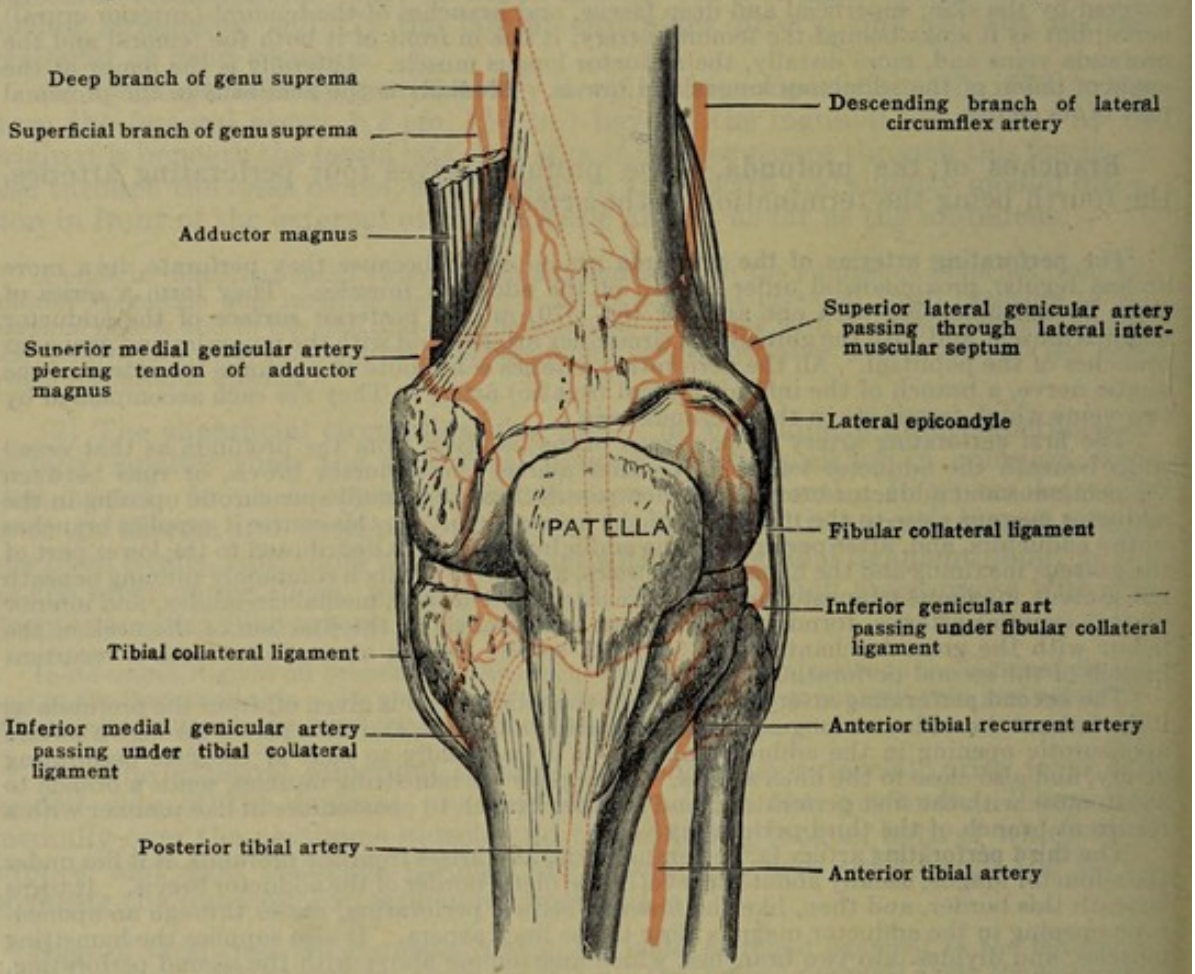

FIG. 575.—THE ANASTOMOSIS ABOUT THE LEFT KNEE-JOINT. (Walsham.) (Semi-diagrammatic.)

as the r. transversus, anastomoses under the gluteus maximus with the inferior gluteal, first perforating and lateral circumflex arteries (cruciform anastomosis).

(7) The **supreme genicular** artery [a. genu suprema] (or anastomotica magna) (figs. 573, 575) arises from the front and medial side of the femoral just before the latter perforates the adductor magnus muscle, and almost immediately divides into branches, (*a*) saphenous, (*b*) muscular, and (*c*) articular. These branches may sometimes come off separately from the femoral.

(*a*) The **saphenous** branch [a. saphena] pierces the aponeurotic covering of the adductor canal, passes between the sartorius and gracilis muscles along with the saphenous nerve, and, perforating the deep fascia, supplies the skin of the proximal and medial side of the leg and anastomoses with the inferior medial genicular branch of the popliteal and the other vessels forming the plexus or rete at the medial side of the knee. In its course it gives twigs to the distal part of the sartorius and gracilis muscles.

(*b*) The **muscular** branches [rr. musculares] run distally in front of the adductor magnus tendon, burrowing amongst the fibers of the vastus medialis as far as the medial condyle. They break up into numerous twigs which supply the distal ends of the vasti muscles and adductor magnus. One branch runs laterally across the distal end of the femur to end in the vastus lateralis.

(*c*) The **articular** branches [rr. articulares] come off from the saphenous and muscular branches and enter the arterial rete on the medial and lateral sides of the knee. They anas-

tomose with the medial and lateral superior genicular branches of the popliteal and the anterior tibial recurrent and supply branches to the joint.

THE POPLITEAL ARTERY

The **popliteal artery** [a. poplitea] (fig. 576) runs through the popliteal fossa. It is a continuation of the femoral, and extends from the aponeurotic opening

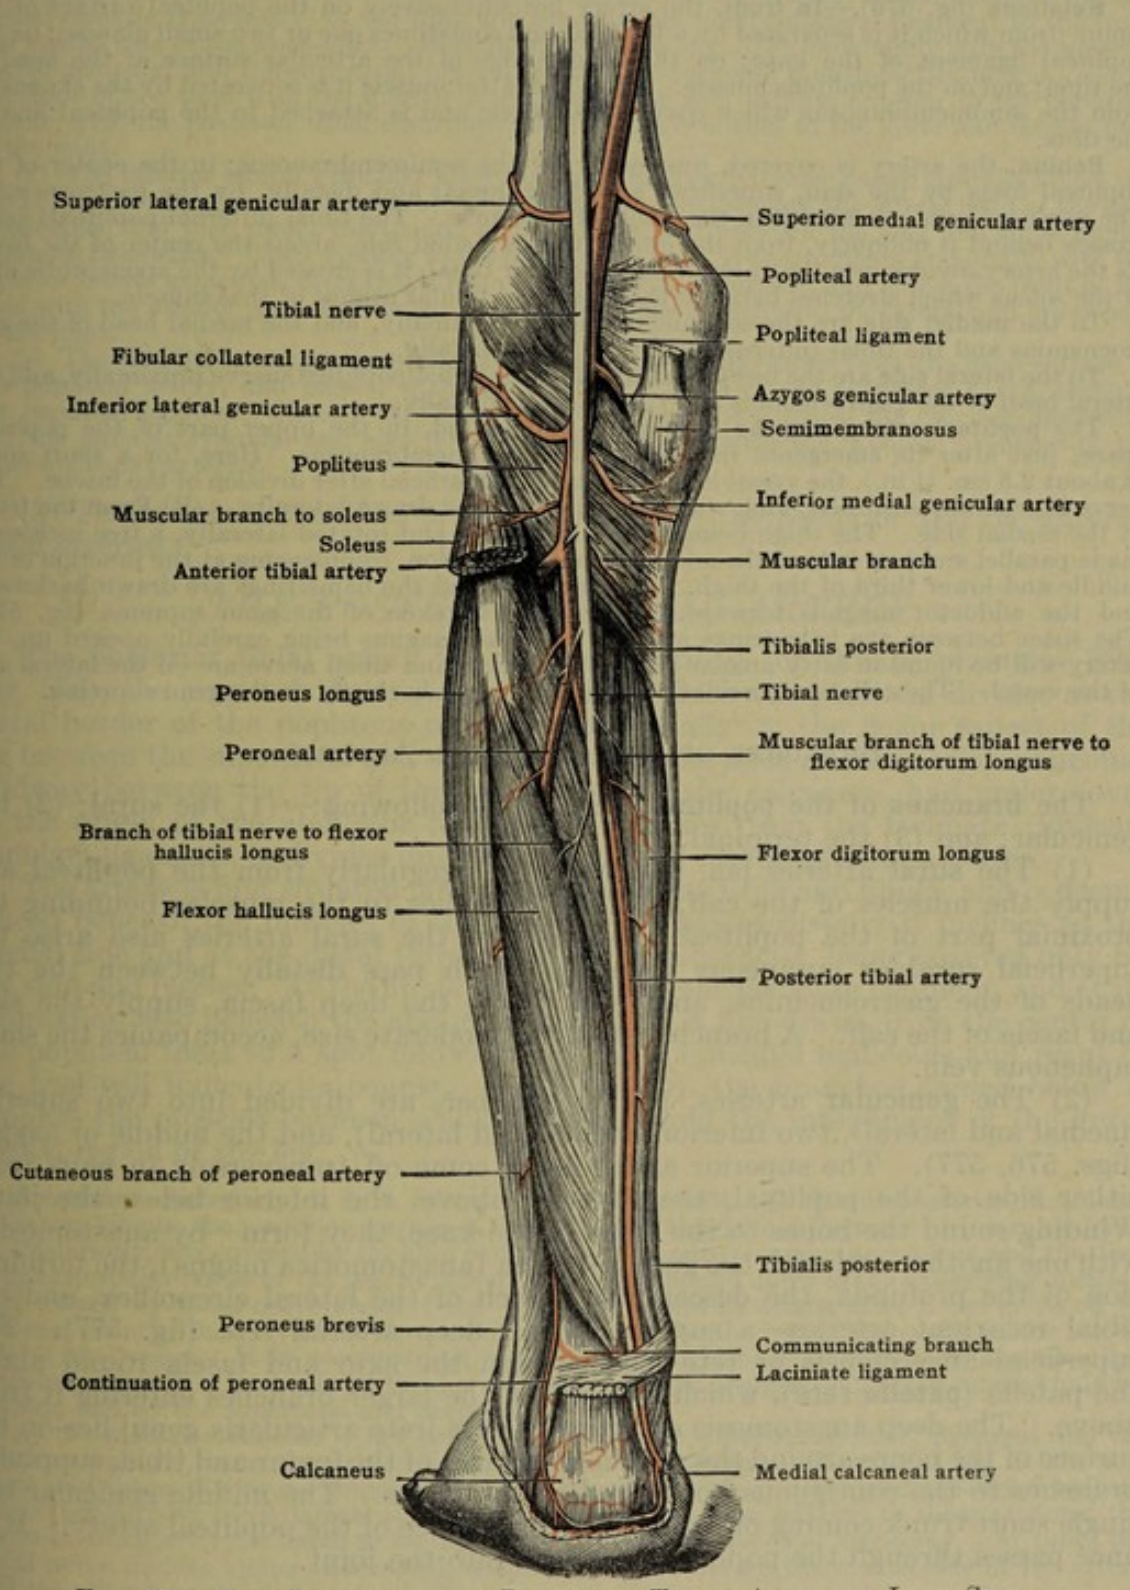

FIG. 576.—THE POPLITEAL AND POSTERIOR TIBIAL ARTERIES, LEFT SIDE.

in the adductor magnus at the junction of the middle with the distal third of the thigh to the lower border of the popliteus muscle, where it terminates by dividing into the anterior and posterior tibial arteries. The proximal part of the artery is accompanied by the branch of the obturator nerve to the knee-joint. The vein is behind the artery throughout; it lies at first a little laterally, but as the vessels pass through the popliteal fossa the vein crosses obliquely over the artery,

and at the termination of the artery lies a little to its medial side. The tibial (internal popliteal) nerve is superficial to both artery and vein. At the proximal part of the fossa it is well to the lateral side of the vessels, but as it descends it crosses behind them and reaches their medial side. The artery in the whole of its course is deeply placed and covered by a considerable amount of fat and areolar tissue.

Relations (fig. 576).—**In front,** the artery lies successively on the popliteal surface of the femur (from which it is separated by a little fat and sometimes one or two small glands); on the popliteal ligament of the knee; on the hinder edge of the articular surface of the head of the tibia; and on the popliteus muscle. From the latter muscle it is separated by the expansion from the semimembranosus which covers the muscle and is attached to the popliteal line on the tibia.

Behind, the artery is covered, proximally by the semimembranosus; in the center of the popliteal fossa by the skin, superficial and deep fascia; and distally, by the gastrocnemius. The popliteal vein is behind it in the whole of its course. The tibial (internal popliteal) nerve crosses behind it obliquely, from the lateral to the medial side, about the center of the fossa. As the artery divides into the anterior and posterior tibial, it is crossed by the aponeurotic arch of the soleus which stretches between the tibial and fibular origins of that muscle.

To the **medial side** are the semimembranosus proximally, and the medial head of the gastrocnemius and the tibial (internal popliteal) nerve distally.

To the **lateral side** are the biceps and the tibial (internal popliteal) nerve proximally, and the lateral head of the gastrocnemius and the plantaris distally.

The **popliteal artery may be ligatured**—(A) **Behind,** in the upper part of the popliteal space, just after its emergence from under the semimembranosus. Here, for a short space of about 2.5 cm. (1 in.), the vessel is comparatively superficial after division of the fasciæ. The nerve is generally seen first, and, with the vein, must be drawn laterally. (B) **From the front,** at the medial side. The thigh being flexed, abducted, and rotated laterally, a free incision is made parallel and just behind the adductor magnus tendon, commencing at the junction of the middle and lower third of the thigh. The sartorius and the hamstrings are drawn backward, and the adductor magnus forward. Care must be taken of the genu suprema (fig. 577). The space between the hamstrings and the adductor magnus being carefully opened up, the artery will be found in fatty areolar tissue. The vein and tibial nerve are on the lateral side of the vessel. The collateral circulation (fig. 575) depends chiefly on the genu suprema.

Branches of the Popliteal Artery

The **branches of the popliteal** include the following:—(1) the sural; (2) the genicular; and (3) the terminal.

(1) The **sural** arteries [aa. surales] arise irregularly from the popliteal and supply the muscles of the calf, sending branches to the muscles bounding the proximal part of the popliteal fossa. From the sural arteries also arise the superficial sural or cutaneous branches which pass distally between the two heads of the gastrocnemius, and, perforating the deep fascia, supply the skin and fascia of the calf. A branch, usually of moderate size, accompanies the small saphenous vein.

(2) The **genicular** arteries, five in number, are divided into two superior (medial and lateral), two inferior (medial and lateral), and the middle or azygos (figs. 576, 577). The superior and inferior come off transversely in pairs from either side of the popliteal, the superior above, the inferior below the joint. Winding round the bones to the front of the knee, they form—by anastomosing with one another and with the genu suprema (anastomotica magna), the termination of the profunda, the descending branch of the lateral circumflex, and the tibial recurrent arteries—a superficial and deep arterial rete (fig. 577). The superficial anastomosis or rete lies between the skin and fascia round about the patella (**patella rete**), which it supplies, the larger branches entering it from above. The deep anastomosis or **articular rete** [rete articularis genu] lies on the surface of the bones around the articular surfaces of the femur and tibia, supplying branches to the contiguous bones and to the joints. The middle genicular is a single short trunk coming off from the deep surface of the popliteal artery. It at once passes through the popliteal ligament into the joint.

(*a*) The **superior lateral genicular** artery [a. genu superior lateralis], the larger of the two superior genicular branches, runs in a lateral direction above the lateral head of the gastrocnemius, and, passing beneath the biceps and through the lateral intermuscular septum and vastus lateralis, enters the substance of the vastus intermedius (crureus), and anastomoses, proximally with the descending branch of the lateral circumflex, distally with the inferior lateral genicular, and across the front of the femur with the superior medial genicular, the genu suprema (anastomotica magna), and termination of the profunda, forming with them, as already described, the deep articular rete. Branches are given off to the patella, to the upper and lateral part of the joint, to the bone, and to the contiguous muscles.

(*b*) The **superior medial genicular** artery [a. genu superior medialis] runs medially just above the medial head of the gastrocnemius, beneath the semimembranosus, and, after perforating the tendon of the adductor magnus, enters the substance of the vastus medialis. Here it anastomoses with the deep branch of the genu suprema (anastomotica magna) and termination of the profunda above, with the inferior medial genicular below, and with the superior lateral genicular across the front of the femur. It supplies small branches to the contiguous muscles, to the femur, to the patella, and to the joint.

(*c*) The **inferior medial genicular** artery [a. genu inferior medialis], the larger of the two inferior genicular arteries, passes in an obliquely medial direction across the popliteus, below the medial condyle (tuberosity) of the tibia and beneath the tibial collateral ligament to the front and medial side of the knee-joint. Here it anastomoses (fig. 575), proximally with the superior medial genicular and the superficial branch of the genu suprema (anastomotica magna), across the front of the tibia with the inferior lateral genicular and distally, anterior to the popliteus muscle, with the posterior tibial recurrent. It supplies branches to the lower and medial part of the joint.

(*d*) The **inferior lateral genicular** artery [a. genu inferior lateralis] passes laterally above the head of the fibula, along the tendon of the popliteus muscle, beneath the lateral head of the gastrocnemius, and then under the tendon of the biceps, and between the long and short fibular collateral ligaments. Then winding to the front of the joint, it anastomoses proximally with the superior lateral genicular, distally with the anterior tibial recurrent, and across the front of the tibia with the inferior medial genicular. It also supplies branches to the lateral and lower part of the joint.

(*e*) The **middle or azygos genicular** artery [a. genu media] arises from the deep surface of the popliteal artery, and passes, with the articular branch of the obturator nerve, through the popliteal ligament, directly into the knee-joint, where it supplies the cruciate ligaments, and the patellar synovial and alar folds. It anastomoses with the intrinsic branches of the other genicular arteries.

(3) The **terminal branches** of the popliteal are the posterior and the anterior tibial arteries.

THE POSTERIOR TIBIAL ARTERY

The **posterior tibial** artery [a. tibialis posterior] (or tibialis plantaris NK) (fig. 576), the larger of the two branches into which the popliteal divides at the distal border of the popliteus muscle, runs distally on the flexor aspect of the leg between the superficial and deep muscles to the back of the medial malleolus. Midway between the tip of the malleolus and the calcaneus, and under cover of the origin of the abductor hallucis as it arises from the laciniate (internal annular) ligament, it divides into the medial and lateral plantar arteries.

The artery is first situated midway between the tibia and fibula, and is deeply placed beneath the muscles of the calf. As it passes distally it inclines to the medial side and at the distal third of the leg is superficial, being covered only by the skin and fasciæ. At the ankle it lies beneath the laciniate ligament, and at its bifurcation also beneath the abductor hallucis. A line drawn from the center of the popliteal fossa to a spot midway between the medial malleolus and point of the heel will indicate its course. In addition to the branches named below it supplies the muscles between which it passes, and the integument of the lower medial region of the leg.

Relations.—**Anteriorly,** it is in relation successively with the tibialis posterior, the flexor digitorum longus, the posterior surface of the tibia, and the deltoid ligament of the ankle-joint.

Posteriorly, it is covered by the skin and fascia, the gastrocneumius and soleus, and the deep or intermuscular fascia of the leg, by which it is tightly bound down to the underlying muscles. It is crossed by tibial nerve about 4 cm. (1¾ in.) beyond its origin, after it has given off its peroneal branch; the nerve first lies on the medial, and for the rest of its course on the lateral side of the vessel. It is accompanied by two veins, which send numerous anastomosing branches across it. In the distal third of the leg the artery is superficial, being covered only by the skin and by the superficial and deep fasciæ.

At the **medial malleolus** it lies beneath the laciniate (internal annular) ligament and the abductor hallucis, upon the deltoid ligament of the ankle-joint. Here it has the tibialis posterior and flexor digitorum longus in front of it, and the tibial nerve and the flexor hallucis longus behind and to its lateral side. On account of its close relation to these tendons, the posterior tibial artery is liable to be injured in the older methods of tenotomy. At times the tibial nerve divides higher than usual, when one branch lies on the medial side of the artery and the other branch on the lateral side.

Ligature of the posterior tibial in the middle of the leg.—The following are the chief points in the technic. An incision, 7.5 to 10 cm. (3 to 4 in.) long, is made 1.2 cm. (½ in.) behind the medial border of the tibia, to avoid the great saphenous vein. The deep fascia being freely opened, the medial head of the gastrocnemius is drawn backward. The tibial attachment of the soleus, thus exposed, is cut through carefully, so as to allow of identification of its central membranous tendon, which must not be confused with the deep intermuscular septum over the flexor. Any sural vessels are now tied. The above-mentioned special septum is next made out, passing between the bones (vertical line descending from oblique line of tibia and oblique line of fibula). On division of this septum the nerve usually comes into view, the artery

lying more laterally. The needle is passed from the nerve; the venæ comitantes may be included. The muscles should now be fully relaxed by flexion of knee and plantar flexion of foot. The ligature will be placed below the peroneal artery. The posterior tibial in its upper part may also be ligated through a straight incision down the middle of the leg posteriorly. Ligation of the posterior tibial is followed by gangrene in a large percentage of cases.

The **branches of the posterior tibial artery** (figs. 576, 577) are:—(1) The fibular; (2) the peroneal; (3) the tibial nutrient; (4) the communicating; (5)

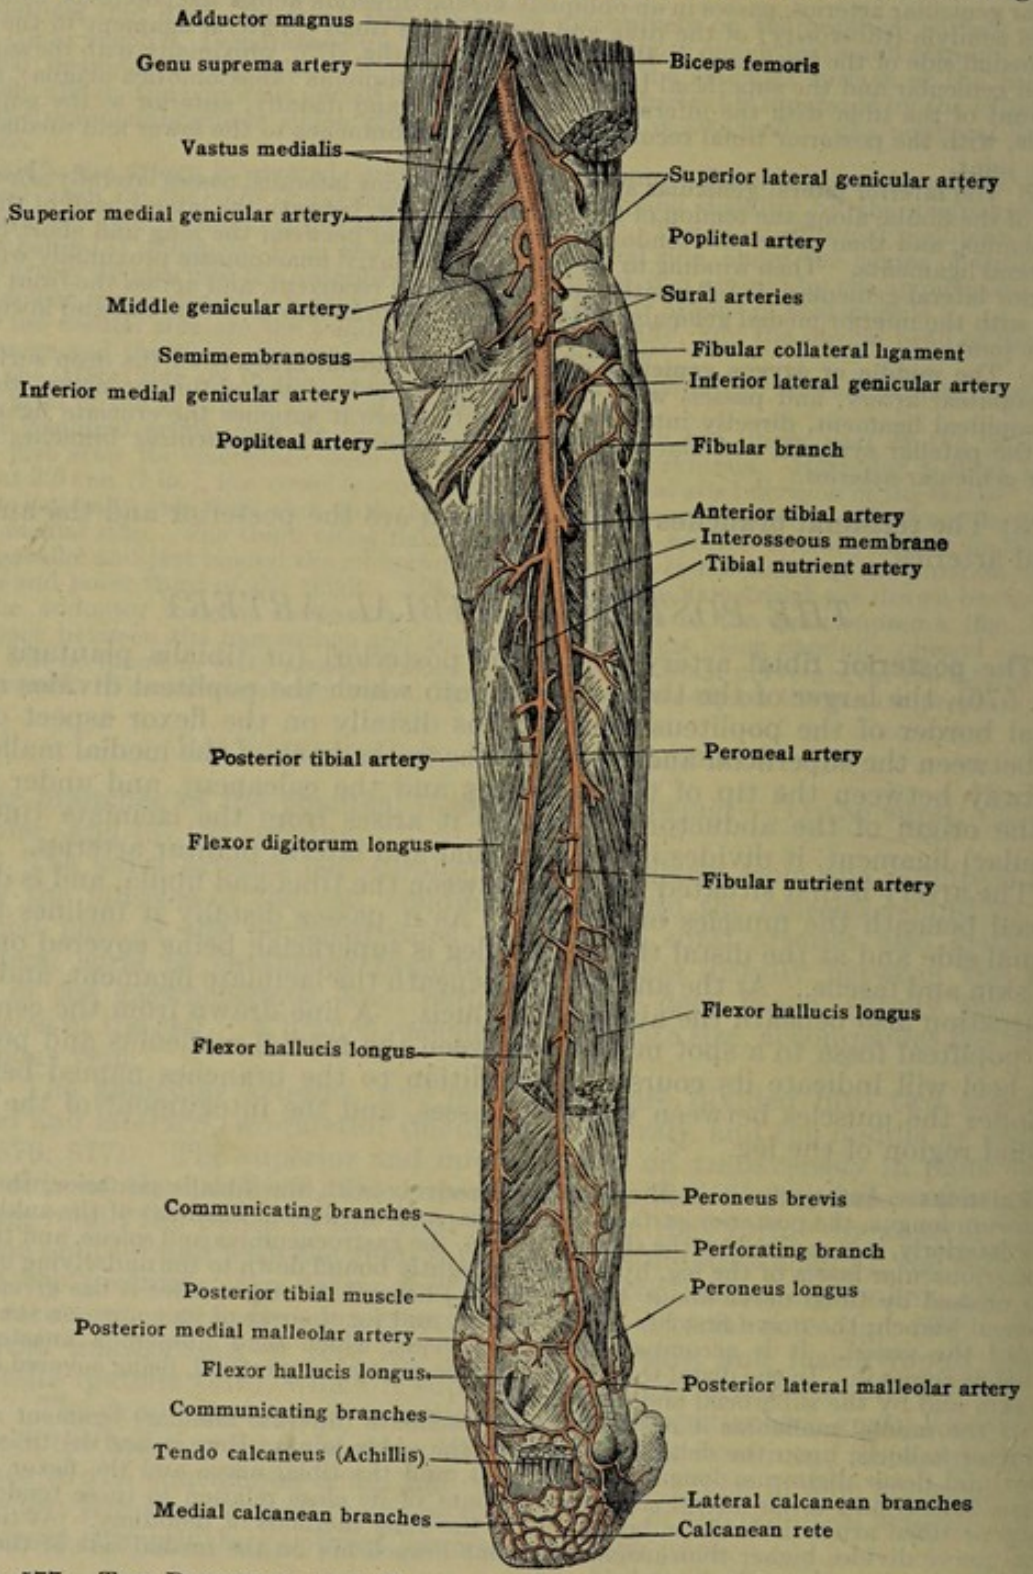

FIG. 577.—THE POPLITEAL, THE POSTERIOR TIBIAL, AND THE PERONEAL ARTERIES.
(After Toldt, 'Atlas of Human Anatomy', The Macmillan Company.)

the posterior medial malleolar; (6) the medial calcanean; and (7) the terminal, medial and lateral plantar. The anastomoses of the posterior tibial branches are shown in fig. 575.

(1) The **fibular** or superior fibular branch [r. fibularis], usually arises from the beginning of the anterior tibial or from the posterior tibial recurrent (see fig. 577). It runs laterally

toward the head of the fibula. It is small and gives twigs to the soleus, peroneus longus, and extensor digitorum longus, and anastomoses with the inferior lateral genicular and the lateral sural arteries.

(2) The **peroneal** artery [a. peronea] is a large vessel which (figs. 576, 577) arises from the posterior tibial about 2.5 cm. (1 in.) below the distal border of the popliteus muscle. It first curves laterally on the tibialis posterior and beneath the soleus muscle, and reaches the fibula at the proximal margin of the flexor hallucis longus muscle. It then dips beneath that muscle and enters a canal bounded by the fibula and the flexor longus hallucis and tibialis posterior muscles. At the distal margin of the latter muscle it lies upon the interosseous membrane where it gives a large perforating (anterior peroneal) branch. It now passes over the tibiofibular syndesmosis to run, under the name of the posterior lateral malleolar (posterior peroneal) branch, upon the posterior aspect of the lateral malleolus. It terminates upon the lateral surface of the tuber calcanei by breaking up into lateral calcaneal branches.

The **branches of the peroneal** artery (fig. 577) are:—(*a*) The fibular nutrient; (*b*) the communicating; (*c*) the perforating; (*d*) the lateral malleolar; and (*e*) the lateral calcaneal.

(*a*) The *fibular nutrient* artery [a. nutritia fibulæ] enters the nutrient canal of the fibula.

(*b*) The *communicating* branch [r. communicans] passes between the interosseous membrane and the tendon of the flexor hallucis longus in the supramalleolar region and joins the communicating branch of the posterior tibial artery.

(*c*) The *perforating* (or anterior peroneal) branch [r. perforans] arises usually a short distance below, but sometimes above, the communicating branch, and passes through the interosseous membrane (fig. 577). It supplies the tibiofibular syndesmosis and anastomoses with the lateral tarsal, arcuate and anterior lateral malleolar arteries.

(*d*) The *lateral posterior malleolar* artery [a. malleolaris posterior lateralis] (or malleolaris plantaris fibularis NK) is the terminal part of the peroneal. It crosses the posterior aspect of the tibiofibular syndesmosis and lateral malleolus to reach the lateral aspect of the tuber calcanei. It gives off branches on the malleolus which anastomose with branches of the anterior *lateral malleolar rete;* also (*e*) the *lateral calcaneal* branches [rr. calcanei laterales] (or fibulares NK) which enter into the formation of the *rete calcaneum.*

(3) The **tibial nutrient** artery [a. nutritia tibiæ], a vessel of large size, leaves the proximal part of the posterior tibial, pierces the tibialis posterior, and enters the nutrient foramen in the proximal third of the posterior surface of the tibia. In the interior of the bone it divides into two branches: a smaller branch, which runs toward the head of the bone; and a larger, which courses toward the distal end. It gives off two or three muscular twigs to the tibialis posterior before it enters the foramen. The nutrient artery of the tibia is the largest artery of its kind in the body, and is accompanied by a nerve given off by the nerve to the popliteus.

(4) The **communicating** branch [r. communicans] arises from the posterior tibial about 5 cm. (2 in.) above the medial malleolus, and, passing transversely across the tibia beneath the flexor hallucis longus, anastomoses with the communicating branch of the peroneal.

Frequently another branch of communication between the posterior tibial and peroneal arteries is likewise present in the loose connective tissue behind the flexor hallucis longus tendon.

(5) The **posterior medial malleolar** branch [a. malleolaris posterior medialis] (or a. malleolaris plantaris tibialis NK) divides for distribution over the medial malleolus, anastomosing with the anterior medial malleolar artery in the *medial malleolar rete* [rete malleolare mediale]. It runs beneath the flexor digitorum longus and tibialis posterior muscles.

(6) The **medial calcanean** branches [rr. calcanei mediales] (or calcanei tibiales NK) are distributed to the soft parts over the medial side of the calcaneus. These branches come off more frequently from the lateral plantar artery than from the posterior tibial; they enter the rete calcaneum and anastomose with the lateral calcaneal and posterior medial malleolar arteries.

(7) The **terminal branches** are the lateral and medial plantar arteries.

As a general rule, in **amputation of the leg** 2.5 cm. (1 in.) below the head of the fibula, only one main artery—the popliteal—is divided. In amputations 5 cm. (2 in.) below the head of the fibula, two main arteries—the anterior and posterior tibials—are divided. In amputations 7.5 cm. (3 in.) below the head, three main arteries—the two tibials and the peroneal—are divided. (Holden.) In an amputation through the middle of the leg, the anterior tibial artery would be found cut on the interosseous membrane between the tibialis anterior and the extensor hallucis longus, the deep peroneal nerve here lying in front of the vessel. The posterior tibial would be between the superficial and deep muscles at the back of the leg lying on the tibialis posterior, its nerve being to the lateral side. The peroneal would be close to the fibula in the flexor hallucis longus.

THE LATERAL PLANTAR ARTERY

The **lateral plantar** artery [a. plantaris lateralis] (or a. plantaris tibialis NK) (figs. 577, 578)—the larger of the two branches into which the posterior tibial divides beneath the laciniate (internal annular) ligament—passes at first laterally and forward across the sole of the foot to the base of the fifth metatarsal bone, where it bends medially, and still running forward sinks deeply into the foot and terminates at the proximal end of the first interosseous space by anastomosing with the deep plantar (communicating) branch of the dorsal artery of the foot.

In its course to the fifth metatarsal bone the artery runs in a more or less straight line obliquely across the foot; while its deep portion, extending from the fifth metatarsal bone to the proximal end of the first interosseous space, forms a slight curve with the convexity forward, and is known as the **plantar arch** [arcus plantaris]. The plantar arch is comparable to the deep volar arch formed by the deep branch of the ulnar anastomosing with the radial through the first interosseous space. The lateral plantar artery is accompanied by two veins. The course of the artery is indicated by a line drawn across the sole of the foot from a point midway between the tip of the medial malleolus and the medial tubercle of the calcaneus to the base of the fifth metatarsal bone, and thence to the lateral side of the base of the first metatarsal.

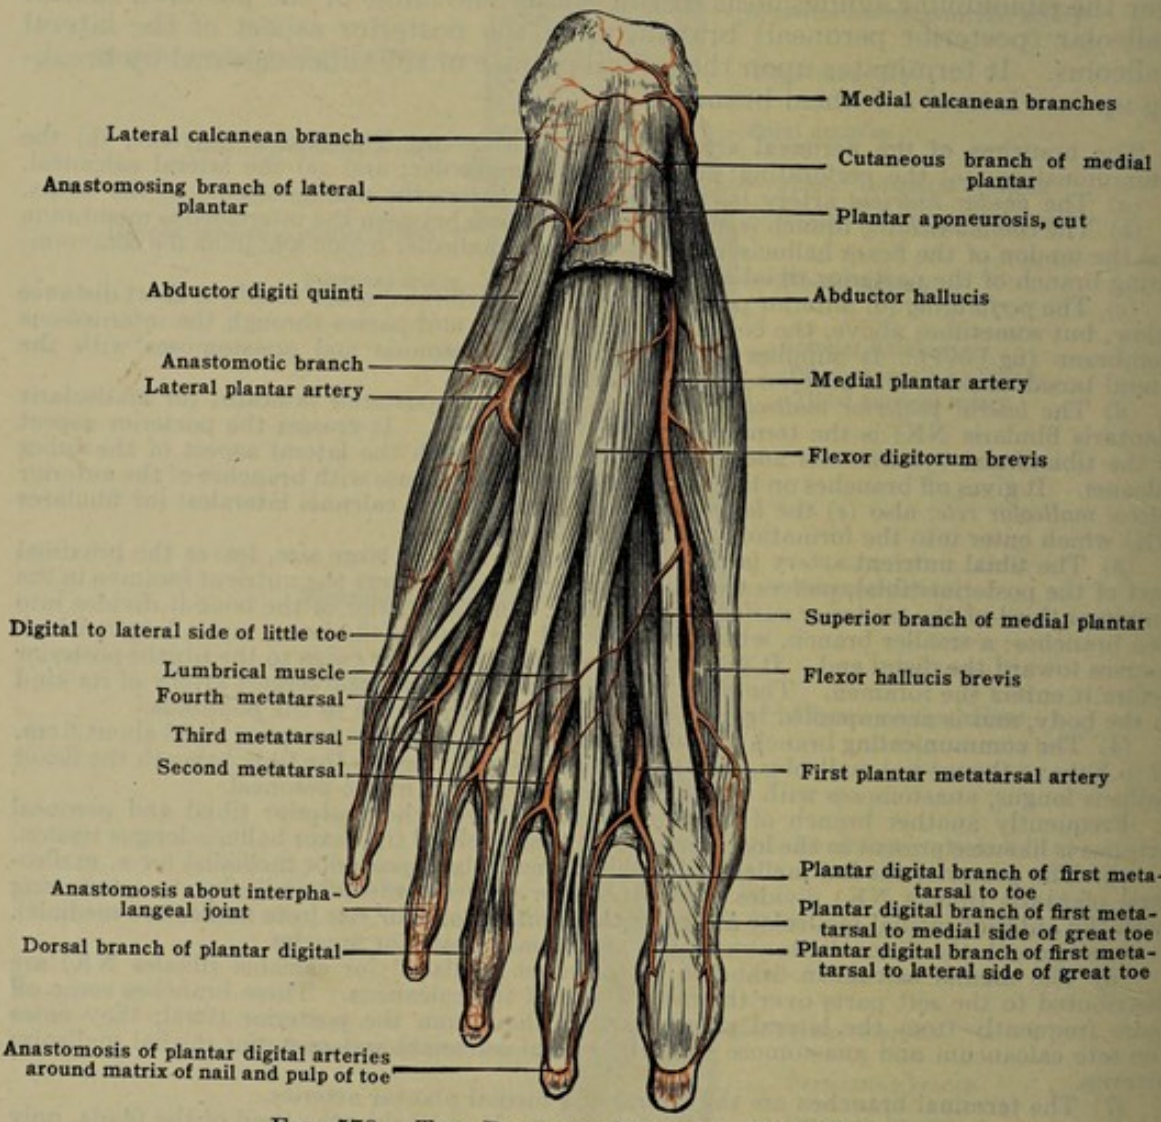

FIG. 578.—THE PLANTAR ARTERIES, LEFT FOOT.
(From a dissection in the Museum of St. Bartholomew's Hospital.)

The lateral plantar artery, besides the branches named below, gives twigs to supply the muscles between which it passes, and the tarsal joints. It almost invariably also gives off a number of medial calcaneal branches. These branches occasionally arise from the posterior tibial artery, and are described with the other branches of that vessel.

Relations.—In the **first part of its course** from the medial malleolus to the base of the fifth metatarsal bone, the artery is covered successively by the abductor hallucis and the flexor digitorum brevis, by which it is separated from the plantar aponeurosis, and may be slightly overlapped in muscular subjects by the abductor quinti digiti. As it approaches the base of the fifth metatarsal bone it lies, as it turns medially before sinking into the foot, in the interspace between the flexor digitorum brevis and the abductor quinti digiti, and is here covered only by the skin and superficial fascia and the plantar aponeurosis. It lies upon the calcaneus, the quadratus plantæ (flexor accessorius), and the flexor digiti quinti brevis. It is accompanied by the lateral plantar nerve, the smaller of the two divisions into which the tibial nerve divides. In this part of its course it gives off small branches to the contiguous muscles and to the heel.

In the **second part of its course** the artery, which is here known as the **plantar arch** [arcus plantaris], sinks into the sole, and is covered, in addition to the skin, superficial fascia, plantar aponeurosis, and flexor digitorum brevis, by the tendons of the flexor digitorum longus, the lumbricales, branches of the medial plantar nerve, and the adductor hallucis. It lies upon the

proximal ends of the second, third, and fourth metatarsal bones and the corresponding interosseous muscles.

The **branches of the lateral plantar artery** are: (1) perforating; and (2) plantar metatarsal (digital).

(1) The **perforating** branches [rr. perforantes], three in number, ascend through the proximal end of the second, third, and fourth spaces, between the two heads of the correspondingly named dorsal interosseous, muscles, and communicate with the proximal ends of the first, second, and third dorsal metatarsal (interosseous) arteries (fig. 581).

(2) The **plantar metatarsal** arteries [aa. metatarseæ plantares] are usually four in number and pass forward in the four intermetatarsal spaces, which are numbered from the medial side. They rest upon the interosseous muscles of their spaces, and are at first under cover of the lumbricals, but as they approach the clefts of the toes each divides into two branches, the **plantar digital** arteries [aa. digitales plantares], which supply the contiguous sides of the toes. The plantar digital branch for the medial side of the great toe is usually given off by the first plantar

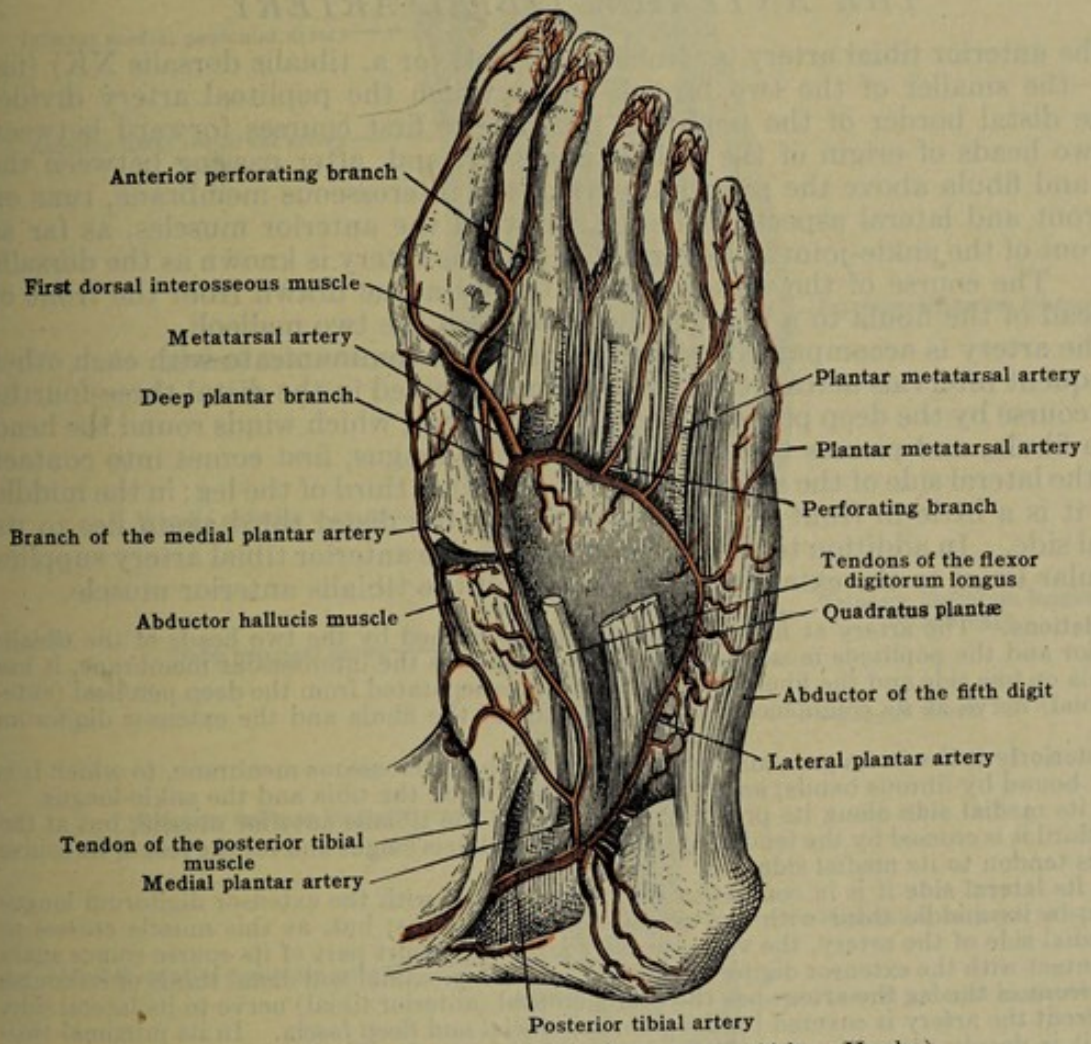

FIG. 579.—DEEP PLANTAR ARTERIES. (After Henle.)

metatarsal; that for the lateral side of the little toe is usually a separate branch from the latera end of the plantar arch.

The plantar metatarsal arteries, immediately before they bifurcate, send to the dorsum of the foot a perforating branch each to the corresponding dorsal metatarsal artery. They anastomose by many small twigs with the dorsal metatarsal arteries. Immediately below each phalangeal joint the plantar digital vessels communicate by cross branches, forming a rete for the supply of the articular end of the phalanges and the contiguous joints. At the distal end of the toes they also freely anastomose with each other, forming a rete beneath the pulp and around the matrix of the nail. The metatarsal and digital arteries are each accompanied by two small veins.

THE MEDIAL PLANTAR ARTERY

The **medial plantar** artery [a. plantaris medialis] (or a. plantaris fibularis NK) (figs. 578, 579)—much the smaller of the two divisions into which the posterior tibial divides—passes forward along the medial side of the sole of the foot usually to the first interosseous space. Here it ends by anastomosing either with the first plantar metatarsal artery derived from the plantar arch, or with the branch given off by the first plantar metatarsal to the medial side of the great toe.

Relations.—The artery is at first under cover of the abductor hallucis, but afterward lies in the interval between that muscle and the flexor digitorum brevis. It is covered by the skin and superficial fascia, but not by the plantar aponeurosis, since it lies between the central and medial portions of that structure.

The **branches of the medial plantar** are:—(1) The deep and (2) the superficial.

(1) The **deep** branch [r. profundus], which at once divides—or it may come off as several branches—to supply the muscles, articulations, and integument of the medial side of the sole. Some of these branches form an anastomosis around the medial margin of the foot, with branches of the dorsalis pedis.

(2) The **superficial** branch [r. superficialis] breaks up into very small twigs which accompany the digital branches of the medial plantar nerves, and anastomose with the plantar metatarsal arteries in the first, second, and third spaces. At times a twig from one of these branches joins the lateral plantar artery to form a superficial plantar arch.

THE ANTERIOR TIBIAL ARTERY

The **anterior tibial artery** [a. tibialis anterior] (or a. tibialis dorsalis NK) (fig. 580)—the smaller of the two branches into which the popliteal artery divides at the distal border of the popliteus muscle—at first courses forward between the two heads of origin of the tibialis posterior, and, after passing between the tibia and fibula above the proximal part of the interosseous membrane, runs on the front and lateral aspect of the leg, between the anterior muscles, as far as the front of the ankle-joint. Beyond the joint the artery is known as the dorsalis pedis. The course of the vessel is indicated by a line drawn from the front of the head of the fibula to a point midway between the two malleoli.

The artery is accompanied by two veins which communicate with each other at frequent intervals across it. It is also accompanied in the distal three-fourths of its course by the deep peroneal nerve. The nerve, which winds round the head of the fibula, and pierces the extensor digitorum longus, first comes into contact with the lateral side of the artery about the proximal third of the leg; in the middle third it is a little in front of the artery, and in the distal third again lies to its lateral side. In addition to the named branches the anterior tibial artery supplies muscular twigs to the extensors of the toes and the tibialis anterior muscle.

Relations.—The artery at first lies in the triangle formed by the two heads of the tibialis posterior and the popliteus muscle; and, as it passes above the interosseous membrane, it has the tibia on one side and the fibula on the other. It is separated from the deep peroneal (anterior tibial) nerve at its commencement by the neck of the fibula and the extensor digitorum longus.

Posteriorly it lies in its proximal two-thirds upon the interosseous menbrane, to which it is closely bound by fibrous bands; and in its distal third upon the tibia and the ankle-longus.

To its **medial side** along its proximal two-thirds is the tibialis anterior muscle; but at the distal third it is crossed by the tendon of the extensor hallucis longus and for the rest of its course has this tendon to its medial side.

On its **lateral side** it is in contact in its proximal third with the extensor digitorum longus muscle; in its middle third with the extensor hallucis longus; but, as this muscle crosses to the medial side of the artery, the vessel usually for a very short part of its course comes again into contact with the extensor digitorum longus. At the proximal and distal thirds of its course on the front of the leg the artery has the deep peroneal (anterior tibial) nerve to its lateral side.

In front the artery is covered by the skin, superficial and deep fascia. In its proximal two-thirds it is deeply placed in the cellular interval between the tibialis anterior on the medial side and the extensor digitorum longus and extensor hallucis longus on its lateral side; and in its distal third it is crossed in the lateromedial direction by the tendon of the extensor hallucis longus, and lies beneath the cruciate (anterior annular) ligament of the ankle-joint. The deep peroneal nerve is usually in front of the artery in the middle third of the leg.

Ligature of the anterior tibial artery at the junction of the upper and middle thirds of the leg. The limb being flexed and rotated medially, an incision is made, 7.5 to 10 cm. (3 to 4 in.) long, in the line of the artery, distant 2.5 cm. (1 in.) or more (according to the size of the leg) from the crest, and beginning about 5 cm. (2 in.) below the head of the tibia. If, on exposure of the deep fascia, the intermuscular septum between the tibialis and long extensor of the toes is not well defined, the fascia must be freely slit up in the line of the artery, and the sulcus felt for. A small muscular artery may lead down to the trunk. The foot is now dorsiflexed and the artery sought for deep on the interosseous membrane. The nerve should be drawn to the outer side. The venæ comitantes may be included in the ligature.

In **senile gangrene** the liability of the tibial arteries to disease and consequent thrombosis and interference with the collateral circulation accounts both for the extension of the disease and the difficulty in detecting pulsation.

The **branches of the anterior tibial artery** are:—(1) The posterior tibial recurrent; (2) the anterior tibial recurrent; (3) the medial anterior malleolar; and (4) the lateral anterior malleolar. In addition, ten or twelve muscular branches are given off irregularly to the adjacent muscles along the artery.

(1) The **posterior tibial recurrent** artery [a. recurrens tibialis posterior] (or a. rec. tib. plantaris NK) passes between the popliteus muscle and the tibia to the popliteal ligament of the knee-joint, supplying these structures and the tibiofibular joint. It anastomoses with a branch of the inferior medial genicular branch of the popliteal artery anterior to the popliteus muscle. In some limbs this vessel arises from the posterior tibial artery.

(2) The **anterior tibial recurrent** artery [a. recurrens tibialis anterior] (or a. rec. tib. dorsalis NK) is given off from the anterior tibial artery immediately after that vessel has passed above

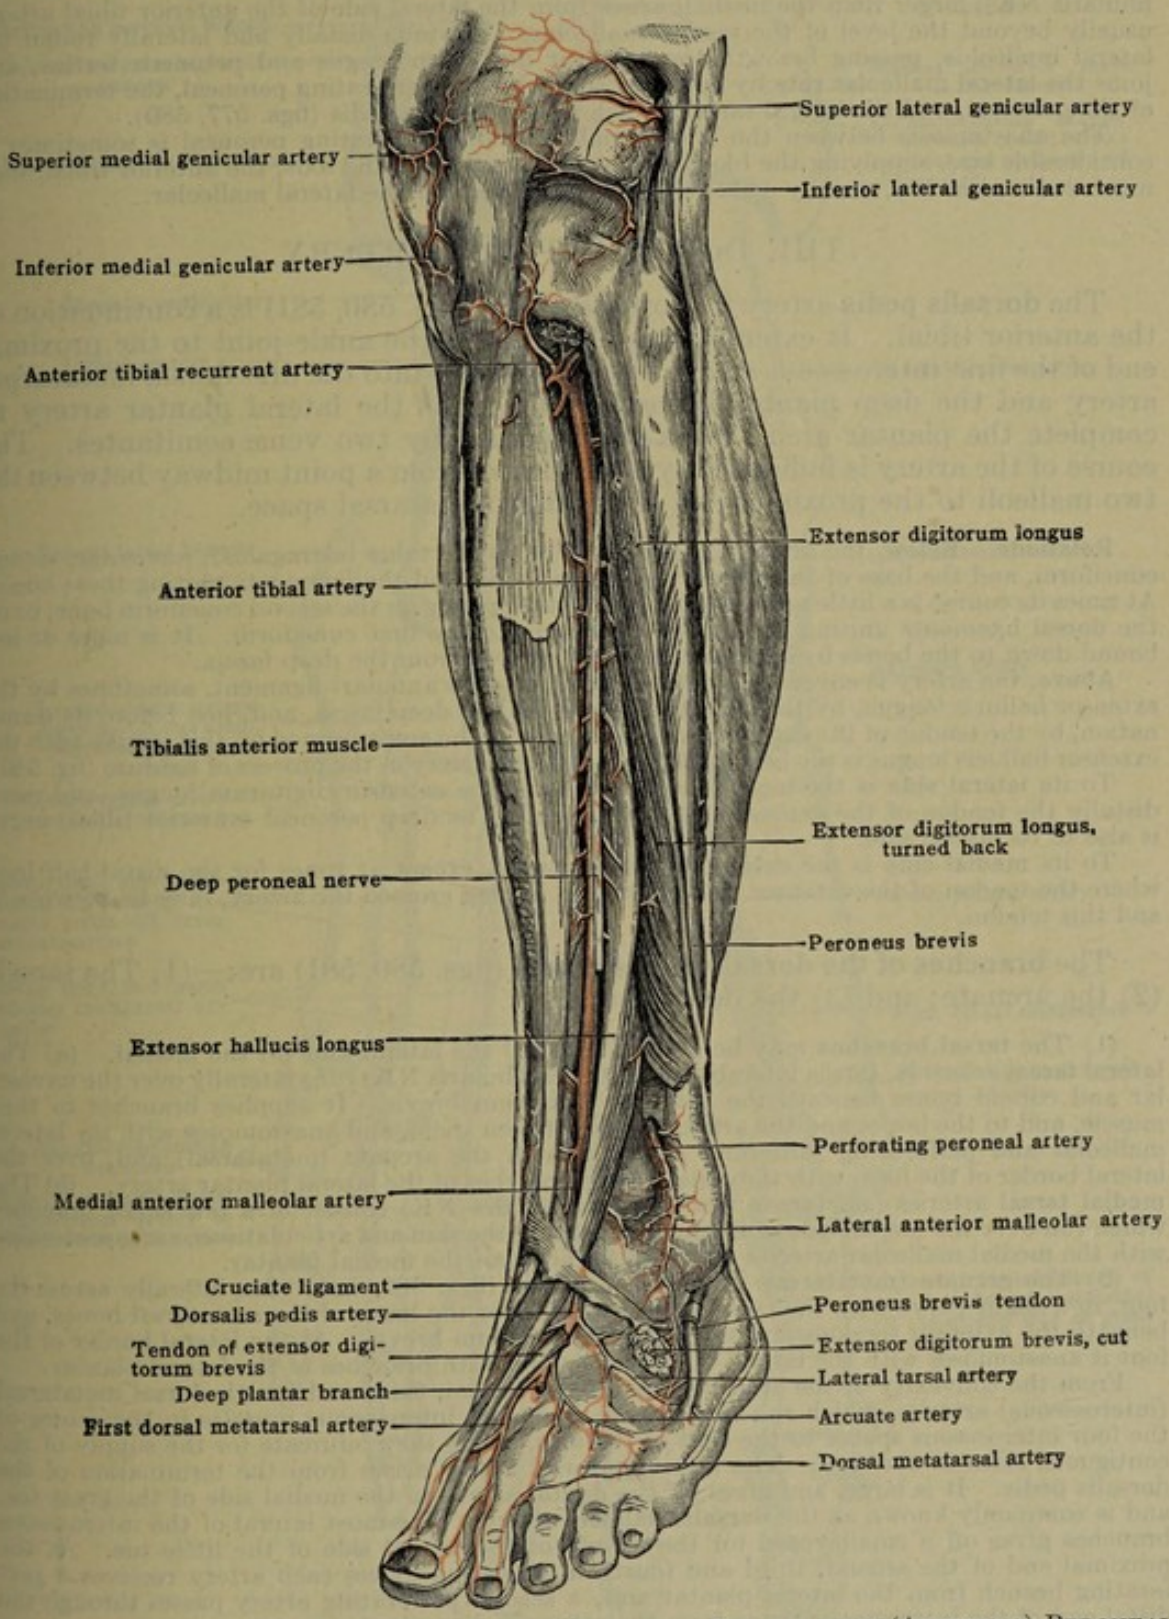

FIG. 580.—THE ANTERIOR TIBIAL, DORSALIS PEDIS AND PERFORATING (ANTERIOR) PERONEAL ARTERIES.

the interosseous membrane. It winds tortuously through the substance of the tibialis anterior muscle, over the lateral condyle (tuberosity) of the tibia close to the bone; and, perforating the deep fascia, ramifies on the lower and lateral part of the capsule of the knee-joint. It anastomoses with the inferior and superior lateral genicular branches of the popliteal, with the descending branch of the lateral circumflex, and somewhat less freely with the medial genicular branches of the popliteal and with the genu suprema (anastomotica magna). It

gives off small branches to the tibialis anterior, the extensor digitorum longus, the knee-joint, and the contiguous fascia and skin.

(3) The **medial anterior malleolar** artery [a. malleolaris anterior medialis] (or a. mal. dorsalis tibiolis NK) arises from the distal part of the anterior tibial artery, usually near the place at which the tendon of the extensor hallucis longus crosses the anterior tibial artery. It winds over the medial malleolus, passing beneath the tibialis anterior, and joins the **medial malleolar rete** anastomosing with branches from the posterior tibial artery.

(4) The **lateral anterior malleolar** artery [a. malleolaris anterior lateralis] (or a. mal. dorsalis fibularis NK), larger than the medial, arises from the lateral side of the anterior tibial artery, usually beyond the level of the medial malleolar. It winds distally and laterally round the lateral malleolus, passing beneath the extensor digitorum longus and peroneus tertius, and joins the **lateral malleolar rete** by anastomosing with the perforating peroneal, the termination of the peroneal, and the lateral tarsal branch of the dorsalis pedis (figs. 577, 580).

The anastomosis between the lateral malleolar and perforating peroneal is sometimes of considerable size, supplying the blood to the dorsal artery of the foot; the anterior tibial, then much reduced in size, usually ends at the place of origin of the lateral malleolar.

THE DORSALIS PEDIS ARTERY

The **dorsalis pedis** artery [a. dorsalis pedis] (figs. 580, 581) is a continuation of the anterior tibial. It extends from the front of the ankle-joint to the proximal end of the first interosseous space, where it divides into the first dorsal metacarpal artery and the deep plantar branch, which joins the lateral plantar artery to complete the plantar arch. It is accompanied by two venæ comitantes. The course of the artery is indicated by a line drawn from a point midway between the two malleoli to the proximal end of the first metatarsal space.

Relations.—**Below,** the artery lies successively on the talus (astragalus), navicular, second cuneiform, and the base of the second metatarsal bone, and the ligaments uniting these bones. At times its course is a little more lateral, lying either partly on the second cuneiform bone, or on the dorsal ligaments uniting the second cuneiform to the first cuneiform. It is more or less bound down to the bones by aponeurotic fibers derived from the deep fascia.

Above, the artery is covered by the cruciate (anterior annular) ligament, sometimes by the extensor hallucis longus, by the skin, the superficial and deep fascia, and, just before its termination, by the tendon of the extensor hallucis brevis. The angle formed by this tendon with the extensor hallucis longus is the best guide to finding the artery in the process of ligature (fig. 580).

To its **lateral side** is the most medial tendon of the extensor digitorum longus, and more distally the tendon of the extensor hallucis brevis. The deep peroneal (anterior tibial) nerve is also to its lateral side.

To its **medial side** is the extensor hallucis longus, except at times for the distal half inch where the tendon of the extensor hallucis brevis, having crossed the artery, may lie between it and this tendon.

The **branches of the dorsalis pedis artery** (figs. 580, 581) are:—(1) The tarsal; (2) the arcuate; and (3) the deep plantar.

(1) The **tarsal branches** may be divided into (*a*) the lateral and (*b*) the medial. (*a*) The **lateral tarsal** artery [a. tarsea lateralis] (or a. tarsea fibularis NK) runs laterally over the navicular and cuboid bones beneath the extensor digitorum brevis. It supplies branches to that muscle, and to the bones and the articulations between them, and anastomoses with the lateral malleolar and perforating (anterior) peroneal, with the arcuate (metatarsal) and, over the lateral border of the foot, with the anastomotic branches of the lateral plantar artery. (*b*) The **medial tarsal** arteries [aa. tarseæ mediales] (or tibiales NK) consist of a few small branches which run over the medial side of the foot, supplying the skin and articulations, and anastomose with the medial malleolar arteries and with branches of the medial plantar.

(2) The **arcuate (metatarsal)** artery [a. arcuata] (figs. 580, 581) runs laterally across the foot, in a slight curve with the convexity forward, over the bases of the metatarsal bones, and beneath the extensor tendons and the extensor digitorum brevis. At the lateral border of the foot it anastomoses with the lateral tarsal artery and with branches of the lateral plantar.

From the convexity of the arch it gives off the second, third and fourth **dorsal metatarsal** (interosseous) arteries, which run forward on the dorsal interosseous muscles in the center of the four interosseous spaces to the cleft of the toes, where they bifurcate for the supply of the contiguous sides of the toes. The first metatarsal artery arises from the termination of the dorsalis pedis. It is large, and gives off the digital artery to the medial side of the great toe, and is commonly known as the **dorsalis hallucis** artery. The most lateral of the interosseous branches gives off a small vessel for the supply of the lateral side of the little toe. At the proximal end of the second, third and fourth interosseous spaces each artery receives a perforating branch from the lateral plantar and, a second perforating artery passes through the distal end of the interosseous space from the corresponding plantar metatarsal.

The **dorsal digital** arteries [aa. digitales dorsales], into which the dorsal metatarsal arteries divide at the cleft of the toes, run along the side of each toe toward the dorsal aspect, anastomosing with each other across the dorsum of the toes and by frequent branches with the digital branches of the plantar metatarsal arteries, which also run along the sides of the toes, but nearer the plantar surface. At the end of the toes they anastomose with each other around the quick of the nail.

(3) The **deep plantar** branch [r. plantaris profundus] (a. metatarsea perforans NK) comes from the dorsalis pedis with the first dorsal metatarsal artery. At the proximal end of the

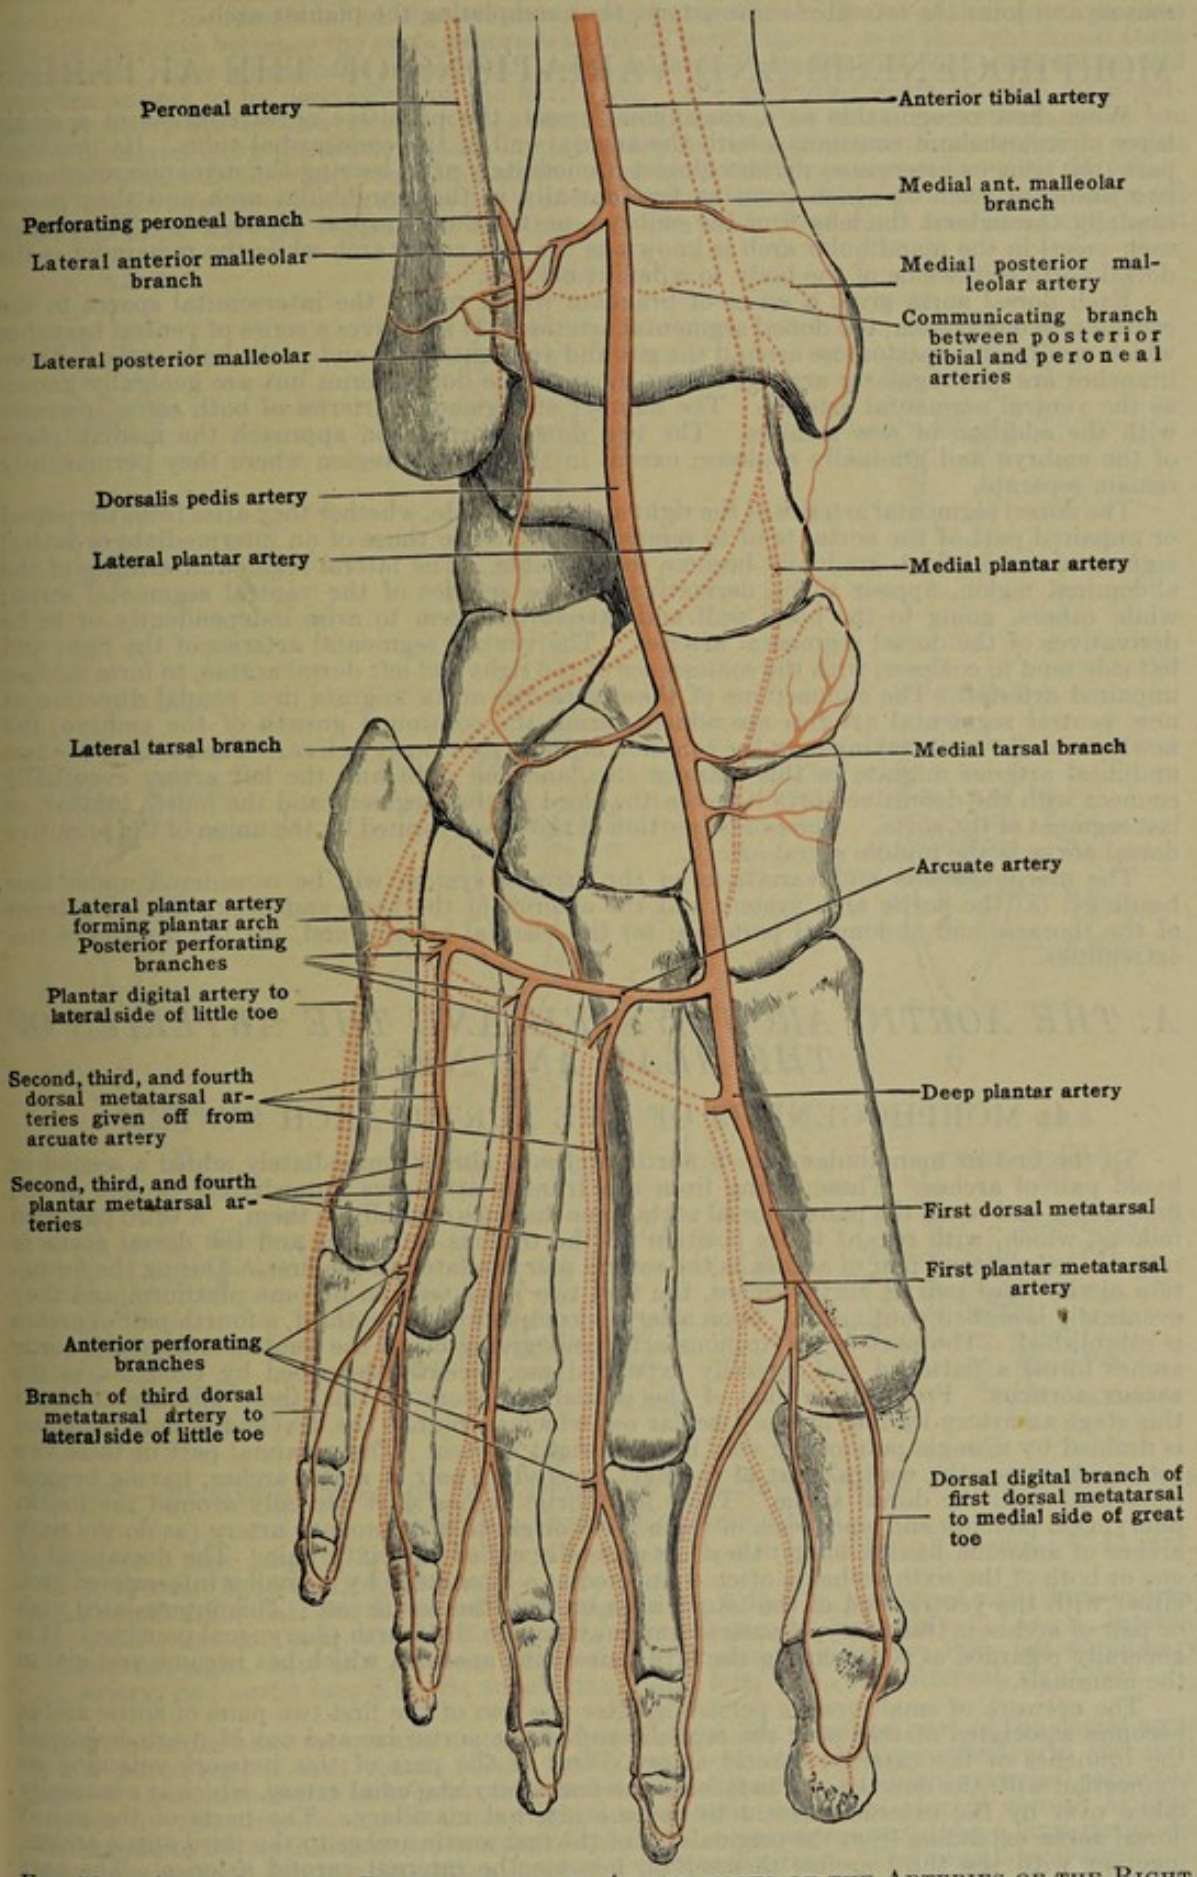

FIG. 581.—SCHEME OF THE DISTRIBUTION AND ANASTOMOSES OF THE ARTERIES OF THE RIGHT FOOT. (Walsham.)
(The plantar arteries are shown in dotted outline; the dorsal in solid red.)

first interosseous space it dips into the sole between the heads of the first dorsal interosseous muscle and joins the lateral plantar artery, thus completing the plantar arch.

MORPHOGENESIS AND VARIATIONS OF THE ARTERIES

When first recognizable as a continuous vessel, the primitive aorta consists of a single layer of endothelium continuous with the arterial end of the endocardial tube. Its proximal part (the truncus arteriosus) divides almost immediately after leaving the myoepicardium into two branches, each of which turns at first dorsally in the mandibular arch and then passes caudally throughout the length of the embryo, on the dorsal aspect of the gut. The part of each vessel in the mandibular arch is known as the first aortic arch while the remainder is the dorsal aorta of the side of the body to which it belongs.

Each dorsal aorta gives a series of branches which run in the intersomital spaces to the central nervous system, the dorsal segmental arteries. It also gives a series of ventral branches which ramify and anastomose around the gut and yolk-entoderm and in the body stalk. These branches are less regularly arranged than those of the dorsal series but are generally known as the ventral segmental arteries. The number of segmental arteries of both series increases with the addition of new somites. The two dorsal aortæ soon approach the median plane of the embryo and gradually coalesce, except in the cervical region where they permanently remain separate.

The dorsal segmental arteries of the right and the left side, whether they arise from the paired or unpaired part of the aorta, tend to remain paired, as do those of an intermediate or lateral segmental series which gradually become recognizable. The lateral segmental arteries of the abdominal region, appear to be derivatives of the arteries of the ventral segmental series; while others, going to the body wall and extremities seem to arise independently or to be derivatives of the dorsal segmental arteries. The ventral segmental arteries of the right and left side tend to coalesce, with the coalescence of the right and left dorsal aortae, to form median unpaired arteries. The connections of these with the aorta migrate in a caudal direction as new ventral segmental arteries are added during the continued growth of the embryo, the newly-formed vessels taking over the function of these previously active. The roots of the two umbilical arteries migrate in this manner also, and the right and the left artery eventually connect with the definitive aorta between the third lumbar segment and the fourth lumbar, or last segment of the aorta. The caudal portion of the vessel formed by the union of the primitive dorsal aortæ is the middle sacral artery.

The morphogenesis and variations of the arterial system will be considered under four headings: (a) the aortic arch system and the arteries of the head and neck; (b) the arteries of the thoracic and abdominal parieties; (c) the visceral arteries and, (d) the arteries of the extremities.

A. THE AORTIC ARCH SYSTEM AND THE ARTERIES OF THE HEAD AND NECK

1. MORPHOGENESIS OF THE AORTIC ARCH SYSTEM

To the first or mandibular pair of aortic arches is almost immediately added a second or hyoid pair of arches. These spring from the truncus arteriosus immediately caudad of the first arches and reach the paired dorsal aorta some distance caudally to them. A third pair soon follows, which, with regard to its position on the truncus arteriosus and the dorsal aortæ is related to the second pair of arches as the second pair is related to the first. During the formation of the third pair of aortic arches, the first two pairs tend to become plexiform and they eventually lose their continuity. Soon after the completion of the third, a fourth pair of arches is established. The part of the truncus arteriosus giving on to the ventral ends of the aortic arches forms a flattened and laterally expanded sac, recently described by Congdon as the **saccus aorticus.** From either side of the caudal periphery of this, there appears at about this stage an artery leading into a vascular net which surrounds the developing lung buds and is drained by a single pulmonary vein into the right atrium. The proximal part of these two arteries becomes the ventral part of the next succeeding pair of aortic arches, having become connected with the dorsal aortæ. These last aortic arches skirt caudally around the fourth pharyngeal pouches and since each of them gives origin to a pulmonary artery (as do the sixth arches of anamnia having lungs) they are generally called the sixth pair. The dorsal end of one or both of the sixth arches is often connected at a later stage by a smaller intercalated arch either with the ventral end of the fourth arch or with the aortic sac. This intercalated arch or pair of arches is transitory, if present and may groove the fourth pharyngeal pouches. It is generally regarded as representing the fifth pair of the anamnia which has become vestigial in the mammals.

The network of small vessels persisting after the loss of the first two pairs of aortic arches becomes associated mainly with the cephalic end of the aortic sac and out of it are developed the branches of the external carotid artery. Out of the part of this network retaining its connection with the dorsal aorta is formed the temporary **stapedial artery,** which is eventually taken over by the external carotid to become internal maxillary. The parts of the paired dorsal aortæ extending from the original site of the first aortic arches to the third aortic arches, together with the third arches themselves, become the **internal carotid** arteries. The part of the dorsal aortæ between the third and fourth pairs of arches disappears. The left fourth aortic arch and the part of the left dorsal aorta between the fourth and the sixth aortic arch becomes the definitive **arcus aortæ.** The corresponding part of the right fourth aortic arch becomes the proximal part of the **right subclavian artery.** The part of the left sixth arch between the pulmonary artery and the dorsal aorta remains patent as the **ductus arteriosus** until birth, but becomes impervious shortly afterwards and persists as the **ligamentum arterio-**

sum. The corresponding part of the right sixth arch has disappeared in embryos about 12 mm. long. The remainder of the left dorsal aorta, together with the entire, now unpaired part of the aorta becomes the **aorta descendens,** while nearly the whole of the right dorsal aorta disappears. The **innominate artery,** both **common carotid arteries** and both **external carotid arteries** appear to be derivatives of the aortic sac. The **ascending aorta** and the main **pulmonary artery** are derivatives of both the saccus aorticus and the truncus arteriosus, which are divided internally by the aortic septum in such a way as to leave the sixth pair of aortic arches in connection with the right ventricle and the other aortic arches in connection with the left.

While the system of aortic arches has been undergoing these changes, the heart has migrated from the upper cervical region into the thorax. The seventh cervical arteries of the dorsal

segmental series have meanwhile migrated upward from the unpaired part of the dorsal aorta to the paired part of that vessel. They finally take a position between the fourth and sixth pairs of aortic arches and form part of the **subclavian arteries.** The higher cervical segmental arteries by this time have lost their original connection with the internal carotid arteries. The second to the sixth segmental arteries of the dorsal series are connected by a large postcostal anastomosis which becomes the second part of a **vertebral artery.** The large lateral segmental arteries which become the axial arteries of the upper extremities are usually associated with the seventh pair of dorsal segmentals. With these the sixth segmental arteries are connected on either side by a precostal anastomosis which becomes the first part of the corresponding vertebral and arises from the subclavian. The left subclavian artery is of segmental origin throughout. The proximal part of the right subclavian is a derivative of the right fourth aortic arch and the adjacent part of the right dorsal aorta. The eighth pair of dorsal segmentals form the proximal

part of the **deep cervical** arteries. The precostal anastomoses between these and the subclavians form the *costocervical* trunks, with which also the upper two or three pairs of thoracic lateral segmentals are connected by precostal anastomoses to form the **superior intercostal** arteries. The third part of the vertebral artery appears to be a postvertebral anastomosis between the second cervical segmental and a vascular rete in the cranium from which the **basilar artery** and its branches are developed. From the anastomosis between this rete and the intracranial part of the internal carotids are formed the **cerebral, choroidal** and **communicating arteries.**

2. VARIATIONS OF THE AORTIC ARCH SYSTEM

The aortic arch may be normal in arrangement but *higher than usual*, its descent having been arrested. In two cases reported by Adachi ('28) this condition was associated with the presence of cervical ribs. A **right aortic arch** may take the place of the left, with or without situs inversus. In this case the contribution of the left and right embryonic arches in the production of the great vessels of the thorax has been reversed. There may be **two aortic arches,** the ascending aorta bifurcating distally into two branches which reunite to form the descending aorta. The left arch passes anteriorly to the trachæa and gives origin to the left common carotid artery and the left subclavian. The right, passing posteriorly to the esophagus

gives the right common carotid and the right subclavian. The right fourth aortic arch has persisted in such cases and the right subclavian artery is equivalent to the left in composition. Several examples have been reported of a persistent right fourth aortic arch giving origin in turn to the left common carotid, right common carotid, right subclavian, left subclavian (the last by Pensa, '30). The left subclavian is dilated at its origin and connected beyond the dilation with the pulmonary artery by a ligamentum arteriosum, around which the recurrent nerve passes. In these cases, the part of the left dorsal aorta below the sixth aortic arch has persisted as far as its junction with the right to form the proximal part of the left subclavian artery (see fig. 583). Other cases have been recorded in which a vessel resembling the persistent right aortic arch crosses between the esophagus and trachea to the left side of the vertebral column to become the descending aorta. Since the right fourth embryonic arch does not occupy this position, the existence of an abnormal vessel of this kind is not explicable on ordinary embryological grounds. Malacarne has reported a case (1788) in which the ascending aorta having given origin to the coronary arteries divided at once into two vessels which passed backwards on either side of the pulmonary artery and rejoined behind the esophagus. Each of them gave off in turn the subclavian, external carotid and the internal carotid of its own side, which persistent fourth aortic arches could not have done. This order of branching and the fact that the aorta contained five semilunar valves suggests abnormality of the aortic septum.

This structure seems to have divided the aortic trunk and sac in such a way as to connect the sixth aortic arches with the left ventricle and the other aortic arches with the right. The sixth aortic arches in this case appear to have persisted in their entirely, the right and left pulmonary arches having retained their connection with the pulmonary division of the aortic sac.

The **branches of the aortic arch** are apt to vary in number and there may be a **single branch, the brachiocephalic.** This ended in the left common carotid in a case recorded by Klinz (1787) and gave origin to the right innominate opposite to the left subclavian. The origin of the innominate and left common carotid by a common trunk depends on the differentiation of the parts of the aortic sac uncommon in man but usual in some other mammals. The mechanism of the separate origin of the left subclavian from the brachiocephalic trunk is not easy to follow. The left dorsal aorta between the third and fourth arches may have persisted in part, to connect with a subclavian derived from a higher dorsal segmental artery than usual. If so, the proximal part of the subclavian must then have migrated from the left internal to the left common carotid artery. Some such migration must occur also in the rare examples of **two branches** of the arch (Biume, Malacarne), in which the left subclavian and left common carotid are associated in the formation of a left innominate. **Three branches** of the aorta may differ

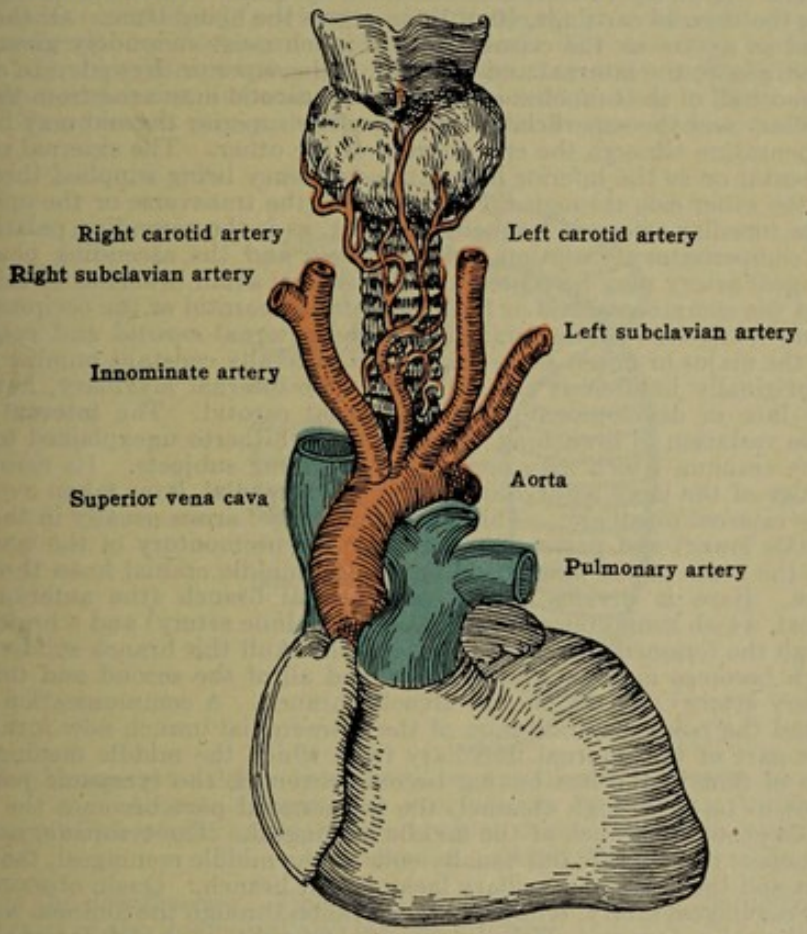

FIG. 584.—THE THYROIDEA IMA. (After Henle.)

from the normal in being the right subclavian, an innominate giving origin to both common carotids, and the left subclavian. In this case the two subclavians are developed normally but the differentiation of the aortic sac has followed an unusual course. **Four branches** may be the right subclavian, right common carotid, left common carotid and left subclavian in turn, or right common carotid, left common carotid, left subclavian and right subclavian. In the first case, the outcome of the development of the aortic arches is as usual but the differentiation of the aortic sac is abnormal. In the second case the right subclavian crosses dorsally to the esophagus and has no relation to the right recurrent nerve, which is not then recurrent. The proximal part of the right subclavian artery is here the persisting part of the right dorsal aorta below the sixth arch, the right fourth arch having disappeared (fig. 583). Four branches may be in turn the innominate, the left external carotid, the left internal carotid and left subclavian. The probable explanation of these cases is revealed by a case published recently by Schmeidel ('30) in which the left internal and external carotids were united by a cord opposite the third thoracic vertebra. This author identifies the proximal part of the left internal carotid as a persistence of the part of the left dorsal aorta between the third and fourth aortic arches. He identifies the proximal part of the left external carotid as the element which usually functions as the left common carotid, and the connection between the two carotids as a vestige of the third aortic arch (fig. 583). The addition of one vertebral, usually the left, or the thyroidea ima artery may make a fourth branch of the arch The mechanism of the origin of the **a. thyroidea ima** from the aortic arch or from the innominate has not been followed in detail but depends no doubt, upon the definitive importance of an unusual connection between the plexus around the embryonic thymus and the aortic sac (fig. 584).

There may be **more than four direct branches** of the arch, as for instance when the right subclavian artery and the right common carotid arise separately and the left vertebral is added.

The left vertebral arising from the aorta separately, is usually medially placed with regard to the subclavian. In this case the sixth left cervical segmental has retained its original connection with the dorsal aorta, not being connected by the usual precostal anastomosis with the seventh (subclavian) segmental artery. The vertebral in a lateral position with regard to the subclavian is the result of a reversal in the definitive connections of the segmental arteries of the region.

The above-mentioned deviations from the usual outcome of the development of the aortic arch system are found in adult subjects. There are many others, associated with gross defects or absence of the aortic, interventricular or interatrial septum, that are incompatible with extrauterine life. Such cases are dealt with in the text-books on Pathology.

3. MORPHOGENESIS AND VARIATIONS OF THE CAROTID AND SUBCLAVIAN ARTERIES

In all the cases hitherto reported of absence of the **common carotid,** this vessel appears actually to be represented by the proximal part of the external carotid. The proximal part of the so-called internal carotid is the part of the dorsal aorta between the third and fourth aortic arches (see p. 706). In 70 out of 295 cases examined by Quain ('44) the common carotid bifurcated higher than the thyroid cartilage, 10 of them above the hyoid bone. Of the 31 that bifurcated lower, 5 did so as low as the cricoid. The branch most commonly given by the common carotid, in addition to the internal and external, is the superior thyroid. In examples of high bifurcation, almost all of the branches of the **external carotid** may arise from the parent trunk except the maxillary and the superficial temporal. The superior thyroid may be absent on one side with compensation through the cricothyroid of the other. The external maxillary may end as the submental or as the inferior labial, the deficiency being supplied through the external maxillary of the other side through the infraorbital, the transverse or the ophthalmic of the same side. The tonsillar artery is frequently absent, as is the ascending palatine occasionally, there being compensatory variation between these and the ascending pharyngeal. The ascending pharyngeal artery may be represented by several small branches or take origin from the bifurcation of the common carotid or from the internal carotid or the occipital.

These compensatory variations of the branches of the external carotid and neighboring arteries arise through the major or minor share taken by a generally constant number of stems in the supply of an originally indifferent arterial rete. The internal maxillary, however, is taken over relatively late in development by the external carotid. The **internal carotid,** which is prone to little variation in branching, is subject to a hitherto unexplained tortuosity immediately below the cranium which may occur even in young subjects. Its caroticotympanic branch is a vestige of the large embryonic artery, the **stapedial,** later taken over by the external carotid as the internal maxillary. This embryonic vessel arises usually in the carotid canal (sometimes a little lower) and passes upwards over the promontory of the tympanum. It then runs between the crura of the stapes and enters the middle cranial fossa through the petrosquamous fissure. Here it divides into a supraorbital branch (the anterior branch of the middle meningeal, which communicates with the ophthalmic artery) and a branch which leaves the skull through the foramen spinosum. Outside the skull this branch subdivides into the infraorbital (which becomes most of the first part and all of the second and third parts of the internal maxillary artery) and the inferior alveolar branch. A communication between the external carotid and the point of subdivision of the extracranial branch now furnishes the remainder of the first part of the internal maxillary from which the middle meningeal then arises. The direction of flow in the last having become reversed, the tympanic part of the stapedial artery ceases to be a through channel, the intracranial part becomes the superior tympanic branch of the posterior branch of the middle meningeal. The tympanic part of the stapedial artery may persist in adult life but usually ends as the middle meningeal, the foramen spinosum being absent and the internal maxillary lacking that branch. Quain observed a case in which the accessory meningeal artery, reinforced by a branch through the foramen rotundum, gave origin to the ophthalmic artery and all the intracranial branches of the left internal carotid; the extracranial part of the internal carotid and the carotid canal, being absent. The communication from the external carotid appears in this case to have taken over the supraorbital branch of the stapedial and the intracranial part of the internal carotid, and to have superseded the extracranial part of the latter.

The **subclavian artery** occasionally pierces or lies anterior to the anterior scalene muscle. The right subclavian in four cases out of 25 examined by Quain ascended from 1 to 1½ inches above the clavicle. Variations of the origin of the subclavian have been noted on p. 706. The vertebral artery may arise directly from the arch of the aorta (p. 707). In some cases in which the right subclavian is the last branch of the arch, the right vertebral arises from the right common carotid. In this case the fourth aortic arch participates in the formation of the vertebral (fig. 583). The **vertebral** artery may arise by two roots from the subclavian or one from the subclavian and one from the aortic arch. One of these roots may ascend as high as the fourth cervical vertebra before entering the arterial foramen and joining its fellow. The two vessels represent two intersegmental anastomoses, a pre- and a postcostal. A vertebral artery arising by a single root may be composed partly of a precostal anastomosis between the lower cervical dorsal segmental arteries, in which case it will enter the transverse foramina at higher level than usual. The place of origin of the branches of the subclavian artery does not vary greatly in position although two of them may be united by means of a common trunk of origin. For example, the inferior thyreoid and vertebral, the internal mammary and thyreocervical or the internal mammary and suprascapular may be so united. The inferior thyreoid may arise from the common carotid and the descending branch of the transverse cervical artery not uncommonly arises from the third part of the subclavian (it is practically the only vessel that ever does so).

The **basilar artery** is a longitudinal anastomosis between the dorsal segmental arteries of the occipital region, originally continuous with the anterior spinal arteries. It retains its

connection with the first cervical segmental arteries through the two vertebrals and with the internal carotids through the posterior cerebral and posterior communicating and middle cerebral arteries. Owing to the wide choice of routes by which blood may reach the arteries of the brain through the circulus arteriosus, either of the internal carotid or vertebral arteries may be small. There may be great inverse variation in size, and this may be further increased by ligature of one of the four supplying vessels without apparent loss of function.

B. THE MORPHOGENESIS AND VARIATIONS OF THE ARTERIES OF THE THORACIC AND ABDOMINAL WALLS

The arteries of the dorsal segmental series gradually become recognizable as the somites make their appearance in the cranio-caudad direction. Arising from the posterior aspect of the at first paired dorsal aortæ, they supply the rapidly developing central nervous system. In the adult thorax and abdomen they are represented by the main stem and the dorsal ramus of the intercostal and lumbar arteries, the latter supplying the longitudinal muscles of the back and the integument in their neighborhood. The original spinal branch is represented by spinal branches arising from the costocervical, thoracic, lumbar, iliolumbar and lateral sacral arteries. A few of these on either side are large and reinforce the anterior and two posterior spinal arteries which are formed by intersegmental anastomoses. There is also a more irregularly distributed series of lateral parietal arteries. Some of these may arise originally from the arteries of the dorsal segmental series, but many of them are found to arise in early stages directly from the aortae. Those which persist, however, are found to soon become associated with the larger

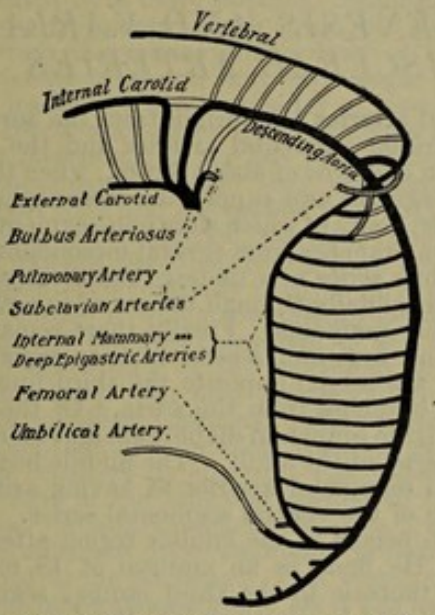

FIG. 585.—DIAGRAM TO SHOW THE DEVELOPMENT OF THE ARTERIES OF THE TRUNK FROM THE AORTIC ARCHES AND THE DORSAL SEGMENTAL ARTERIES.
The arteries which persist are black; those which degenerate are in outline; those newly formed are shaded. (After Mall.)

arteries of the dorsal series. They enlarge with the growth of the body walls and become the anterior rami of the intercostal and lumbar arteries.

The anterior rami of the intercostal and lumbar arteries are connected beneath the developing mammary line by a longitudinal anastomosis which later becomes the internal mammary and inferior epigastric arteries (fig. 585). The former receives its blood through the lateral ramus of the 7th cervical artery of the dorsal segmental series (the subclavian) and the latter through the inferior epigastric branch of the external artery or, occasionally, through the obturator branch of the hypogastric. The first two or three pairs of intercostal ventral rami become joined to the subclavian by a precostal anastomosis to form the superior intercostal artery and the costocervical trunk, the lower six thoracic anterior rami anastomose with the musculophrenic branch of the internal mammary. More laterally placed longitudinal anastomoses between the intercostal and lumbar anterior rami may be provided by the lateral costal connection with the internal mammary artery (p. 642) and the lateral epigastric branch of the deep circumflex iliac (p. 686).

The common iliac-hypogastric trunk is a lateral branch arising between the fourth segment of the aorta and the beginning of the middle sacral artery. Its course is comparable to that of the other lateral lumbar and sacral segmental arteries but it soon takes over the umbilical artery, the proximal part (ventral root) of which disappears early in development. The umbilical artery and the visceral pelvic arteries thus come to arise from the hypogastric but the parietal pelvic arteries (including the embryonic sciatic artery) are derivatives of the common iliac-hypogastric trunk.

The **costocervical and superior intercostal** arteries may traverse the foramen in the transverse process of the seventh cervical vertebra and pass between the first two thoracic transverse processes and the neck of the corresponding ribs. In this case the intersegmental union has been effected by a postcostal in place of the usual precostal anastomosis. The number of **intercostal or lumbar arteries** of either side may be reduced through the supply of two or more of them from a single segment, through a precostal anastomosis.

The **external iliac** artery, usually the first branch of the common iliac-hypogastric trunk may arise directly from the aorta, in which case the **common iliac** artery, as such, is absent. The external iliac may be the last, or nearly the last branch of the common iliac-hypogastric trunk, in which case the **hypogastric** artery is said to be absent (it is really larger than usual). When this occurs, the common iliac is continued as the hypogastric into the pelvis, the abnormal external iliac mounts from there into its usual position and is continued as the femoral. Through the anastomosis between the pubic branch of the inferior epigastric and that of the obturator, the proximal part of the latter may be wanting and a short **obturator** artery arises from the inferior epigastric or, sometimes from the external iliac (p. 686). Apart from the large size of the **inferior gluteal** in the very rare cases in which it is continued as a sciatic artery (p. 713) supplying the parts below the knee, the general distribution of the branches of the hypogastric artery is prone to little variation. The internal pudendal artery, however, is sometimes very small in its perinaeal part and is then reinforced by an **accessory pudendal.** The latter may arise from the hypogastric from the inferior vesical, the obturator or from the internal pudendal itself or more rarely from the external iliac or inferior epigastric. It runs forward on either side of the lower part of the bladder and the prostate and enters the urogenital diaphragm to end as the artery of the penis or clitoris. The internal pudendal proper ends under these circumstances as the superficial perineal or as the artery to the bulb, and usually anastomoses with the accessory pudendal near the prostate. The variability of the site of **origin of the branches of the hypogastric** artery has been referred to on p. 677. This appears to be the outcome of the free anastomosis occurring in the embryo between the parietal branches of the common iliac-hypogastric trunks and the pericloacal branches from the primary root of the umbilical arteries.

C. THE MORPHOGENESIS AND VARIATIONS OF THE VISCERAL ARTERIES

The **lateral visceral segmental arteries** take origin from the aorta in series, intermediate in position between the lateral parietal segmental arteries and the ventral segmentals. They reach their fullest development in embryos of about 8 mm., when they extend from the seventh cervical to the twelth thoracic segment and supply the mesonephros. At this stage Broman found twenty arteries on each side, many of which were non-segmental. As the suprarenals and gonads develop, they each receive branches from several mesonephric arteries. The arteries at the cephalic end of the mesonephric series now undergo rapid retrogression and the suprarenal and gonadic branches are shifted caudally through the series to newly formed (non-segmental) arteries opposite the upper lumbar segments. Finally there remain three suprarenal arteries opposite the twelfth thoracic and first and second lumbar segments and a gonadic artery (*ovarian or internal spermatic* of the adult) opposite the third lumbar segment. All of these vessels now appear to be direct branches from the aorta. Of the three suprarenal branches, the upper and lower each gives a large branch to diaphragm and kidney respectively and become the *inferior phrenic* and *renal arteries* of the adult. The middle becomes the *middle suprarenal.* Felix regards the visceral lateral segmental arteries as having arisen from longitudinal anastomoses connecting the members of the ventral segmental series. He places a different interpretation upon the vessels which persist in the lumbar region after the disappaearance of the thoracic mesonephric arteries. He finds in an embryo of 18 mm. nine arteries on either side, extending from the ninth thoracic to the third lumbar segment, all of which he looks upon as mesonephric. These arteries he classifies into three groups: Cranial, which reach the mesonephros by passing dorsally to the suprarenal; caudal which pass ventrally to the suprarenal, and middle which pass through it. Inasmuch as the arteries anastomose in the mesonephros there is great liability to variation in the number and position of the stems which persist in the adult. The suprarenal arteries are usually derived from the caudal group, the renals from the caudal or middle and the spermatics from the middle. When accessory, renals or spermatics occur in the adult their place of origin and course indicate the group from which they have been derived.

The **ventral segmental arteries** appear very early. In an embryo of seven somites (ca. 2 mm.) described by Dandy there is a right and a left series of twelve arteries, each arising from the still ununited dorsal aortæ, the artery at the caudal end of each series being the umbilical, and the remainder vitelline arteries. In an embryo of 4.9 mm. (35 somites) described by Ingalls the originally paired vitelline arteries have united (as have the dorsal aortæ in part) to form unpaired vessels. There are unpaired ventral segmental arteries as follows: one opposite the seventh cervical segment (celiac); five opposite the first four thoracic (omphalomesenterics, united by a longitudinal anastomosis), and one vessel of doubtful significance opposite the fifth and sixth thoracic segments. The paired umbilical arteries are opposite the first lumbar segment.

It has been found from more fully developed stages that the inferior mesenteric artery is distinguishable at a stage of 8 mm. opposite the second lumbar segment. Also that the ventral segmental vessels undergo a process of apparent migration until they reach their definitive positions, the *celiac* opposite the twelfth thoracic segment; the *superior mesenteric* opposite the first, the *inferior mesenteric* opposite the third, and the umbilicals between third and fourth lumbar segments, respectively. The umbilical arteries are connected in the earlier stages of development with branches of the omphalomesenteric artery on the yolk-sac. This connection is effected by the *subintestinal* artery, which usually disappears as soon as the hind-gut begins to become tortuous. The esophageal and bronchial arteries of the adult do not appear to arise directly from any of the arteries of the ventral series but are probably derived from the same common source.

The *umbilical arteries* become connected by anastomosis with the common iliac-hypogastric trunks. The original (or ventral) roots of the umbilical arteries soon disappear and the umbilical arteries are subsequently supplied through the common iliac-hypogastric trunks alone.

Multiple **renal arteries** occur with great frequency and represent unusual persistences of arteries of the mesonephric series. The supernumerary arteries may enter through the anterior convexity of the organ instead of the hilus; occasionally they enter posteriorly. They are usually branches of the aorta but may, particularly when the kidney is lower than usual, arise from the common iliac artery or from the middle sacral. The **spermatic or ovarian** arteries may be reduplicated and may arise from another member of the mesonephric series, particularly the renal. The **phrenic** arteries, and thus the **superior suprarenal** arteries may arise from a common stem with the celiac. One or even two members of the suprarenal series, on either side, may be absent, with compensatory enlargement of the one or two that are present.

The right **bronchial** artery may arise from the left instead of the right first intercostal, and there are rarely two right bronchials. The bronchial arteries for the two lungs may arise by a common stem from the aorta. All of these variations are dependent upon the free anastomosis which occurs between the local visceral and parietal arteries of the embryo. This anastomosis accounts also for the occasional origin of one or both of the bronchial arteries from branches of the subclavian, such as the costocervical, internal mammary or thyrocervical.

The **coeliac** and **superior mesenteric** arteries may arise as a single celiomesenteric trunk as in some other mammals. Anastomatic connections between these two arteries occur in many cases near the aorta and their enlargement may alter the site of origin of one or more of their branches. The **hepatic** is particularly liable to arise from the superior mesenteric, in which case the celiac is reduced to a **gastrolienal trunk**, or the left or the right hepatic may so arise. The superior mesenteric may give origin by the same means to a right or left **accessory hepatic.** In some cases the medium of transfer of the hepatic artery to the superior mesenteric artery is furnished by the pancreaticoduodenal arterial arch, but this means of transfer is less common than that effected by a more proximal communication. Any or all of the usual branches of the celiac may arise independently from the aorta, as may the **gastroduodenal,** which may arise directly from the celiac, independetly of the hepatic. The artery, besides the additional branches referred to above, may give origin to the inferior **mesenteric.** The jejunal and ileal branches leading to the first series of mesenteric arterial arcades may vary considerably in number. Blood may enter the continuous arterial arch extending from the termination of the superior mesenteric to the left colic artery by a varying number of direct branches of the superior mesenteric. When they are diminished in number, the **ileocolic** and the **right colic** or the right colic and the **middle colic** may be united by a common stem or origin. The apparent absence of the ileocolic, the right colic or the middle colic is due in this case to differences in the number of the direct routes from the aorta through which the arterial plexus of the embryonic mesentery eventually receives its supply.

A few cases have been recorded in which the superior mesenteric artery crossed to the navel and was continued through the somatic mesoderm of the umbilical cord to the placenta. Hafferl has given a careful description of the conditions in an adult female cadaver which throws light on cases of this kind. An ileal branch of the superior mesenteric crossed the intestine and joined the right umbilical ligament. The connection between the superior mesenteric and the cord representing the right umbilical artery is, no doubt, a persisting **subintestinal** artery, which in this case retained its lumen. The persisting **omphalomesenteric** artery sometimes found at birth, runs in the funicular coelom to the vestigial yolk-sac and has no connection with the placenta. A large branch of the aorta is sometimes found at birth (usually associated with imperforate anus and other anomalies preventing viability) to go through the somatic mesoderm of the cord to the placenta. This vessel, since it does not pass through the mesentery, is not a persistent omphalomesenteric (as it has been regarded). It is an **umbilical** artery which, not having been taken over by the common iliac-hypogastric trunk, has retained its original connection with the aorta.

The branches of the **inferior mesenteric** artery arise from the superior mesenteric in the rare cases in which the former is absent. The branches themselves vary little in distribution. The middle and left colic have been recorded by Hyrtl as arising from a 'middle mesenteric' which arose in this case from the common iliac.

D. THE MORPHOGENESIS AND VARIATIONS OF THE ARTERIES OF THE EXTREMITIES

Of the several small lateral segmental arteries originally supplying the embryonic limb, one gains ascendency over the others, and becomes the axial artery of the extremity. This gives origin to innumerable small branches leading into an anastomosing network drained originally into the umbilical vein. A drainage system is soon established which consists of a superficial marginal vein. The ulnar limb of the marginal vein of the upper extremity becomes the basilic, axillary and subclavian veins; the fibular vein of the lower extremity becomes the v. saphena parva.

The axial artery of the **upper extremity** persists until maturity and becomes the subclavian, axillary, and brachial arteries continued as the part of the ulnar artery beneath the m. pronator teres, the common and volar interoseous arteries, the volar carpal rete and the deep arteries of the palm. The distal perforating branch of the axial artery persists as the perforating branch of the volar interoseous, and its continuation forms the dorsal carpal rete and dorsal interoseous and digital arteries. To these the radial and dorsal interoseous arteries, the remaining part of the ulnar and the superficial volar arch are added during the progress of development.

The chief **variations** due to the unusual persistence of normal embryonic arteries are: (1) the origin of the **radial** artery in the wrist from the volar interoseous through the volar or dorsal radial carpal, or both, the radial artery in the forearm being small or absent; and (2) a **median** artery of unusual size. The median artery is large in the embryo but dwindles after having been instrumental in forming the superficial volar arch. The other principal variations consist of the persistence of abnormal arteries that do not appear to occur normally at any stage of development. These abnormal vessels include the following. 1. The **caudal axillary** artery

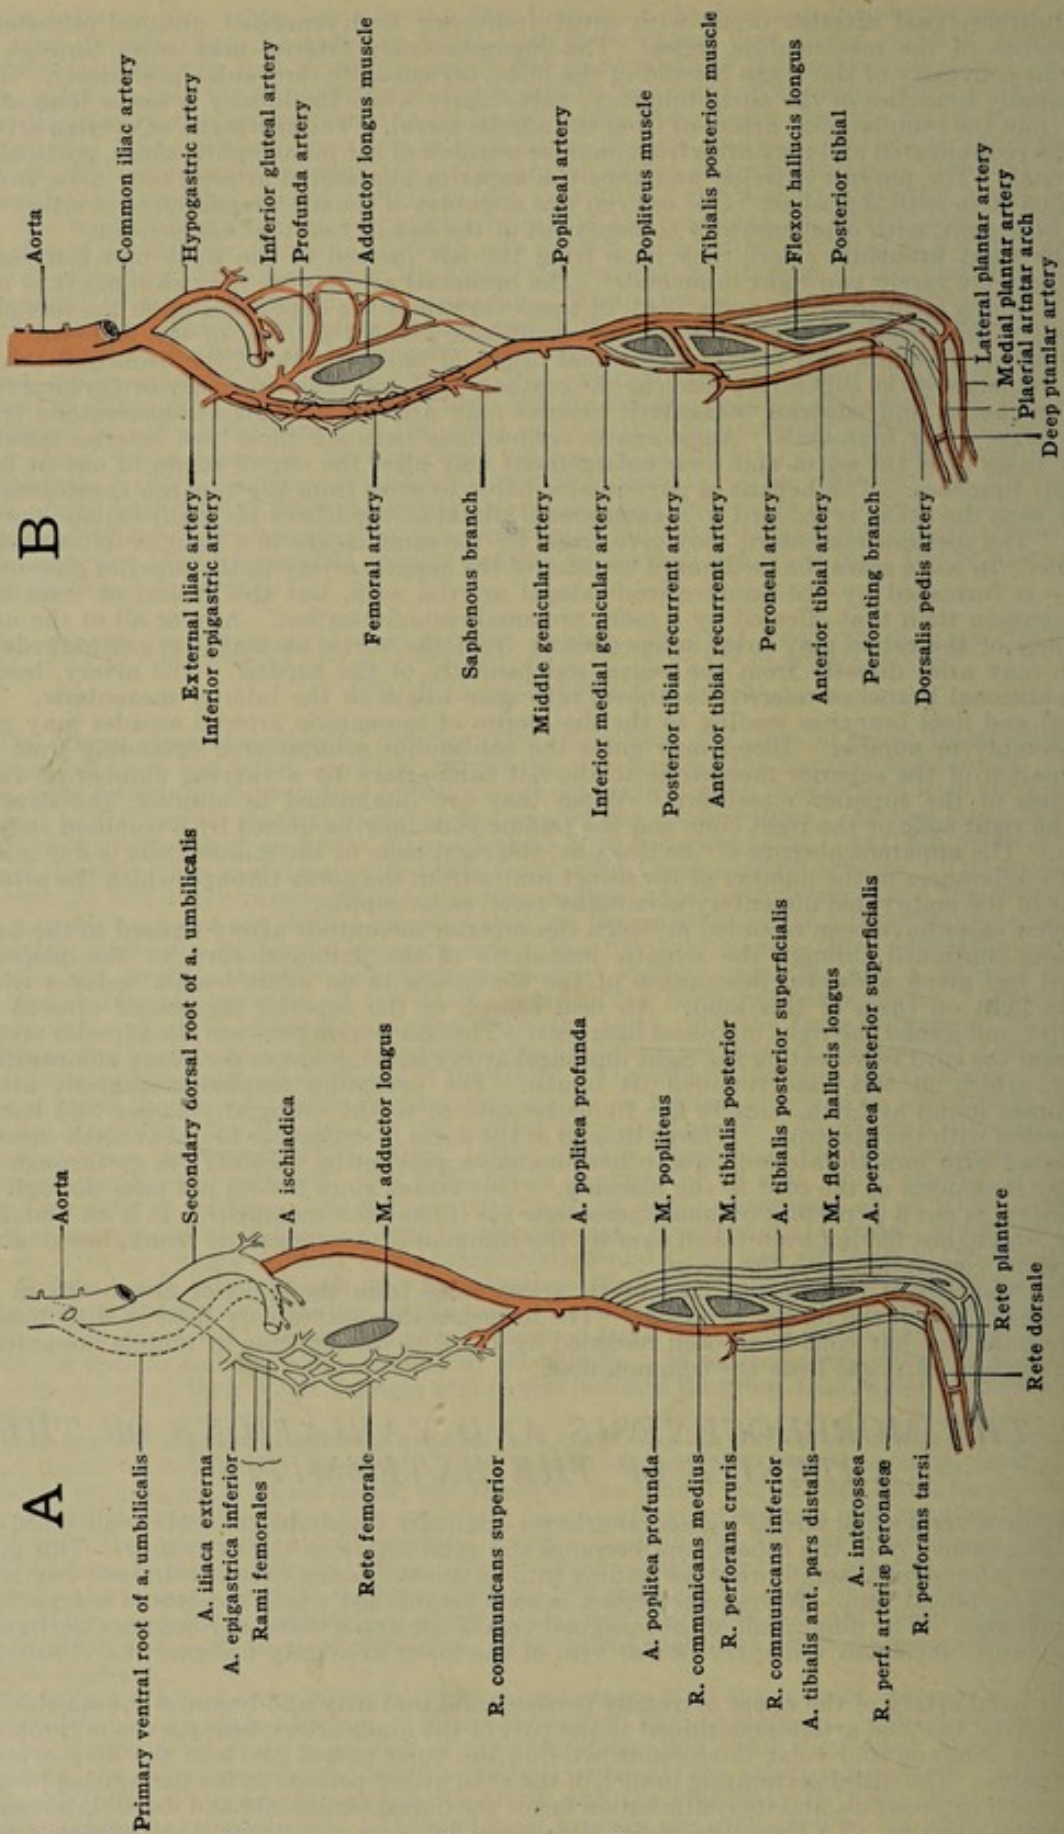

FIG. 586.—DIAGRAM INDICATING THE METHOD OF DEVELOPMENT OF THE ARTERIES OF THE RIGHT LOWER EXTREMITY.

The embryonic arteries are outlined in black. In *A*, the axial artery of the developing limb, and some of its branches are colored red; the original, or ventral, root of the umbilical artery is indicated by a broken line. In *B*, the adult arteries are colored red.

which does not traverse the ventral plate of the brachial plexus in the ventro-dorsal direction, above the loop of the median nerve, as does the axillary part of the axial artery. It reaches the dorsal side of the ventral plate by curving around the caudal aspect of the plexus. 2. The **superficial brachial** artery. This vessel may arise from the axillary above, and cross superficially to, the median nerve loop (a. brachialis superficialis superior) or it may arise from any part of the brachial (a. brachialis superficialis inferior). In either case it crosses the median nerve superficially in the arm, to reach its medial side. Both the superior and inferior superficial brachial may rejoin the brachial artery proper (forming a vas aberrans); or may be continued as a normal radial artery. In the latter case the superficial brachial may or may not be connected at the bend of the elbow with the brachial, which is continued as a normal ulnar artery. In some cases the superficial brachial is continued as a superficial antibrachial artery, or as the radial and a superficial antibrachial. The **superficial antibrachial** artery passes across the muscles arising from the medial epicondyle (occasionally going deep to the palmaris longus) and ends either as a large median artery or as the ulnar artery, in the hand. In the latter case the part of the ulnar artery not included in the original axial artery is absent. In other cases, the superficial brachial artery is very large and supplies the entire limb beyond the elbow. In this case it has a large branch (known as the **profunda axillaris**), which represents the brachial part of the axial artery of the embryo and passes deeply above the loop of the median nerve. This branch gives origin to the circumflex humeral arteries, the subscapular, the profunda brachii and the superior ulnar collateral and ends as the inferior ulnar collateral.

The caudal axillary and the superficial brachial artery, either superior or inferior, arise in the embryo as accessory vessels which may definitively supplant or accompany a part of the original axial trunk. Since they appear to be abnormal, not only in the adult but in the embryo, the study of normal development as such, throws no light on the manner or the time of their appearance. The superficial antibrachial artery supplants the part of the ulnar artery which does not form part of the axial, but it, also, does not seem to occur during the usual course of development.

In limbs in which there is a supracondylar hook on the humerus, the brachial artery and the median nerve pass behind it (and deep to an accessory head of the m. pronator teres which is generally present in these cases) before reaching their usual position in the antecubital fossa. Such a course, normal in some other mammals, appears to be inherited from a common ancestor in which the brachial artery passed through a supracondylar foramen.

The **lower extremity** offers a contrast to the upper in that all of the commoner and more important variations represent persistencies of arteries that occur normally in the embryo. The axial artery arises from the common iliac-hypogastric trunk (the secondary root of the umbilical artery) and forms the sciatic, which is continued in turn as the popliteal and the interoseous artery of the embryo and the deep arteries of the sole. The distal perforating branch (a. perforans tarsi) traverses the sinus tarsi and its continuation forms the dorsal tarsal and metatarsal arteries (fig. 586). The sciatic part of the axial artery is represented at maturity only by the inferior gluteal artery and the anastomosis between the perforating arteries. Of the popliteal part only the portion between the hiatus tendineus and the popliteus muscle persists; the remainder, which passes between the popliteus muscle and the tibia, ceases to act as a through channel. The interoseous part is lost entirely, except for the small portion of it which enters into the formation of the anterior tibial artery and another small part incorporated in the definitive peroneal artery. The external iliac artery, the femoral, the posterior tibial and the remaining part of the anterior tibial and peroneal arteries are all secondarily formed vessels. The distal part of the popliteal artery (like the neighboring part of the posterior tibial) is formed by the proximo-distal union between the predecessor of the posterior tibial and that of the greater part of the peroneal artery (fig. 586).

The **sciatic** artery persists rarely to supply the parts beyond the knee, at the expense of the **femoral** which is small. The embryonic (deep) popliteal may persist either as a popliteal artery anterior to the popliteus muscle, or as a part of the **anterior tibial.** In the latter case the **popliteal artery** divides behind the knee into an anterior tibial-peroneal trunk and a posterior tibial artery which does not give origin to the peroneal. It divides more rarely into an anterior tibial which passes anteriorly to the popliteus muscle and a posterior tibial artery which branches in the usual way. The predecessor of the greater part of the peroneal (the a. peronaea posterior superficialis) which takes over the supply of the sole from the interoseous artery, may persist in its entirety to be continued as the lateral plantar artery, the **posterior tibial** being small or absent. Or, the posterior tibial being small or absent, that embryonic artery may enter in the usual way into the formation of a peroneal artery, which is continued as the lateral plantar. Besides irregularities of the origin of the **anterior tibial,** the artery may be small. The **dorsalis pedis** in this case arises from the peroneal, through the perforating peroneal branch of the interoseous part of the axial.

Only two of the definitively abnormal arteries of the lower extremity are, like the majority of those of the upper extremity, anomalous alike in the embryo and in the adult. These are the abnormal **great saphenus** and **great sural** arteries. The former arises from the a. genu suprema and assists in the supply of the medial region of the foot. The latter is a large superficial sural branch of the popliteal which helps to supply the lateral region of the foot. Neither of these has yet been found in the embryonic limb so that their history is unknown. The irregularities in the origin of the larger muscular branches of the femoral artery are referred to on page 690.

3. THE SYSTEMIC VEINS

The **systemic veins** are naturally divided into three groups—(A) the veins of the heart; (B) the vena cava superior and its tributaries, namely the veins of the head, neck, upper extremity, and thorax; and (C) the vena cava inferior and its

tributaries; namely, the portal system, and the veins of the abdomen, pelvis, and lower extremity.

A. THE VEINS OF THE HEART

The veins of the heart have already been described (p. 598).

B. THE VENA CAVA SUPERIOR AND ITS TRIBUTARIES

THE VENA CAVA SUPERIOR

The **vena cava superior** (or cranialis NK) (fig. 587) carries to the heart the blood returned from the head and neck and upper extremities through the right

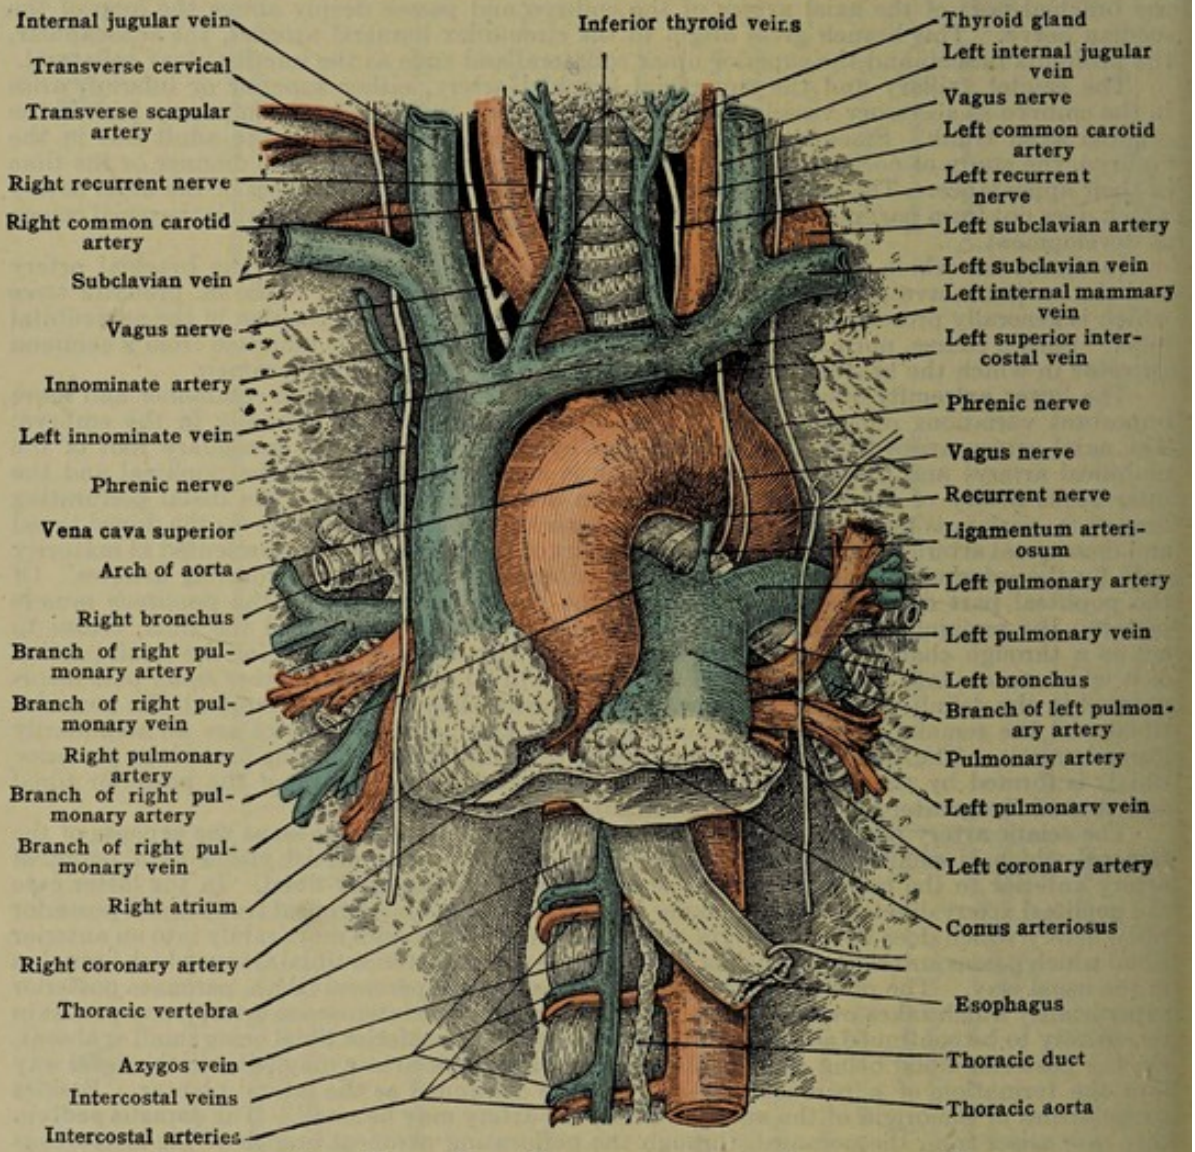

FIG. 587.—THE VENA CAVA SUPERIOR AND THE INNOMINATE VEINS.
(Modified from a dissection in St. Bartholomew's Hospital Museum.)

and left innominate veins, and from the walls of the thorax, either directly through the azygos vein, or indirectly through the innominate veins. It is formed by the confluence of the right and left innominate veins behind the first right sternochondral articulation. Descending from its origin in a gentle curve with its convexity to the right and in a direction slightly backward behind the sternal end of the first and second intercostal spaces and second costal cartilage, it terminates in the right atrium of the heart on a level with the third right costal cartilage in front and the seventh thoracic vertebra behind. It measures about 7 to 8 cm. (3 in.) in length. A little more than its lower half (4 cm.) is contained within the pericardium, the serous layer of that membrane being reflected obliquely over it immediately below the spot where it is joined by the vena azygos, and

on a lower level than the reflection of the pericardium on the aorta. The vena cava superior contains no valves.

Relations.—**In front,** in addition to the first and second intercostal spaces and the second costal cartilage, it is covered by the remains of the thymus gland, the intrathoracic fascia, and the pericardium, and is overlapped by the right pleura and lung.

Behind are the vena azygos (major), the right bronchus, the right pulmonary artery, and the superior right pulmonary vein; and below, the fibrous layer of the pericardium. The serous layer is reflected over the front and sides of the vessel, but not over its posterior part.

To the **right side** are the right lung and pleura and the phrenic nerve.

To the **left side** are the innominate artery and the ascending aorta.

Tributaries.—In addition to the right and left innominate veins and the vena azygos it receives small veins from the mediastinum and pericardium.

THE INNOMINATE VEINS

The **innominate** veins [vv. anonymæ] return the blood from the head and neck and upper extremity. They are formed on each side by the confluence of the internal jugular and subclavian veins behind the sternal end of the clavicle. They terminate behind the first costal cartilage on the right side by uniting to form the vena cava superior. The innominate veins have no valves.

The **right innominate** vein [v. anonyma dextra] (fig. 587) measures about 2 to 3 cm. (1 to 1½ in.) in length, and descends from its origin behind the sternal end of the clavicle, very slightly forward and medially, along the right side of the subclavian and innominate arteries, to its junction with the left vein behind the first costal cartilage close to the sternum. It is superficial to the innominate artery.

Relations.—**In front** are the origins of the sternohyoid and sternothyroid muscles, the clavicle, the first costal cartilage, and the remains of the thymus gland. **Behind** are the pleura and lung. To the **right** are the right pleura and lung and the phrenic nerve. To the **left** are the right subclavian artery, the innominate artery, the right vagus nerve, and the trachea.

The **left innominate** vein [v. anonyma sinistra] (fig. 587) measures 6 to 7.5 cm. (2½ to 3 in.) in length, and extends from its origin behind the sternal end of the left clavicle obliquely across the three main branches of the arch of the aorta to unite with the right innominate vein behind the cartilage of the first rib close to the sternum to form the vena cava superior. In this course it runs from left to right with an inclination downward and slightly backward. A line drawn obliquely across the upper half of the manubrium of the sternum, from the sternoclavicular articulation on the left side to the lower border of the first costal cartilage at its junction with the sternum on the right side, will indicate its course. The left innominate vein is on a level with the top of the sternum at birth.

Relations.—**In front,** in addition to the manubrium of the sternum, it has the origins of the sternohyoid and sternothyroid muscles, and the remains of the thymus gland, the sternal end of the left clavicle, and the sternoclavicular articulation. **Behind** are the three chief arteries arising from the arch of the aorta, the trachea, and the left phrenic and left vagus nerves. **Below** it is the arch of the aorta. **Above** it are the cervical fascia, the inferior thyroid, and thyroidea ima veins.

Tributaries.—In addition to the internal jugular and subclavian veins, by the confluence of which the innominate veins are formed, each vein receives on its upper aspect the vertebral, the deep cervical, and inferior thyroid veins; and on its lower aspect the internal mammary vein. The left vein, moreover, is joined by the thyroidea ima, the left superior intercostal, and by the thymic, tracheal, esophageal, superior phrenic, anterior mediastinal, and pericardiac veins. At the confluence of the internal jugular and subclavian veins on the right side the three lymphatic trunks or the right lymphatic duct open; on the left side the thoracic duct.

THE VEINS OF THE HEAD AND NECK

The **veins of the head and neck** may be divided for purposes of description into the **superficial,** which return the blood from the external parts of the head and neck; and the **deep,** which return the blood from the deeper structures. All the veins, whether superficial or deep, terminate in the internal jugular or subclavian, or open directly into the innominate veins at the root of the neck. Through the latter all the blood from the head and neck ultimately passes on its way to the heart.

THE SUPERFICIAL VEINS OF THE HEAD AND NECK

The venous blood from the anterior part of the scalp and integument of the face is returned, through the **anterior and posterior facial** veins, to the **common facial,** a tributary of the internal jugular vein. From the posterior part of the scalp and from the integument of the neck venous blood is returned, through the **external jugular** and its tributaries, to the subclavian vein.

A. The Anterior Facial Vein

The **anterior facial** vein [v. facialis anterior] (v. facialis NK) (fig. 588) begins a little below the medial end of the eyebrow where it is formed by the union

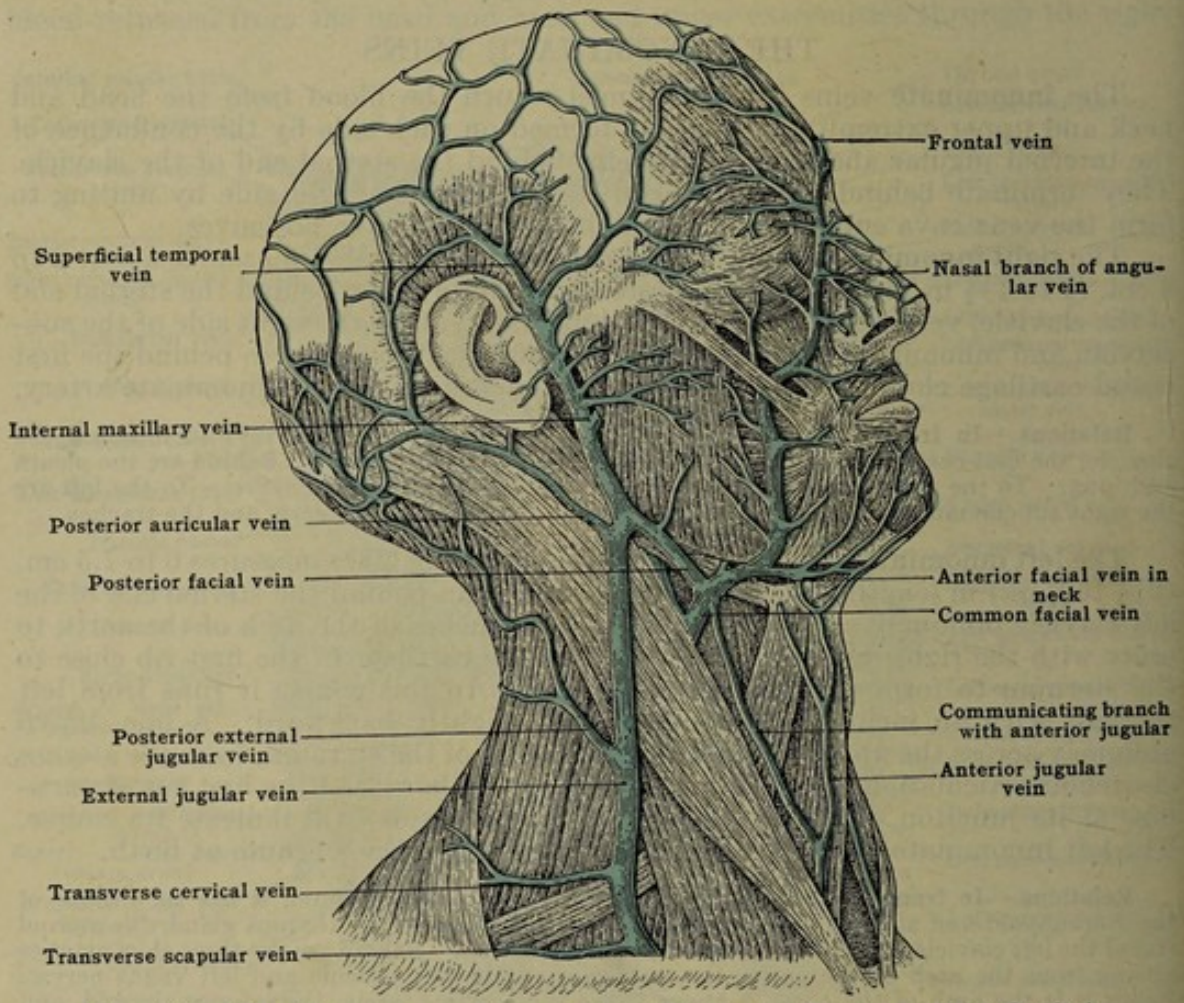

Fig. 588.—The Superficial Veins of the Face and Scalp. (After Quain.)

of the frontal and supraorbital veins. It descends near the medial angle of the orbit, and then by the side of the nose to the cheek, which it crosses obliquely, to the anterior edge of the masseter muscle. Thence it passes through the digastric triangle to the upper border of the hyoid bone, where it terminates in the common facial vein. In this course it is reinforced by numerous collateral veins, and gradually increases in size. It has, moreover, numerous communications with the deep veins. The portion of this vein above the lower margin of the orbit is called the **angular** [v. angularis]. In the remainder of its course over the face and neck it is termed the **anterior facial** vein.

The angular vein skirts around the medial margin of the orbit, lying with the angular artery on the frontal (nasal) process of the maxillary bone slightly medial to the lacrimal sac. Branches pass from the posterior part of the angular vein into the orbit to join the ophthalmic.

The angular, the facial, and the ophthalmic veins contain no valves. The blood, therefore, can pass either forward from the ophthalmic into the angular, or backward through the facial and angular into the ophthalmic, and so on to the cavernous and other venous sinuses of the cranium.

The anterior facial vein runs in a more or less direct line behind its corresponding artery, the external maxillary (facial), which itself pursues a tortuous

course. It usually passes deep to the zygomatic muscle, the zygomatic head of the quadratus labii superioris, and the risorius, but superficial to the other muscles. At the anterior edge of the masseter it meets the external maxillary artery, lying immediately posterior to it. In the neck it lies beneath the platysma and cervical fascia, and is usually separated from the external maxillary artery by the submaxillary gland and the stylohyoid and posterior belly of the digastric muscles, below which it is joined by the posterior facial, to form the **common facial** vein.

Tributaries.—It receives, from above downward:—(a) the frontal vein; (b) the supraorbital vein; (c) the superior palpebral veins; (d) the external nasal veins; (e) the inferior palpebral veins; (f) the superior labial vein; (g) the inferior labial vein; (h) the masseteric veins; (i) the anterior parotid veins; (j) the palatine vein and (k) the submental vein.

(a) The **frontal** vein [v. frontalis] (figs. 588, 589) begins about the level of the coronal suture in a venous plexus which communicates with the anterior division of the temporal vein. Soon forming a single trunk, it passes vertically downward over the frontal bone, a short distance from the middle line and parallel with its fellow of the opposite side, to the medial end of the eyebrow where it terminates in the angular vein.

(b) The **supraorbital** vein [v. supraorbitalis] begins over the frontal eminence by intercommunication with the middle temporal vein. It receives tributaries from the forehead and eyebrow, and, running obliquely, medially and downward, opens into the termination of the frontal vein to form the angular. It communicates with the ophthalmic vein, and receives the frontal vein of the diploë as the latter vein issues from the bone at the bottom of the supraorbital notch.

(c) The **superior palpebral** veins [vv. palpebrales superiores] (vv. palp. frontales NK) arise in the upper eyelid and open into the lateral side of the angular vein. They communicate with the middle temporal vein.

(d) The **external nasal** veins [vv. nasales externæ] form three or four stems on either side. The upper veins run upward into the angular and the lower, from the ala, pass more horizontally into the anterior facial vein.

(e) The **inferior palpebral** veins [vv. palpebrales inferiores] (vv. palp. malares NK) arise in the lower eyelid, and, passing medially and downward over the cheek from which they receive tributaries, open into the lateral side of the anterior facial vein. They communicate with the infraorbital vein.

(f) The **superior labial** vein [v. labialis superior] (v. lab. maxillaris NK) and (g) the **inferior labial** vein [v. labialis inferior] (v. lab. mandibularis NK) arise from venous plexuses in the upper and lower lips. They run laterally to open into the medial side of the facial vein.

(h) The **masseteric** veins [vv. masstericæ] and (i) the **anterior parotid** veins [vv. parotidæ anteriores], of small size, drain the cheek over the masseteric and parotid regions.

(j) The **palatine** vein [v. palatina] accompanies the ascending palatine or tonsillar artery from the venous plexus about the tonsil and soft palate, and joins the anterior facial vein just below the body of the mandible.

(k) The **submental** vein [v. submentalis] lies on the mylohyoid muscle superficial to the submental artery. Running back in the submental triangle, it joins the anterior facial vein just after the latter has passed over the body of the mandible. It communicates with the anterior jugular vein.

Communications.—The tributaries of the anterior facial vein communicate freely with the anterior and middle temporal, ophthalmic, infraorbital and anterior jugular veins. The main trunk has a large **communicating branch with the pterygoid plexus.** This vein, sometimes known as the deep facial, opens into the anterior facial below the zygomatic bone under cover of the zygomaticus muscle.

B. The Posterior Facial Vein

The **posterior facial** vein [v. facialis posterior] (v. retromandibularis NK) (figs. 588, 589) is formed in the region of the root of the zygoma by the union of the superficial and middle temporal veins. It passes downward behind the ramus of the mandible through the substance of the parotid gland—here lying lateral to the superficial temporal and external carotid arteries. At the angle of the mandible it runs medially and somewhat forward, and, passing either deep or superficial to the stylohyoid and digastric muscles, joins the anterior facial to form the common facial vein.

The **tributaries** received by the posterior facial vein are:—(a) the superficial temporal vein; (b) the middle temporal vein; (c) the transverse facial vein; (d) the articular veins; (e) the posterior parotid veins; (f) the anterior auricular veins; (g) the stylomastoid vein; and (h) the internal maxillary vein or veins, through which occurs the principal drainage of the pterygoid plexus.

(a) The **superficial temporal** vein [v. temporalis superficialis] returns blood from the parietal region of the scalp. It is formed by the union of an anterior and a posterior branch: the former communicates with the supraorbital and frontal veins; the latter with the posterior auricular and occipital veins and the temporal vein of the opposite side. These branches lie superficial to the corresponding branches of the superficial temporal artery, which they roughly

though not accurately follow. Like the artery, they lie between the skin and the galea aponeurotica, and descend over the temporal fascia to unite a little above the zygoma, and just in front of the auricle, to form the superficial temporal trunk. The vein thus formed continues its course downward with the trunk of the temporal artery, and opposite the zygoma is joined by the middle temporal vein to form the common temporal vein.

(b) The **middle temporal** vein [v. temporalis media] communicates in front with the ophthalmic vein, the external palpebral veins, and the infraorbital veins, and then runs backward between the layers of the temporal fascia to join the superficial temporal vein. The middle temporal vein communicates with the deep temporal veins, and through them with the pterygoid venous plexus.

(c) The **transverse facial** vein [v. transversa faciei] corresponds to the transverse facial artery. (d) **Articular** veins [vv. articulares mandibulæ] form the plexus around the temporomandibular joint; this plexus receives the **tympanic** veins [vv. tympanicæ], which, together

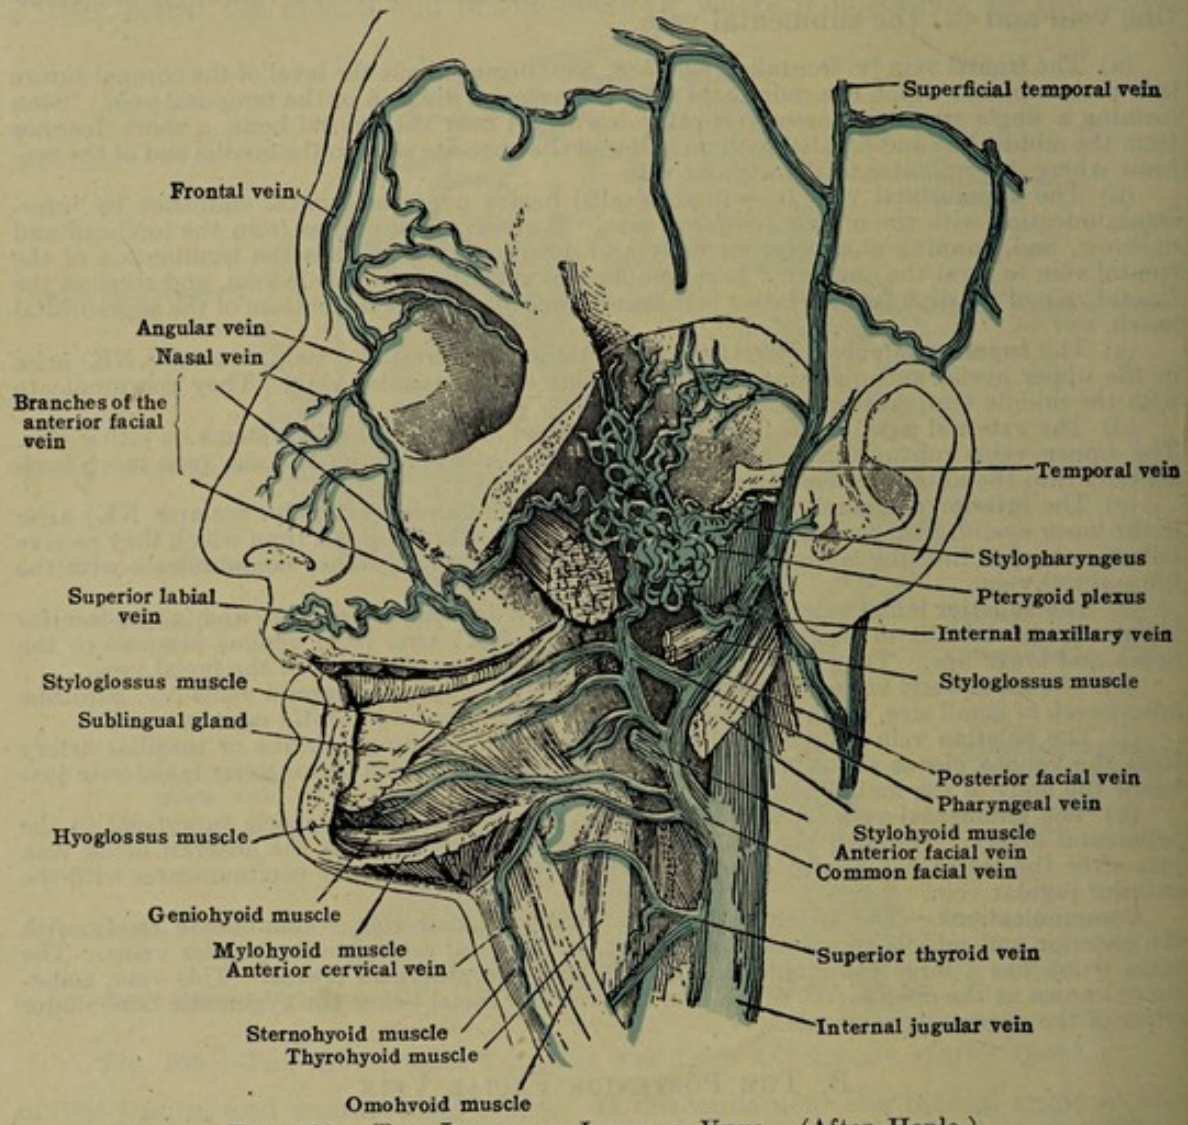

FIG. 589.—THE INTERNAL JUGULAR VEIN. (After Henle.)

with the corresponding artery, passes through the petrotympanic fissure. (e) **Posterior parotid** veins [vv. parotideæ posteriores] emerge from the substance of the parotid gland. (f) **Anterior auricular** veins [vv. auriculares anteriores] (vv. praeauriculares NK), from the auricle. (g) **Stylomastoid** vein [v. stylomastoidea] from the facial canal. (h) The **internal maxillary** veins begin at the posterior confluence of the veins forming the pterygoid plexus, and pass backward between the stylomandibular ligament and the neck of the mandible to join the posterior facial vein.

Deeper tributaries of the common facial vein.—The **pterygoid plexus** [plexus pterygoideus] is formed by the veins which correspond to the branches of the internal maxillary artery. It is situated, partly on the medial surface of the internal pterygoid muscle, and partly around the external pterygoid muscle. The veins entering into this plexus are:—the two **middle meningeal** veins [vv. meningeæ mediæ] (vv. men. temporales NK), which accompany the artery of that name; the **posterior superior alveolar** (dental); the **inferior alveolar** (dental); the **masseteric**; the **buccal**; the **pterygoid** veins from the pterygoid muscles; the **deep temporal** veins [vv. temporales profundæ], by which the plexus communicates with the temporal plexus; the **sphenopalatine** vein; the **infraorbital**; the **superior palatine**; a branch of communication with the lower branch of the **ophthalmic** vein, which courses through the inferior orbital (sphenomaxillary) fissure; and the **rete foraminis ovalis** and **Vesalian** vein, through which the plexus communicates with the cavernous sinus. The plexus ends posteriorly in a vein, or veins accompanying the internal maxillary artery, and joining the posterior facial vein. It is drained

by a communicating vessel (the deep facial vein), which passes forward and downward between the buccinator and masseter muscles to join the anterior facial vein.

The veins forming by their confluence the pterygoid plexus correspond in their course so nearly with that of their companion arteries that a detailed description is not necessary. Although for convenience described with the superficial veins, they are all deeply placed.

Near the angle of the mandible there is almost always a communicating branch between the posterior facial and the external jugular veins. When large, this branch may drain the greater part of the blood from the posterior facial.

C. The Common Facial Vein

The **common facial** vein [v. facialis communis] (fig. 588) is a short thick stem contained within the carotid triangle. It is formed, just below the angle of the mandible, by the union of the anterior and posterior facial veins. It ends opposite the hyoid bone, by opening into the internal jugular vein. In addition to the vessels which form it, sometimes it receives the superior thyroid, the pharyngeal, and the lingual or the sublingual veins. According to the NK terms, the common facial is considered as a part of the facial vein.

D. The External Jugular Vein

The **external jugular** vein [v. jugularis externa] (v. jug. superficialis dorsalis NK) (fig. 588) is formed by the confluence of the posterior auricular and a short communicating trunk from the posterior facial vein. It runs obliquely downward and backward across the sternomastoid muscle to a point opposite the middle of the clavicle, where it terminates as a rule in the subclavian vein. A line drawn from a point midway between the mastoid process and angle of the mandible to the middle of the clavicle will indicate its course. It is covered by the skin, superficial fascia, and platysma, and is crossed by a few branches of the cervical plexus, the great auricular nerve running parallel with it at the upper part of the neck. It is separated from the sternomastoid by the anterior layer of the deep cervical fascia.

Just above the clavicle it perforates the cervical fascia, by which it is prevented from collapsing, the fascia being attached to its walls. It then opens into the subclavian vein, occasionally into the internal jugular, or into the confluence of the subclavian and internal jugular veins. It contains a pair of valves about 2.5 to 5 cm. (1 to 2 in.) above the clavicle, and a second pair where it enters the subclavian vein. Neither of these valves is sufficient to prevent the blood from regurgitating, or injections from passing from the larger vein into the external jugular.

Tributaries and communications.—These include:—(a) The posterior auricular vein; (b) the occipital vein; (c) a branch of communication with the posterior facial vein; (d) the posterior external jugular vein; (e) the transverse scapular vein; and (f) the anterior jugular vein. The transverse cervical vein (p. 742) is also included in many cases.

(*a*) The **posterior auricular** vein [v. auricularis posterior] (v. retroauricularis NK) begins in a venous plexus on the posterior part of the parietal bone. This plexus communicates with the vein of the opposite side across the sagittal suture, and with the posterior branch of the superficial temporal vein in front, and with the occipital vein behind. It descends over the back part of the parietal bone and the mastoid process of the temporal bone, lying with its artery behind the ear, and joins a branch from the posterior facial vein to form the external jugular.

(*b*) The **occipital** vein [v. occipitalis] begins at the back of the skull in a venous plexus which anastomoses with the posterior auricular and the posterior branch of the superficial temporal veins. It passes downward over the occipital bone, and usually perforates the trapezius with the occipital artery, to join a plexus drained by the deep cervical and vertebral veins. It also communicates with the posterior auricular, and in many cases this forms the chief path of drainage. One of its branches, usually the most lateral, receives a **mastoid emissary** vein [emissarium mastoideum] which issues through the mastoid foramen of the temporal bone, and in this way forms a communication with the transverse sinus.

(*c*) The branch of **communication with the posterior facial** vein occurs a short distance below the point at which the posterior facial receives the internal maxillary vein. It is very constant and is placed immediately behind the angle of the mandible. Through it the external jugular usually receives a considerable proportion of the blood returning from the temporal and pterygoid regions.

(*d*) The **posterior external jugular** vein (fig. 588) descends from the upper and back part of the neck, receiving small tributaries from the superficial structures and muscles. At times it communicates with the occipital, or may appear as a continuation of that vein. It opens into the external jugular as the latter vein is leaving the sternomastoid muscle.

(*e*) The **transverse scapular** vein [v. transversa scapulæ] corresponds to the transverse scapular (suprascapular) artery. If double, these venæ comitantes usually form one trunk before they open into the external jugular vein. They contain well-marked valves.

(*f*) The **anterior jugular vein** [v. jugularis anterior] (v. jug. superficialis ventralis NK) begins below the chin by communicating with the mental, submental, inferior labial, and inferior hyoid veins. It descends near the mid-line, receiving branches from the superficial structures at the front and side of the neck, and occasionally a branch from the larynx and thyroid gland. Just above the clavicle it turns laterally, and, piercing the fascia, passes beneath the sternomastoid muscle and opens into the external jugular vein just before the latter joins the subclavian; at times it opens into the subclavian vein itself. In its course down the neck it communicates with the external jugular; and, as it turns laterally beneath the sternomastoid, sends a branch across the trachea, between the layers of cervical fascia, to join the anterior jugular of the opposite side. This communicating vein, the **jugular venous arch** [arcus venosus juguli], may open directly into the external jugular or into the internal jugular vein; occasionally one or both ends may open into the subclavian or innominate vein. It may be divided in the operation of tracheotomy, and is then often found greatly engorged with blood. Another branch, often of considerable size, courses along the anterior margin of the sternomastoid and joins the anterior facial vein. When the anterior jugular vein is large, the external jugular is small, and *vice versa*. It is usually also of large size when the corresponding vein on the opposite side is absent, as is frequently the case. It contains no valves.

THE DEEP VEINS OF THE HEAD AND NECK

The **deep veins of the head and neck** may be divided into:—(1) the veins of the diploë; (2) the venous sinuses of the dura mater encephali; (3) the veins of

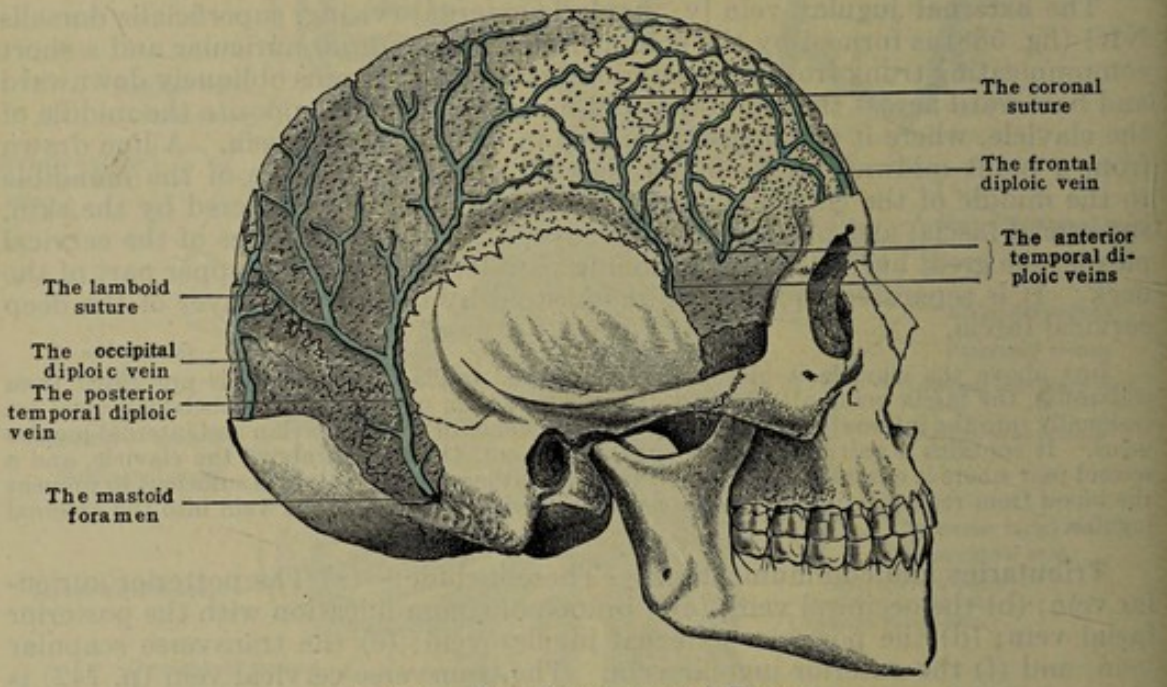

FIG. 590.—THE VEINS OF THE DIPLOË.
(From a specimen in St. Bartholomew's Hospital Museum.)

the brain; (4) the veins of the nasal cavities; (5) the veins of the ear; (6) the veins of the orbit; (7) the veins of the pharynx and larynx; and (8) the deep veins of the neck. The veins of the diploë terminate partly in the superficial veins already described, partly in the venous sinuses of the cranium, and partly in the deep veins of the neck. The venous sinuses open into the deep veins of the neck. The veins of the brain terminate in the venous sinuses. The veins of the nasal cavities terminate partly in the deep, and to some extent in the superficial veins. The veins of the ear join both the superficial and deep veins and the venous sinuses. The veins of the orbit terminate partly in the superficial veins, but chiefly in the venous sinuses. The veins of the pharynx and larynx enter the deep veins of the neck.

1. THE VEINS OF THE DIPLOË

The **veins of the diploë** [venæ diploicæ] (fig. 590) are contained in bony channels in the cancellous tissue between the laminæ of the cranial bones. They are of comparatively large size, with very thin walls, and form numerous irregular communicating channels. They have no valves. They terminate in four or five main descending channels, which open, some outward through the external cranial lamina into some of the superficial and deep veins of the head and face, and some inward through the internal lamina into the venous sinuses. They are divided into the frontal, anterior temporal, posterior temporal, and occipital.

The **frontal diploic veins** are contained in the anterior part of the frontal bone. They converge anteriorly to a single vein [v. diploica frontalis] which passes downward, perforates the external lamina through a small aperture in the roof of the supraorbital notch, and terminates in the supraorbital vein. They also communicate with the superior sagittal sinus.

The **anterior temporal diploic veins** [vv. diploicæ temporalis ant.] are contained in the posterior part of the frontal and in the anterior part of the parietal bone. They pass downward, and end, partly in the temporal veins by perforating the greater wing of the sphenoid bone, and partly in the sphenoparietal sinus.

The **posterior temporal diploic vein** [v. diploica temporalis post.] ramifies in the parietal bone, and coursing downward to the posterior inferior angle of that bone, passes either through a foramen in its inner table, or through the mastoid foramen into the transverse sinus.

The **occipital diploic vein** [v. diploica occipitalis] ramifies chiefly in the occipital bone, and opens into the occipital vein or into the transverse sinus.

The diploic veins freely anastomose with one another in the adult; but in the fetus, before the bones have united, each system of veins is distinct.

2. THE VENOUS SINUSES OF THE DURA MATER

The **venous sinuses of the dura mater** [sinus duræ matris] are endothelial-lined blood-spaces, situated between the periosteal and meningeal layers of the

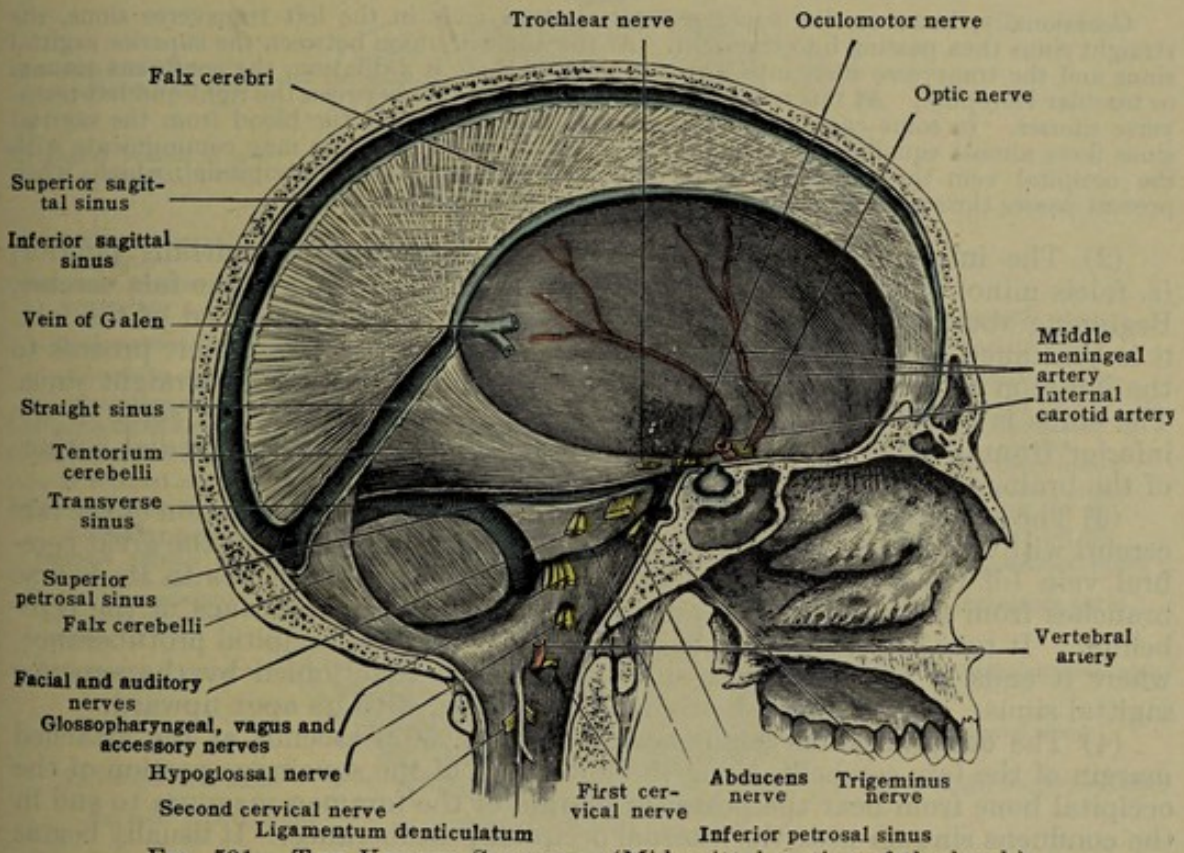

FIG. 591.—THE VENOUS SINUSES. (Midsagittal section of the head.)

dura mater. They are the channels by which the blood is conveyed from the cerebral veins, and from some of the veins of the meninges and diploë, into the veins of the neck. The sinuses at the base of the skull also carry most of the blood from the orbit. In certain places the sinuses communicate with the superficial veins by small vessels known as the emissary veins, which run through foramina in the cranial bones.

The venous sinuses are sixteen in number, six being median and unpaired, the remaining ten consisting of five lateral pairs. The median sinuses are:—(1) the superior sagittal; (2) the inferior sagittal; (3) the straight; (4) the occipital; (5) the circular; and (6) the basilar plexus. The lateral and paired sinuses are:—(7) the two transverse; (8) the two superior petrosal; (9) the two inferior petrosal; (10) the two cavernous; and (11) the two sphenoparietal. Occasionally there are two additional sinuses, the two petrosquamous.

(1) The **superior sagittal** (or longitudinal) **sinus** [sinus sagittalis superior] (or s. falcis major NK) (fig. 591) lies in the median groove on the inner surface of the cranium along the attached margin of the falx cerebri. It extends from the foramen cecum to the internal occipital protuberance. It grooves from

before backward the frontal bone, the contiguous sagittal margins of the parietal bones, and the squamous portion of the occipital bone. In the fetus, and occasionally in the adult, it communicates (through the foramen cecum) with the nasal veins. It communicates throughout life with each superficial temporal vein by means of a **parietal emissary** vein [emissarium parietale] which passes through the parietal foramen. It is triangular on section, and crossing it are a number of fibrous bands known as the *chords of Willis*. Communicating with it on either side are irregular diverticula from the main channel known as the *lacunæ laterales* into which the arachnoidal (Pacchionian) granulations project (fig. 594). In front the sinus is quite small, but it increases greatly in caliber as it runs backward. It receives at intervals the superior cortical cerebral veins and the veins from the falx. The former, for the most part, open into it in the direction opposite to that in which the blood is flowing in the sinus. They pass for some distance in the walls of the sinus before opening into it. Posteriorly, at the internal occipital protuberance, the superior sagittal sinus turns sharply, and ends usually in the right transverse (lateral) sinus; the straight sinus terminating in the left transverse sinus.

Occasionally, however, the superior sagittal sinus ends in the left transverse sinus, the straight sinus then passing into the right. At the angle of union between the superior sagittal sinus and the transverse sinus into which it empties there is a dilation, the **confluens sinuum** or torcular Herophili. At this point there is a communication between the right and left transverse sinuses. In some cases the communication is so free that the blood from the sagittal sinus flows almost equally into each transverse sinus. The confluens may communicate with the occipital vein through the **occipital emissary** vein [emissarium occipitale], which, when present passes through a minute foramen in the occipital protuberance.

(2) The **inferior sagittal** (or longitudinal) **sinus** [sinus sagittalis inferior] (s. falcis minor NK) (fig. 591) is situated at the free margin of the falx cerebri. Beginning about the junction of the anterior with the middle third of the falx, it is continued backward along the concave or lower margin of that process to the junction of the falx with the tentorium, where it ends in the straight sinus. The sinus is cylindrical in section and of small size, and receives some of the inferior frontal veins of the brain, some of the veins from the medial surface of the brain, and some of the veins of the falx.

(3) The **straight sinus** [sinus rectus] (fig. 591) lies along the junction of the falx cerebri with the tentorium cerebelli. It is formed by the union of the great cerebral vein (of Galen) and the inferior sagittal sinus. It receives in its course branches from the tentorium cerebelli and from the upper surface of the cerebellum. It runs downward and backward to the internal occipital protuberance, where it ends in the transverse sinus opposite to that joined by the superior sagittal sinus. On section it is triangular in shape, with its apex upward.

(4) The **occipital sinus** [sinus occipitalis] (fig. 592) ascends at the attached margin of the falx cerebelli, along the lower half of the squamous portion of the occipital bone from near the posterior margin of the foramen magnum to end in the confluens sinuum near the internal occipital protuberance. It usually begins in a right and a left branch, known as the **marginal sinuses.**

These proceed from the termination of each transverse sinus, run around the foramen magnum where they communicate with the venous vertebral retia, and unite at a variable distance from the internal occipital protuberance to form the single occipital sinus. Sometimes they remain separate as far as the internal occipital protuberance, then forming two occipital sinuses. It receives veins from the falx cerebelli, and from the inferior surface of the cerebellum. It communicates through the plexus of veins which surrounds the hypoglossal nerve [**rete canalis hypoglossi**] in the hypoglossal (anterior condyloid) canal with the vertebral vein and the longitudinal vertebral venous sinuses.

(5) The **circular sinus** [sinus circularis] (fig. 593) encircles the hypophysis cerebri. It consists of the two cavernous sinuses and their communications across the median line by means of the **anterior and posterior intercavernous sinuses.** The intercavernous sinuses are small and cross the median line in front of and behind the hypophysis, respectively.

(6) The **basilar plexus** [plexus basilaris] is a venous plexus in the substance of the dura mater over the basilar part of the occipital bone and the posterior part of the body of the sphenoid. It extends from the cavernous sinus to the margin of the foramen magnum below. It communicates laterally with the inferior petrosal sinus, and inferiorly with the marginal sinuses internal verte-

bral venous plexuses. One of the larger of the irregular venous channels forming the plexus passes transversely from one inferior petrosal sinus to the other. This venous plexus is serially homologous with the longitudinal vertebral venous sinuses on the posterior surfaces of the bodies of the vertebræ.

(7) The **transverse** (or lateral) **sinus** [sinus transversus] (figs. 591–592) extends from the internal occipital protuberance to the jugular fossa. In this course it lies in the corresponding groove along the squamous portion of the occipital bone, the mastoid angle of the parietal bone, the mastoid portion of the temporal bone, and the jugular process of the occipital bone. It at first runs laterally and forward horizontally between the two layers of the tentorium cerebelli, following the curve of the groove on the occipital and on the mastoid angle of the parietal bone. On reaching the groove in the mastoid portion of the temporal bone it leaves the tentorium and curves medially and downward and then forward over the jugular process of the occipital bone. It then passes through the posterior compartment of the jugular foramen and ends at the jugular fossa in the superior bulb of the internal jugular vein. The S-shaped part of the

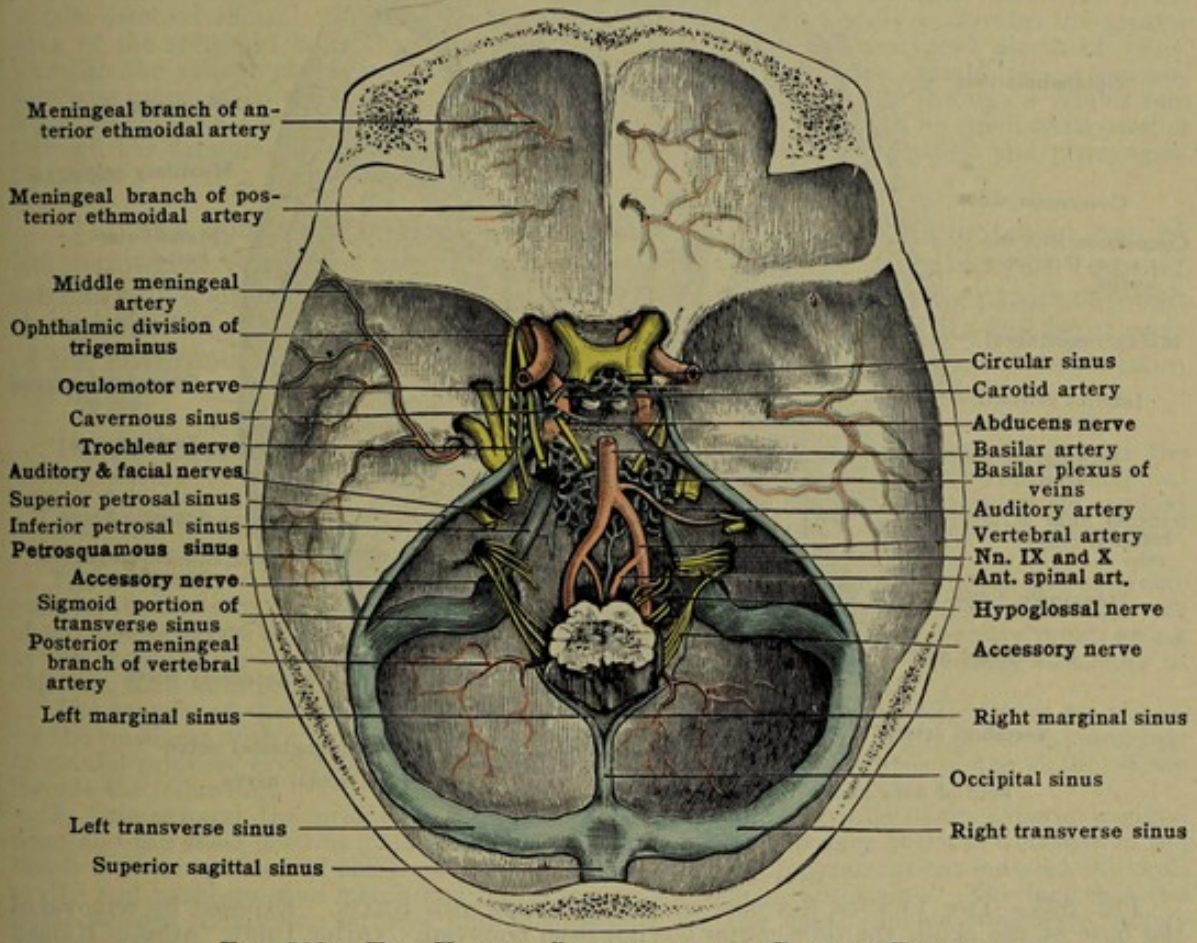

FIG. 592.—THE VENOUS SINUSES IN THE CRANIAL FLOOR.
(From a dissection by W. J. Walsham in St. Bartholomew's Hospital Museum.)

sinus which lies on the mastoid portion of the temporal and jugular portion of the occipital bone is sometimes known as the **sigmoid sinus.**

The transverse sinus receives from the labyrinth, the **internal auditory** veins [vv. auditivæ internæ] which emerge from the internal auditory meatus. It also receives veins from the temporal lobe of the cerebrum, some of the superior and inferior cerebellar veins, some of the veins of the medulla and pons, the occipital, and the posterior temporal and occipital veins of the diploë. At the point where it leaves the tentorium it drains the superior petrosal sinus and, when present, the petrosquamous sinus. It communicates with the occipital and vertebral veins through the mastoid and posterior condyloid foramina by means of the **mastoid** and **condyloid emissary** veins. As the transverse sinus lies between the layers of the tentorium it is triangular in cross-section, while the sigmoid portion is semicircular.

The **right** transverse sinus is usually the larger and forms the direct continuation of the superior sagittal sinus. It hence conveys the chief part of the blood from the cortical surface of the brain and vault of the skull. The **left** transverse sinus is usually the smaller and the direct continuation of the straight sinus, and hence returns the chief part of the blood from the central ganglia of the brain. The right and left sinuses communicate at the confluens sinuum.

The relation of the lateral sinus to the outside of the skull, especially to the mastoid process of the temporal bone, is of importance with reference to operations in this region. The course of the sinus corresponds to a line drawn from the external occipital protuberance to the base of the mastoid process, or to the asterion, and thence over the back of the mastoid process in a curved line toward its apex.

(8) The **superior petrosal sinus** [sinus petrosus superior] (figs. 591, 592) runs at the attached margin of the tentorium cerebelli, along the upper border of the petrous portion of the temporal bone. It connects the cavernous with the transverse sinus. Leaving the lateral and back part of the cavernous sinus just below the trochlear nerve, it crosses the trigeminus nerve, and, after grooving the

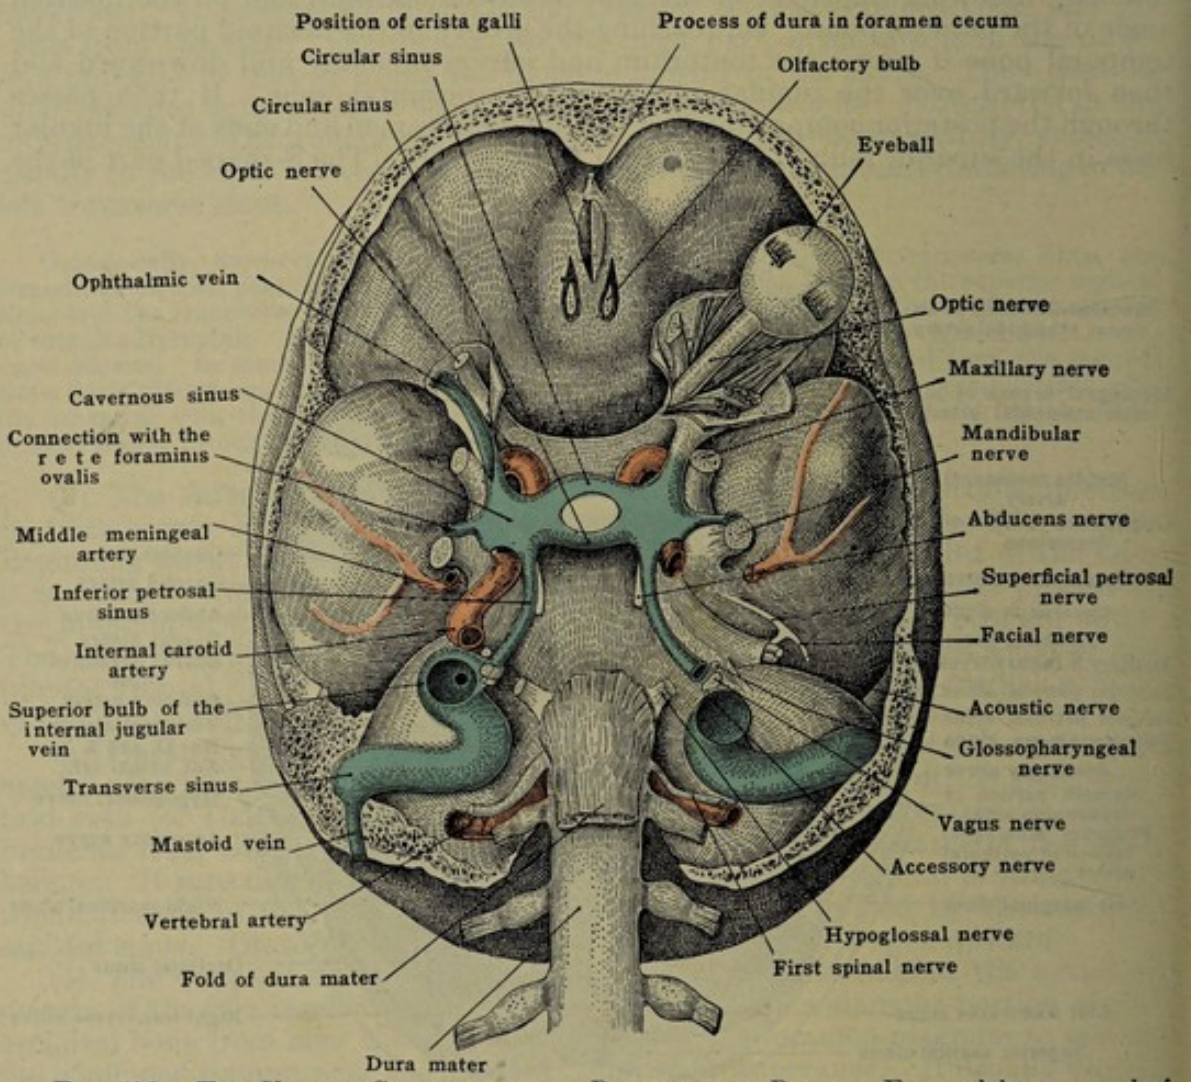

FIG. 593.—THE VENOUS SINUSES AT THE BASE OF THE BRAIN. Exposed by removal of the base of the skull; the dura mater has not been removed. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

petrous bone, ends in the transverse sinus as the latter turns downward on the mastoid portion of the temporal bone. It receives veins from the temporal lobe of the cerebrum, veins from the cerebellum, veins from the tympanum through the squamopetrosal fissure, and sometimes the anterior temporal veins of the diploë.

(9) The **inferior petrosal sinus** [sinus petrosus inferior] (s. petrobasilaris NK) (figs. 591, 592) runs posteriorly from the cavernous sinus along the line of the petro-occipital suture, and passes through the anterior compartment of the jugular foramen to terminate in the commencement of the internal jugular vein. It is shorter than the superior petrosal, but considerably wider.

As it passes to the anterior compartment of the jugular foramen, it separates the glossopharyngeal from the vagus and accessory nerves. It receives veins from the inferior surface of the cerebellum, from the medulla and pons, and from the internal ear. The **vein of the cochlear canaliculus** [v. canaliculi cochleæ], issues through the canaliculus cochleæ and terminates in the lower part of the inferior petrosal sinus or the adjacent part of the internal jugular vein.

(10) The **cavernous sinus** [sinus cavernosus] (fig. 592) is an irregularly shaped venous space situated between the meningeal and periosteal layers of the dura mater on the side of the body of the sphenoid bone. It extends from the medial end of the superior orbital (sphenoidal) fissure in front to the apex of the petrous bone behind. Its lateral wall contains the oculomotor and trochlear nerves, and the ophthalmic division of the trigeminus. The nerves take the above-mentioned order from above downward, and in the mediolateral direction. The internal carotid artery and the abducens nerve are contained in the thinner medial wall of the sinus. The right and left cavernous sinuses communicate across the middle line with the opposite sinus in front and behind the hypophysis cerebri as before mentioned.

The cavernous sinus is traversed by numerous trabeculæ or fibrous bands, so that there is no central cavity, but rather a number of endothelial-lined irregular lacunæ communicating with one another. **In front** it receives the ophthalmic vein, with which it is practically continuous, and just above the third nerve, the sphenoparietal sinus. **Medially** it communicates with the opposite sinus, and **posteriorly** it ends in the superior and inferior petrosal sinuses. It also receives veins from the inferior surface of the frontal lobe of the brain, and some of the middle cerebral veins. Through the Vesalian vein, which occasionally perforates the greater wing of the sphenoid bone the sinus may communicate with the pterygoid plexus of veins. Through the **venous plexus around the petrosal portion of the internal carotid** [plexus venosus caroticus internus], it communicates with the internal jugular vein; and through a venous rete which leaves the cranium by the foramen ovale [rete foraminis ovalis] and by small veins passing through the foramen lacerum medium, it communicates with the pterygoid and pharyngeal plexuses.

(11) The **sphenoparietal sinus** [sinus sphenoparietalis] originates in one of the meningeal veins near the apex of the lesser wing of the sphenoid and, running medially, in a slight groove on the inferior surface of the lesser wing passes through the sphenoidal fold of dura mater above the oculomotor nerve into the front part of the cavernous sinus. It generally receives the anterior temporal veins from the diploë.

The **petrosquamous sinus** is occasionally present. It lies in a groove which separates the anterior surface of the petrous from the cerebral surface of the squamous portion of the temporal bone. It opens posteriorly into the transverse sinus where the latter enters on its sigmoid course. In front it sometimes communicates, through a foramen between the mandibular fossa and the external acoustic meatus, with the deep temporal vein.

The emissary veins.—These are communications between the sinuses within, and the veins outside, the cranium. Most of them are temporary, corresponding to the chief period of growth of the brain. Thus in early life, when the development of the brain has to be very rapid, owing to the approaching closure of its case, a free escape of blood is most essential, especially in children, with their sudden explosions of laughter and passionate crying.

The gravity of these emissary veins and their free communications with others are shown by the readiness with which they become the seat of thrombosis, and thus of blood-poisoning, in cranial injuries, erysipelas, infected wounds of the scalp, and necrosis of the skull. They include the following:

1. Vein through the foramen cecum, between the anterior extremity of the superior sagittal sinus and the nasal mucous membrane. The value of this temporary outlet is well seen in the timely profuse epistaxis of children. Other more permanent communications between the skull cavity and nasal mucous membrane pass through the ethmoid foramina. The fact that the nasal mucous membrane is loose and ill-supported on the nasal conchæ (turbinate bones) allows its vessels to give way readily, and thus forms a salutary safeguard to the brain, possibly warding off attacks of apoplexy. 2. Vein through the mastoid foramen, between the transverse (lateral) sinus and the posterior auricular and occipital veins. This is the largest, the most constant, and the most superficial of the emissary veins. 3. Vein through the posterior superior angle of the parietal between the superior sagittal sinus and the veins of the scalp. 4. Vein through the condyloid foramen between the transverse (lateral) sinus and the deep veins of the neck. 5. Vein through the hypoglossal canal between the occipital sinus and the deep veins of the neck 6. Ophthalmic veins communicating with the cavernous sinus and the angular vein. These veins may be the source of fatal blood-poisoning, by transmitting septic material in acute periostitis of the orbit, or in osteitis of the jaws. 7. Minute veins through the foramen ovale between the cavernous sinus and the pharyngeal and pterygoid veins. 8. Communications between the frontal diploic and the supraorbital veins, between the anterior temporal diploic and the deep temporal veins, and between the posterior temporal and the occipital diploic veins and the transverse sinus. In addition to the veins specially mentioned, the scalp and sinuses communicate by numerous diploic veins and by those in the sutural membranes.

3. THE VEINS OF THE BRAIN

The **veins of the brain** present the following peculiarities:—(*a*) They do not accompany the cerebral arteries. (*b*) Ascending veins do not, as in other situations, run with descending arteries, but with ascending arteries, and *vice versa*.

(*c*) The deep veins do not freely communicate. (*d*) The veins have very thin walls, no muscular coat, and no valves. (*e*) The veins opening into the sagittal, and some of those opening into the transverse (lateral) sinus pour in their blood in a direction opposite to that of the current in the sinus concerned. (*f*) The flow of blood in the sinuses is further retarded by the trabeculæ stretching across their lumen.

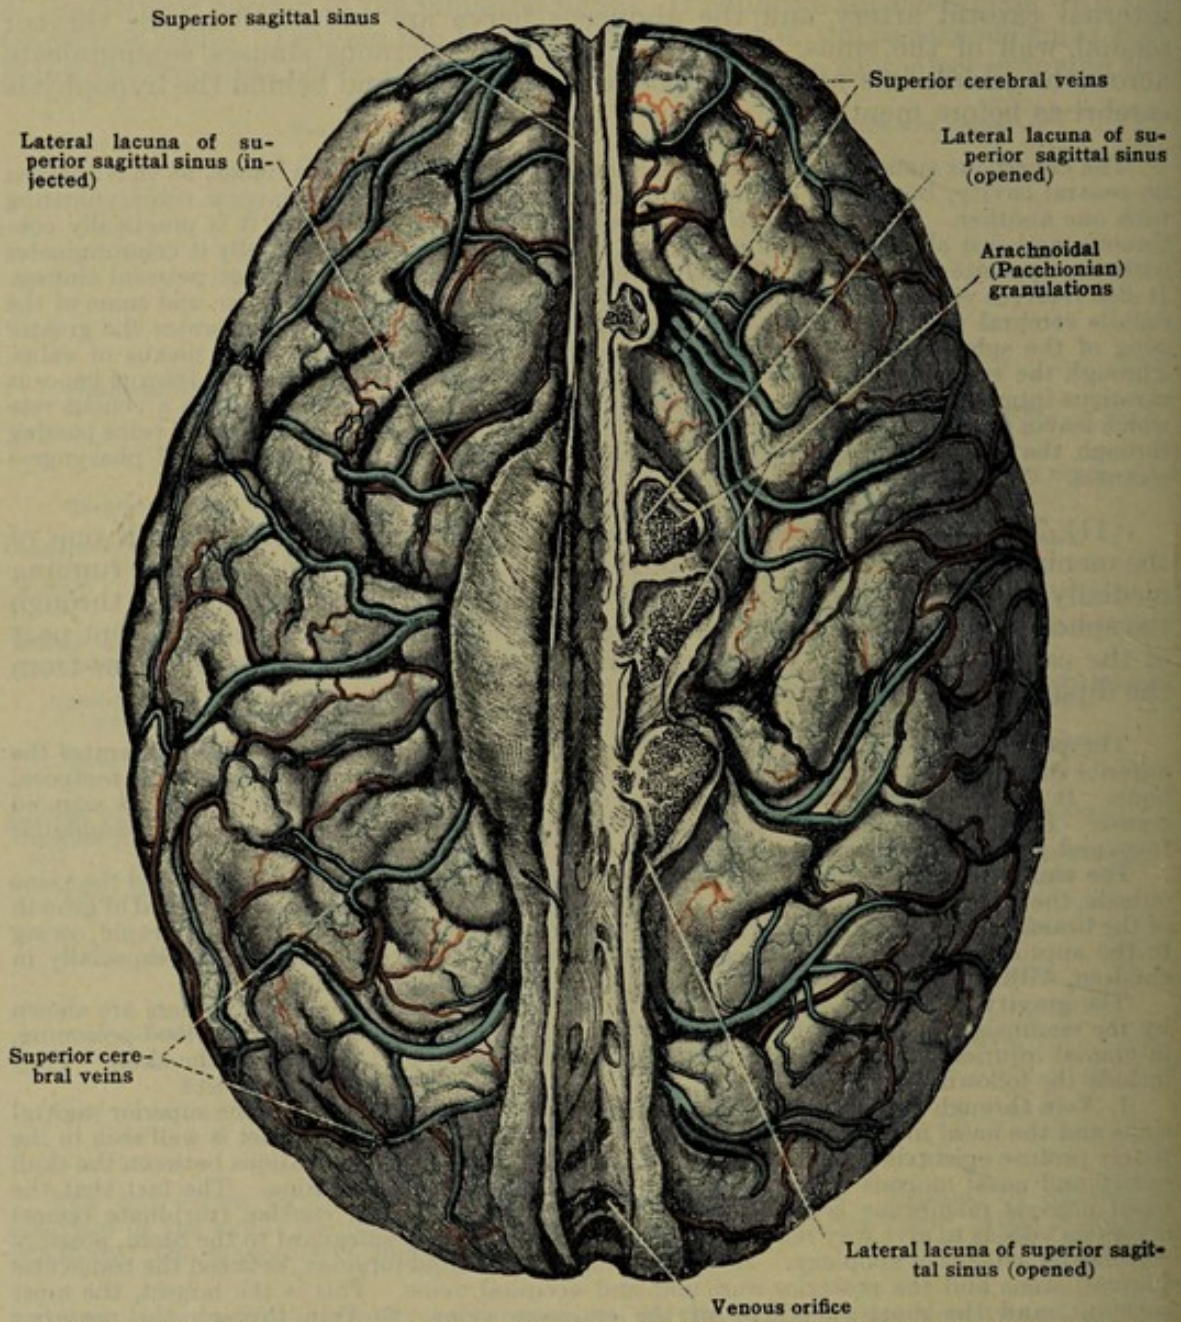

FIG. 594.—THE VEINS OF THE BRAIN, SUPERIOR SURFACE. (After Toldt, 'Atlas of Human Anatomy', The Macmillan Company.)

The veins of the brain may be divided into the **cerebral** and the **cerebellar.**

THE CEREBRAL VEINS

The **cerebral** veins (vv. encephali NK), like the cerebral arteries, may be divided into the **cortical** and the **central.**

The **cortical** or **superficial** veins ramify on the surface of the brain and return the blood from the cortical substance into the venous sinuses. They lie for the most part in the sulci between the gyri, but some pass over the gyri from one sulcus to another. They consist of two sets: a superior and an inferior.

(1) The **superior cerebral** veins [venæ cerebri superiores] (vv. cerebrales superficiales NK) (fig. 594), some eight to twelve in number on each side, are formed by the union of veins from the convex and medial surfaces of the cerebrum. Those from the convex surface pass medially

and forward toward the longitudinal fissure, where they are joined by the veins coming from the medial surface. After receiving a sheath from the arachnoid, they enter obliquely into the superior sagittal sinus, running for some distance in its walls. These veins freely communicate with each other, thus differing from the cortical arteries. They also communicate, with the inferior cortical veins. They may be roughly divided into (*a*) frontal; (*b*) paracentral; (*c*) central; (*d*) occipital.

(2) The **inferior cerebral** veins [venæ cerebri inferiores] (vv. cerebrales basales NK) (fig. 595), ramify on the base of the hemisphere and the lower part of its lateral surface. Those on the inferior surface of the frontal lobe pass, in part into the inferior sagittal sinus, and in part into the cavernous sinus. Those on the temporal lobe enter in part into the superior petrosal

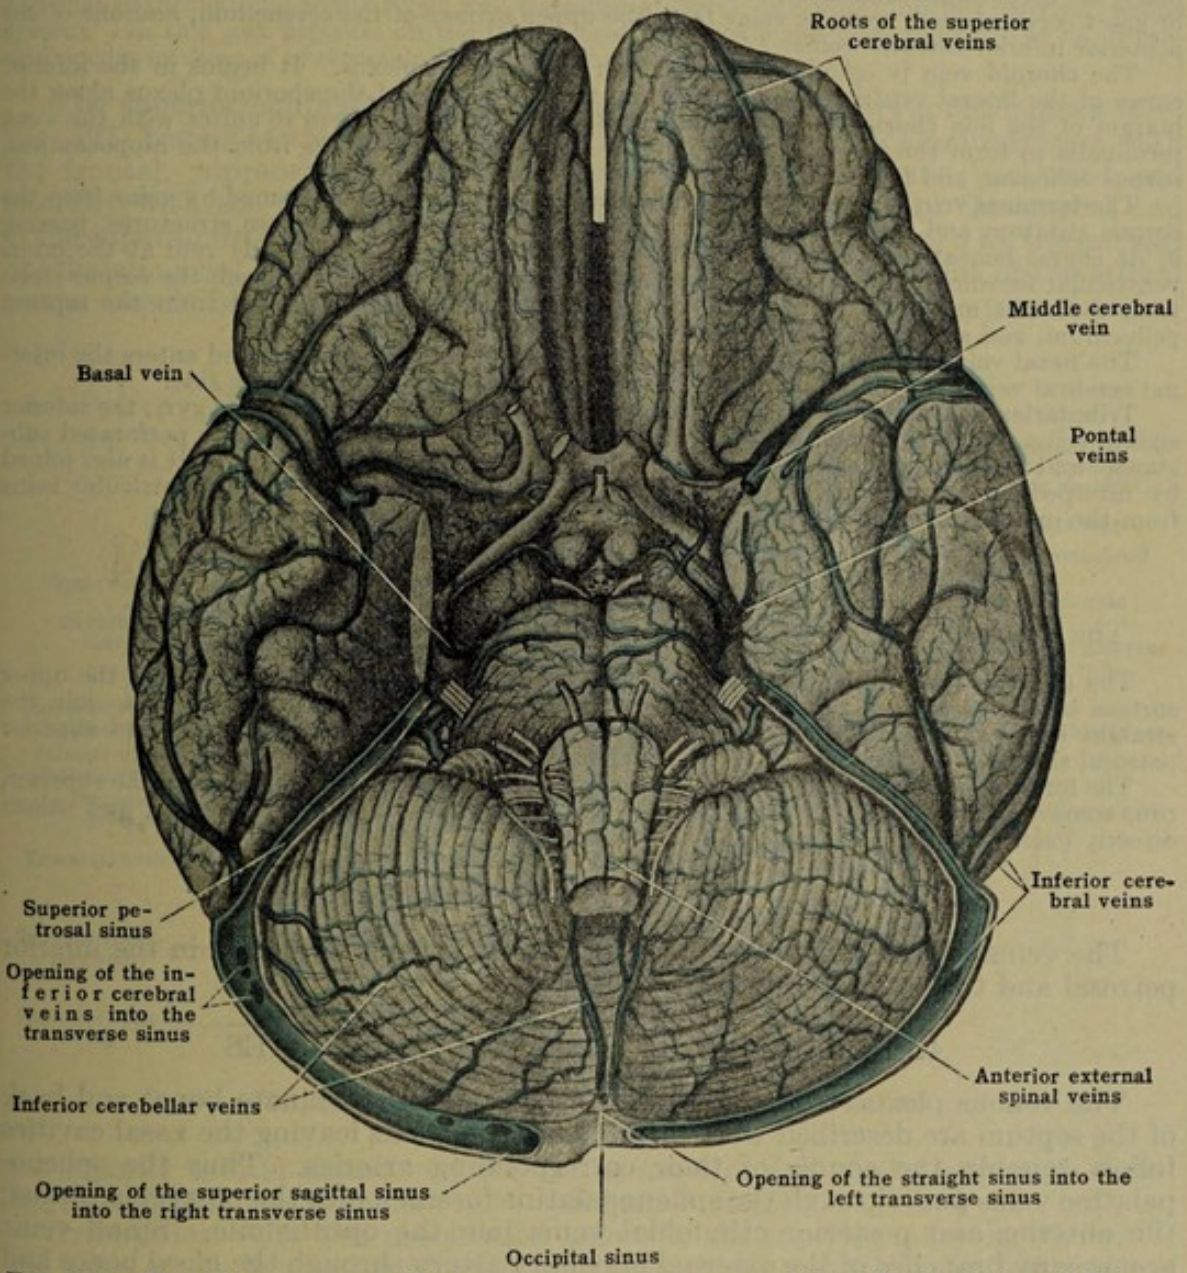

FIG. 595.—THE VEINS OF THE BRAIN, INFERIOR SURFACE. (After Toldt, 'Atlas of Human Anatomy', The Macmillan Company.)

sinus, and in part into the transverse sinus, passing into the latter from before backward. A large vein from the occipital lobe winds over the cerebral peduncle and joins the great cerebral vein (of Galen) just before the latter enters the straight sinus. One of the inferior cortical veins is called the **middle cerebral** vein [v. cerebi media], it runs in the lateral fissure (of Sylvius) and ends in the cavernous sinus. This vein is sometimes called the superficial Sylvian vein. Another, the great anastomosing vein of Trolard, establishes a communication between the superior sagittal and cavernous sinuses by connecting the middle cerebral veins with one of the superior cerebral veins. A second anastomotic vein, that of Labbé, is also a tributary of the middle cerebral, and connects the veins over the temporal lobe with the transverse sinus.

A small inferior cerebral vein, the **ophthalmomeningeal vein,** establishes a communication between the cerebral veins and those of the orbit. It communicates with the veins of the base and is usually drained by the superior ophthalmic vein. It occasionally opens into the superior petrosal sinus.

The **central** or **deep** (ganglionic) veins return blood from the internal parts of the cerebrum, and converge to the great cerebral vein.

(3) The **internal cerebral** veins [vv. cerebri internæ] are two large venous trunks (the venæ Galeni) which leave the brain at the transverse fissure, that is, between the splenium of the corpus callosum and the corpora quadrigemina. In this region they unite to form the **great cerebral** vein [v. cerebri magna, Galeni], which opens into the anterior end of the straight sinus. The internal cerebral veins are formed by the union of the choroid vein with the vena terminalis near the interventricular foramen. They run backward parallel to each other, between the layers of the tela chorioidea.

Tributaries of the internal cerebral veins.—In addition to the vena terminalis and the choroidal, the internal cerebral veins also receive the basal vein, the veins of the thalamus, the vein of the choroid plexus of the third ventricle, and veins from the corpus callosum, the pineal body, the corpora quadrigemina, and posterior horn of the lateral ventricle. The united trunk, or great cerebral vein, receives veins from the upper surface of the cerebellum, and one of the posterior inferior cerebral veins.

The **choroid** vein [v. chorioidea] runs with the chorioid plexus. It begins in the inferior cornu of the lateral ventricle, and ascends on the lateral side of the chorioid plexus along the margin of the tela chorioidea to the interventricular foramen, where it unites with the vena terminalis to form the internal cerebral vein. It receives tributaries from the hippocampus, corpus callosum, and fornix.

The **terminal** vein (or vein of the corpus striatum) [v. terminalis], formed by veins from the corpus striatum and thalamus, runs forward in the groove between those structures, passing in its course beneath the stria terminalis, and joins the chorioid (choroid) vein at the interventricular foramen. **Tributaries.**—It receives, in addition to the veins from the corpus striatum, thalamus and fornix, the **vena septi pellucidi** which receives blood from the septum pellucidum, and anterior cornu of the lateral ventricle.

The **basal** vein [v. basalis], runs backward over the cerebral peduncle, and enters the internal cerebral vein near the union of that vessel with the vein of the opposite side.

Tributaries.—A vein, the deep Sylvian, from the insula and the opercular gyri; the inferior striate veins from the corpus striatum, which they leave through the anterior perforated substance; and the anterior cerebral veins from the front of the corpus callosum. It is also joined by interpeduncular veins from the structures in the interpeduncular space; ventricular veins from the inferior cornu of the lateral ventricle; and by mesencephalic veins.

The Cerebellar Veins

The **cerebellar** veins are divided into the **superior** and **inferior.**

The **superior** [vv. cerebelli superiores] (vv. cerebellares dorsales NK) ramify on the upper surface of the cerebellum; some of them run medially over the superior vermis to join the straight sinus and great cerebral vein; others run laterally to the transverse and superior petrosal sinuses.

The **inferior** [vv. cerebelli inferiores] (vv. cerebellares basiales NK) larger than the superior, run, some forward and laterally to the inferior petrosal and transverse sinuses, and others directly backward to the occipital sinus.

The Veins of the Medulla and Pons

The veins from the **medulla oblongata** and the **pons** terminate in the inferior petrosal and transverse sinuses.

4. THE VEINS OF THE NASAL CAVITIES

The venous plexuses on the inferior nasal concha (turbinate bone) and back of the septum are described with the Nose. The veins leaving the nasal cavities follow roughly the course of their corresponding arteries. Thus the sphenopalatine veins pass through the sphenopalatine foramen into the pterygoid plexus; the anterior and posterior ethmoidal veins join the ophthalmic. Small veins accompany branches of the external maxillary artery through the nasal bones and frontal processes of the maxillary bones, and end in the angular and anterior facial veins; and other small veins pass from the nose anteriorly into the superior labial, and thence to the anterior facial.

5. THE VEINS OF THE EAR

The veins from the external ear and external acoustic meatus join the posterior facial and posterior auricular veins. The veins from the tympanum open into the superior petrosal sinus and posterior facial vein. The blood from the labyrinth flows chiefly through the **internal auditory** veins [vv. auditivæ internæ], which accompany the internal auditory artery in the internal acoustic meatus, and enters the transverse or the inferior petrosal sinus.

Some of the blood from the labyrinth, however, passes through the vestibular vein, which lies in the aqueductus vestibuli, into the inferior petrosal sinus. Some also passes through the **vena canaliculi cochleæ** which traverses the canal of the same name and empties into the commencement of the internal jugular vein or the terminal portion of the inferior petrosal sinus.

6. THE VEINS OF THE ORBIT

The blood from the eyeball and orbit is returned by the superior ophthalmic vein into the cavernous sinus. This vein and its tributaries have no valves, and communicate with the frontal, supraorbital, inferior cerebral, and pterygoid veins (fig. 596).

Under certain conditions, as from pressure on the cavernous sinus, the blood may flow in the contrary direction to the normal—i.e., from behind forward into the frontal and supraorbital, and thence through the angular vein into the anterior facial; or upward into the cerebral venous system. In this way pressure on the retinal veins is quickly relieved, and little or no distension occurs in cases of obstruction in the cavernous sinus.

The **superior ophthalmic** vein [v. ophthalmica superior] (v. ophthalmica NK) (fig. 597) begins at the medial angle of the eyelid by a free communication with the frontal, supraorbital, and angular veins, and thence runs backward and laterally with the ophthalmic artery across the optic nerve to the medial end of the superior orbital (sphenoidal) fissure, where it is usually joined by the inferior ophthalmic vein. It then passes backward between the two heads of the lateral rectus muscle below the sixth nerve, leaves the orbit through the medial end of

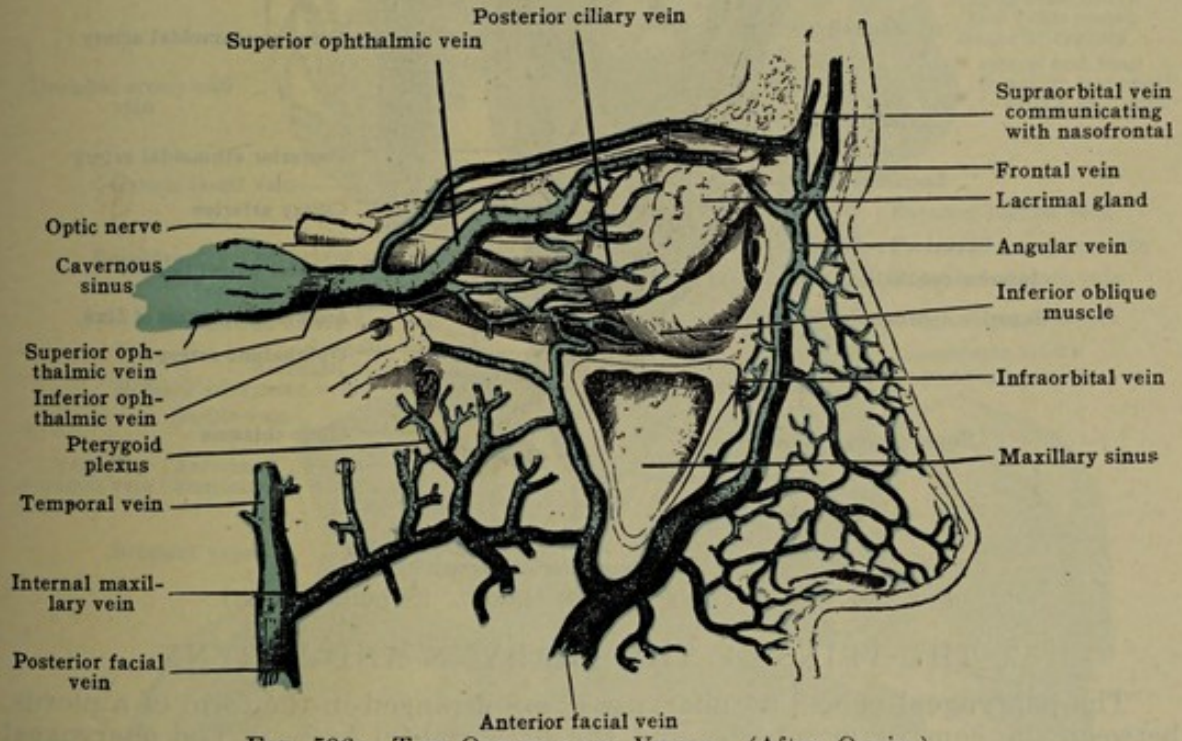

FIG. 596.—THE OPHTHALMIC VEINS. (After Quain.)

the superior orbital fissure and enters the anterior end of the canverous sinus. In this course it is superficial to the ophthalmic artery.

Tributaries.—(1) The nasofrontal vein; (2) the superior muscular veins; (3) the veins of the lids and conjunctiva; (4) the ciliary veins; (5) the anterior and posterior ethmoidal veins; (6) the lacrimal vein; (7) the central vein of the retina; and (8) the inferior ophthalmic vein.

(1) The **nasofrontal** vein [v. nasofrontalis] begins by a free communication with the supraorbital vein and enters the orbit through the frontal notch or foramen. It frequently joins the superior ophthalmic vein quite far back in the orbit (see fig. 596).

(2) The **muscular** veins [vv. musculares] are derived from the levator palpebræ, superior rectus, superior oblique, and medial rectus.

(3) The **palpebral** and **conjunctival** veins [vv. palpebrales; vv. conjunctivales ant. et post.], both anterior and posterior, open into the superior ophthalmic.

(4) The **ciliary** veins, the veins of the eyeball, are divided into anterior and posterior groups. The **anterior ciliary veins** [vv. ciliares ant.] emerge from the eyeball with the anterior ciliary arteries, and open into the muscular veins returning the blood from the four recti. They form a circumcorneal ring of **episcleral** veins [vv. episclerales]. The **posterior ciliary veins** (vv. choroideæ minores NK), which drain the **venæ vorticosæ** (vv. chorioideæ majores NK), leave the globe midway between the cornea and the entrance of the optic nerve. The upper veins of this group end in the superior, and the lower in the inferior ophthalmic vein (fig. 596).

(5) The **anterior and posterior ethmoidal** veins [vv. ethmoidales ant. et post.] (vv. ethm. olfactoria et labyrinthica NK), correspond in their course with the arteries of the same name.

They enter the orbit through the anterior and posterior ethmoidal foramina, and join either the superior ophthalmic or one of superior muscular branches.

(6) The **lacrimal** vein [v. lacrimalis] returns the blood from the lacrimal gland, and corresponds in its course to the lacrimal artery.

(7) The **central vein of the retina** [v. centralis retinæ] runs with the central artery in the optic nerve. It joins the superior ophthalmic at the back of the orbit.

(8) The **inferior ophthalmic** vein [v. ophthalmica inferior] (v. ophth. maxillaris NK) smaller than the superior, is formed near the front of the orbit by the confluence of the inferior muscular with the lower posterior ciliary veins. It runs backward below the optic nerve, along the floor of the orbit and either joins the superior ophthalmic vein, or opens separately into the cavernous sinus. A large communicating branch passes downward through the inferior orbital (sphenomaxillary) fissure to join the pterygoid plexus of veins (fig. 596). It receives muscular twigs from the inferior and lateral rectus and from the inferior oblique, and some posterior ciliary veins.

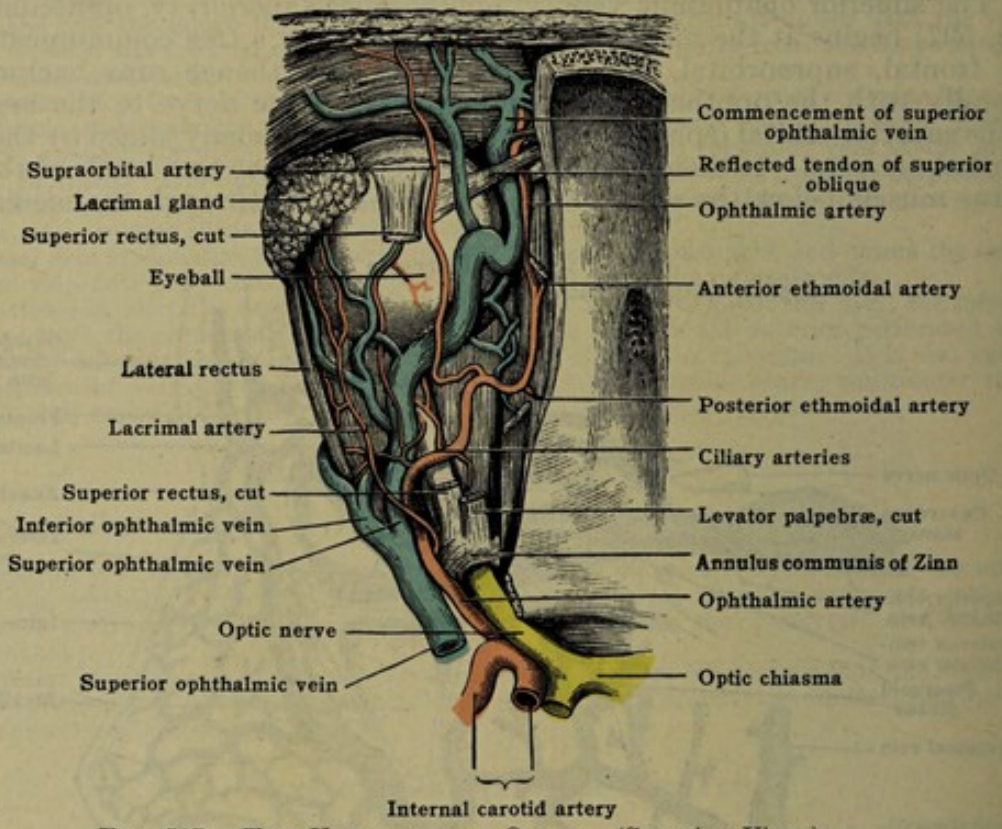

FIG. 597.—THE VEINS OF THE ORBIT. (Superior View.)

7. THE VEINS OF THE PHARYNX AND LARYNX

The **pharyngeal** veins [vv. pharyngeæ] are arranged in the form of a plexus, between the constrictor muscles and the prevertebral fascia. The **pharyngeal plexus** receives branches from the mucous membrane, the pterygoid canal [vv. canalis pterygoidei] from the soft palate, the auditory (Eustachian) tube and the anterior recti and longus colli muscles. Above, it communicates with the pterygoid plexus of veins; below it drains into the internal jugular vein.

The **veins of the larynx** end partly in the **superior laryngeal** vein [v. laryngea superior], which opens into the superior thyroid vein, and partly in the **inferior laryngeal** vein [v. laryngea inferior], which terminates in the plexus thyroideus impar. The laryngeal plexus of veins communicates with the pharyngeal plexus.

8. THE DEEP VEINS OF THE NECK

The **deep veins of the neck** include the internal jugular, vertebral, deep cervical, inferior thyroid, thyroidea ima, thymic, tracheal, and esophageal veins.

THE INTERNAL JUGULAR VEIN

The **internal jugular** vein [v. jugularis interna] (figs. 589, 598) begins at the jugular fossa, and is the continuation of the transverse sinus. It passes down the neck, in company first with the internal carotid artery and then with the common carotid artery, to a point a little lateral to the sternoclavicular articulation, where it joins the subclavian to form the innominate vein. At its commencement in the larger posterior and lateral part of the jugular foramen, it is somewhat

dilated, forming the **superior bulb** of the jugular vein [bulbus v. jugularis superior]. This dilated part of the internal jugular vein lies in the jugular fossa of the temporal bone and is therefore in immediate relation to the floor of the tympanum. At first the internal jugular lies in front of the rectus capitis lateralis, and behind the internal carotid artery, from which it is separated by the hypoglossal, glossopharyngeal, and vagus nerves, and by the carotid plexus of the sympathetic. As it descends it passes gradually to the lateral side of the internal carotid, and

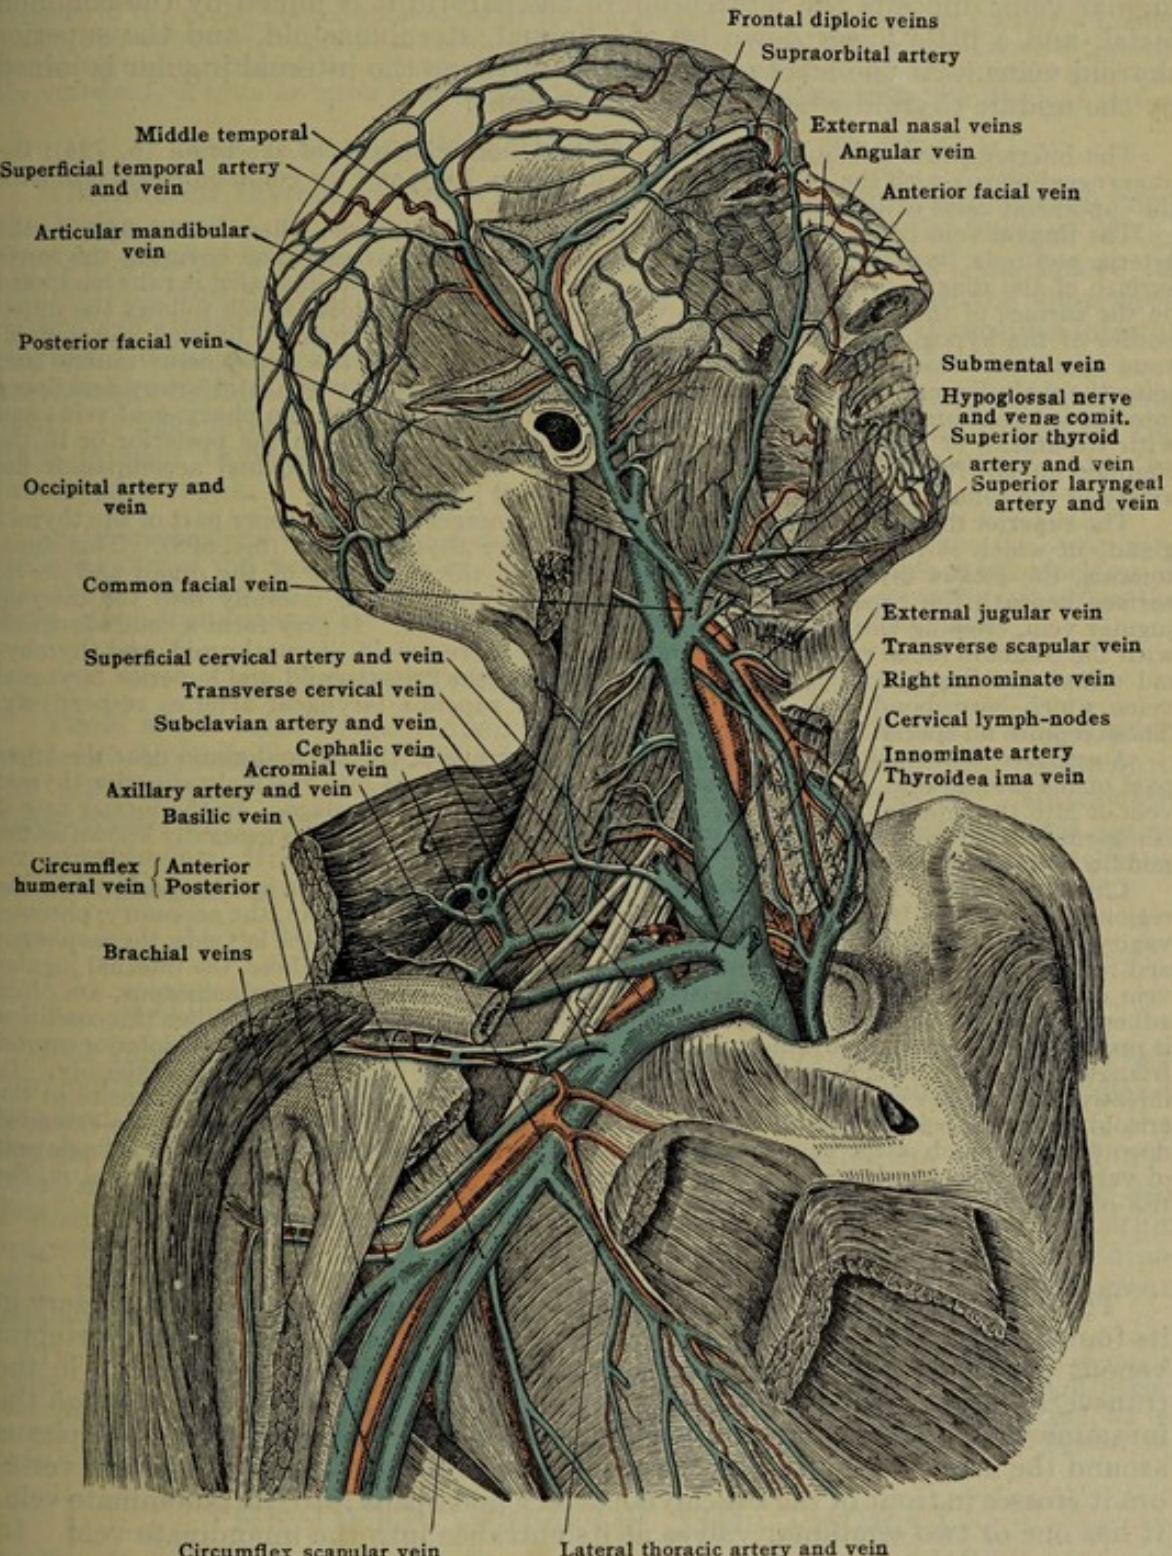

FIG. 598.—THE VEINS OF THE HEAD, NECK, AND AXILLA. (After Toldt, 'Atlas of Human Anatomy', The Macmillan Company.)

retains this relation as far as the upper border of the thyroid cartilage. Thence it runs to its termination along the lateral side of the common carotid artery, being contained in the same sheath with it and the vagus nerve, but separated from these structures by a distinct septum. The vein generally overlaps the artery in front. About 2.5 cm. (1 in.) above its termination it contains a pair of imperfect valves below which a second dilation usually occurs in the vein. This,

the **inferior bulb** [bulbus v. jugularis inferior], extends as low as the junction of the internal jugular with the subclavian. It not infrequently receives the termination of the external jugular vein.

Tributaries.—At the superior bulb the internal jugular vein receives the inferior petrosal sinus; the vein of the cochlear canaliculus (which may join the inferior petrosal sinus), and a meningeal vein; opposite the angle of the jaw, veins from the pharyngeal plexus, and often a communicating branch from the external jugular vein; opposite the bifurcation of the carotid it is joined by the common facial, and a little lower down by the lingual, sternomastoid, and the superior thyroid veins. At the level of the cricoid cartilage the internal jugular is joined by the middle thyroid when this vein is present.

The inferior petrosal sinus is described with the other sinuses of the brain (p. 724); the pharyngeal plexus with the veins of the pharynx (see p. 730); and the common facial vein with the superficial veins of the scalp and face (p. 719).

The **lingual** vein [v. lingualis], begins near the tip of the tongue, where it accompanies the arteria profunda linguæ. It lies at first beneath the mucous membrane covering the lower surface of the tongue. After receiving the **sublingual** vein [v. sublingualis] it runs backward on the surface of the hyoglossus as the **v. comitans nervi hypoglossi** which follows the upper border of the hypoglossal nerve. The dorsal lingual veins [vv. dorsales linguæ] join a small vena comitans, which accompanies the lingual artery beneath the hypoglossus muscle and joins the main lingual trunk. The trunk finally crosses the common carotid artery and opens into the internal jugular vein. The lingual vein communicates with the pharyngeal veins and with tributaries of the anterior facial. It occasionally terminates in the posterior or in the common facial vein. The **sternomastoid** vein [v. sternocleidomastoidea] accompanies the artery of the same name and empties into the internal jugular.

The **superior thyroid** vein [v. thyroidea superior] emerges from the upper part of the thyroid gland, in which it freely anastomoses with the other thyroid veins (fig. 598). This anastomosis, the **plexus thyroideus impar,** occurs both in the substance of the organ and on its surface beneath the capsule. The vein then passes upward and laterally into the internal jugular vein, crossing the common carotid artery in its course. It may form a common trunk with the common facial vein. Its **tributaries** are the sternohyoid, sternothyroid, and thyrohyoid veins from the muscles bearing those names; and the cricothyroid and superior laryngeal veins which correspond with the cricothyroid and superior laryngeal arteries respectively. These require no special description.

A separate vein frequently passes out from the capsule of the thyroid gland near the lower part of the lateral lobe, crosses the common carotid, and opens into the main superior thyroid vein or into the internal jugular vein a little below the cricoid cartilage. In the former case it is regarded as part of the superior thyroid vein system; in the latter it is generally known as the **middle thyroid** vein.

Clinical aspects. Several structures of especial clinical importance are encountered in the region of the carotid triangles. These include the internal jugular vein, the accessory, phrenic, vagus and hypoglossal nerves, the thoracic duct, low down and deep on the left side, the esophagus and recurrent nerve in difficult operations on the thyroid gland. Of these, the internal jugular vein is, in some ways, the most important. Glands, tuberculous or carcinomatous, are often adherent to its sheath, especially those which drain the submaxillary group. When this condition is present or suspected, it is always well to begin the dissection low down in the inferior carotid triangle, where the structures are probably normal and the landmarks easy to identify. In infective thrombosis of the transverse sinus the internal jugular is often tied opposite to the cricoid cartilage, being either divided between two ligatures, or, if the thrombus has extended downward, as much of the vein as is possible is removed. This vein contains only a single pair of valves low down in the neck. In all operations here on it and the other two jugulars, the risk of entry of air is to be remembered.

The Vertebral Vein

The **vertebral** vein [v. vertebralis] does not accompany the vertebral artery in its fourth stage, that is, within the cranium, but begins in the posterior vertebral venous plexus of the suboccipital triangle. It then enters the foramen in the transverse process of the atlas, and passes with the vertebral artery through the foramina in the transverse processes of the cervical vertebræ, forming a plexus around the artery. On leaving the transverse process of the sixth cervical vertebra it crosses in front of the subclavian artery and opens into the innominate vein. It has one or two semilunar valves at its entrance into the innominate vein. In the suboccipital triangle it communicates with the internal vertebral venous plexuses, with the deep cervical, and occipital veins, and is joined by veins from the recti and oblique muscles and the pericranium.

Tributaries.—As it passes down the neck it receives (1) intervertebral veins, which issue along with the cervical nerves, from the spinal canal; (2) tributaries from the anterior and posterior vertebral venous plexus from the bodies of the cervical vertebræ and their transverse processes; and (3) tributaries from the deep cervical muscles. Just before it terminates in the innominate it is joined by (4) the anterior vertebral vein, a small vein which accompanies the ascending cervical artery, and, sometimes, by the deep cervical vein.

The Deep Cervical Vein

The **deep cervical** vein [v. cervicalis profunda], larger than the vertebral, passes down the neck posterior to the cervical transverse processes. It corresponds to the deep cervical artery from which it is separated by the semispinalis cervicis muscle.

It begins in the posterior vertebral venous plexus and receives tributaries from the deep muscles of the neck. It communicates with, or entirely drains, the occipital vein by a branch which perforates the trapezius muscle. The deep cervical vein then passes forward beneath the transverse process of the seventh cervical vertebra to open into the innominate vein near the vertebral, or into the latter near its termination. Its orifice is guarded by a pair of valves.

The Inferior Thyroid and Thyroidea Ima Veins

The **inferior thyroid** veins [vv. thyreoideæ inferiores] (fig. 598) descend from the lower part of the *plexus thyroidea impar* which invests the surface of the thyroid gland. The **right vein** crosses the innominate artery just before its bifurcation, and ends in the right innominate vein a little above the vena cava superior or joins the left to form a single vena thyroidea ima. It receives inferior laryngeal veins and veins from the trachea. The **left vein** passes obliquely over the trachea behind the sternothyroid muscle, and opens into the left innominate vein. It also receives laryngeal and tracheal veins, and may be joined by the right inferior thyroid vein. It is guarded by valves where it opens into the innominate trunk.

The **thyroidea ima** vein [v. thyreoidea ima] can be said to exist only when the veins from the lower part of the plexus thyroidea impar unite at once to form a single trunk which opens into the left innominate vein, or when the right inferior thyroid vein joins the left before the latter, which then becomes the v. thyroidea ima, opens into the left innominate.

The Thymic, Tracheal and Esophageal Veins

These small veins usually open into the left innominate vein. The **thymic** veins [vv. thymicæ], small in the adult, open into the left innominate vein or into the inferior thyroid or thyroidea ima. The **tracheal** veins [vv. tracheales] anastomose with the laryngeal and bronchial veins. The **esophageal** veins vv. œsophageæ] from the upper part of the esophagus, anastomose with the ower esophageal veins and with the pharyngeal plexus.

THE VEINS OF THE THORAX

THE SUPERFICIAL VEINS OF THE THORAX

The **superficial veins** of the front of the thorax can be seen in fig. 599. They form a plexus over the entire chest, of which the portion over the mammary gland is called the mammillary venous plexus. The lateral thoracic vein drains the mammary plexus, the costoaxillary and the thoracoepigastric veins and terminates in the axillary vein (p. 742). The veins nearer the median line are drained by the internal mammary vein and its anterior intercostal and superior epigastric tributaries. The veins over the entire thorax are in free communication with the superficial veins of the abdominal wall, which drain into the great saphenous and femoral veins and into the deeper veins of the abdomen.

The **thoracoepigastric** vein (fig. 599) joins the veins of the chest, e. g., the long thoracic above with the superficial epigastric below. Its valves directing the blood downward below and upward above (Stiles) may be rendered incompetent when this vessel is enlarged, as in interference with the portal vein (with which it communicates by a vein in the round ligament), or in blocking of the inferior vena cava.

THE DEEP VEINS OF THE THORAX

The **deep veins of the thorax** are:—the pulmonary veins, and the vena cava superior and its innominate and other tributaries. Of these veins, the pulmonary, the vena cava superior, and the innominate veins have already been described, as have the tributaries of the latter arising in the neck.

The following veins are described below:—(1) The azygos and ascending lumbar veins, which discharge their blood into the vena cava superior; (2) the veins of the vertebral column, which are tributary to the azygos veins through the intercostals; (3) the internal mammary veins, and (4) the superior phrenic, an-

terior mediastinal and pericardiac veins, all of which open into the innominate veins.

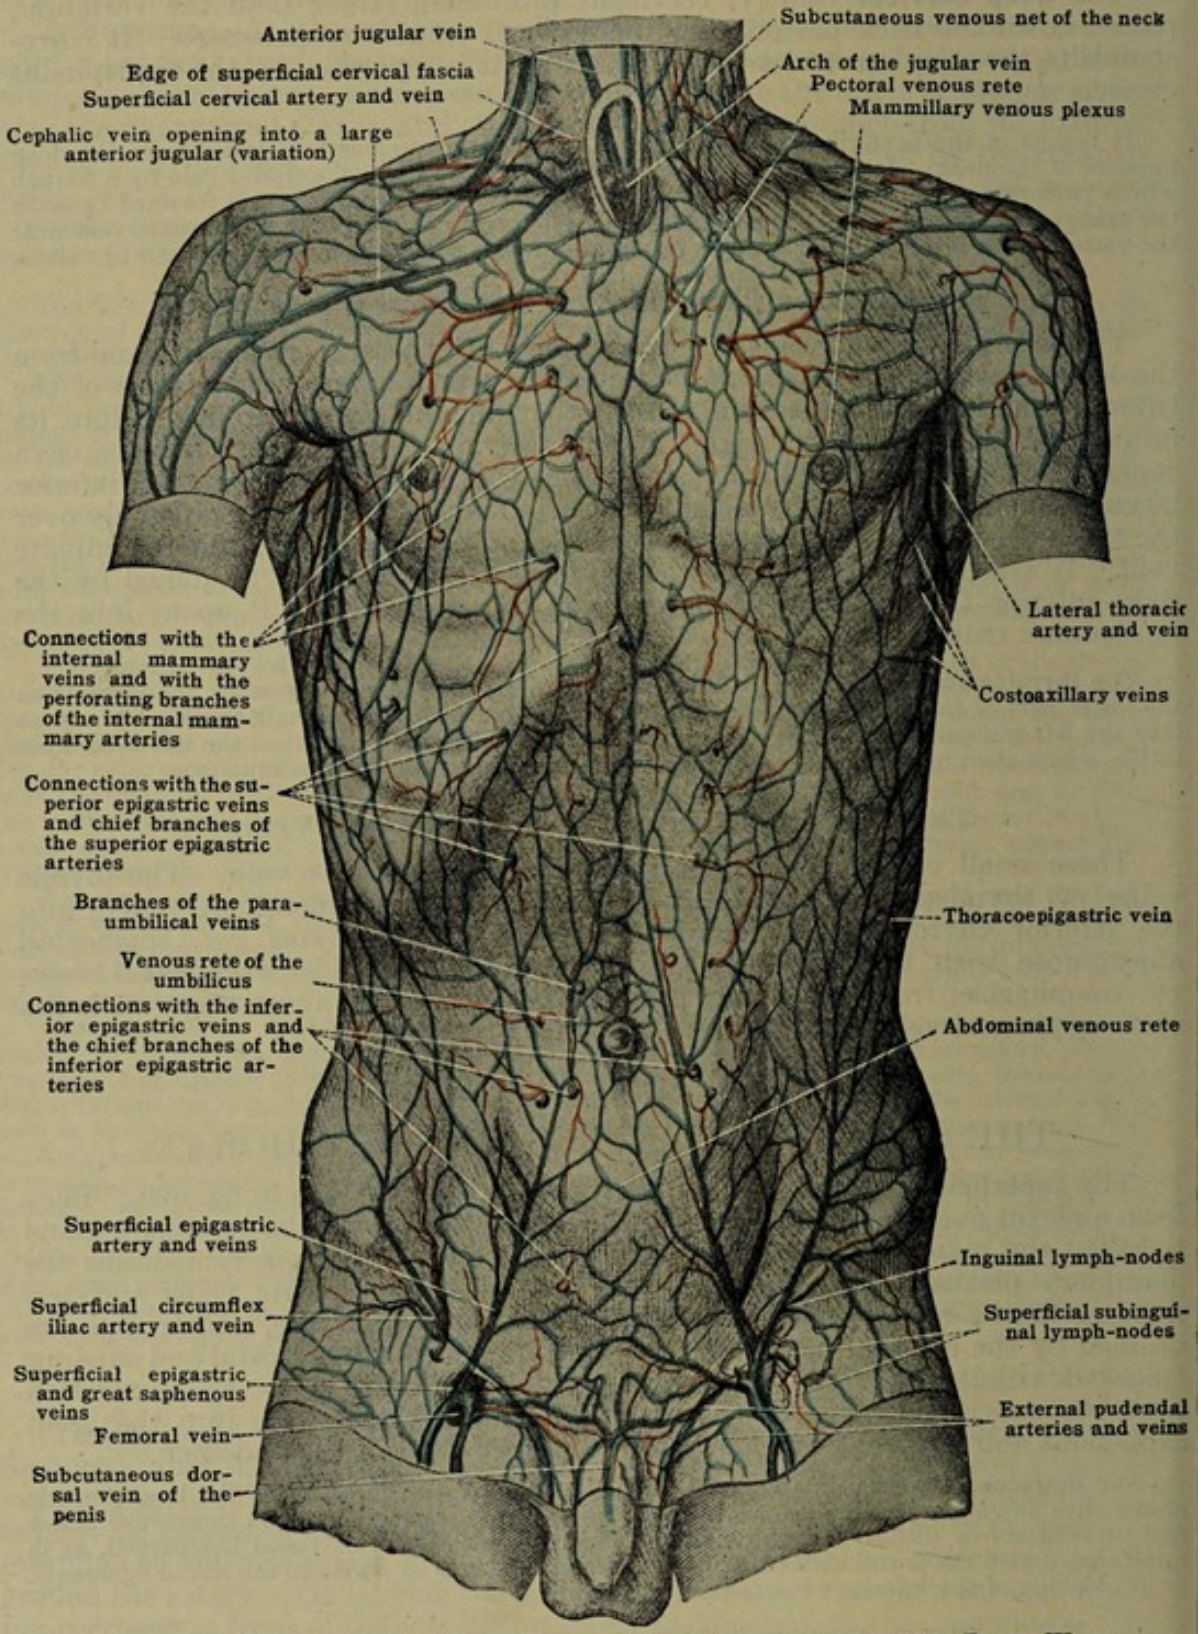

FIG. 599.—THE SUBCUTANEOUS ARTERIES AND VEINS OF THE ANTERIOR BODY WALL. (After Toldt, 'Atlas of Human Anatomy', The Macmillan Company.)

1. THE AZYGOS AND ASCENDING LUMBAR VEINS

The azygos system (v. thoracica longitudinalis NK) consists of a series of longitudinal collecting trunks for the *intercostal veins*. They lie along the sides of the thoracic vertebræ, and are the upward continuation of the **ascending lumbar veins** which take origin in the abdomen. The azygos veins are three in number: the azygos (azygos major) on the right side, and the hemiazygos (azygos minor) and accessory hemiazygos (azygos tertia) on the left.

The **azygos** vein [v. azygos] (v. thor. long. dextra NK) (figs. 600, 613) begins in the abdomen as the right ascending lumbar vein. It is in this way linked with the right common iliac and right renal veins and has other connections with the vena cava inferior which may become very important in cases of obstruction of the latter vessel. It runs beneath the right medial crus of the diaphragm, to the right of the aorta and the thoracic duct to reach the posterior mediastinum. Here it runs on the right side of the front of the bodies of the thoracic vertebræ as high as the fourth, still lying to the right of the aorta and thoracic duct; it then curves forward over the root of the right lung, and opens into the vena cava superior immediately before the latter pierces the pericardium.

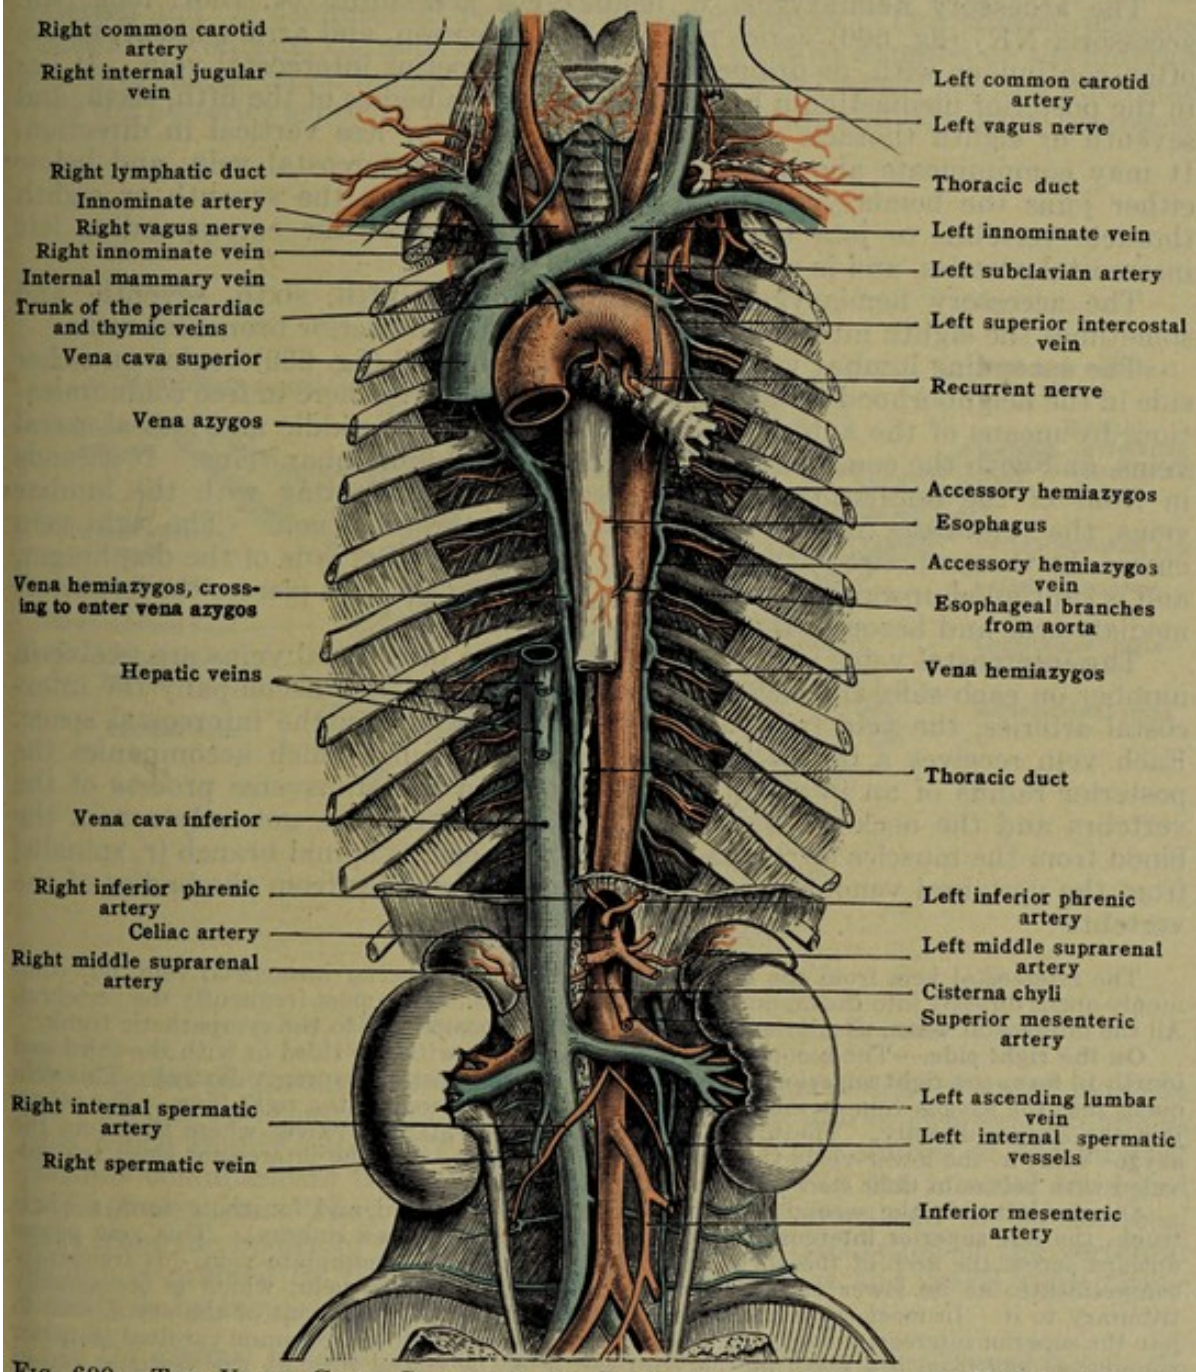

FIG. 600.—THE VENÆ CAVÆ SUPERIOR AND INFERIOR, THE INNOMINATE VEINS, AND THE AZYGOS VEINS.

The azygos vein usually contains an imperfect pair of valves at the point where it turns forward from the fourth thoracic vertebra to arch over the root of the lung; and still more imperfect valves are found at varying intervals lower down the vein.

It receives the intercostal veins of the right side, except the first two or three. These veins (usually excepting the first) are collected into a common trunk, the right superior intercostal vein, before joining the azygos. It also receives the hemiazygos and accessory hemiazygos, the right posterior bronchial vein, and small esophageal and posterior mediastinal veins.

The **hemiazygos** vein [v. hemiazygos] (v. thor. long. sinistra NK) (fig. 600) begins in the abdomen by communicating, like the azygos vein, with the ascending

lumbar vein of its own side. It passes through the left intermediate crus of the diaphragm and courses up the posterior mediastinum to the left of the bodies of the lower thoracic vertebræ as high as the eighth or ninth. Here it turns obliquely to the right and, crossing in front of the vertebral column behind the aorta and the esophagus, opens into the vena azygos. In its course it crosses over three or four of the lower left intercostal arteries, and is covered by the pleura.

The hemiazygos receives the lower four or five left intercostal veins the lower end of the accessory hemiazygos vein (sometimes), the small left mediastinal veins, and the lower left esophageal veins.

The **accessory hemiazygos** [v. hemiazygos accessoria] (v. thor. long. sin. accessoria NK) (fig. 600) varies much in size, position, and arrangement, and is often continuous with, or drained by, the left superior intercostal vein. It lies in the posterior mediastinum by the left side of the bodies of the fifth, sixth, and seventh or eighth thoracic vertebræ, and is more or less vertical in direction. It may communicate above with the left superior intercostal vein, and below either joins the hemiazygos or passes obliquely across the seventh or eighth thoracic vertebra to join the azygos vein. It crosses the corresponding left intercostal arteries, and is covered by the pleura.

The accessory hemiazygos receives the fourth, fifth, sixth, seventh, and sometimes the eighth intercostal veins, and the left posterior bronchial veins.

The **ascending lumbar** vein [v. lumbalis ascendens] (fig. 600) begins on either side in the neighborhood of the sacral promontory. It is here in free communication, by means of the anterior sacral plexus, with the middle and lateral sacral veins, and with the common iliac, hypogastric and iliolumbar veins. It ascends in front of the lumbar transverse processes communicating with the lumbar veins, the vena cava inferior and, usually, with the renal vein. The right vein enters the thorax between the aorta and the right medial crus of the diaphragm, and is continued upward as the vena azygos. The left vein pierces the left intermediate crus and becomes the hemiazygos.

The intercostal veins [vv. intercostales].—The intercostal veins are twelve in number on each side, the last one being subcostal. They accompany the intercostal arteries, the vein lying above the artery whilst in the intercostal space. Each vein receives a dorsal tributary [ramus dorsalis] which accompanies the posterior ramus of an intercostal artery between the transverse process of the vertebra and the neck of the rib. These dorsal branches not only return the blood from the muscles of the back, but receive each a spinal branch [r. spinalis] from the vertebral venous plexuses and small tributaries from the bodies of the vertebræ.

The intercostal vein from the first space may join the superior intercostal vein, but commonly opens directly into the innominate or one of its tributaries, most frequently the vertebral. All the intercostal veins, usually excepting the first, lie posteriorly to the sympathetic trunk.

On the right side.—The second intercostal vein joins, with the third or with the third and fourth to form the **right superior intercostal** vein [v. intercostalis suprema dextra]. This vein opens into the azygos vein as the latter is arching over the root of the right lung. The others join the azygos directly. The upper of these have well-marked valves where they join the azygos vein; in the lower veins these valves are imperfect. All the intercostal veins are provided with valves in their course between the muscles.

On the **left side** the second intercostal vein joins the third and fourth to form a single trunk, the **left superior intercostal** vein [v. intercostalis suprema sinistra]. This vein passes upward across the arch of the aorta and opens into the left innominate vein. It frequently communicates at its lower end with the accessory hemiazygos vein, which is occasionally tributary to it. In most cases a small tributary runs up over the front of the aortic arch to join the superior intercostal vein; it is a vestige of the embryonic left common cardinal (superior vena cava) and from it a small fibrous cord can often be traced through the vestigial fold of the pericardium to the oblique vein of the left atrium (p. 599).

The left fourth, fifth, sixth and seventh intercostal veins commonly open into the accessory hemiazygos, and the eighth or ninth and succeeding veins into the hemiazygos. The method of termination of the intercostal veins of the left side is subject to such variation that a normal arrangement can scarcely be said to exist at all. The eighth may open directly into the azygos, as may the seventh and ninth or even more or all of the veins; the hemiazygos and accessory hemiazygos veins may thus be very limited in extent or even altogether absent.

The **posterior bronchial** veins [vv. bronchiales posteriores] correspond to the bronchial arteries, but do not return the whole of the blood carried to the lungs by those vessels—that part which is distributed to the smaller bronchial tubes and the alveoli being brought back by the pulmonary veins. The posterior bronchial veins issue from the lung substance behind the structures forming the root of the lung. The right vein generally joins the vena azygos just before the latter vein enters the vena cava superior. The left vein opens into the accessory

hemiazygos vein. The bronchial veins at the root of the lung receive small tributaries from the bronchial glands, from the trachea, and from the posterior mediastinum.

The **esophageal** veins [vv. œsophageæ] from the thoracic portion of the esophagus end in part in the vena azygos, and in part in the vena hemiazygos. They anastomose with the upper esophageal veins, which empty into the left innominate vein, and with the coronary vein of the stomach (fig. 608).

The **posterior mediastinal** veins, small and numerous, open into the azygos and hemiazygos veins.

2. THE VEINS OF THE VERTEBRAL COLUMN

The venous plexuses around and within the vertebral column extending from the cranium to the coccyx (fig. 601) may be divided into two categories:—(1) the **external** and (2) the **internal vertebral venous plexuses.** The external plexuses consist of two parts, the *anterior vertebral venous plexuses* situated on the anterior aspect of the vertebral bodies and the *posterior vertebral venous plexuses* ramifying over the posterior aspect of the vertebral arches, spines, and transverse processes.

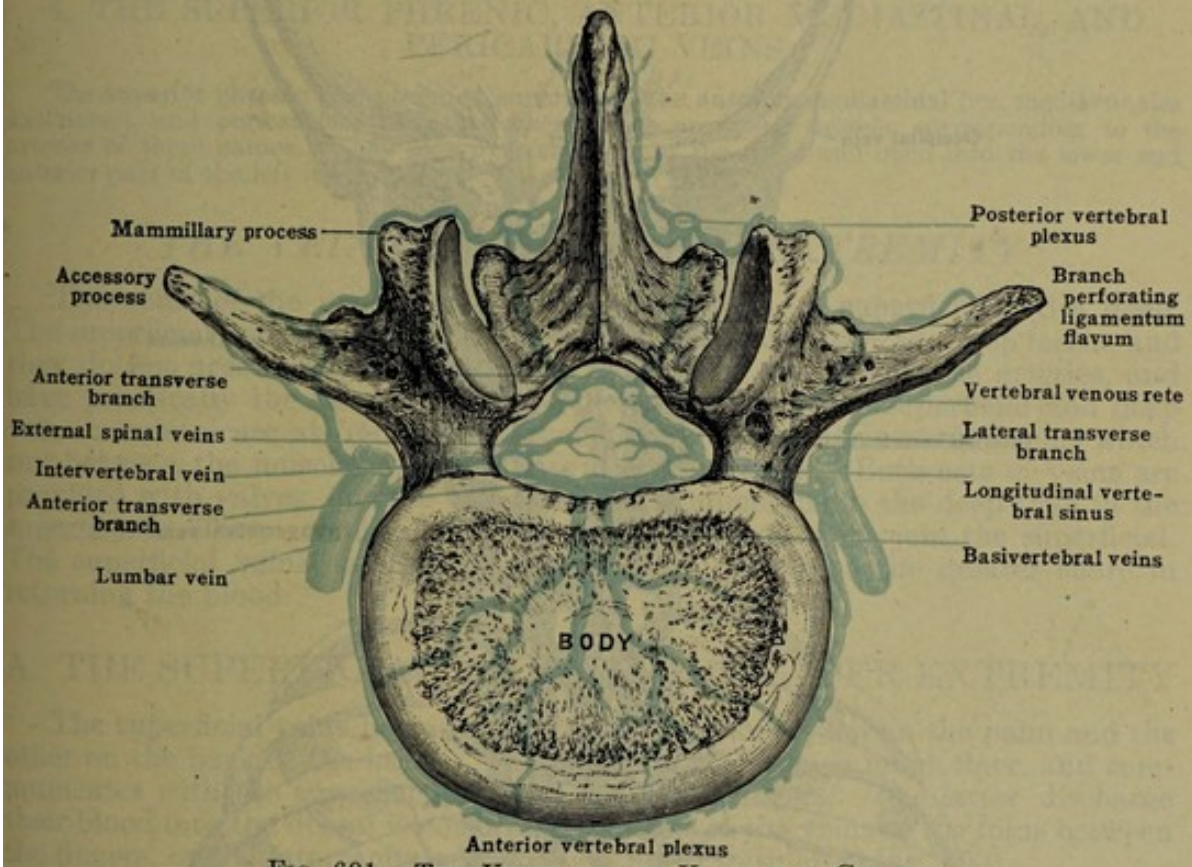

FIG. 601.—THE VEINS OF THE VERTEBRAL COLUMN.

The internal plexuses consist of *two longitudinal venous sinuses* situated between the vertebræ and the posterior longitudinal ligament, and of two *vertebral venous retia* which ramify externally to the dura mater. The sinuses of the internal plexuses communicate freely with one another and with the internal retia and external plexuses. They receive the external spinal veins and the *basivertebral veins* from the bodies of the vertebræ. The venous circulation of the vertebral column is drained by the vertebral, intercostal, lumbar and sacral veins either directly or by means of (3) the **intervertebral** veins.

1. The **external vertebral** venous plexuses [plexus venosi vertebrales externi] include the following:—

(*a*) The **anterior vertebral venous plexuses** [plexus venosi vertebrales anteriores] (fig. 601), consist of small veins ramifying in front of the bodies of the vertebræ. These veins communicate with the basivertebral veins and are larger in the cervical region than elsewhere.

(*b*) The **posterior vertebral venous plexuses** [plexus venosi vertebrales posteriores] (fig. 601) are situated around the transverse, articular, spinous processes and laminæ of the vertebræ. Communications take place between the plexuses of each segment and with the veins of the neighboring muscles and integuments. Branches are also sent, through the ligamenta flava, to the internal vertebral venous plexuses, and, between the transverse processes, to the intervertebral veins.

2. The **internal vertebral venous plexuses** [plexus venosi vertebrales interni] (figs. 601, 602):—

(*a*) The two **longitudinal vertebral sinuses** [sinus vertebrales longitudinales] run throughout the entire length of the vertebral canal. They are situated behind the bodies of the verte-

bræ on either side, between the bone and the posterior longitudinal ligament. The sinuses have extremely thin walls, and their interior is made irregular by numerous folds but no true valves are present. The caliber of the longitudinal sinuses is reduced by constrictions opposite the intervertebral disks; the constrictions alternating with dilatations opposite the vertebral bodies. At each dilatation there occurs a cross communication between the longitudinal sinuses of either side, and each receives a basivertebral vein from the corresponding vertebral body. Opposite every intervertebral foramen and anterior sacral foramen each longitudinal sinus is joined by the corresponding intervertebral vein. The longitudinal sinuses communicate very freely with one another, and with the vertebral retia. At the foramen magnum they communicate with the basilar plexus and with the occipital sinus and, by means of the **rete canalis hypoglossi**, with the internal jugular vein.

(*b*) The **venous retia of the vertebræ** [retia venosa vertebrarum] (fig. 601) extend from the foramen magnum to the coccyx. They consist of two main retia situated posteriorly and laterally to the dura between the latter and the vertebral arch. They communicate very freely with one another across the median line; with the posterior external plexus by means of twigs perforating the ligamenta flava; and with the longitudinal vertebral sinuses by means of lateral branches. At the foramen magnum they communicate with the occipital sinus.

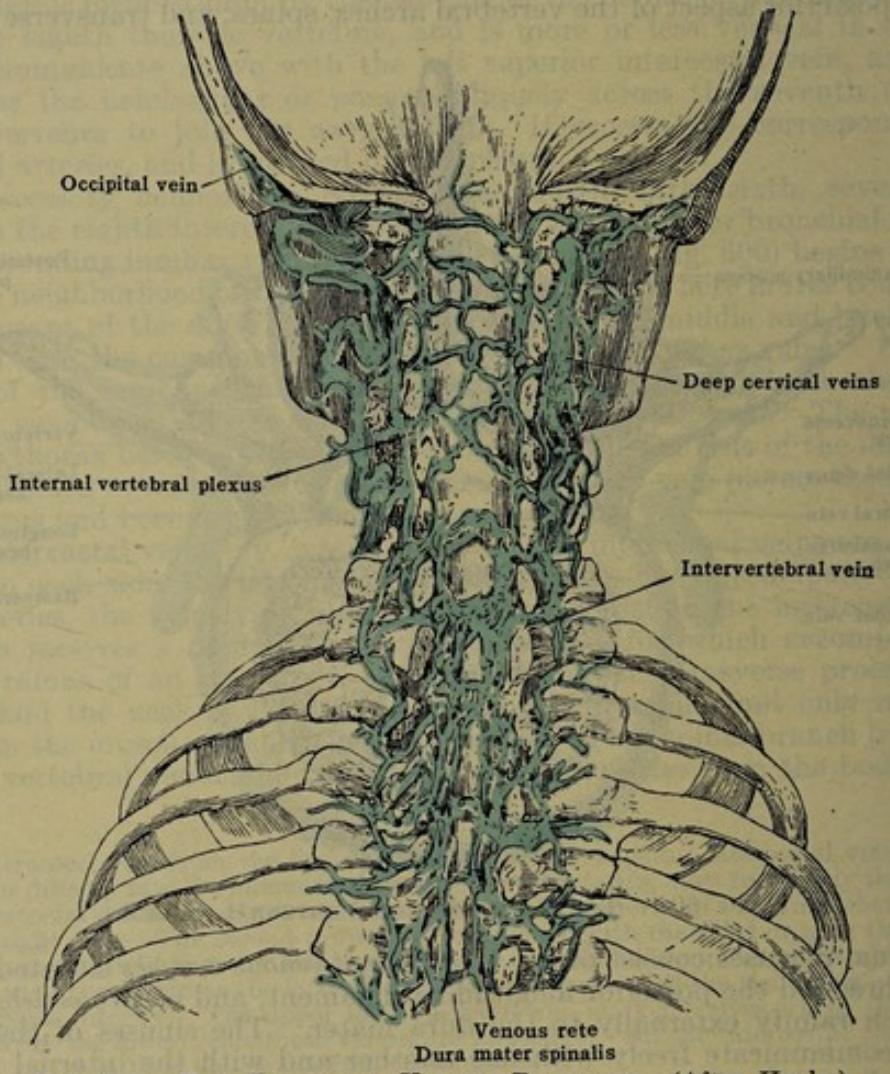

FIG. 602.—THE VERTEBRAL VENOUS PLEXUSES. (After Henle.)

(*c*) The **external spinal** veins (fig. 601) consist of two sets—anterior and posterior—which are drained by means of veins following the nerve roots, into the internal vertebral venous plexus.

The **anterior external spinal** veins [vv. spinales externæ anteriores] form a tortuous anastomosing vessel in the region of the anterior median fissure.

The **posterior external spinal** veins [vv. spinales externæ posteriores], smaller than the anterior run longitudinally on the posterior surface of the cord.

The external spinal veins form a wide-meshed plexus in the pia mater which drains the **internal spinal** veins [vv. spinales internæ] (see SPINAL CORD).

(*d*) The **basivertebral** veins [vv. basivertebrales] (fig. 601) collect the blood from the cancellous tissue of the bodies of the vertebræ, and consist of a tunica intima only. They take a radial direction converging to the transverse vessels connecting the longitudinal vertebral sinuses. They communicate with the anterior external plexus and with the intercostal veins.

3. The **intervertebral** veins [vv. intervertebrales] (figs. 601, 602), emerge from each longitudinal sinus and pass out through the intervertebral or anterior sacral foramina. They open into the vertebral, intercostal, lumbar or sacral veins according to region and receive numerous tributaries from the anterior and posterior external vertebral venous plexuses. They are instrumental in draining the venous system of the vertebral column and spinal cord.

3. THE INTERNAL MAMMARY VEIN

The internal mammary vein [v. mammaria interna] (v. thoracica interna NK) (fig. 542) is formed by the union of the venæ comitantes corresponding to the superior epigastric and musculophrenic arteries. The right and left internal mammary veins pass upward, in company with the corresponding arteries, to open into the right and left innominate veins, respectively.

Tributaries.—In addition to the superficial veins of the thorax, the internal mammary veins receive the anterior intercostal, anterior bronchial and pericardiac veins.

The **superior epigastric** vein [v. epigastrica superior] assists in the drainage of the subcutaneous abdominal veins [vv. subcutaneæ abdominis].

The **anterior bronchial** veins [vv. bronchiales anteriores] arise in the bronchial walls and communicate with the tracheal and posterior bronchial veins.

4. THE SUPERIOR PHRENIC, ANTERIOR MEDIASTINAL, AND PERICARDIAC VEINS

The **superior phrenic** [vv. phrenicæ superiores], the **anterior mediastinal** [vv. mediastinales anteriores], and **pericardiac** [v. pericardiacæ] veins are small vessels, corresponding to the arteries of those names. They pass over the arch of the aorta and open into the lower and anterior part of the left innominate.

THE VEINS OF THE UPPER EXTREMITY

The **veins of the upper limb** consist of two sets—a **superficial** and a **deep.** The superficial veins ramify in the subcutaneous tissue above the deep fascia, and they do not accompany arteries. The deep veins accompany the arteries, and have practically the same relations as those vessels. The superficial and deep veins communicate at frequent intervals through the intermuscular veins which run between the muscles and perforate the deep fascia. Both sets of veins are provided with valves, but the valves are more numerous in the deep than in the superficial. There are usually valves where the deep veins join the superficial. The superficial veins are larger than the deep, and take the greater share in returning the blood.

A. THE SUPERFICIAL VEINS OF THE UPPER EXTREMITY

The **superficial veins** begin in two irregular plexuses, one in the palm and the other on the back of the hand. The plexus in the palm is much finer, and communicates with the superficial volar veins of the fingers. The latter discharge their blood into the dorsal venous rete by means of the veins of the folds between the fingers, or the **intercapitular** veins [vv. intercapitulares] (fig. 603).

The veins of the back of the hand begin in a longitudinal plexus over the fingers, and at the bases of the fingers the veins of the adjacent digits are connected by **digital venous arches** [arcus venosi digitales], from which arise the **dorsal metacarpal** veins [vv. metacarpeæ dorsales]; these form upon the back of the hand a **dorsal venous rete** [rete venosum dorsale manus] (fig. 604).

Of the veins of the arm, two stand out prominently, the basilic and the cephalic. Both of these arise from the veins of the back of the hand, curve around to the volar surface of the forearm, and pass to the arm (fig. 603).

The **basilic** vein [v. basilica],* arises on the back of the hand from the ulnar end of the dorsal venous rete, which usually forms an arch. It curves around the ulnar side of the forearm to the volar surface just distally to the elbow and reaches the arm, where it lies in the median bicipital sulcus. It extends up to about the middle third of the sulcus, and, piercing the brachial fascia, joins the brachial venæ comitantes to form the axillary vein.

The **cephalic** vein [v. cephalica],* begins at the radial end of the dorsal venous rete or arch and curves around the radial border of the forearm to the volar

* The basilic vein here described corresponds to the posterior ulnar and the basilic; the cephalic corresponds to the median, median cephalic and cephalic of the older terminology employed in English text-books. The BNA terminology has the great advantage that it can be used to describe any form of venous pattern. The older terminology applies only to cases in which the **M**-shaped arrangement occurs upon the volar surface of the elbow. Berry and Newton found the latter arrangement in only 13 per cent. of 300 cases.

surface a short distance above the wrist. It passes over the volar surface of the elbow and here receives a large tributary from the radial border of the forearm, the accessory cephalic [v. cephalica accessoria], and reaches the lateral aspect

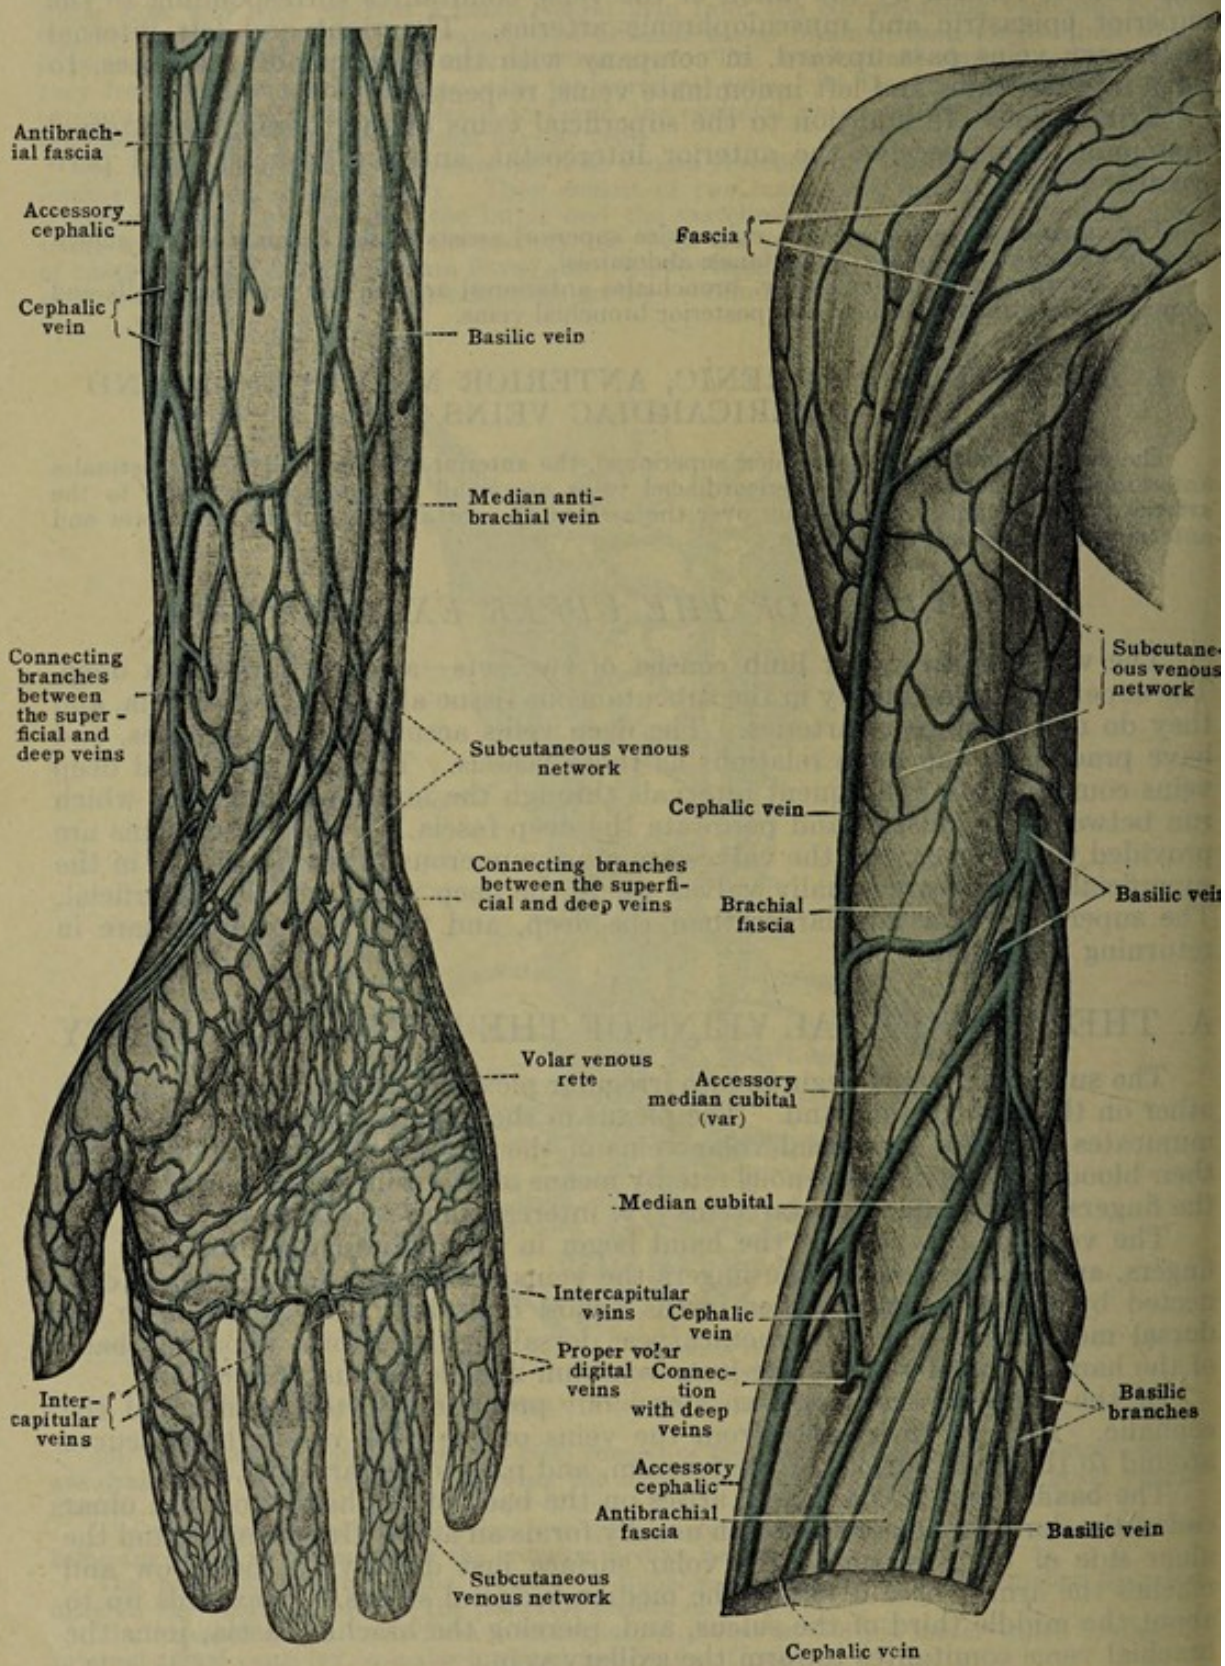

FIG. 603.—THE SUPERFICIAL VEINS OF THE ARM AND FOREARM. (After Toldt, 'Atlas of Human Anatomy', The Macmillan Company.) In this case the cephalic vein of the forearm is drained more directly (through the median cubital) into the basilic than into the proximal part of the cephalic.

of the arm. It lies at first in the lateral bicipital sulcus and then in the groove between the pectoralis major and the deltoid. Just below the clavicle it turns into the depth, and empties into the axillary vein.

At the elbow there is usually an oblique connecting branch, the **median cubital** vein [v. mediana cubiti] (figs. 603, 605) (formerly termed median basilic) which, beginning from the cephalic a little distally to the crease of the elbow, ends in the basilic just proximally to the elbow.

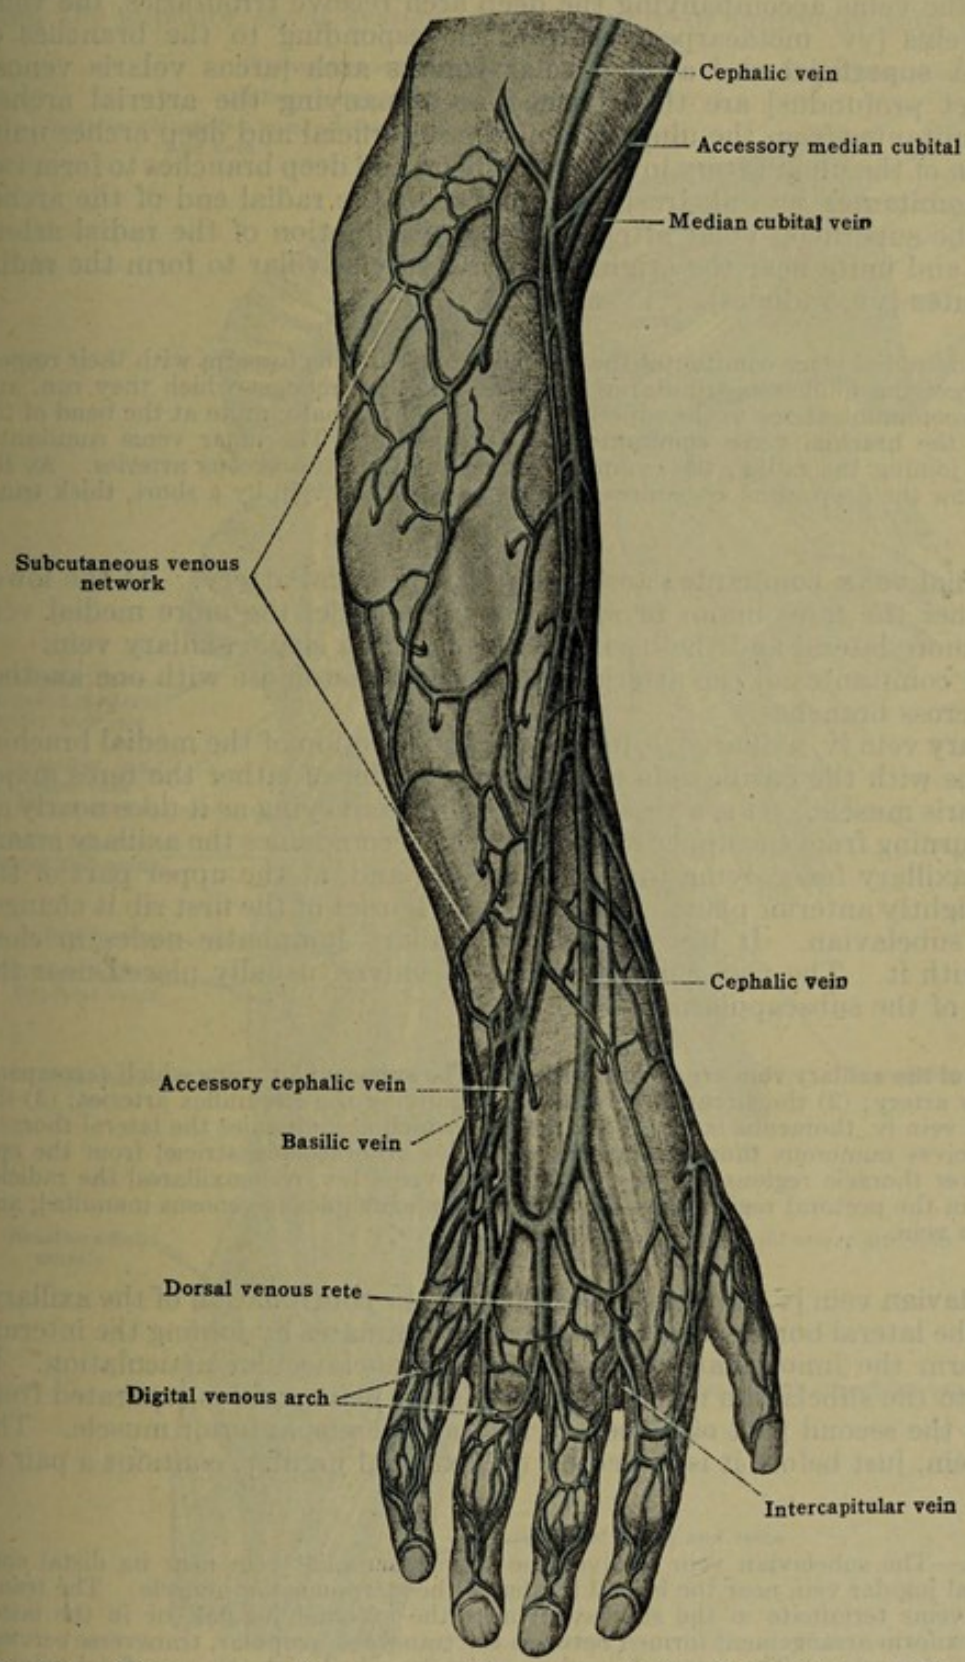

FIG. 604.—VEINS OF THE BACK OF THE FOREARM. (After Toldt, 'Atlas of Human Anatomy' The Macmillan Company.)

B. THE DEEP VEINS OF THE UPPER EXTREMITY

The **deep veins of the upper extremity** accompany their corresponding arteries. Distal to the axilla, each artery is accompanied by two veins known as the venæ comitantes. The deep veins all contain numerous valves, and communicate at frequent intervals through intermuscular veins with the superficial vessels.

Beginning at the fingers, two minute **proper volar digital** veins [venæ digitales volares propriæ], accompany each digital artery along the sides of the fingers, and uniting at the cleft, form **common volar digital** veins [vv. digitales volares communes], which join the venæ comitantes of the superficial volar arch. In like manner the veins accompanying the deep arch receive tributaries, **the volar metacarpal** veins [vv. metacarpeæ volares], corresponding to the branches of that arch. A **superficial** and a **deep volar venous arch** [arcus volaris venosi, superficialis et profundus] are thus formed accompanying the arterial arches. The venæ comitantes from the ulnar side of the superficial and deep arches unite at the division of the ulnar artery into its superficial and deep branches to form two **ulnar venæ comitantes** [vv. ulnares]; while those at the radial end of the arches accompany the superficial volar artery and the termination of the radial artery respectively, and unite near the origin of the superficial volar to form the **radial venæ comitantes** [vv. radiales].

The ulnar and radial venæ comitantes thus formed course up the forearm with their respective arteries, receiving numerous tributaries from the muscles amongst which they run, and giving frequent communications to the superficial veins. They finally unite at the bend of the elbow to form the **brachial venæ comitantes** [vv. brachiales]. The ulnar venæ comitantes receive, before joining the radial, the companion veins of the interosseous arteries. At the bend of the elbow the deep veins are connected with the cephalic vein by a short, thick trunk (fig. 603).

The **brachial venæ comitantes** accompany the brachial artery. At the lower border of either the teres major or subscapularis muscle, the more medial vein receives the more lateral and the basilic vein, to form a single axillary vein.

The venæ comitantes of the arteries of the arm anastomose with one another by frequent cross branches.

The **axillary** vein [v. axillaris], is formed by the junction of the medial brachial vena comitans with the basilic vein at the lower border of either the teres major or subscapularis muscle. It is a vessel of large size, conveying as it does nearly all the blood returning from the upper extremity. It accompanies the axillary artery through the axillary fossa, lying to its medial side and, at the upper part of the space, on a slightly anterior plane. At the lateral border of the first rib it changes its name to subclavian. It has one or two axillary lymphatic nodes in close connection with it. The vein contains a pair of valves, usually placed near the lower border of the subscapularis muscle.

Tributaries of the axillary vein are as follows:—(1) The **subscapular** veins which accompany the subscapular artery; (2) the **circumflex** veins accompanying the circumflex arteries; (3) the **lateral thoracic** vein [v. thoracalis lateralis] a large vein which accompanies the lateral thoracic artery and receives numerous **thoracoepigastric** veins [vv. thoracoepigastricæ] from the epigastric and lower thoracic regions; (4) the **costoaxillary** veins [vv. costoaxillares] the radicles of which arise in the pectoral region from the **mammary plexus** [plexus venosus mamillæ]; and (5) the **cephalic** vein.

The **subclavian** vein [v. subclavia] (fig. 605), is the continuation of the axillary. It begins at the lateral border of the first rib and terminates by joining the internal jugular to form the innominate, opposite the sternoclavicular articulation. It lies anterior to the subclavian artery and on a lower plane, and is separated from the artery in the second part of its course by the scalenus anterior muscle. The subclavian vein, just before it is joined by the external jugular, contains a pair of valves.

Tributaries.—The subclavian vein receives the thoracoacromial vein near its distal end, and the external jugular vein near the lateral border of the sternomastoid muscle. The transverse cervical veins terminate in the subclavian near the external jugular, or in the latter vein, or in a plexiform arrangement formed between the transverse scapular, transverse cervical and external jugular veins. The external jugular vein is described with the superficial veins of the head and neck (p. 719).

The **thoracoacromial** vein [v. thoracoacromialis], receiving tributaries corresponding to the branches of the artery of the same name, terminates near the lateral border of the first rib.

The **transverse cervical** veins [vv. transversæ colli] receive tributaries corresponding in distribution to the branches of the transverse cervical artery. They emerge from beneath the trapezius muscle, cross the posterior triangle, and usually terminate in the subclavian vein. They usually terminate as a single vein the orifice of which is guarded by a pair of valves. Occasionally the cephalic vein, or a branch from the cephalic (the jugulocephalic), passes over the clavicle to the subclavian.

C. THE VENA CAVA INFERIOR AND ITS TRIBUTARIES

All the veins of the abdomen, pelvis, and lower extremities, with the exception of the superior epigastric (p. 739), and ascending lumbar vein (p. 736), which join the superior caval system, enter directly or indirectly into the vena cava

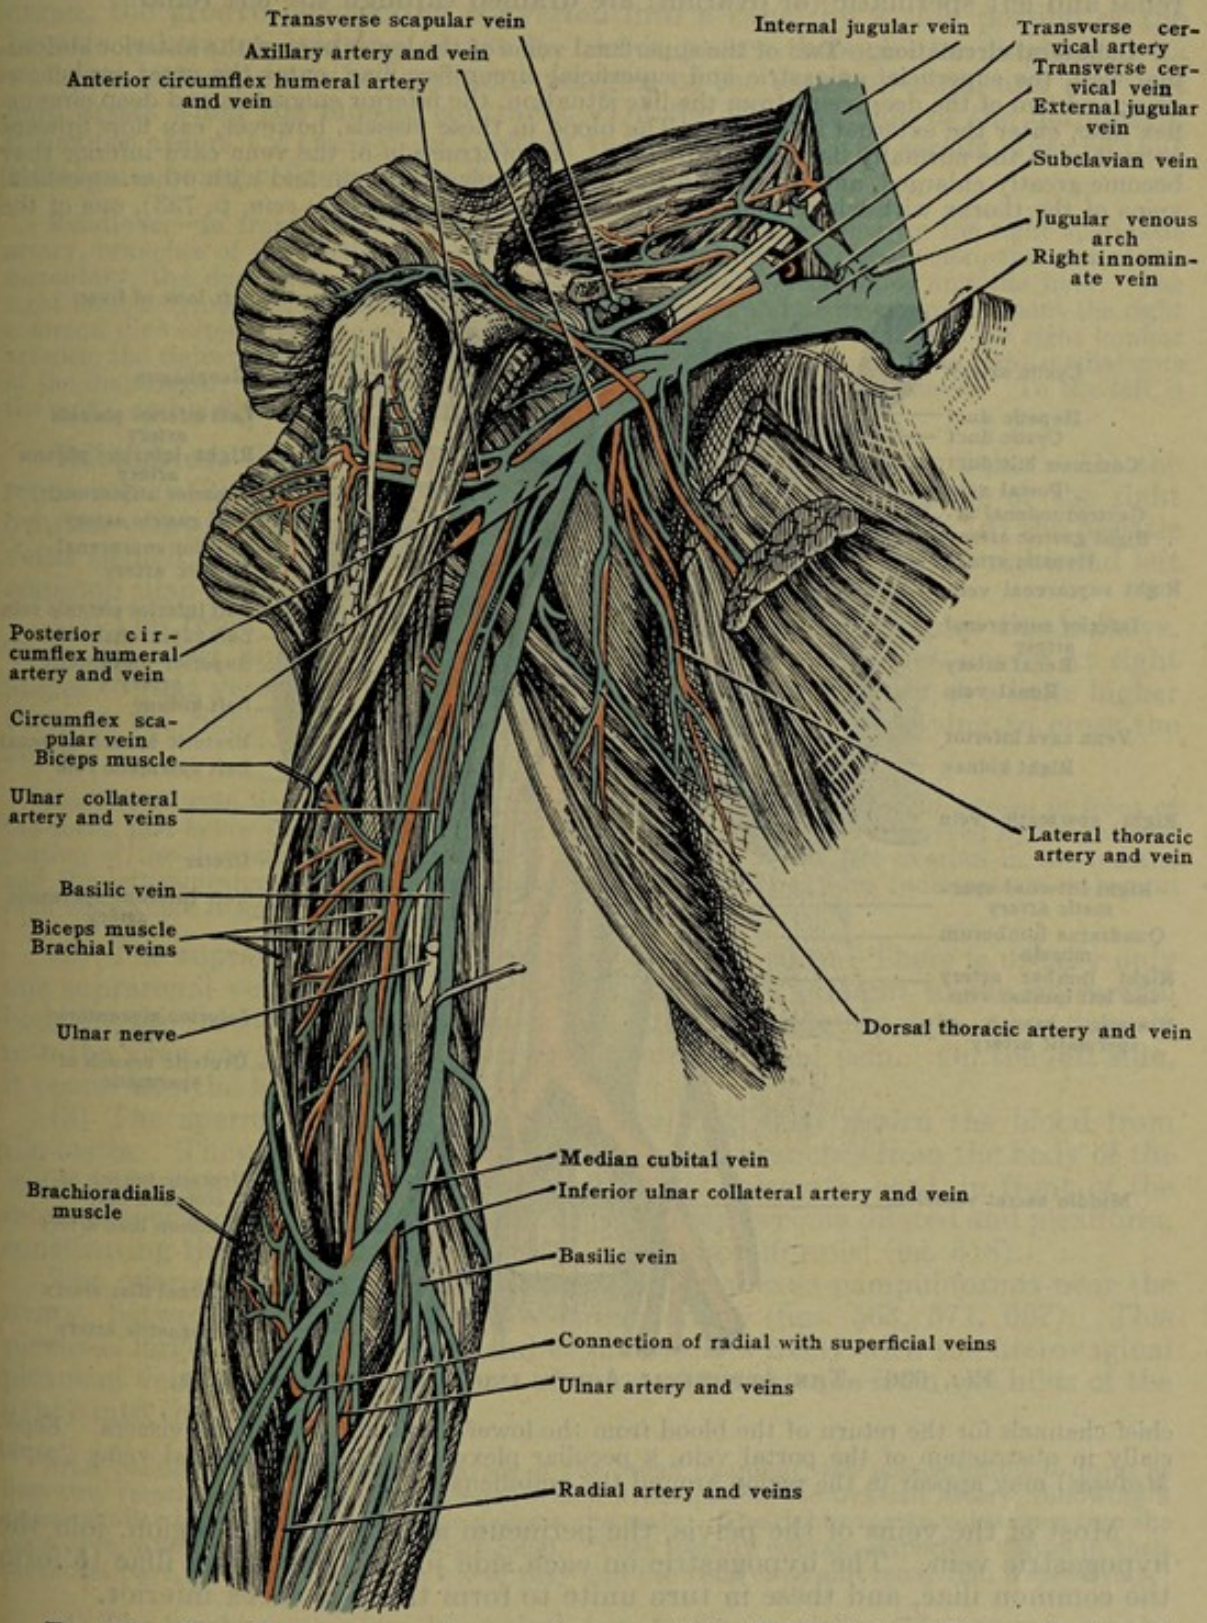

FIG. 605.—DEEP VEINS OF THE ARM AND AXILLA. (After Toldt, 'Atlas of Human Anatomy', The Macmillan Company.) The cephalic vein, incomplete above the elbow is drained through the median basilic into the basilic.

inferior. The veins corresponding to the parietal branches of the abdominal aorta, except the middle sacral vein, open directly into the vena cava inferior; the middle sacral vein only indirectly through the left common iliac vein. Of the visceral veins corresponding to the visceral branches of the abdominal aorta, those which return the blood from the stomach, intestines, pancreas, and the

spleen end in a common trunk called the portal vein. The portal vein breaks up into capillaries (sinusoids) in the liver, whence the blood is carried by the hepatic veins to the vena cava inferior.

Of the other visceral veins, both renals, the right suprarenal, and the right spermatic or ovarian open directly into the vena cava inferior; the left suprarenal and left spermatic (or ovarian) are drained through the left renal.

Collateral circulation.—Two of the superficial veins of the lower part of the anterior abdominal wall, the superficial epigastric and superficial circumflex iliac, enter the great saphenous vein; and two of the deep veins from the like situation, the inferior epigastric and deep circumflex iliac, enter the external iliac vein. The blood in these vessels, however, can flow upward as well as in the normally downward direction. In obstruction of the vena cava inferior they become greatly enlarged, and form, with the superior epigastric vein and with other superficial veins of the thorax with which they anastomose (see *thoracoepigastric vein*, p. 733), one of the

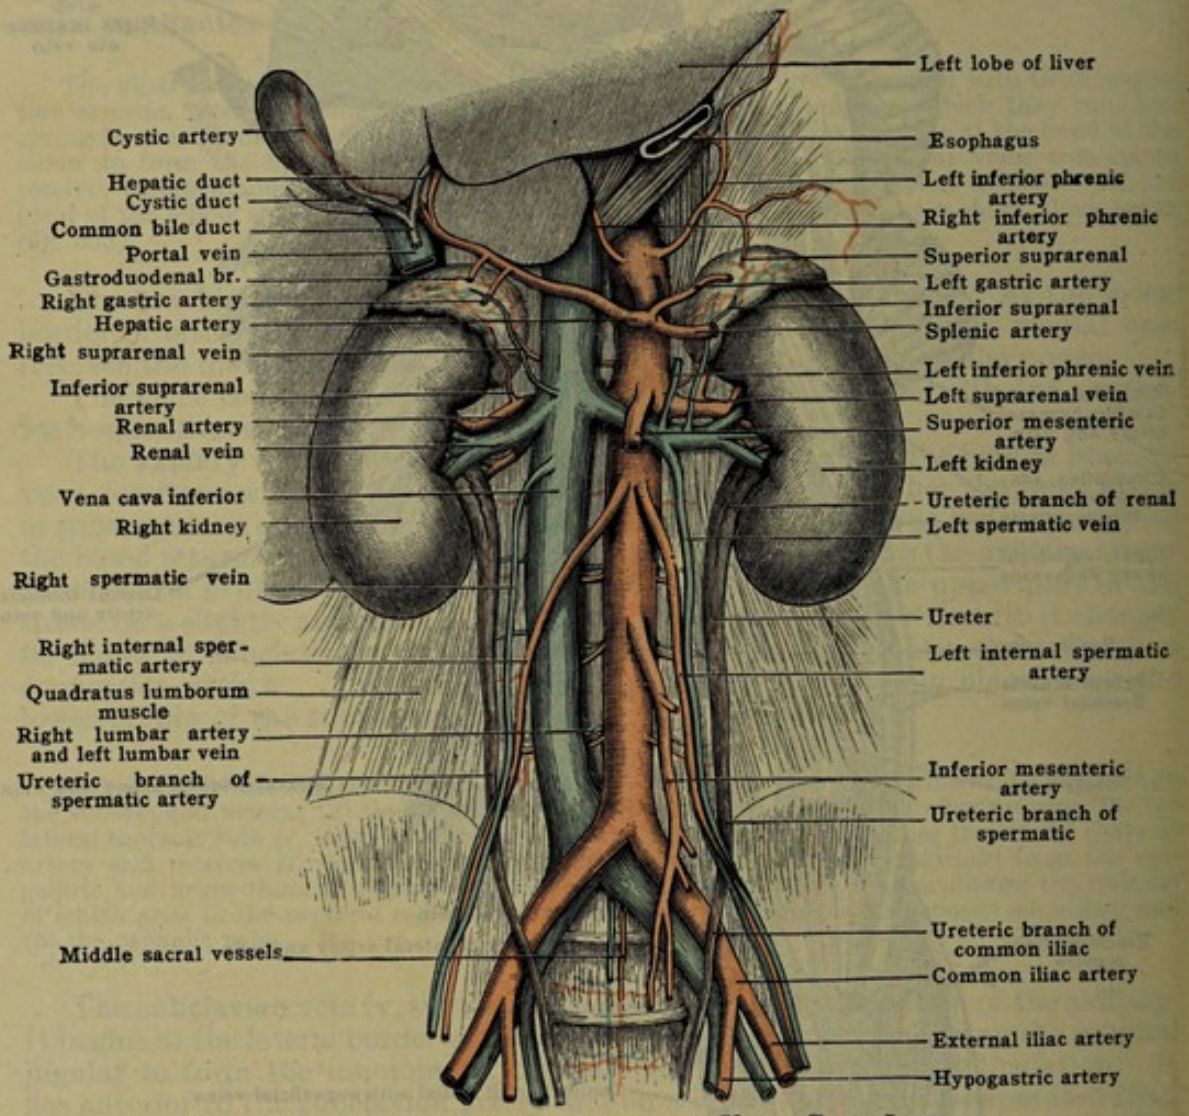

FIG. 606.—THE ABDOMINAL AORTA AND VENA CAVA INFERIOR.

chief channels for the return of the blood from the lower limbs and abdominal viscera. Especially in obstruction of the portal vein, a peculiar plexus of swollen superficial veins (*'caput Medusæ'*) may appear in the region around the umbilicus.

Most of the veins of the pelvis, the perineum and the gluteal region, join the hypogastric vein. The hypogastric on each side joins the external iliac to form the common iliac, and these in turn unite to form the vena cava inferior.

THE VENA CAVA INFERIOR

The **vena cava inferior** (or caudalis NK) (fig. 606) is the large vessel which returns the blood from the lower extremities and the abdomen and pelvis. It is formed by the confluence of the right and left common iliac veins opposite the body of the fifth lumbar vertebra, ascends in front of the lumbar vertebræ to the right of the abdominal aorta, passes through the caval opening in the diaphragm, and ends in the lower and back part of the right atrium of the heart usually about

the level of the ninth thoracic vertebra. At its origin it lies behind the right common iliac artery on a plane posterior to the aorta, but as it ascends it passes slightly forward and to the right, reaching a plane anterior to the aorta, and becomes separated from that artery by the right medial and intermediate crura of the diaphragm and the caudate lobe of the liver. While in contact with the liver it lies in a deep groove [fossa venæ cavæ] on the posterior surface of that organ, the groove being often converted into a canal by a thin portion of the hepatic substance bridging across it. As it passes through the diaphragm its walls are attached to the tendinous margins of the caval opening, and are thus held apart when the muscle contracts. On the thoracic side of the diaphragm it lies for about 1.2 cm. (½ in.) within the pericardium, the serous layer of that membrane being reflected over it (fig. 516).

Relations.—**In front** it is covered by the peritoneum, and crossed by the right spermatic artery, branches of the aortic plexus of the sympathetic, the transverse colon, the root of the mesentery, the duodenum, the head of the pancreas, the portal vein, and the liver. The right lumbar lymphatic nodes are also in front of it below, and at its commencement the right common iliac artery rests upon it. **Behind,** it lies on the lumbar vertebræ, the right lumbar arteries, the right renal artery, the right celiac (semilunar) ganglion, and the right medial crus of the diaphragm. To the **right** are the peritoneum, liver, and psoas muscle. To the **left** is the aorta, and higher up the right medial crus of the diaphragm.

Tributaries.—The vena cava inferior receives the following veins:—(1) the renal veins; (2) the right suprarenal vein; (3) the right spermatic or the right ovarian vein; (4) the lumbar veins; (5) the inferior phrenic veins; (6) the hepatic veins (which indirectly receive blood from the portal); and (7) the right and left common iliac veins.

(1) The **renal** veins [vv. renales] (fig. 606) return blood from the kidneys. They are short but thick trunks, and open into the vena cava nearly at right angles to that vessel. The vein on the left side, like the kidney, is a little higher than on the right, and is also longer, in consequence of its having to cross the aorta.

Each renal vein lies in front of its corresponding artery. The left vein crosses in front of the aorta, just below the origin of the superior mesenteric artery and is covered by the inferior portion of the duodenum. It receives the left spermatic, or the left ovarian in the female, and the left suprarenal, and sometimes the left phrenic. There are rudiments of valves in each vein where it joins the vena cava.

(2) The **suprarenal** veins [vv. suprarenales] (fig. 606).—There is usually only one suprarenal vein on each side to return the blood brought to the suprarenal body by the three suprarenal arteries. On the **right side** the vein opens directly into the vena cava, above the opening of the right renal vein. On the **left side,** it opens into the left renal.

(3) The **spermatic** veins [vv. spermaticæ] (fig. 606) return the blood from the testes. They begin by the confluence of small branches from the body of the testis and epididymis. As they proceed up the spermatic cord, in front of the internal spermatic artery and ductus deferens, they become dilated and plexiform, constituting the **pampiniform plexus** [plexus pampiniformis] (fig. 618).

The **ovarian** veins [vv. ovaricæ] begin at the plexus pampiniformis near the ovary, between the layers of the broad ligament (figs. 563, 571, 607). This plexus is larger than in the male and communicates freely with the uterovaginal plexus of veins, and with the plexus of veins which extends from the hilus of the ovary into the ovarian ligament.

After passing from between the layers of the broad ligament, the plexus unites to form at first two vessels and then a single vessel, which accompanies the ovarian artery, following a course similar to that of the spermatic veins in the male. The right ovarian veins open into the vena cava inferior, the left into the left renal. They usually contain imperfect valves in their plexiform part, and a perfect valve where they join the vena cava and renal vein respectively.

(4) The **lumbar** veins [vv. lumbales], four to five on either side accompany the lumbar arteries and collect venous blood from the muscles of the back and abdomen.

They terminate by passing beneath the tendinous arches of the psoas major, along the sides of the lumbar vertebræ, and opening into the vena cava inferior. The veins of the left side are longer than those of the right and pass behind the aorta. Each vein receives a dorsal tributary corresponding in distribution to the dorsal branch of the lumbar artery. Between the dorsal tributaries and the posterior vertebral venous plexus there occurs a free communication.

There is also an anastomosis between the main lumbar veins and the anterior vertebral venous plexus around the bodies and transverse processes of the lumbar vertebræ. By means of these communications the intervertebral veins, the internal and external vertebral and spinal plexuses are partly drained. In addition to these anastomoses the lumbar veins are connected with one another and with common iliac, hypogastric, iliolumbar, renal, azygos and hemiazygos veins, or some of these, by means of the *ascending lumbar veins* (p. 736).

(5) The **inferior phrenic** veins [v. phrenica inferior] follow the course of the inferior phrenic arteries; the right opens into the vena cava direct; the left into the suprarenal, the left renal, or the vena cava.

(6) The **hepatic** veins [vv. hepaticæ], the largest visceral tributaries of the vena cava, return the blood from the liver. Commencing in the substance of

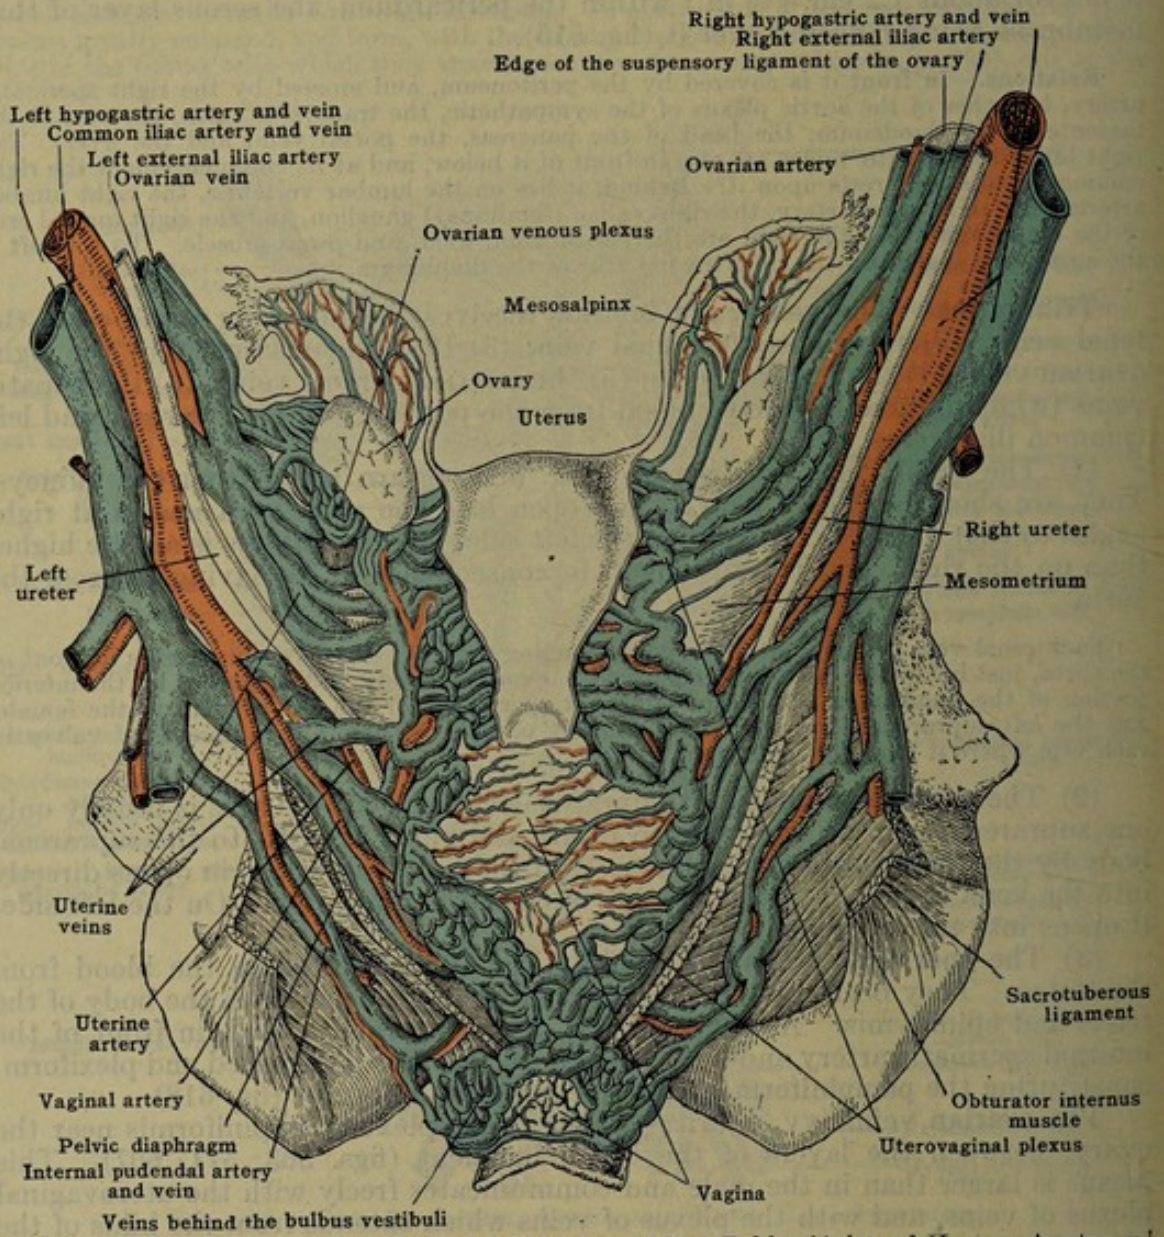

FIG. 607.—THE VEINS OF THE FEMALE PELVIS. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

the liver (see LIVER), they converge as they approach its posterior surface, and unite to form two or three large trunks, which open into the vena cava as it lies in the fossa venæ cavæ.

Some smaller vessels from the caudate lobe, and other parts of the liver in the neighborhood of the caval fossa, open directly into the vena cava. The hepatic veins contain no valves, but, in consequence of opening obliquely into the vena cava, a semilunar fold occurs at the lower margin of each orifice. The hepatic veins transmit the blood brought into the liver by both the hepatic artery and the portal vein.

THE PORTAL VEIN

The veins corresponding to the inferior mesenteric, the superior mesenteric, and to some of the branches of the celiac artery, do not join the vena cava infe-

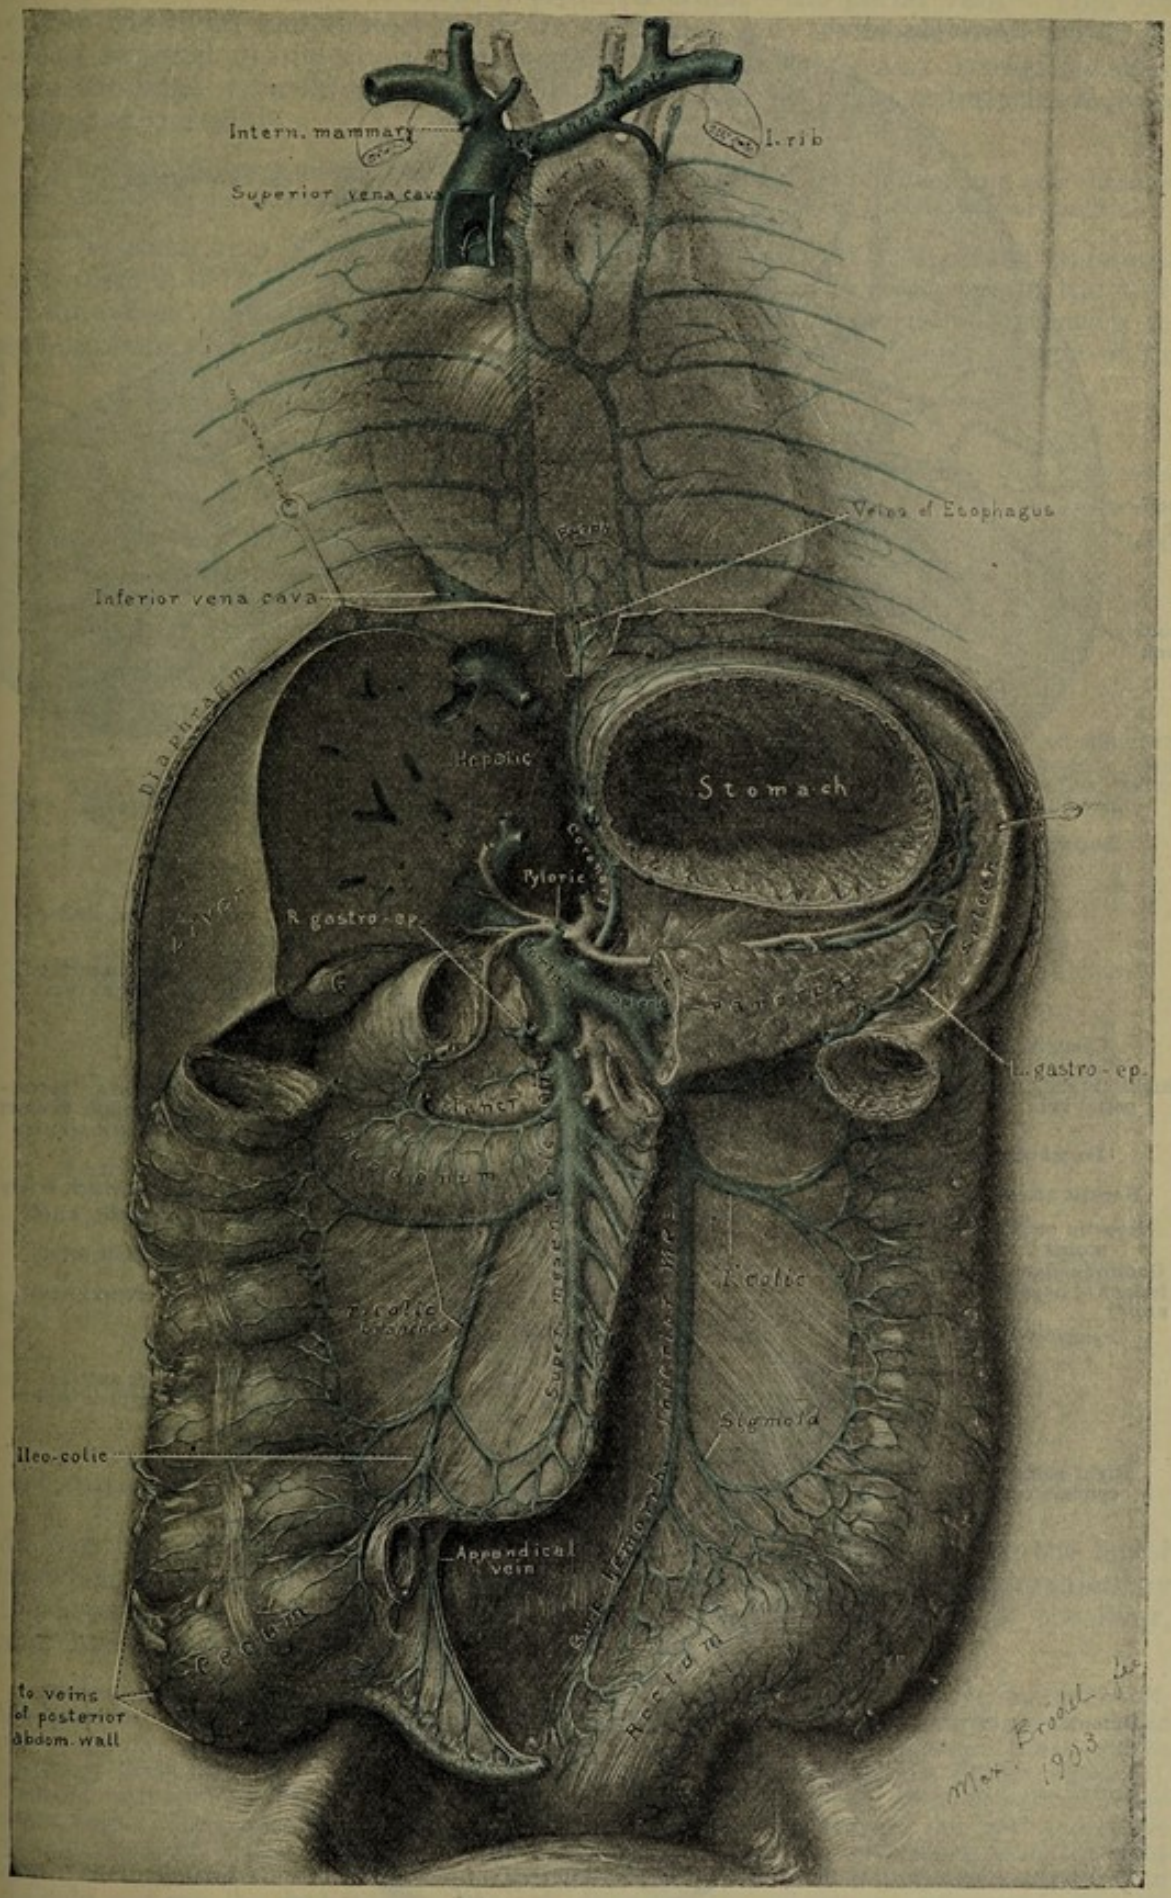

FIG. 608.—THE PORTAL VEIN. (From Kelley, by Brödel.)

(From a dissection by W. J. Walsham.)

rior directly, but unite to form a common trunk—the **portal vein.** This vein enters the liver, and breaks up in its substance into **sinusoids** from which the blood is again ultimately collected by the hepatic veins, and carried by them into the vena cava inferior. The portal vein and its larger tributaries have no valves in the adult.

A few valves are found at birth in the tributaries of the gastroepiploic and the coronary vein and in the veins from the colon, but practically all of these are lost before maturity.

The **portal** vein [v. portæ] (fig. 608), is a thick trunk 7 or 8 cm. (3 in.) in length. It is formed behind the neck of the pancreas, opposite the right side of the body of the second lumbar vertebra, by the union of the superior mesenteric with the splenic vein. It passes upward and to the right behind the superior part of the

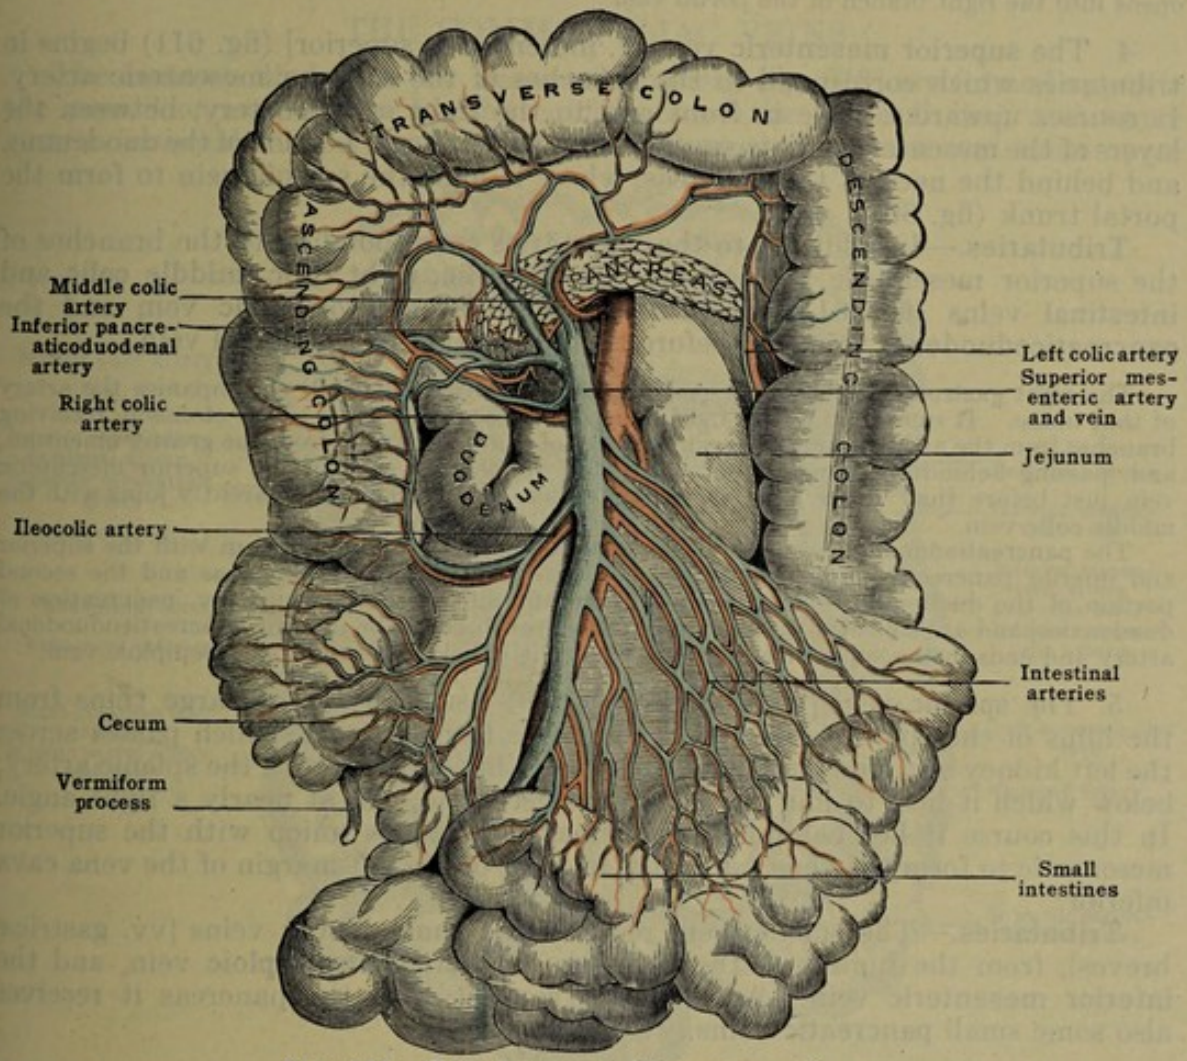

FIG. 611.—THE SUPERIOR MESENTERIC VEIN.
(The colon is turned up, and the small intestines are drawn over to the left side.)

duodenum, and then between the layers of the lesser omentum. In the latter situation it passes in front of the foramen epiploicum and is accompanied by the hepatic artery and the bile-duct. Finally it enters the porta of the liver, and there divides into a right and a left branch.

In this course the hepatic artery and the common bile-duct are in front the, former to the left, the latter to the right. It is surrounded by branches of the hepatic plexus of the sympathetic nerve, and by numerous lymphatic vessels and some glands. The connective tissue sheath enclosing these structures is called the **fibrous capsule of Glisson** [capsula fibrosa, Glissoni]. Just before it divides it is somewhat dilated, the dilated portion being called the **sinus of the portal vein.** The division into right and left branches takes place toward the right end of the porta of the liver. The **right branch** is shorter and thicker than the left, and supplies the right lobe of the liver and a branch to the quadrate lobe. The **left branch** is longer and smaller than the right, and supplies the left lobe, and gives a branch to the caudate (Spigelian) and quadrate lobes. It is joined, as it crosses the left sagittal fossa, by a fibrous cord, known as the **ligamentum teres hepatis.** This represents the wall of the left *vena umbilicalis*, which throughout the greater part of embryonic life is the only channel through which arterial blood is transmitted from the placenta. Opposite this is a second fibrous cord, the **ligamentum venosum** (obliterated **ductus venosus**) which passes from the left portal branch to the hepatic part of the vena cava

inferior. The position of the original course of the umbilical vein across the left portal is marked, in adult life, by a dilation of the latter vein, called the **umbilical recess** (fig. 609).

Tributaries.—The portal vein receives (1) the pyloric; (2) the coronary (gastric); (3) the cystic; (4) the superior mesenteric; and (5) the splenic veins.

1. The **pyloric** vein (figs. 608, 610) begins near the pylorus in the lesser curve of the stomach, and, running from left to right with the right gastric artery, opens directly into the lower part of the portal vein. It receives branches from the pancreas and duodenum.

2. The **coronary** vein [v. coronaria ventriculi] (figs. 608, 610) runs with the left gastric artery, first from right to left, along the lesser curvature of the stomach, toward the cardiac end, and then, turning to the right, passes across the spine from left to right and downward to end in the portal trunk, a little higher than the pyloric vein. At the cardiac end of the stomach it receives small branches from the esophagus.

3. The **cystic** vein [v. cystica] (fig. 610) returns the blood from the gall-bladder. It usually opens into the right branch of the portal vein.

4. The **superior mesenteric** vein [v. mesenterica superior] (fig. 611) begins in tributaries which correspond to the branches of the superior mesenteric artery. It courses upward a little in front and to the right of the artery, between the layers of the mesentery. It passes in front of the inferior portion of the duodenum, and behind the neck of the pancreas, where it joins the splenic vein to form the portal trunk (fig. 608).

Tributaries.—In addition to the tributaries corresponding to the branches of the superior mesenteric artery—viz. the **ileocolic, right colic, middle colic** and **intestinal** veins (fig. 611)—it receives the **right gastroepiploic** vein and the **pancreaticoduodenal** vein just before its termination in the portal vein.

The **right gastroepiploic** vein [v. gastroepiploica dextra] (fig. 610) accompanies the artery of that name. It runs from left to right along the greater curvature of the stomach, receiving branches from the anterior and posterior surfaces of that viscus, and from the greater omentum, and, passing behind the superior portion of the duodenum, ends in the superior mesenteric vein just before that vessel joins the portal trunk. In fig. 608, it apparently joins with the middle colic vein.

The **pancreatioduodenal** veins [vv. pancreaticoduodenales] (fig. 608) run with the superior and inferior pancreaticoduodenal arteries between the head of the pancreas and the second portion of the duodenum. They receive **pancreatic** and **duodenal** veins [vv. pancreaticæ et duodenales] and are collected into a single stem which follows the inferior pancreaticoduodenal artery and ends in the superior mesenteric vein a little below the right gastroepiploic vein.

5. The **splenic** vein [v. lienalis] (fig. 608) issues as several large veins from the hilus of the spleen. These soon unite to form a trunk, which passes across the left kidney and suprarenal and their veins in company with the splenic artery, below which it lies, to join the superior mesenteric vein at nearly a right angle. In this course it lies behind the pancreas; and at its union with the superior mesenteric to form the vena porta it is in front of the left margin of the vena cava inferior.

Tributaries.—The splenic vein receives the **short gastric** veins [vv. gastricæ breves], from the fundus of the stomach, the **left gastroepiploic** vein, and the **inferior mesenteric** vein. As it lies in contact with the pancreas it receives also some small **pancreatic** veins [vv. pancreaticæ].

The **left gastroepiploic** vein [v. gastroepiploica sinistra] (fig. 610) accompanies the left gastroepiploic artery. It runs from right to left along the greater curvature of the stomach, receives branches from the stomach and omentum, and opens into the commencement of the splenic vein.

The **inferior mesenteric** vein [v. mesenterica inferior] (fig. 612) begins at the rectum as the superior hemorrhoidal vein (v. rectalis cranialis NK). This emerges from the hemorrhoidal plexus (plexus rectalis NK) in which it communicates freely with the middle and inferior hemorrhoidal veins. It passes out of the pelvis with the inferior mesenteric artery; but, after receiving the **sigmoid** and **left colic** veins [vv. sigmoideæ et v. colica sinistra] which accompany the arteries of the same names, it leaves the artery and runs upward on the psoas to the left of the aorta and behind the peritoneum. On approaching the pancreas it turns medially, and passes obliquely behind that gland to join the splenic vein just before the latter unites with the superior mesenteric to form the vena porta.

The absence of valves adversely affects the circulation of blood within the portal system. The liability to excessive pressure in the most dependent part of it, is evidenced by the great frequency of the condition known as piles (hemorrhoids), due to dilation of the veins of the internal hemorrhoidal plexus.

The accessory portal veins.—Since the blood returning from the abdominal portion of the digestive tract and spleen must pass through the hepatic capillaries before returning to the heart, extensive obliteration of these capillaries, such as occurs in certain diseases of the liver, would prevent the return of the portal blood to the heart were it not for anastomoses between tributaries of the portal vein and those of the caval systems, constituting what have been termed accessory portal veins. Some of the more important of these are—(1) between the branches of the coronary vein of the stomach and the esophageal veins which open into the vena azygos; (2) between the **parumbilical** veins [vv. parumbilicales], which communicate with the portal vein above and descend upon the ligamentum teres to the anterior abdominal wall to anastomose with the superior and inferior epigastric and superior vesical veins; (3) between the superior hemorrhoidal veins with the middle and inferior hemorrhoidal veins, which are drained directly or indirectly into the hypogastric, and (4) between a wide-meshed retroperitoneal plexus of veins which communicates with the portal vessels over the posterior surface of the liver and the veins of the pancreas, duodenum and ascending and descending colon on the portal side, and with the phrenic and azygos veins on the systemic.

THE COMMON ILIAC VEINS

The **common iliac** veins [vv. iliacæ communes], (fig. 613) are formed opposite the sacroiliac articulation by the confluence of the external iliac and hypogastric (internal iliac) veins. They converge as they ascend, and unite oppo-

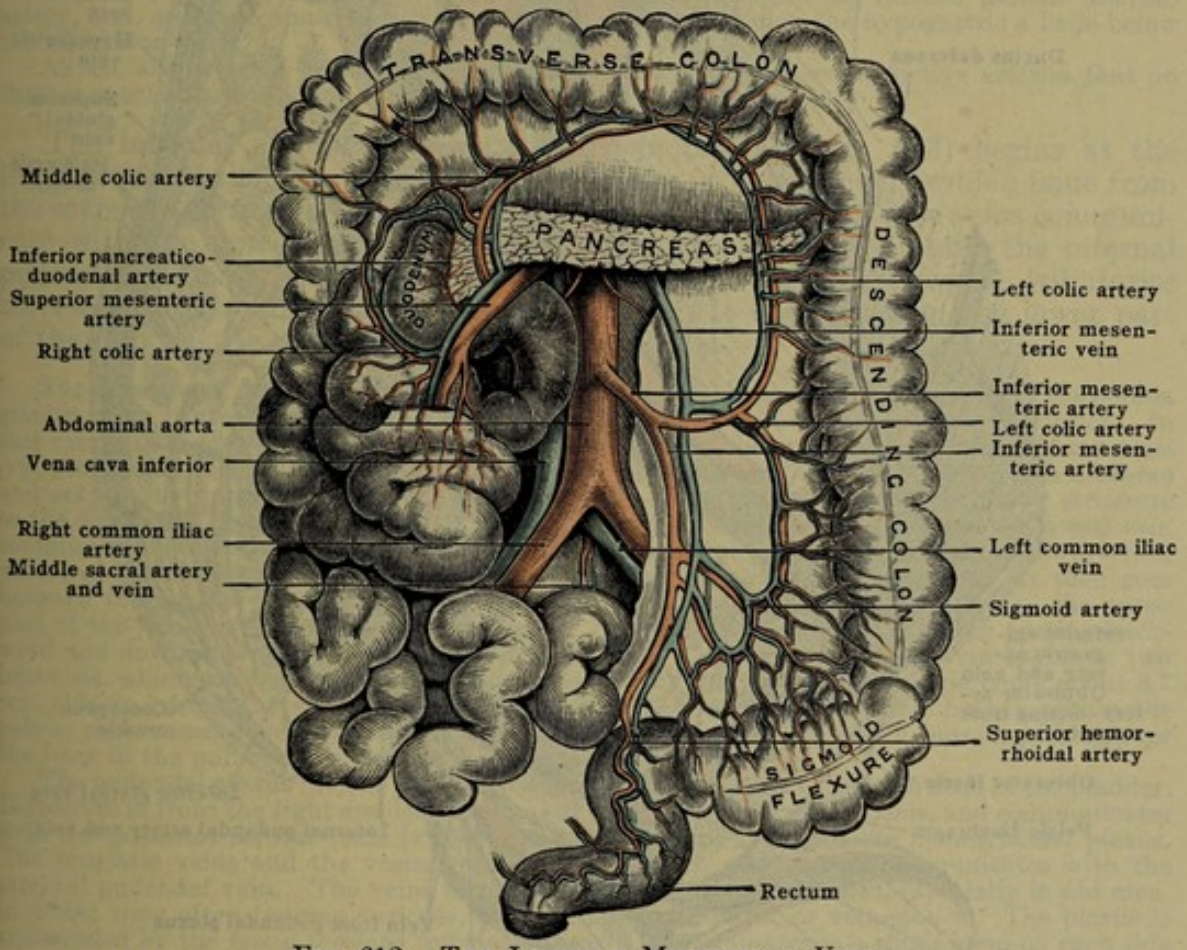

FIG. 612.—THE INFERIOR MESENTERIC VEIN.
(The colon is turned up, and the small intestines are drawn to the right side.)

site the upper border of the fifth lumbar vertebra and a little to the right of the median line to form the vena cava inferior.

The **right** vein, shorter and more vertical in direction than the left, passes obliquely behind the right common iliac artery to its lateral side, where it is joined by the left common iliac vein.

The **left** vein lies to the medial side of the left common iliac artery, and, after crossing in front of the promontory of the sacrum and the fifth lumbar vertebra below the bifurcation of the aorta, passes beneath the right common iliac artery to join the right vein and form the vena cava inferior. Valves may occur but are usually not present.

Tributary.—The iliolumbar veins may enter the lower part of the common iliac, or open into the hypogastric vein. The left vein receives the middle sacral vein.

The **middle sacral** vein [v. sacralis media] opens usually as a single trunk into the left common iliac vein. The venæ comitantes which form it ascend on either side of the middle sacral artery in front of the sacrum. They communicate with the lateral sacral veins, forming the **anterior sacral plexus** [plexus sacralis anterior] which receives the sacral intervertebral veins, and anastomoses freely with the neighboring lumbar and pelvic veins. Below, the middle sacral veins communicate with the hemorrhoidal veins.

THE VEINS OF THE PELVIS

The veins of the pelvis consist of the hypogastric vein, the spermatic or ovarian veins (according to sex) and the middle sacral vein. The spermatic and ovarian veins (p. 745) and the middle sacral vein have already been described.

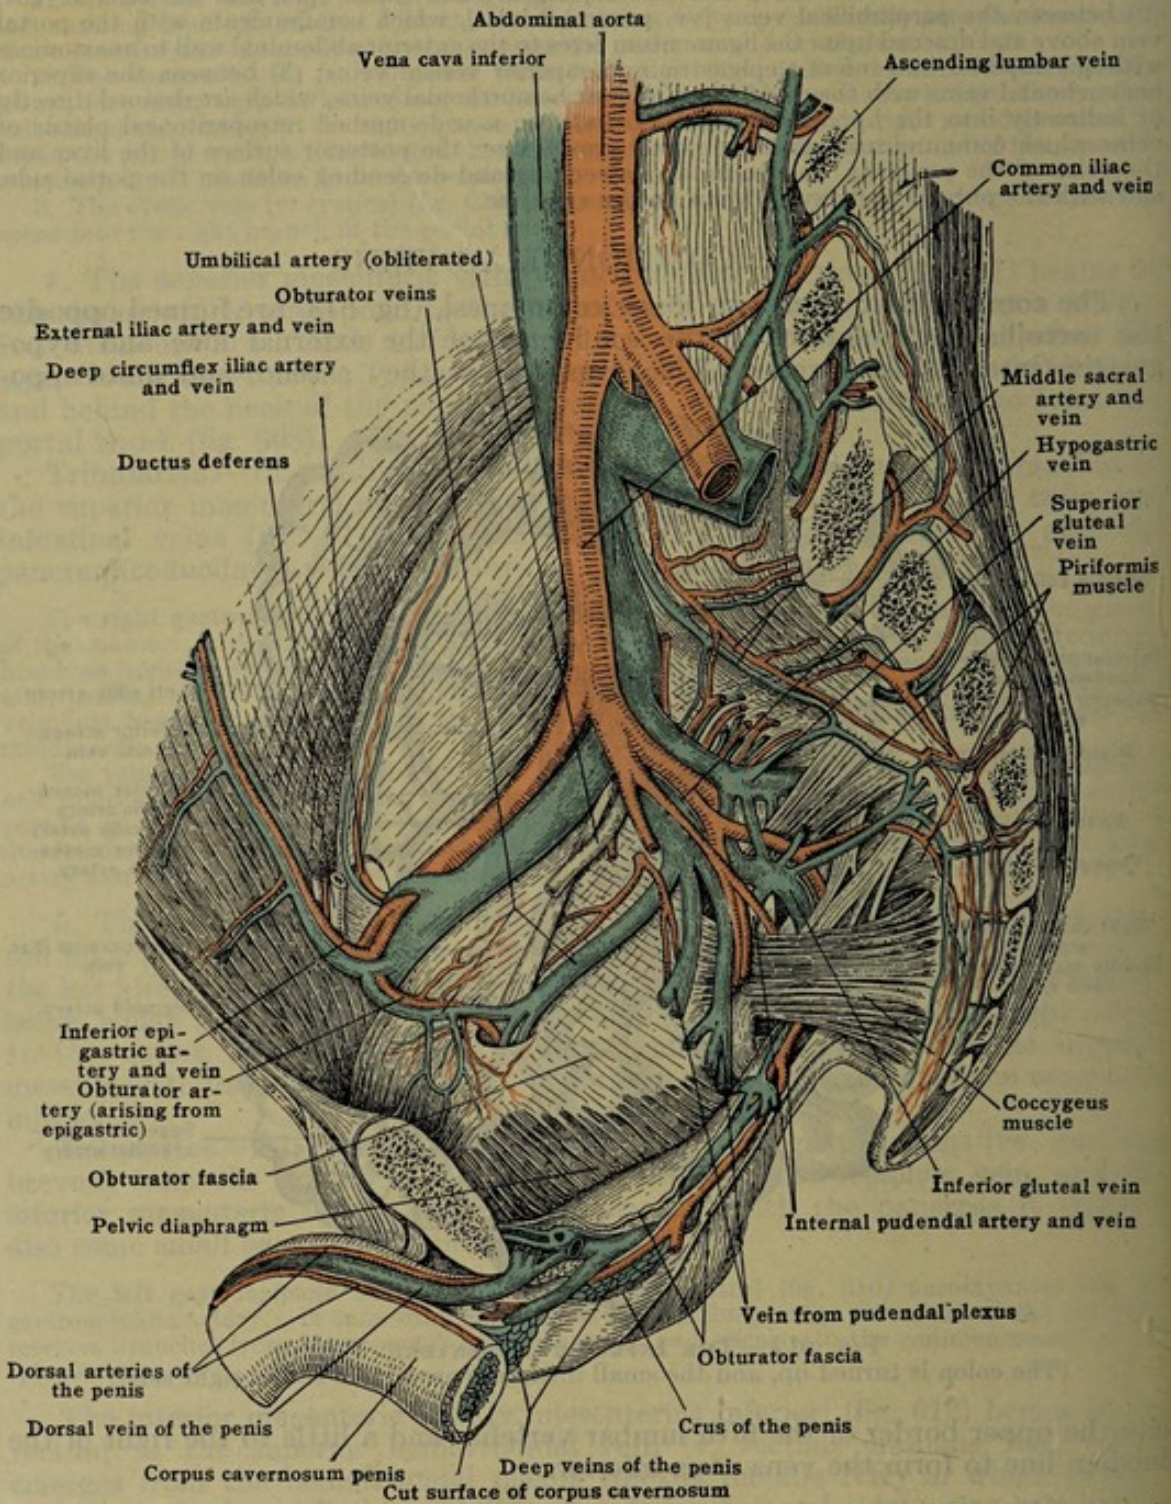

FIG. 613.—THE VEINS OF THE PELVIS, MALE. (After Toldt, 'Atlas of Human Anatomy', The Macmillan Company.)

THE HYPOGASTRIC VEIN

The **hypogastric (internal iliac)** vein [v. hypogastrica] (or v. ilica interna NK) (fig. 613) is formed by the confluence of the veins (except the umbilical) corresponding to the branches of the hypogastric artery on each side. It varies considerably in length, but is usually quite a short trunk, extending from the upper part of the great sciatic foramen to the sacroiliac articulation, where it joins the external iliac to form the common iliac vein. It lies behind and a little medially to the hypogastric artery. It contains no valves.

Tributaries.—The hypogastric vein receives directly or indirectly the following vessels on each side:—the superior gluteal, iliolumbar, lateral sacral, obturator, inferior gluteal (sciatic), internal pudendal, and (in the female) the uterine veins; also branches from the pudendal, vesical, and hemorrhoidal plexuses. The **single umbilical vein**—corresponding to the right and left umbilical arteries—does not enter the pelvis, but, leaving the umbilical arteries at the navel, passes along the falciform ligament to the liver. After birth it is converted into the ligamentum teres hepatis. (See PORTAL VEIN, p. 749.)

The **superior gluteal** veins [vv. gluteæ superiores] (fig. 613) accompany the superior gluteal artery and, passing through the upper part of the great sciatic foramen, open into the hypogastric vein near its termination, either separately or as a single trunk.

The **iliolumbar** veins [vv. iliolumbales] open into the hypogastric a little higher than the superior gluteal. At times they join the common iliac vein.

The **lateral sacral** veins [vv. sacrales laterales] (fig. 613) join the superior gluteal or the hypogastric at or about the same situation as the gluteal. They form with the middle sacral veins a plexus in front of the sacrum, which receives tributaries from the sacral canal.

The **obturator** vein [v. obturatoria] (fig. 613), which lies below the obturator artery as it crosses the side of the pelvis, opens into the front of the hypogastric vein or into the inferior epigastric vein, or into both. Its branches correspond to those of the artery.

The **inferior gluteal** vein [vv. gluteæ inferiores] accompany the inferior gluteal (sciatic) artery, and, as a rule, unite to form a single trunk before joining the hypogastric a little below the obturator vein.

All the above veins so closely follow the ramifications of their respective arteries that no further special description is required. They all contain valves.

The **internal pudendal** vein [v. pudenda interna] (fig. 613) begins at the termination of the deep veins of the penis [vv. profundæ penis] which issue from the corpus cavernosum penis with the artery of that body. These veins communicate with the dorsal vein at the root of the penis. In its course the internal pudendal vein runs with the internal pudendal artery, receiving tributaries corresponding to the branches of that vessel. It terminates in the lower part of the hypogastric vein.

The **dorsal vein of the penis** [v. dorsalis penis] (fig. 613) begins in a plexus around the corona glandis, then runs along the mid-dorsal line of the penis between the two dorsal arteries. In this course it receives large tributaries from the interior of the organ, the *deep veins of the penis* [vv. profundæ penis]. These emerge for the most part between the corpus cavernosum urethrae and corpus cavernosum penis, wind obliquely over the lateral surface of the latter structure to the dorsum of the penis and end in the dorsal vein. At the root of the penis the dorsal vein communicates with the subcutaneous veins of the dorsum of the penis and, leaving the arteries, passes straight backward between the two layers of the suspensory ligament. It then goes between the arcuate ligament and the transverse ligament of the pelvis, formed by the upper part of the fascia of the urogenital diaphragm. Here it bifurcates, each branch passing backward and downward to the pudendal plexus of veins. At times the dorsal vein begins as two branches, which run between the dorsal arteries and only unite to form a single trunk about 3.7 cm. (1½ in.) from the symphysis. After dividing into a right and a left branch within the pelvis, each vessel generally communicates with the obturator vein by a branch passing over the back of the pubis to the obturator foramen.

The **pudendal plexus** [plexus pudendalis] surrounds the prostate and the neck of the bladder. It receives in front the right and left divisions of the dorsal veins of the penis, and communicates with the posterior scrotal veins [vv. scrotales posteriores] and with the hemorrhoidal plexus. The prostatic veins and the vesical plexus open into it, and it also communicates with the internal pudendal vein. The veins forming the plexus are of large size, especially in old men, in whom they often become varicose, and contain phleboliths, or vein-stones. The plexus is surrounded by the *fascia prostatæ* (prostatic sheath); it terminates in a single stem on each side which opens into the hypogastric vein.

In the female the smaller pudendal plexus surrounds the urethra and the lower part of the vagina, and is contained in a fibrous sheath similar in structure to the prostatic sheath of the male. It receives the **dorsal and deep veins of the clitoris** [vv. dorsales et profundæ clitoridis], veins from the vestibule, and the **posterior labial** veins [vv. labiales posteriores]. It communicates freely with the uterovaginal plexus and is drained by the hypogastric veins.

The vesical plexus [plexus vesicalis] surrounds the apex, the sides, and the anterior and posterior surfaces of the bladder. It is situated between the muscular coat and the peritoneum, and where the bladder is uncovered by peritoneum external to the muscular coat in the pelvic cellular tissue. It opens into the pudendal plexus, with which it forms the plexus vesicopudendalis (NK).

The **uterovaginal plexus** [plexus uterovaginalis] connects with the hemorrhoidal, vesical, and uterine plexuses. Its lower part drains through the internal pudendal veins and the pudendal plexus, and its upper portion largely through the ovarian veins, and partly through the **uterine veins** [vv. uterinæ] to the hypogastric (fig. 607).

The **hemorrhoidal plexus** [plexus hemorrhoidalis] (plexus rectalis NK) surrounds the rectum, and is situated at the lower part of that tube. It consists of two portions, one of which, the internal hemorrhoidal plexus, is situated between the muscular and mucous coats, while the other, the external hemorrhoidal plexus, rests upon the outer surface of the muscular coat. The veins of this latter plexus terminate in the inferior, middle, and superior hemorrhoidal

veins. The **inferior** [vv. hemorrhoidales inferiores] (vv. anales NK) join the internal pudendal; the **middle** [v. hemorrhoidalis media] accompanies the middle hemorrhoidal artery and opens into the hypogastric and superior hemorrhoidal veins; the **superior** (p. 750) forms the com-

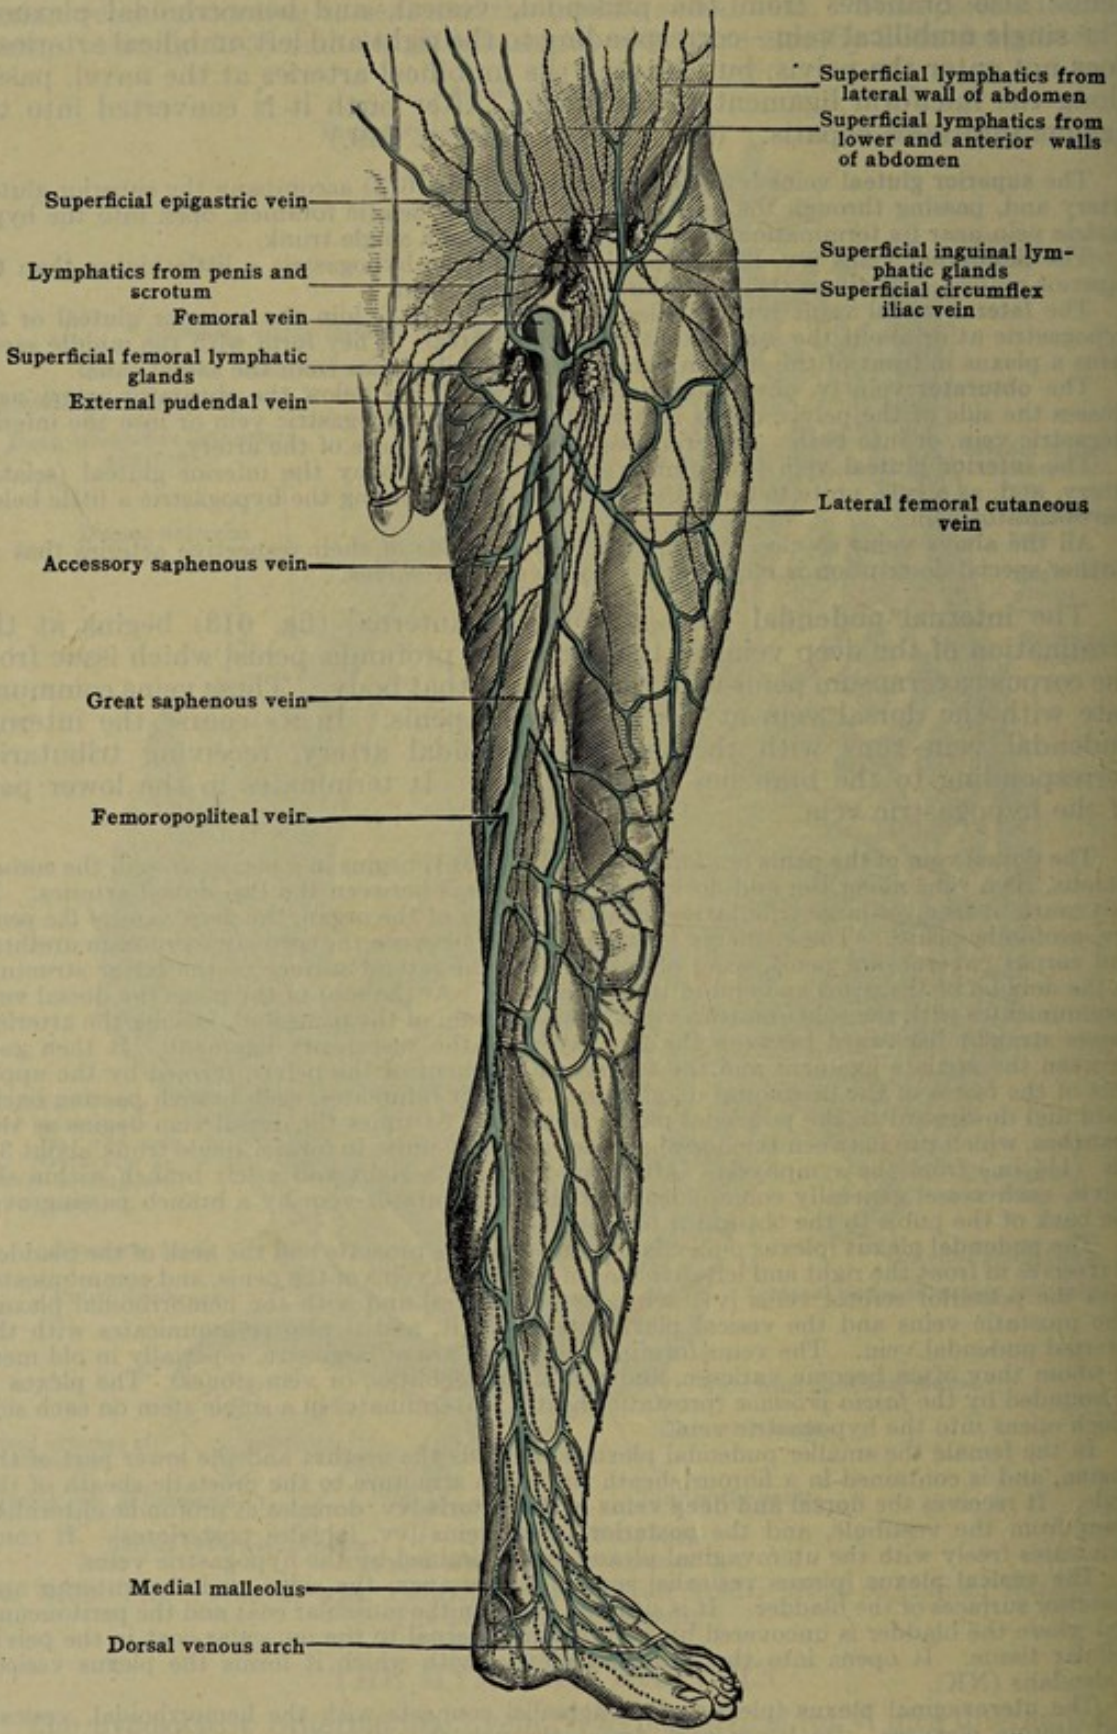

FIG. 614.—THE SUPERFICIAL VEINS AND LYMPHATICS OF THE LEFT LOWER LIMB. (Walsham.)

mencement of the inferior mesenteric vein, and through this the blood reaches the portal vein. None of these veins has any valves, hence the enlargement of the inferior hemorrhoidal veins, when the portal vein is obstructed, as in cirrhosis of the liver. Through the hemorrhoidal veins a free communication is established between the systemic and portal system of veins.

THE EXTERNAL ILIAC VEIN

The **external iliac** vein [v. iliaca externa] (fig. 613), is the upward continuation of the femoral. Beginning at the distal border of the inguinal ligament, it accompanies the external iliac artery along the brim of the minor pelvis, lying at first on the superior ramus of the pubis, and then on the psoas major muscle. It terminates by joining the hypogastric vein behind the hypogastric artery, opposite the sacroiliac articulation, to form the common iliac vein. It lies at first medially to the external iliac artery, and on the left side remains medial to the artery throughout its course. On the right side, however, as it ascends, it gradually gets behind the artery. It contains one or two valves.

In addition to the femoral, the external iliac receives the **inferior epigastric** vein [v. epigastrica inferior] (fig. 613) and the **deep circumflex iliac** vein [v. circumflexa ilium profunda] (fig. 618), which accompany the arteries of the same name. They anastomose with the superior epigastric, lumbar, iliolumbar, and superior gluteal veins, and with the superficial epigastric and superficial circumflex iliac veins.

THE VEINS OF THE LOWER EXTREMITY

The **veins of the lower extremity** are divided into (1) the superficial and (2) the deep. The **superficial** veins lie in the subcutaneous tissue superficial to the deep fascia, through which they receive numerous communicating branches from the deep veins. They are collected chiefly into two main trunks, which, beginning on the foot, extend upward, one, the great saphenous, lying anteromedially, and the other, the small saphenous, posterolaterally. The former finally joins the femoral vein by passing through the deep fascia at the groin; the latter reaches the popliteal by perforating the fascia at the ham. The **deep** veins, on the other hand, accompany their corresponding arteries. All the veins of the lower limb have valves which are more numerous than in the veins of the upper extremity and more numerous in the deep than in the superficial veins.

THE SUPERFICIAL VEINS OF THE LOWER EXTREMITY

The **superficial veins of the lower limb** begin in the plexuses of the foot. The **dorsal digital** veins [vv. digitales pedis dorsales] collect blood from the dorsal surfaces of the toes and unite in pairs, around each cleft, to form the **dorsal metatarsal** veins [vv. metatarseæ dorsales pedis]. The dorsal metatarsal veins, of which the first and fifth are larger than the others, join the **dorsal venous arch** [arcus venosus dorsalis pedis]. This arch is convex toward the toes and crosses near the bases of the metatarsal bones. From the medial and lateral ends of the arch the great and small saphenous veins, respectively, take origin. The area of the dorsum of the foot contained between the arch and the two saphenous veins is covered by the **dorsal venous rete** (rete venosum dorsale pedis] which extends as high as the ankle-joint (figs. 614, 615).

On the plantar surface the **plantar digital** veins [vv. digitales plantares] return the venous blood to the clefts of the toes and unite to form the **common digital** veins [vv. digitales communes pedis]. The common digital veins join freely with one another on the sole to form the **plantar venous rete** [rete venosum plantare]. There are numerous communications between the superficial veins of the dorsum and sole. These occur both in the clefts of the toes, by means of the **intercapitular** veins [vv. intercapitulares], and around the margins of the foot. Communications between the superficial and deep veins of the foot are very free (fig. 616).

The **great** (or internal) **saphenous** vein (v. saphena magna] (fig. 614) commences at the medial end of the dorsal venous arch, and, after receiving branches from the sole which join it by turning over the medial border of the foot, it turns proximally in front of the medial malleolus. It passes about a finger's breadth behind the medial border of the tibia in company with the saphenous nerve, which becomes superficial just below the knee. It then passes behind the medial epicondyle, and then runs up on the medial side of the front of the thigh to about 3.7 cm. (1¼ in.) below the inguinal ligament, where it dips through the fossa ovalis (saphenous opening) in the fascia lata, and ends in the femoral vein.

Tributaries.—In its course through the leg and thigh the great saphenous receives numerous unnamed cutaneous tributaries. In the thigh it often receives a large vein, the femoropopliteal which communicates with the small saphenous, and several of the cutaneous veins on the lateral part of the thigh, and a second vein, the **accessory saphenous** [v. saphena accessoria], formed by the union of the cutaneous veins from the medial and back part of the thigh (fig. 614). The great saphenous vein contains from six to twenty valves.

Immediately before entering the fossa ovalis the great saphenous vein receives the superficial epigastric, superficial circumflex iliac, and external pudendal veins, though any of these veins—or all of them—may pierce the fascia separately and enter the femoral vein.

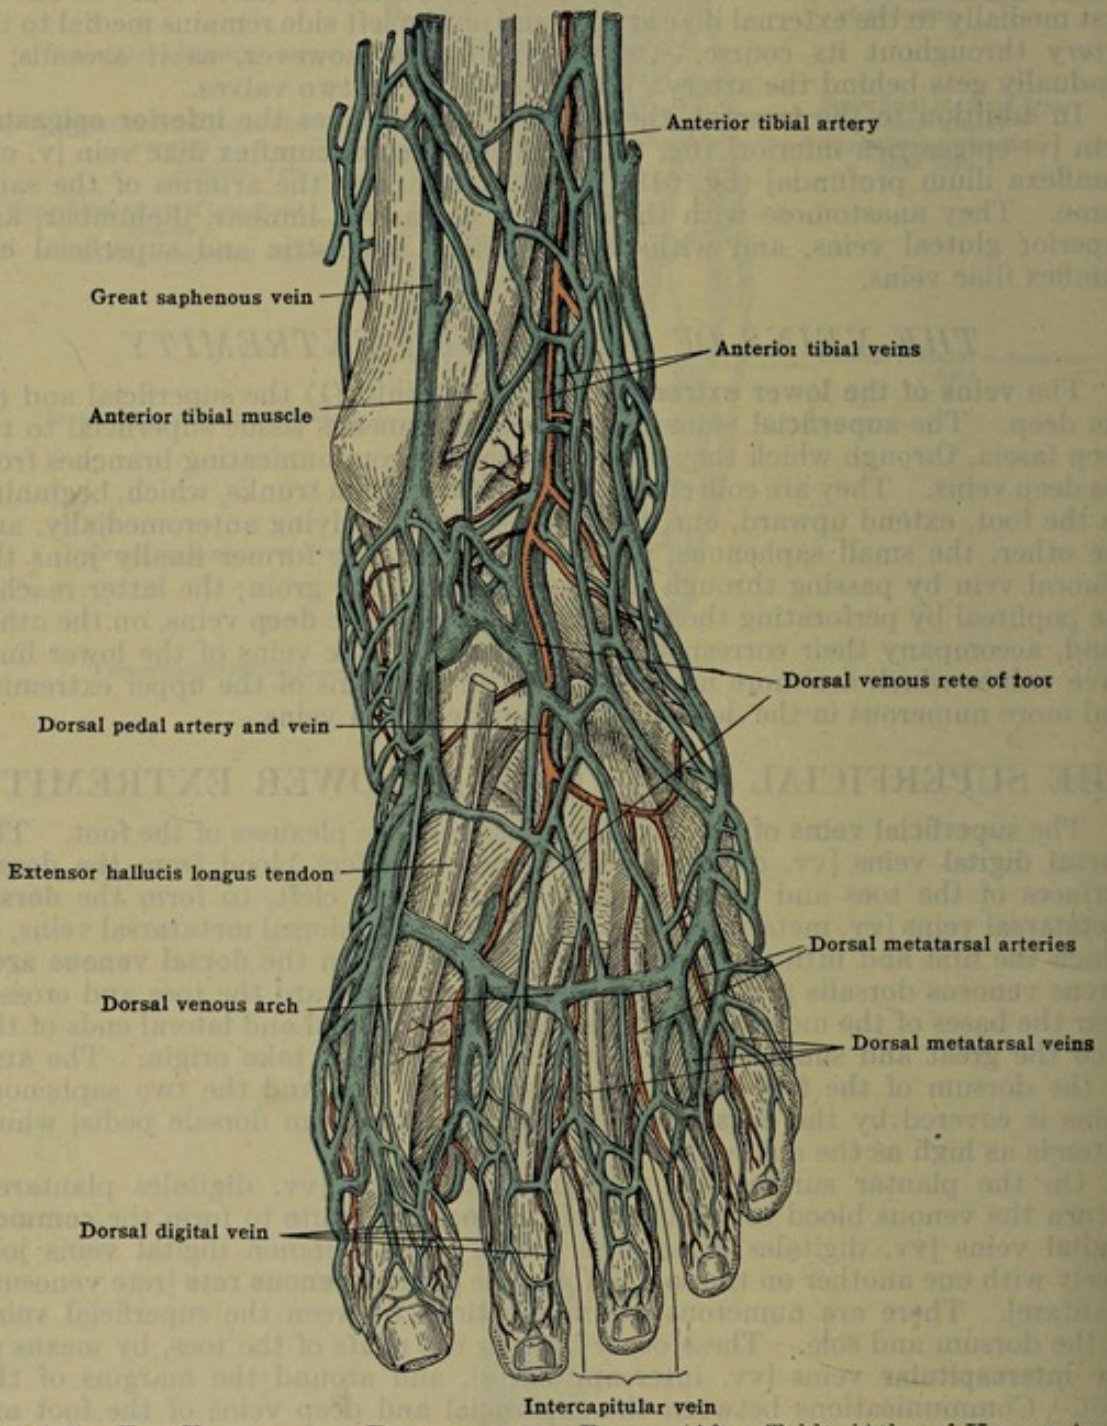

FIG. 615.—THE VEINS OF THE DORSUM OF THE FOOT. (After Toldt, 'Atlas of Human Anatomy', The Macmillan Company.)

The **superficial epigastric** vein [v. epigastrica superficialis] anastomoses with the superficial abdominal, and parumbilical veins.

The **superficial circumflex iliac** vein [v. circumflex ilium superficialis] anastomoses with the thoraco-epigastric and the superficial circumflex iliac veins.

The **external pudendal** veins [vv. pudendæ externæ] collect venous blood from the **anterior scrotal or labial** veins, which anastomose with the posterior scrotal or labial veins, and from the **subcutaneous veins of the dorsum of the penis** [vv. dorsales penis subcutaneæ].

The **small saphenous** vein [v. saphena parva] (fig. 617) begins at the lateral end of the venous arch on the dorsum of the foot. After receiving branches from

the sole, which turn over the lateral border of the foot, it passes behind the lateral malleolus, and turns proximally, passing at first along the lateral side of the tendo calcaneus (Achillis), afterward along the back of the calf, in company with the sural (short saphenous) nerve, to about the lower part of the popliteal fossa, where it perforates the deep fascia, and, sinking between the two heads of the gastrocnemius, opens into the popliteal vein.

Tributaries.—As it passes along the calf between the superficial and deep fascia, it receives numerous cutaneous veins from the heel, and the lateral side and back part of the leg, and communicates at intervals, through transverse or intermuscular branches, with the deep veins

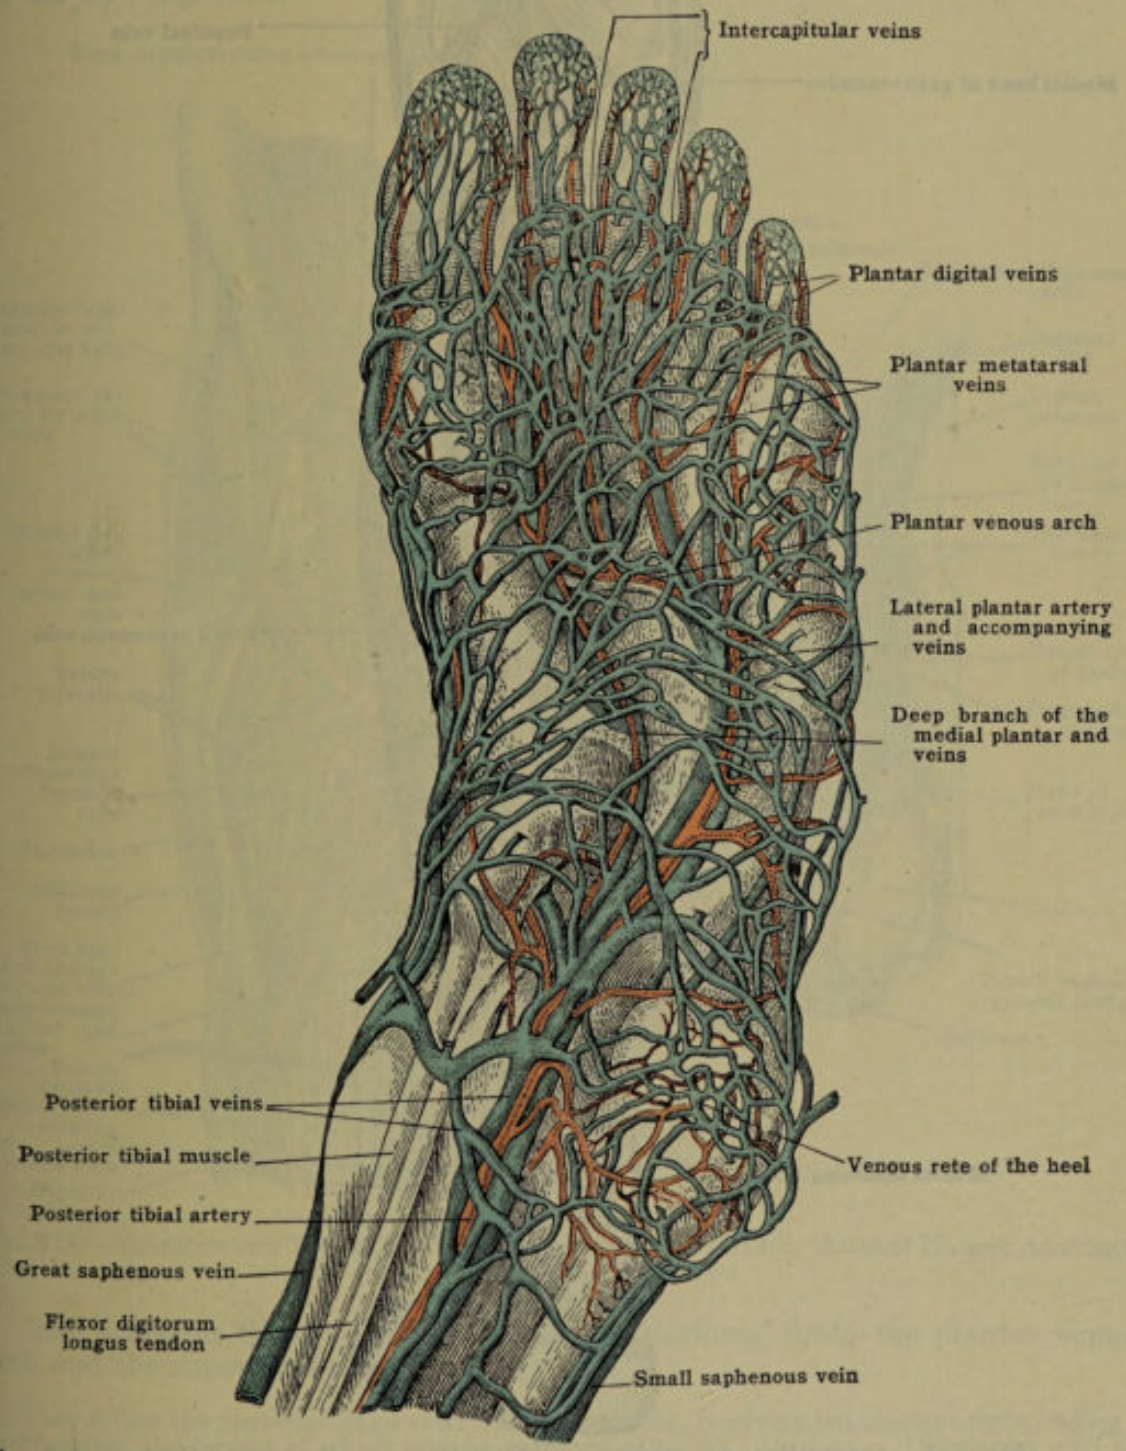

FIG. 616.—THE VEINS OF THE SOLE OF THE FOOT. (After Toldt, 'Atlas of Human Anatomy', The Macmillan Company.)

accompanying the peroneal artery. Just before perforating the deep fascia, it receives a large descending branch, the **vena femoropoplitea** (fig. 614), from the lower and back part of the thigh. This communicates with a plexus of veins upon the posterior and lateral regions of the thigh and with the great saphenous. In many cases the small saphenous vein is entirely drained, by means of the femoropopliteal, into the great saphenous. Under these circumstances the usual place of termination of the small saphenous is marked by a small vein opening into the popliteal. A small offshoot from the inferior sural branch of the popliteal artery accompanies this vein for a short distance along the back of the calf. The small saphenous vein contains from nine to twelve valves.

Clinical aspects of the saphenous veins are important, owing to the tendency of these and their branches to become varicose. The **great saphenous** vein, having passed from the arch on the dorsum over the medial malleolus, runs up close to the medial border of the tibia, where it is to be avoided in ligature of the posterior tibial, to the back of the medial condyle; here this vessel is to be remembered in operations on the knee-joint; then upward along the thigh, over the roof of the adductor (Hunter's) canal, to the fossa ovalis (saphenous opening) where it joins the femoral by perforating the cribriform fascia and the femoral sheath.

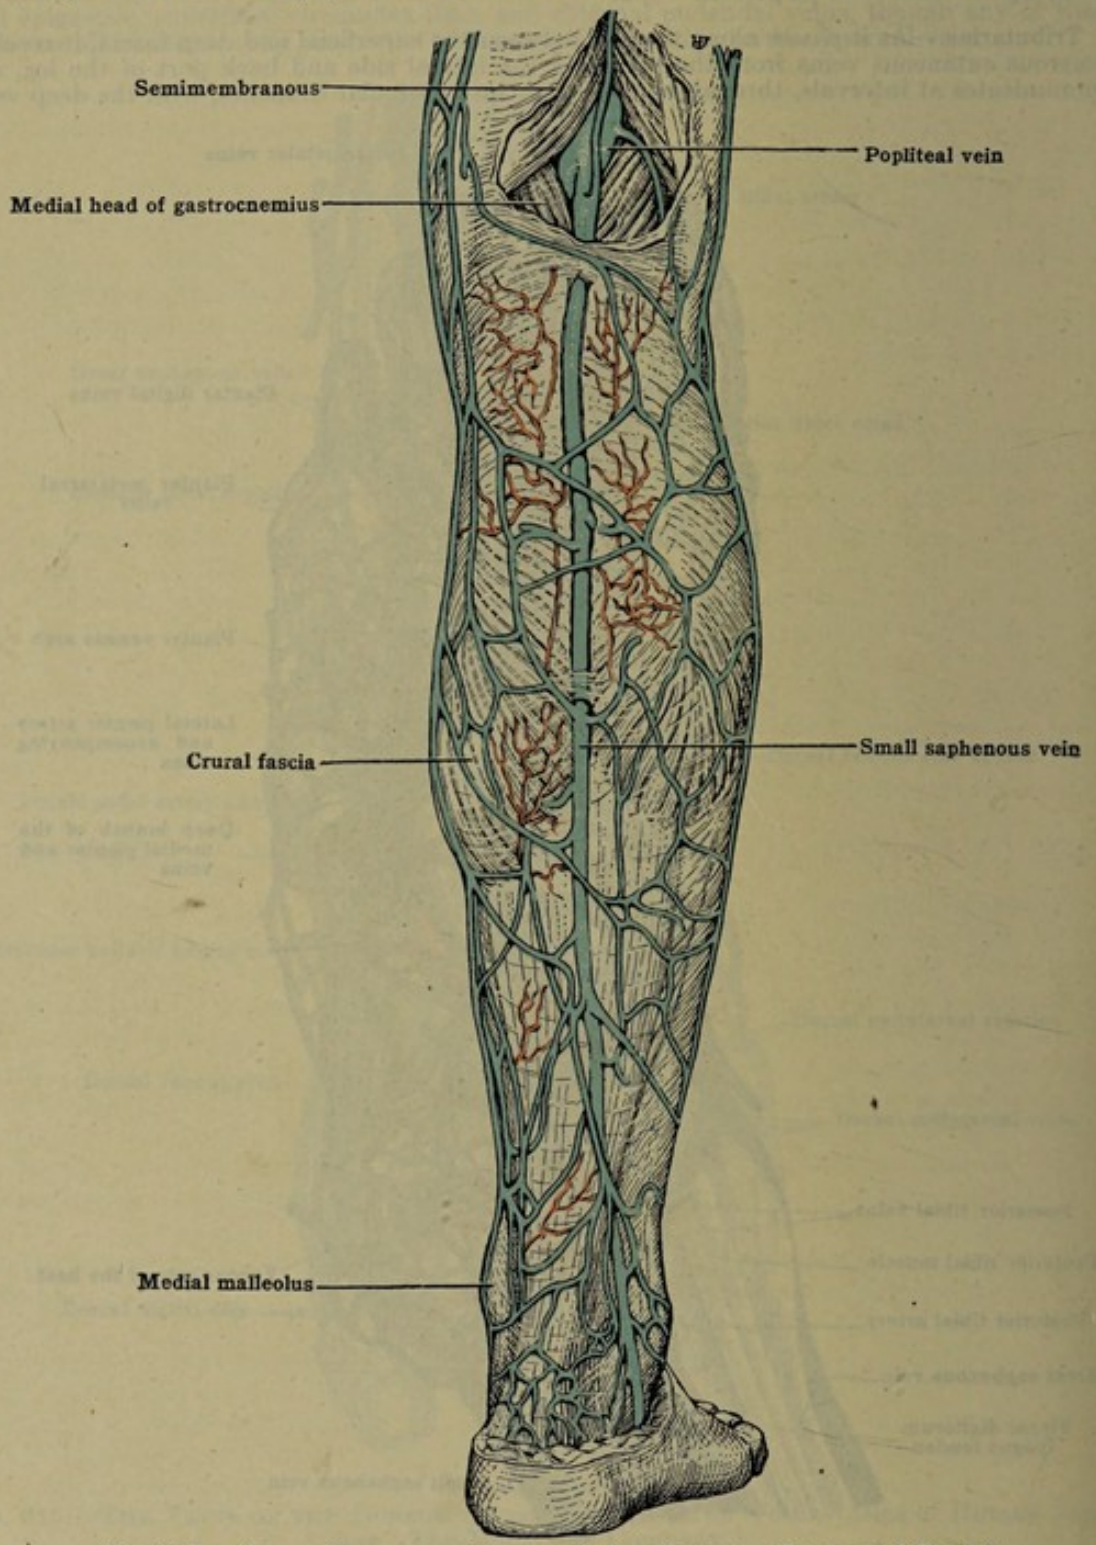

FIG. 617.—SMALL SAPHENOUS VEIN. (After Bonamy, Broca and Beau.)

The 'dangerous area,' or that in which thrombosis is most likely to occur, reaches from the center of the thigh to the middle of the leg (Bennett). The saphenous nerve joins the vein below the knee, having been under the sartorius above this point. The surface-marking of the upper part of the vein is a line drawn from the posterior border of the sartorius or the adductor tubercle to the lower part of the fossa ovalis.

THE DEEP VEINS OF THE LOWER EXTREMITY

The **deep veins of the lower extremity** [venæ comitantes] accompany the arteries, and have received corresponding names. From the foot to the knee

there are two veins to each artery. These veins run on either side of the corresponding artery, and communicate at frequent intervals with each other across it. From the knee upward there is a single main vein to each artery, except at the back of the thigh and in the gluteal region, where there are commonly two.

The veins of the foot and leg.—The deep veins of the foot become separated from the superficial where the **plantar metatarsal** veins [vv. metatarseæ plantares] leave the plantar digital and intercapitular veins to accompany the plantar metatarsal arteries. The plantar metatarsal veins empty into the **plantar venous arch** [arcus venosus plantaris] which accompanies the arterial plantar arch in the depth of the sole (fig. 616).

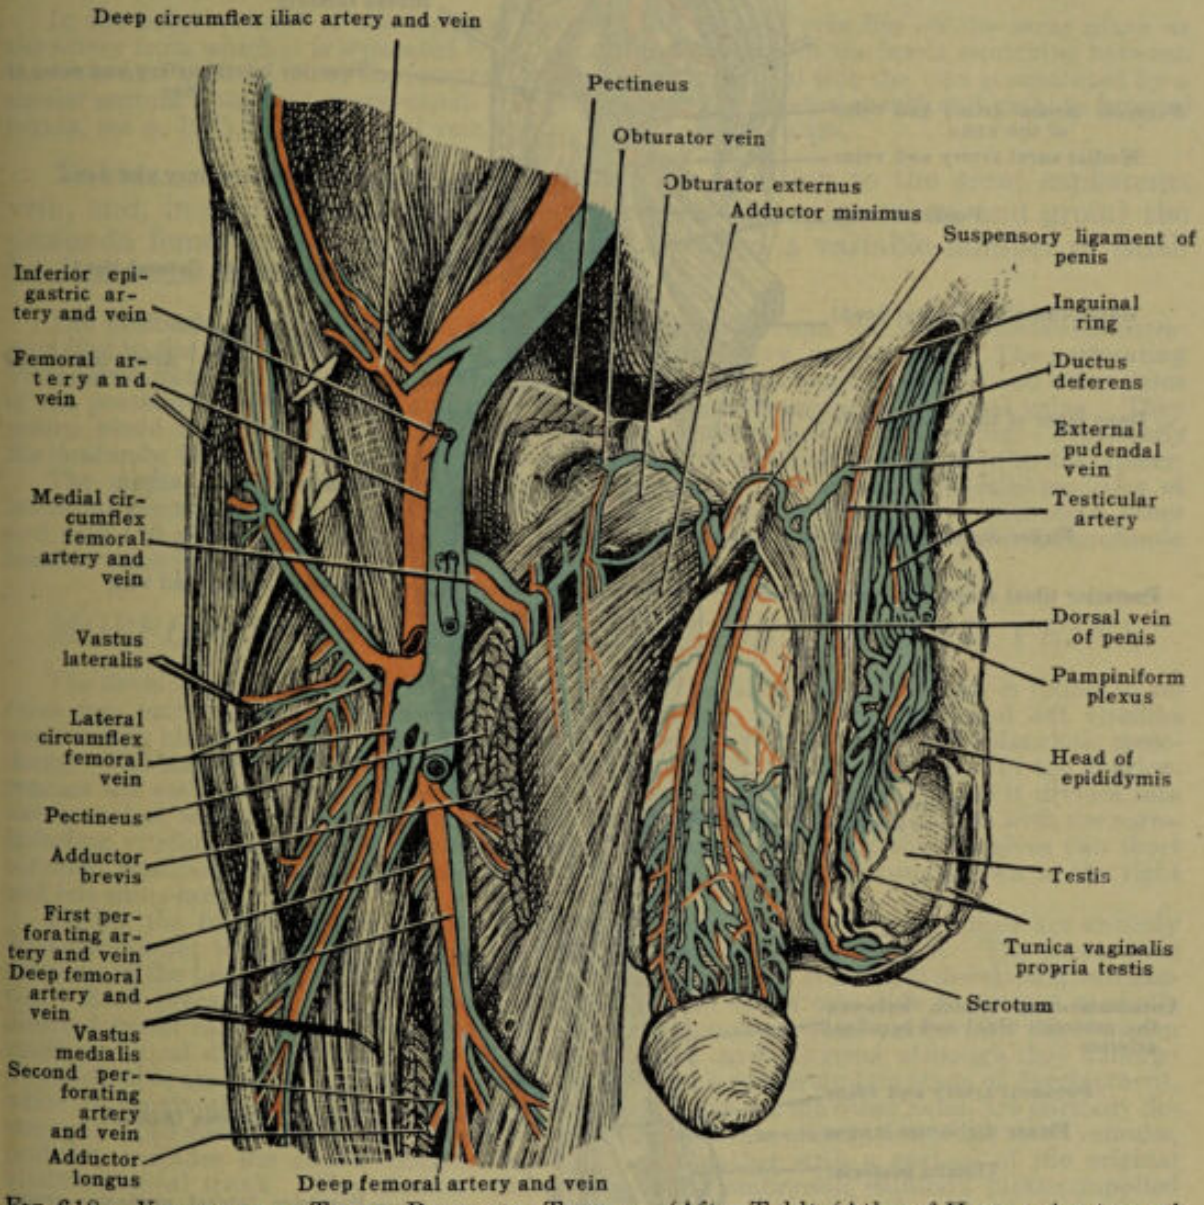

FIG. 618.—VEINS OF THE THIGH, PENIS AND TESTIS. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

The **posterior tibial** veins [vv. tibiales posteriores] drain the plantar venous arch and the superficial rete (fig. 619).

They follow the posterior tibial artery through the leg, receiving tributaries corresponding to its branches, the largest of which are the **peroneal veins** [vv. peroneæ]. They unite with the anterior tibial venæ comitantes at the lower border of the popliteus muscle.

The **anterior tibial** veins [vv. tibiales anteriores] begin in the dorsal venous rete and accompany the anterior tibial artery through the leg receiving tributaries corresponding to branches of the artery.

They pass backward between the interosseous membrane and the tibia and fibula to unite with the posterior tibial veins. The posterior and anterior tibial veins unite at the distal border of the popliteus muscle to form the popliteal vein.

All these veins contain numerous valves, and communicate, by means of intermuscular branches, with the superficial veins.

The **popliteal** vein [v. poplitea] (fig. 619), is formed by the confluence of the venæ comitantes of the anterior and posterior tibial arteries at the distal border of the popliteus, and extends proximally to the opening in the adductor magnus at the junction of the middle and distal third of the thigh, where it changes its name to femoral.

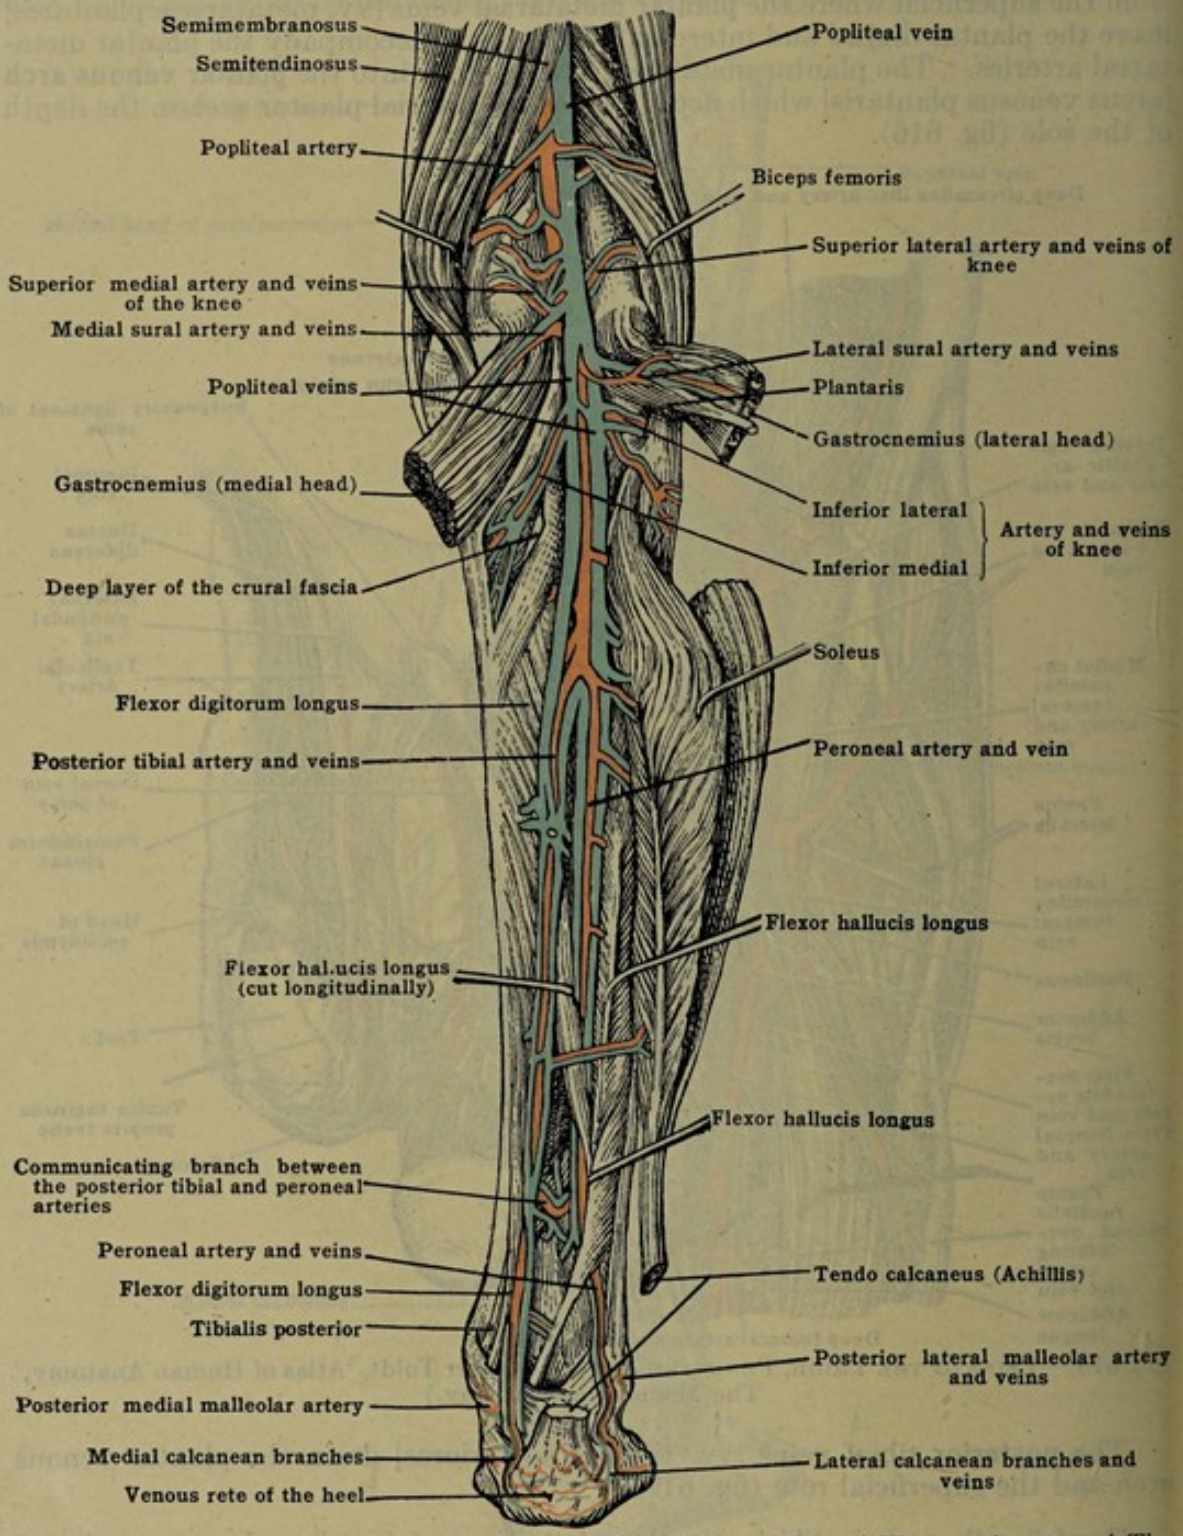

FIG. 619.—THE DEEP VEINS OF THE LEG. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

The popliteal vein accompanies the popliteal artery, lying superficial to it in the whole of its course, and tightly bound down to it by its fascial sheath. At the lower part of the fossa it is a little medial to the artery, but, crossing the vessel obliquely as it ascends, lies a little lateral to it at the proximal part of the fossa. The tibial (internal popliteal) nerve lies superficial to the vein, being lateral to it above, then posterior to it, and then a little to its medial side. The close relation of the vein and nerve explains the early stiffness of the knee, the pains below (often called 'rheumatic') and the edema in popliteal aneurism. The popliteal vein contains two or three valves.

The popliteal receives the small saphenous vein. It is also joined on its lateral and medial sides by the *accessory popliteal* veins [vv. popliteæ accessoriæ] which form common trunks of

termination of the sural and articular veins of the respective sides. The medial vein receives in addition, through a plexus extending as high as the opening in the adductor magnus, the veins accompanying the a. genu suprema.

The **femoral** vein [v. femoralis], the continuation of the popliteal extends from the tendinous opening in the adductor magnus to the inguinal ligament. In this course its relations are similar to those of the femoral artery. As the vein passes through the adductor canal, it lies behind and a little lateral to the artery. At the apex of the femoral trigone (Scarpa's triangle) it is still posterior to the artery, but gradually passes to the medial side as it passes through the trigone (fig. 618).

In the neighborhood of the inguinal ligament the femoral vein lies on the same plane as the artery from which it is separated by a delicate prolongation of the fascia stretching between the front and back layers of the femoral sheath. On the medial side the vein is separated by a similar septum from the femoral canal. For relations of the femoral sheath and canal to femoral hernia, see p. 1275. The femoral vein contains five pairs of valves.

Tributaries.—The femoral vein receives (in addition to the great saphenous vein, and, in some cases the superficial veins of the epigastrium and groin) the profunda femoris and circumflex femoral veins and a variable number of small femoral venæ comitantes.

The **profunda femoris** veins [vv. profundæ femoris] arise from the venæ comitantes corresponding to the perforating branches of the profunda artery [vv. perforantes]. The **perforating** veins accompany the perforating arteries and anastomose with femoropopliteal and other veins of the posterior femoral region, and with the circumflex and accessory popliteal veins. They return blood from the femur and the adductor, hamstring and vasti muscles. Proximally the profunda femoris veins generally unite to form a vein which lies anterior to the artery.

The **medial** and **lateral femoral circumflex** veins [vv. circumflexæ femoralis mediales et laterales] accompany the femoral circumflex arteries and anastomose freely with each other and with the gluteal and genicular veins. They open either into the femoral or the profunda femoris veins (fig. 618).

MORPHOGENESIS AND VARIATIONS OF THE VEINS

The developing heart, as soon as it has assumed the simple tubular form, is found to receive two pairs of veins, the vitelline and umbilical (fig. 39). The right and left vitelline veins return blood from the yolk-sac and reach the heart by transversing the splanchnic mesoderm. The single umbilical vein, which returns blood from the placental part of the chorion. reaches the embryo by way of the body-stalk. Before entering the body-wall it divides into two branches, each of which transverses the somatopleure of its own side to unite with the corresponding vitelline vein near the venous end of the heart. The heart thus receives two short common vitelloumbilical trunks which join the parts of the sinus venosus known as the right and left sinus-horns.

During the further course of development two pairs of veins appear which are entirely intraembryonic; they are the right and left precardinals and postcardinals. The precardinal veins drain the head and neck, while the postcardinals drain the trunk and developing extremities. Each precardinal vein joins the postcardinal vein of its own side to form a medially directed vessel called the common cardinal. Each common cardinal unites with the common vitelloumbilical stem of its own side. The two common cardinal veins, although they undergo a considerable amount of shifting, are recognizable until a relatively late stage of development, while the proximal parts of the vitelline and umbilical veins, on the other hand, are partially destroyed. The *duct of Cuvier*, the venous trunk which leads into either horn of the sinus venosus, probably includes the entire common cardinal vein together with a portion of the original vitelloumbilical trunk. The efferent components of the embryonic capillary plexus supplied at first from the aortic sac and later from the sixth pair of aortic arches by the pulmonary arteries converge to form a single *pulmonary vein*, which opens into the left atrium. That these components occasionally form abnormal connections with systemic veins is indicated by some of the anomalies which may occur. One or other of the pulmonary veins has been found to open into the vena cava superior, into the left innominate, or into the vena azygos.

THE VENA CAVA SUPERIOR AND ITS TRIBUTARIES

1. MORPHOGENESIS

(*a*) **Vena cava superior.**—The *precardinal veins* at first return blood from the head and neck only (fig. 39). As the heart gradually migrates toward the thorax, however, relative positions become altered and the precardinal veins soon receive, through the subclavian veins, the blood returning from the upper extremities also. By the time the venous end of the heart has entered the thoracic region the Cuverian ducts no longer preserve their original transversely dorsoventral position. They begin to assume a longitudinal direction and become the proximal portions of the symmetrically placed venæ cavæ superiores.

At a stage of about 16 mm. the thymicothyroid veins, which open into the right and left precardinals, become connected and form a transverse venous channel between the two precardinal veins. This soon becomes a large vessel, and its presence allows of a revision of the

nomenclature of the neighboring venous channels. The cross-branch itself becomes the major part of the *left innominate vein*. The part of the right precardinal which extends from the right extremity of the cross-branch to the proximal end of the right subclavian vein, becomes the *right innominate vein*, while the part extending from the cross-branch to the right duct of Cuvier becomes the distal portion of the right *superior cava*. On the left side the parts immediately above and below the cross-branch, become the left end of the left innominate and the distal

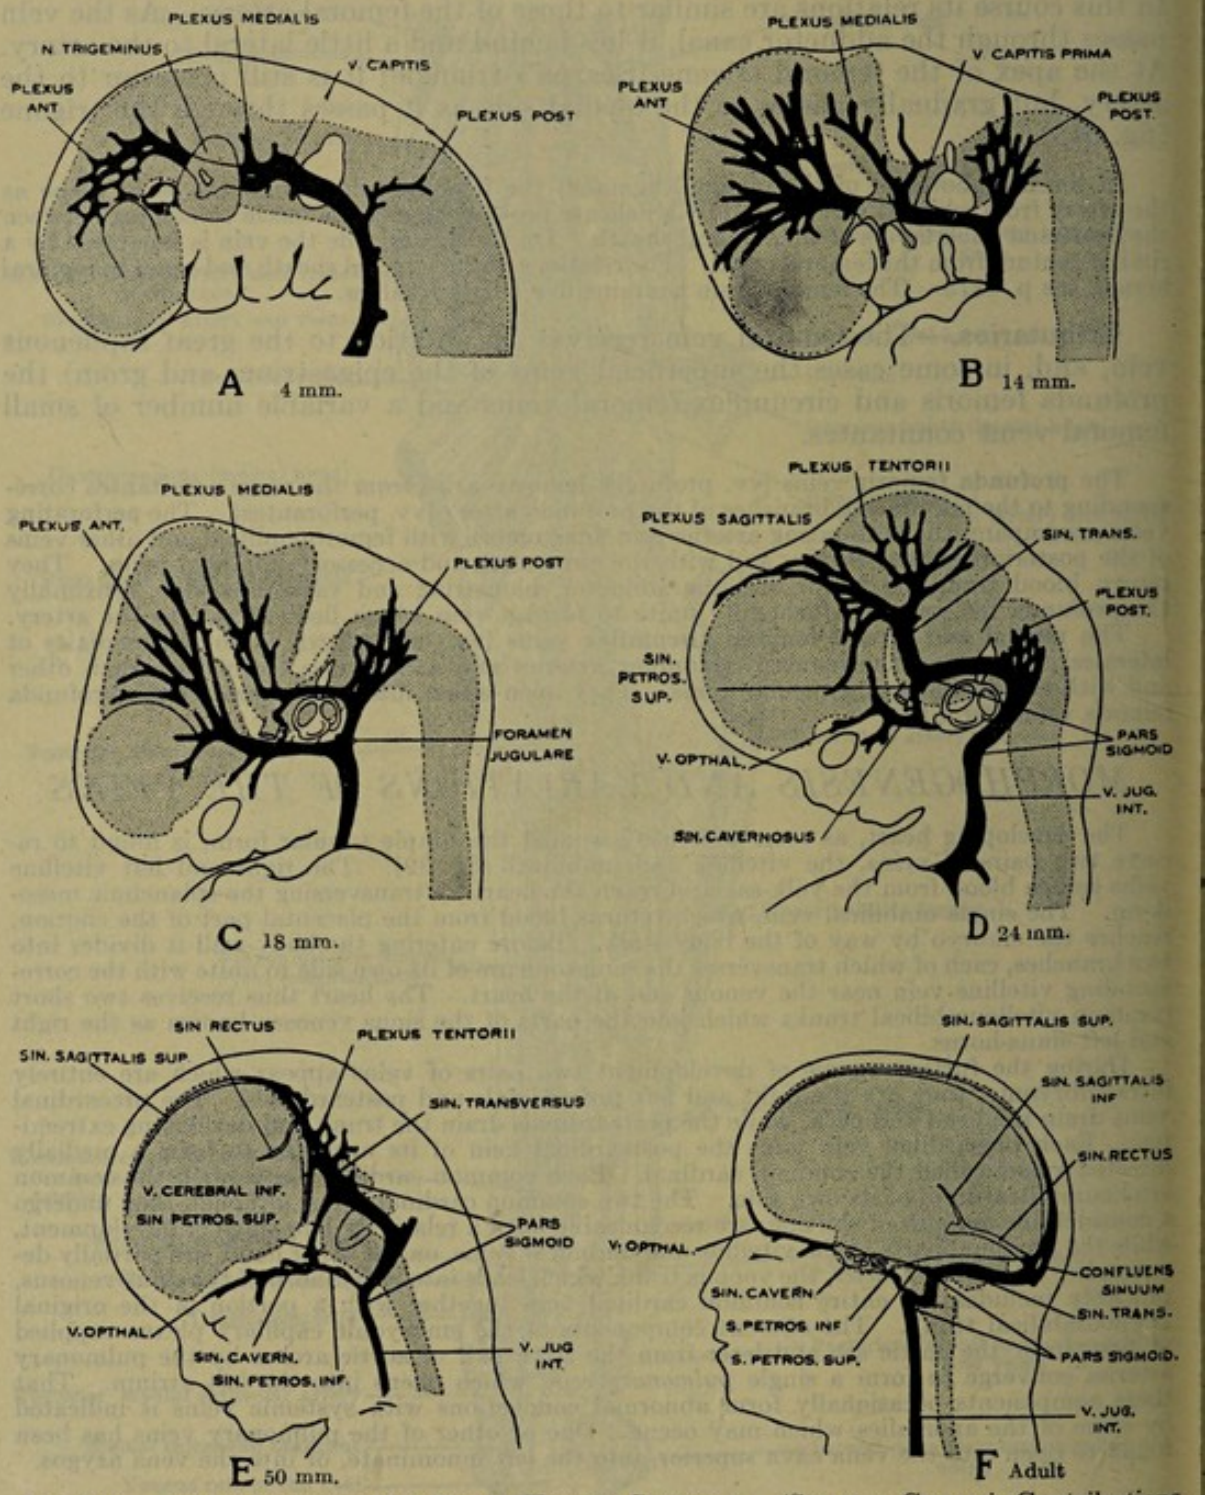

FIG. 620.—DEVELOPMENT OF THE DURAL VENOUS SINUSES. (Streeter, Carnegie Contributions to Embryology, 1918.)

portion of the left superior cava respectively. The left innominate vein rapidly increases in size and the right superior cava gradually usurps the function of the corresponding vessel of the left side. The left vena cava superior eventually disappears but evidences of its former presence are recognizable in the adult as the *oblique vein of Marshall* (p. 599).

(*b*) **The veins of the neck and upper extremity.**—The portion of the precardinal vein extending from the innominate vein to the base of the skull on either side appears to become divided longitudinally to produce the *internal jugular* and *vertebral* veins (Thyng). The former drains the dural sinuses, while the latter receives the segmental veins which drain the vertebral plexuses. The embryonic *linguofacial vein* drains the submental and anterior and posterior facial regions into the internal jugular veins (F. T. Lewis), and becomes the *common facial vein*. The *external and anterior jugular veins*, which appear relatively late in development, may take over parts of the original linguofacial area of drainage.

The veins of the *upper extremity* at first form part of the general superficial venous plexus of the neck and thorax, which is drained by the umbilical vein and by the cardinals. A marginal vein soon becomes apparent upon the free border of the developing limb, the preaxial and postaxial limbs of which are known as the radial and ulnar vein respectively. The drainage of the upper extremity and the chest is now taken over by a large channel which connects the ulnar vein with the precardinal. The ulnar vein receives the largest vein of the chest, the thoracoepigastric, while the radial vein becomes reduced to a plexus. The ulnar vein becomes the *basilic* and the *axillary vein*, the thoracoepigastric becomes the *lateral thoracic*. The *subclavian* vein replaces the original channel of connection between the ulnar vein and the precardinal. The *venæ comitantes* of the deep arteries of the limb, and the *cephalic vein* appear later in development; the latter at first opens into the external jugular.

(*c*) **The venous sinuses of the dura mater** (fig. 620).—The forebrain and midbrain are closely invested, at an early stage of development, by a plexus of capillaries which eventually becomes converted into the circulus arteriosus and the cerebral and choroidal arteries and veins. This plexus is drained on either side by a vein which courses along the ventrolateral aspect of the hindbrain and is connected by an occipital intersegmental vein with the corresponding precardinal. The longitudinal vein which forms the first part of the drainage line of the forebrain and midbrain has long been known as the *v. capitis medialis*, for it lies upon the medial side of the cranial ganglia. It was formerly thought to pass, by a form of anastomotic migration, to the lateral side of the ganglia, and thus become converted into the *v. capitis lateralis*. Sabin, however, finds that these vessels are formed independently and substitutes for them the terms *vasa primitiva rhombencephali* and *vena capitis prima*, respectively.

The plexus formed from the vasa primitiva rhombencephali is fed by arterial offshoots of the aortic arch system. It is subsequently converted into the arteries and veins of the hindbrain. In addition to receiving the venous stem of the forebrain and midbrain plexus, the vena capitis prima receives two other branches from the plexuses of the anterior and posterior parts of the hindbrain, respectively. By the time the three main tributaries of the *v. capitis prima* are fully formed, the forebrain and midbrain plexus consists of a superficial part, which drains the dura, and of the original deeper part in which cerebral arteries and veins are undergoing differentiation. The blood entering the three tributaries is derived very largely from the dural layer of the head. On this account the terms *anterior*, *middle*, and *posterior dural plexus* have been substituted by Streeter for the terms anterior, middle and posterior cerebral veins (of Mall).

The main dural venous channels present in embryos of the stage of 4 mm., and the alterations in their arrangements which lead to the production of the adult arrangement, are indicated in fig. 620. It will be seen that at the stage of 18 mm. (C), a new connection has arisen between the middle and posterior plexuses; this, together with the stem of the posterior plexus, will become the sigmoid part of the *sinus transversus*. At the stage of 21 mm. (D), the anterior and middle dural plexus have coalesced to form the sagittal and tentorial plexuses. The part of the *v. capitis prima* upon the medial side of the trigeminal ganglion, now the *sinus cavernosus*, receives the *ophthalmic* and *middle cerebral* veins. The remainder of the v. capitis prima having been lost, the blood from the cavernous sinus drains into the transverse sinus through the *sinus petrosus superior*, originally the lower part of the stem of the middle plexus. The drainage of the entire venous system of the dura mater is now effected through the sinus transversus. During the succeeding stages of development (E and F) the *inferior petrosal sinus* appears and the sagittal plexus becomes differentiated into the *sagittal sinuses* and *sinus rectus*. The tentorial plexus becomes the *confluens sinuum* and the horizontal part of the s. transversus, its connections with the posterior dural plexus form the *sinus occipitalis*, and the plexus itself persists, in part, as the *marginal sinuses*.

(*d*) **The azygos system of veins.**—The asygos, hemiazygos, accessory hemiazygos and superior intercostal veins are the adult representatives of the thoracic portion of a pair of embryonic veins to which Huntington and McClure have applied the term *supracardinal*. The supracardinal veins pursue a longitudinal course through the abdomen and thorax lying dorsolaterally to the aorta. They take over the drainage of the lumbar and intercostal veins from the postcardinals which eventually disappear almost entirely. The right and left supracardinal veins intercommunicate in several places, the persistence of one or two communications, at about the level of the eighth thoracic segment, usually determines the eventual drainage of the larger part of the left supracardinal vein into the right. The latter vein is connected superiorly, through a small persisting portion of the postcardinal, with the right duct of Cuvier (vena cava superior); its intrathoracic part becomes the vena azygos. The part of the left supracardinal above the fourth thoracic segment becomes the *left superior intercostal* vein. The part of the supracardinal which now drains downward, and across into the azygos becomes the *accessory hemiazygos*, while the remainder of the intrathoracic portion of the left supracardinal becomes the *hemiazygos* vein.

2. VARIATIONS

(*a*) **Vena cava superior.** The connection between the embryonic thymicothyroid veins of the two sides may fail to persist. In this case both embryonic venæ cavæ will persist and each receive the subclavian and internal jugular vein of its own side, the left innominate vein being absent and the right not marked off from the remainder of the right superior cava. The left vena cava superior may coexist with the right even when the embryonic connection between them has appeared in the usual way. The innominate veins are present in such cases, but the left is commonly small. A left vena cava superior may altogether replace the right of the adult in association with *situs inversus* or as an independent variation. The left superior cava is formed from the left duct of Cuvier and the adjacent part of the left precardinal vein and joins the coronary sinus. The abnormal termination of the vena cava inferior in the vena cava superior is mentioned below under the azygos system.

(*b*) **Veins of the neck and upper extremity.** The comparative size of the two internal jugular veins depends upon the manner of drainage of the dural sinuses. Either *the anterior* or *the external* jugular vein may be absent. In such cases the *common facial* vein resembles more closely than usual the embryonic linguofacial from which it is derived. The external or the anterior jugular vein may, on the other hand, almost entirely replace the common facial; variations in the relative extent of the areas drained by these three veins are extremely common.

The *cephalic* vein may be absent, or it may cross the clavicle to enter the external jugular. The *lateral thoracic* (embryonic thoracoepigastric) may be very large. The *subclavian* vein occasionally passes between the subclavius muscle and the clavicle.

(*c*) **Venous sinuses of the dura mater.** The *superior sagittal sinus* may be partially reduplicated, or it may bifurcate at the lambda and follow the limbs of the lambdoid suture to join the lateral ends of the transverse sinuses (Malacarne). It may be small, or altogether absent. In either case the s. rectus and s. sagittalis inferior are large and receive the superior cerebral veins through dilated channels in the falx.

An accessory sinus or series of sinuses in the falx may drain both the s. sagittalis inferior and the v. magna cerebri in cases in which the *s. rectus* is absent. The s. rectus may drain only the v. magna cerebri in cases in which the *s. sagittalis inferior* is absent, or, being present, is drained into the superior sagittal sinus by large veins of the falx.

The *transverse sinuses* may be equal in size when the confluens sinuum is large, or the horizontal part may be absent from one side. Both ss. transversi may be small in cases in which the *s. occipitalis* is large enough to carry most of the blood from the confluens to the *marginal sinuses* and so to the jugular veins. The occipital and marginal sinuses may be absent.

The variations mentioned above seem to afford instances of lack of uniformity in the selection of channels from amongst the many alternative routes afforded by a plexiform system. The appearance of the *s. petrosquamosus* depends, in all probability, upon the occasional persistence of an anterior tributary to the stem of the middle dural plexus.

(*d*) **The azygos system of veins.** Variations in the details of the drainage of the intercostal veins are very common. They are referable either to an increase in the number of transverse connections between the two embryonic supracardinal veins or to the absence of some or all of them. In extreme cases, all of the left intercostal veins may terminate in the v. azygos, the hemiazygos vein and accessory hemiazygos being absent. In such cases the single azygos vein usually opens into the vena cava superior; it may, however, open through a persistent left duct of Cuvier into the coronary sinus (Gruber). In the absence of the part of the vena cava inferior normally derived from the right subcardinal connecting with the hepatic vein, the lower part of the vena cava may be continued into the azygos (Winslow, etc.), or into the hemiazygos and so into the azygos (Quain), or into a left-sided azygos vein which opens into the coronary sinus.

B. THE VENA CAVA INFERIOR AND ITS TRIBUTARIES

1. MORPHOGENESIS

The vena cava inferior is a vessel of a composite origin. The upper part of it receives the hepatic veins, which contain the venous blood returning from the alimentary viscera; its development is described in connection with that of the portal system of veins. The lower part of the vena cava inferior receives venous blood from the remainder of the abdominal viscera, and from the abdominal walls and lower extremities; its development is described with that of its tributaries.

(*a*) The **portal system** of veins arises by means of a series of transformations which take place in the vitelline and umbilical veins of the embryo. The proximal ends of the vitelline veins, where they lie between the umbilicals, are early enveloped in, and invaded by, the growing liver. The columns of liver cells, while not penetrating the endothelium, subject the vitelline veins to a process of fenestration by which the original channels are subdivided into innumerable smaller vessels or sinusoids. The *sinusoids* arising from the two vitelline veins intercommunicate to form a continuous network within the liver in which the vessels are larger in the afferent (portal) and efferent (hepatic) areas than in the intermediate zone.

The two umbilical veins now form communications with the portal area of the sinusoidal network and eventually lose their original connection with the sinus venosus (fig. 621). The fate of the umbilical veins differs on the two sides; the right degenerates, from the sinus venosus to the common umbilical vein, while the left persists to receive all the blood flowing from the placenta. The left umbilical vein, having lost its connection with the sinus venosus, discharges its blood partly into the portal sinusoidal zone, and partly, by means of a direct channel of new formation, the *ductus venosus*, into the right vitelline (fig. 621).

The hepatic portion of the left vitelline vein eventually loses its connection with the sinus venosus and becomes reduced to sinusoidal channels, while that of the right increases very considerably in caliber. The hepatic portion of the right vitelline now forms the only means of transit between the hepatic sinusoids and the sinus venosus of the heart, and is called the *common hepatic* vein. The main venous channels of the lower abdomen, having undergone a series of changes meanwhile, acquire a connection with the common hepatic vein, which thus becomes the upper part of the *vena cava inferior*.

The single vitelline vein of the yolk-stalk separates into right and left veins before entering the liver. In a position intermediate between the proximal and distal anastomoses between the right and left vitelline veins, which occur (ventrally to the intestine) within the liver and upon the yolk-stalk, respectively, a third connection appears on the dorsal aspect of the duodenum. The formation of the *portal vein* is effected by the disappearance of the portion of the right vitelline vein on the distal side of the dorsal connection and of the portion of the left vitelline upon the proximal side. The portal vein is joined by the *superior mesenteric* vein upon the left side of the duodenum and by the *splenic vein* behind it; the portion of the common vitelline vein beyond the junction of the superior mesenteric with the left vitelline subsequently disappears.

(*b*) **The lower part of the vena cava inferior.** At an early stage of development the postcardinal veins are invaded by the growing Wolffian bodies and here become transformed into in intercommunicating system of sinusoids, which is drained by three longitudinal venous channels. One of these traverses the dorsal region of the organ, and retains the name postcardinal; one traverses the medial region and is called the *subcardinal* vein (F. T. Lewis). The third vein traverses the ventral region and does not share in the development of the vena cava inferior or its tributaries. The subcardinals are united across the median line, on a level subsequently occupied by the kidneys, by what is commonly known as the *renal anastomosis*, and each subcardinal receives a vein from the suprarenal gland and from the gonad of its own side. The postcardinal veins for a long time remain the chief drainage channels for the Wolffian bodies and for the iliac veins; they later, however, relinquish the drainage of the veins of the body-wall to a pair of veins of later formation, the *supracardinals* (Huntington and McClure, Am. Jour. Anat., vol. 6, 1907).

Each supracardinal vein pursues a longitudinal course near the dorso-lateral aspect of the aorta; it is connected with the postcardinal near the place of entry of the iliac veins, and, extends to the anterior end of the postcardinal vein of its own side, into which it opens a short distance below the duct of Cuvier. The supracardinal veins intercommunicate at frequent intervals and eventually replace the thoracic portion of the postcardinal veins. A large communication between the supracardinal and the subcardinal vein occurs, at the level of the renal anastomosis, so that the aorta is surrounded by a venous ring, the renal collar.

The drainage of the left common iliac vein is now transferred by means of a cross anastomosis, to the right supracardinal, which becomes the part of the vena cava inferior below the renal anastomosis. The remainder of the vena cava inferior is formed from the right half of the renal collar, part of the right subcardinal vein above the renal anastomosis and a venous communication between this and the common hepatic vein. The embryonic components of the vena cava inferior become enormously enlarged and the left supracardinal vein diminishes in size.

As soon as the kidneys have attained their permanent position, the ureter is found to pass between the supracardinal vein and the postcardinal; the dorsal loop of the periureteral ring

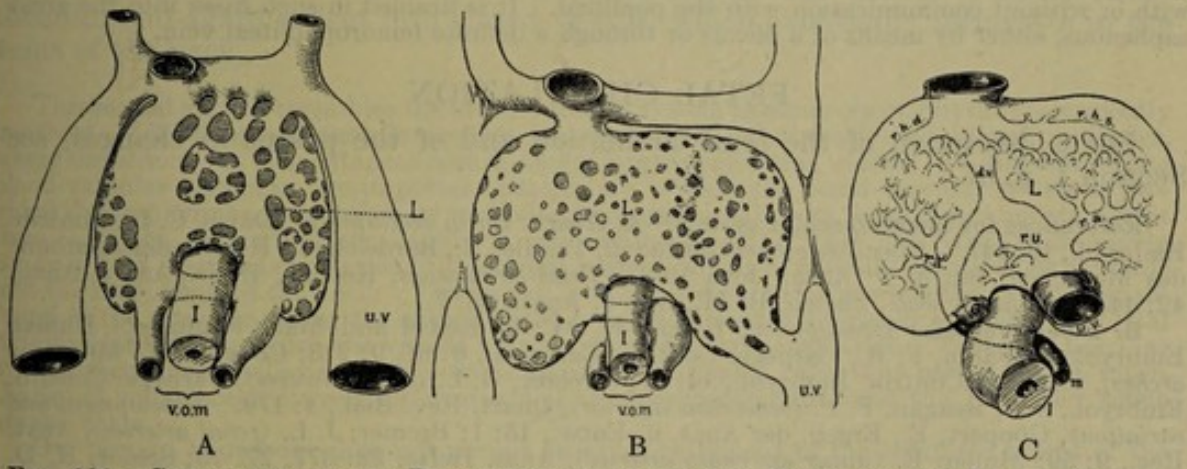

FIG. 621.—SEMIDIAGRAMMATIC RECONSTRUCTIONS OF THE VEINS OF THE LIVER, VENTRAL ASPECT (MALL). A, EMBRYO OF 4.5 MM. LONG; B, 4 MM. (MORE ADVANCED THAN A); C, 7 MM. d.v., ductus venosus; I., intestine; L., liver; m., superior mesenteric (continued as portal) vein; r.a., ramus angularis; r.a′., right branch of portal vein; r.h.d., right hepatic vein; r.h.s., left hepatic vein; r.u., recessus umbilicalis; u.v., left umbilical vein (the right umbilical vein is not labelled); v.o.m., vitelline veins.

described by Hochstetter in 1893 is, therefore, a part of the supracardinal vein. Two veins (dorsal and ventral) leave each kidney to open into the corresponding side of the renal collar. The left ventral kidney-vein retains its connection with the renal anastomoss, forming the left renal vein of the adult. The ventral kidney-vein of the right side persists as the right renal vein of the adult, which opens into the vena cava inferior. The portion of the left subcardinal vein above the renal anastomosis becomes the left suprarenal vein. The corresponding portion of the right subcardinal vein forms a part of the vena cava inferior and the entire right suprarenal vein. The part of the postcardinal vein contained within the Wolffian body diminishes in size and forms a connection between the gonadic vein of each side and the corresponding subcardinal. Some part of the postcardinal vein persists, therefore, as the spermatic (or ovarian), the right opening into the vena cava inferior and the left into the left renal vein.

(*c*) **The veins of the lower extremity.** The superficial plexus of the developing limb is at first drained by the postcardinal and umbilical veins. It soon becomes condensed into a marginal vein, the fibular limb of which enters the pelvis as the hypogastric vein and continuing as the common iliac vein, joins the postcardinal. The external iliac vein grows from the common iliac, and forms a connection with the plexiform tibial limb of the marginal vein. This connecting branch receives the venous drainage of the thigh and lower abdomen and subsequently forms the proximal part of the femoral and great saphenous veins. The deep veins of the limb appear somewhat later. The popliteal takes over the distal part of the fibular marginal vein, which then becomes the small saphenous. The proximal part of the fibular vein is transformed into a plexus upon the back of the thigh, which is drained by the great saphenous vein and the hypogastric veins. The drainage of the common iliac veins is later transferred from the postcardinal to the supracardinal veins, and the upper part of the left common iliac vein is formed by an inter-supracardinal anastomosis.

2. VARIATIONS

(*a*) **The portal system of veins.** Major variations of the *portal system* of veins are practically unknown. In cases in which the lower part of the vena cava inferior is continued into the vena azygos, or into the v. hemiazygos in postnatal life, the common hepatic vein is smaller than usual and transmits blood from the portal system only.

(*b*) **The lower part of the vena cava inferior.** The left renal vein not uncommonly passes on the dorsal (instead of the ventral) side of the aorta. This condition is due to the persistence of the dorsal, and not the ventral, of the two embryonic kidney-veins which open into the left side of the 'renal collar.' The left suprarenal, and the left spermatic vein open, in such cases, into the vena cava inferior and not into the left renal vein.

The *vena cava inferior* lies upon the left side of the aorta in cases of *situs inversus*, and in some cases without situs inversus. In the latter case the left supracardinal vein, instead of the right, has persisted below the level of the renal veins; the left inferior vena cava is continued across the front of the aorta and, receiving the left spermatic and the left suprarenal vein, passes to the right atrium in the usual way. There are occasionally two venæ cavæ, one on each side of the aorta; the two persisting supracardinal veins are united, in such cases, by the embryonic renal anastomosis. In all cases in which the left vena cava is present, with or without a right, the part which crosses the aorta is derived from the embryonic renal anastomosis and, therefore, corresponds in origin to the proximal part of the left renal vein.

Cases of dissociation of the embryonic antecedents of the vena cava inferior have already been mentioned (see azygos system). The venous blood from the lower part of the vena cava inferior in such cases finds an outlet through the thoracic portion of one of the supracardinal veins.

The renal vein of either side may open into the common iliac, particularly in cases in which the organ is lower than usual. The vein of a pelvic kidney may open into the middle sacral vein. Many interesting anomalies of a less striking character may occur.

(*c*) **The veins of the lower extremity.** Major variations of the veins of the lower extremity are not common. The small saphenous vein is frequently continued upon the back of the thigh, with or without communication with the popliteal. It is drained in such cases into the great saphenous, either by means of a plexus or through a definite femoropopliteal vein.

FETAL CIRCULATION

For a discussion of the fetal circulation and of the postnatal changes, see Section I, p. 37.

SECTION VII

THE LYMPHATIC SYSTEM

By ELIOT R. CLARK, A.B., M.D.

PROFESSOR OF ANATOMY, UNIVERSITY OF PENNSYLVANIA

GENERAL ANATOMY OF THE LYMPHATIC SYSTEM

THE blood-vascular system has, as a part of its function, the collection of substances from the various tissues of the body which are to be conducted to the other tissues. In carrying on this function it is assisted by a second system of collecting vessels, the lymphatics. The lymphatic system consists of a set of closed vessels which start as closed capillaries in the various organs and tissues, continue as closed vessels, pass through lymph-nodes in which the vessels break up into capillaries and spaces separated from the outside fluid by endothelium, and again collect into closed vessels, which eventually terminate in the veins of the neck.

This second system resembles the blood-vascular system in many ways, but differs markedly in others. Like the blood-vascular system, it is made up of minute endothelial-lined capillaries, where the absorption of substances occurs, and of larger conducting vessels. It differs from the blood-vascular system in two important particulars. While the blood-vascular system is provided with a pumping mechanism by which its fluid content is driven through a complete circuit from the heart, through artery, capillary, vein and back to the heart, the lymphatics merely conduct fluid *from* the capillaries to the larger vessels, which eventually empty their contents into the large veins of the neck. The second important difference between the two systems is found in the presence, along the course of the lymphatic vessels, of glands or nodes (fig. 625) [lymphoglandulæ] in which the vessels branch out into lymph-capillaries. These are lined, as are the absorbing capillaries, with a single layer of endothelial cells, thus permitting an interchange of substances between the contents of the lymph-capillaries and the lymphoid tissue around them.

Our present knowledge does not permit an exact statement of the complete extent of the lymphatic system. While, in a general way, the lymphatics may be said to be present wherever blood-capillaries occur, there are certain tissues where lymphatics have not been definitely demonstrated. The *tissue-spaces* outside the lymphatic endothelium, which are filled with a fluid or semifluid material, which has often been termed 'lymph' but which would better be termed 'tissue-fluid, are not part of the lymphatic system. Similarly, the various serous cavities —pleural, percardial, synovial, cerebrospinal, etc.—while they may serve, as in the case of the cerebrospinal spaces and the intraocular spaces, a somewhat similar function, are not considered as parts of the lymphatic system.

The general constitution of the lymphatic system will be considered under three heads—(1) the capillaries, (2) the collecting vessels and (3) the lymphoid organs.

1. *THE LYMPHATIC CAPILLARIES*

The lymphatic capillary, like the blood-capillary, is the portion of the lymphatic system which is chiefly concerned in the specific function of this system. In the blood-capillaries, where the blood is separated from the outside tissues by a single layer of flat endothelial cells, there occurs the interchange of fluid substances and of cells, while the heart, arteries and veins serve to transport the blood, modified in the capillaries, to other parts of the body. Similarly in the lymphatic system, it is in the capillaries, both those most peripheral and those in the lymph nodes, where the absorption and interchange of fluid substances and of cells takes place. Consequently it becomes of prime importance to obtain a clear understanding of the structure of the lymphatic capillaries, their relation to the other tissues, and their mode of functioning. At the outset, however, it must be admitted that our knowledge on this subject is far from complete.

Historical.—Previous to the development of microscopic anatomy, in the middle third of the 19th century, there was no accurate knowledge of such small structures as the lymphatic capillary. In order to explain the absorption of substances by the lymphatics, as well as the passage of substances from the blood-vessels through the tissues, various theories were invented. Prominent among such theories was that of the 'vasa serosa,' of H. Boerhaave and other 18th century anatomists and physiologists, which was perhaps most elaborately developed by Bichat, 1801-03. According to this theory there are two sets of minute vessels. The one set leads from the blood-capillaries onto the various surfaces and into the loose spaces in the tissues—the 'exhalants.' The other set leads from the body surfaces (including the serous cavities) and the loose spaces in the tissues to the lymphatics—the inhalants or 'absorbents.' This theory was somewhat shaken by the criticism of early 19th century anatomists who developed the technic of injection of lymphatics to a high point.

Our present conception of the lymphatic capillaries may be said to have started with Kölliker who, in 1846, saw, with the aid of the microscope, the lymphatic capillaries in the transparent tails of living frog larvæ. Like Schwann who, in 1837, had studied the blood-capillaries in the tail of the frog larva, he erroneously supposed that the fine processes of the lymphatic capillaries were continuous with similar processes of the surrounding connective tissue cells. Since, according to the conception current at the time, cells were thought to be hollow structures, it was concluded that the mode of transmission of fluid from blood to lymphatic capillary took place through canaliculi inside these cells. This conception was elaborated by Virchow, in his

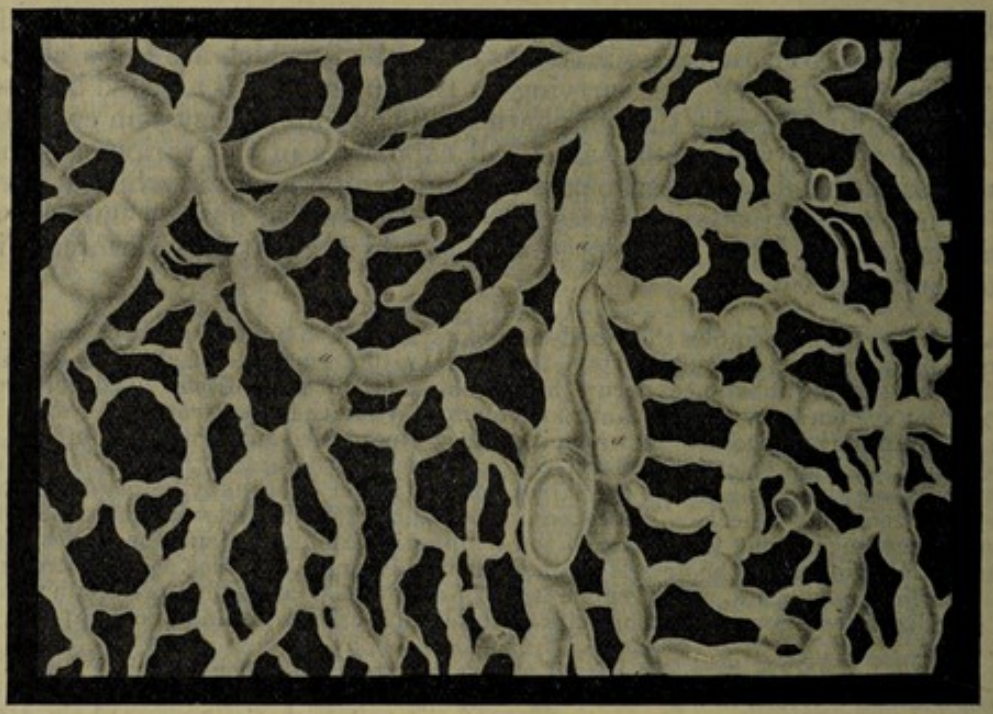

FIG. 622.—THE LYMPHATICS OF THE SCROTUM. (AFTER TEICHMANN.) SHOWING the transition of the capillaries to the vessels with valves (*a*, *a*, *a*).

Cellular-Pathologie. In 1862 von Recklinghausen by means of the silver nitrate staining method discovered that the lymphatic vessels are lined with an endothelium made up of flattened cells. He also described open communications ('stomata') between the lymphatics and the peritoneal cavity. Cohnheim described similar though smaller openings in blood-capillaries, and His described them in other lymphatic capillaries. Arnold termed the openings in the vessels 'stigmata,' as distinguished from the openings into the peritoneal cavity, or 'stomata.' More recent investigators (Kolossow, A. W. Meyer, W. G. MacCallum) have failed to find these 'stomata.' Careful studies of the lymphatic capillaries in the transparent tails of living frog larvæ, which may be clearly seen with the higher magnifications of the microscope, show that the endothelial lining of these capillaries is complete, with no trace of an opening into the spaces in the tissue outside (E. R. Clark). In microscopic studies made on lymphatics which have grown into a thin space left in a double-walled transparent chamber introduced in the rabbit's ear, the lymphatics have been found to be closed, normally. However, when, under abnormal conditions, a lymphatic capillary is broken open at the tip at a place where free fluid is present outside the lymphatic, the opening may persist for several days, permitting the direct passage of cells, fluids or debris from the outside into the lymphatic. (Clark and Clark.)

Form.—The shape of the lymphatic capillaries has been found to vary enormously in the different parts of the body where they have been studied. In general they form richly anastomosing plexuses, from which may extend cul-de-sacs, which end blindly. Such cul-de-sacs are especially noticeable in the dermal papillæ, in the filiform papillæ of the tongue, and in the intestinal villi. The plexuses are often present in two layers—a superficial and a deep. The vessels of the superficial plexus are of smaller caliber than those of the deep. These two sets of plexuses are particularly well seen in the skin and the gastrointestinal tract. In relation to the blood-capillaries, the lymphatic capillaries are generally the more deeply placed. In caliber, unlike the comparatively uniform diameter of blood-capillaries, the lymphatics vary enormously. In the same capillary a very narrow part may be succeeded by a very wide

ne (figs. 622–624). Teichmann found lymphatic capillaries varying in diameter from a few nicra to one millimeter or more. The capillaries are without valves.

Activity.—That the lymphatic endothelium is not exclusively a passive membrane has been hown by Clark in studies on the lymphatics in the transparent tails of living frog larvæ. The ymphatics here are seen to send out protoplasmic processes which, somewhat like an ameba, ctively take into the interior of the lymphatic red blood-cells accidentally forced from the lood-capillaries into the tissue-spaces. The mode of passage of leucocytes into or out of the ymphatics offers no such difficulties as that of the fluids, for they are able, by ameboid move- ient, to pass independently through the endothelium—a process first directly observed by Cohnheim.

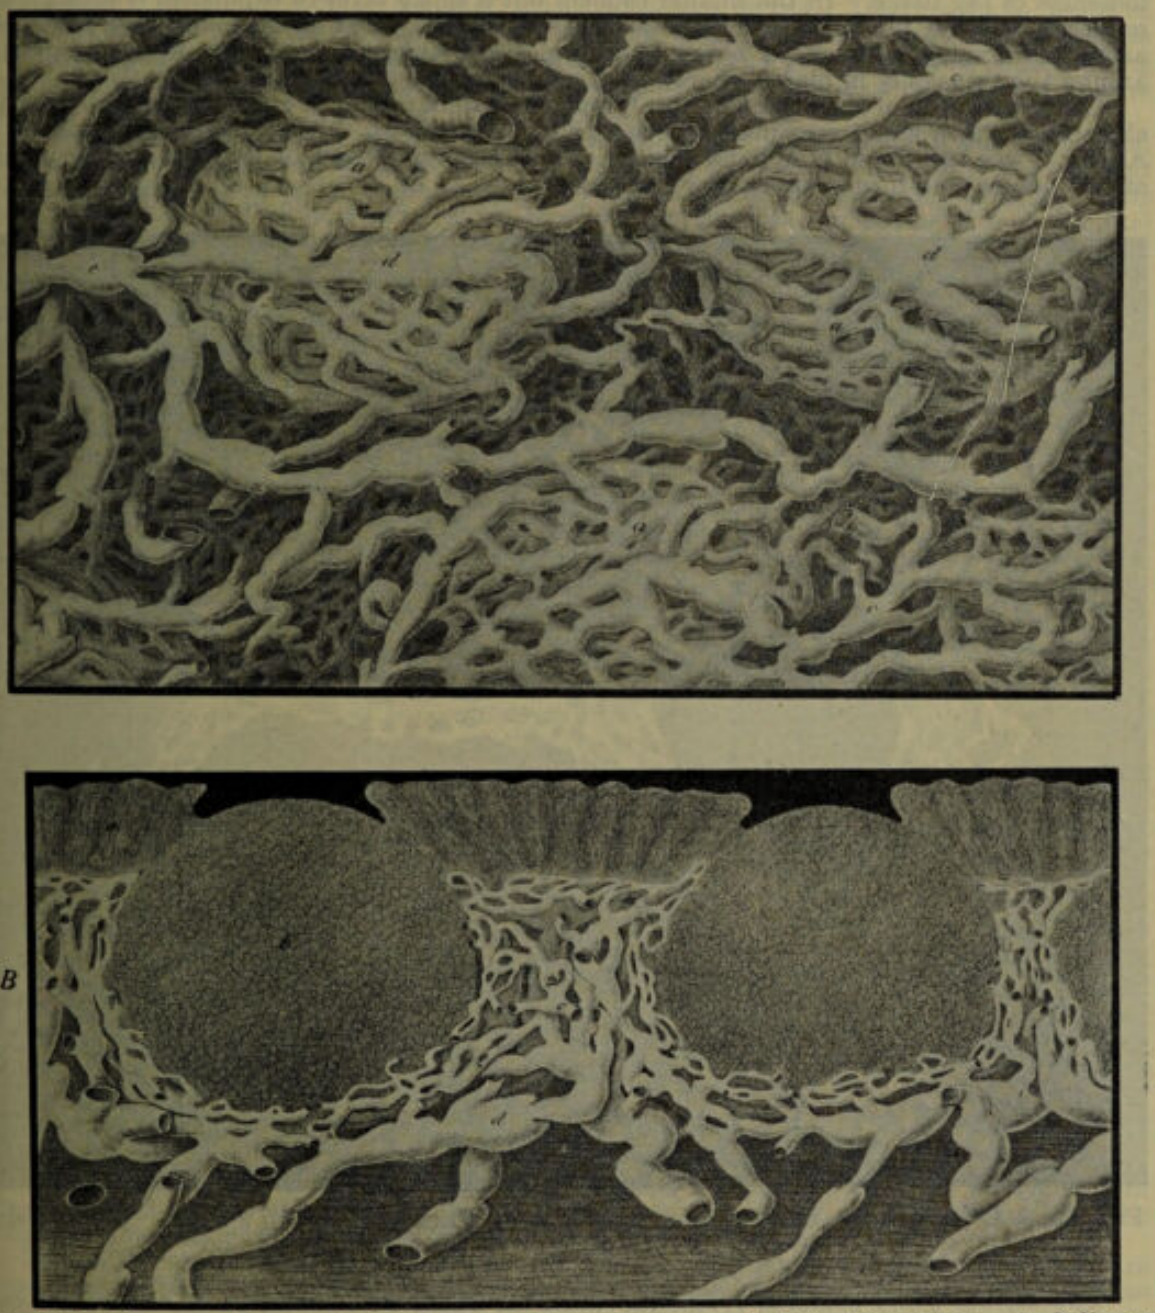

FIG. 623.—SURFACE VIEW AND SECTION OF LYMPH-NODES OF THE INTESTINE. A. Solitary follicle. B. Peyer's patch. (After Teichmann.)

THE EXTENT AND CHARACTER OF LYMPHATIC CAPILLARIES

The *skin* over the entire surface of the body is richly provided with lymphatic capillaries. They form two sets of plexuses in the dermis, a superficial and a deep. The superficial set sends out blind cul-de-sacs into the dermal papillæ. The richest skin plexuses are found in the scrotum, the palms of the hand and palmer side of the fingers and in the soles of the feet and plantar side of the toes. In the loose *subcutaneous* fascia, according to Teichmann, there are present only the larger collecting vessels, with no lymphatic capillaries. Lymphatic capillaries of the *scrotum* are shown in fig. 622.

The *conjunctiva*, both the sclerotic and corneal, is supplied with a rich plexus of capillaries, which are narrower in the corneal than in the sclerotic portion. At the corneal border the capillaries form a fairly regular ring which has been called by Teichmann a circulus lymph- aticus (fig. 636).

At the various *orifices* of the body, the skin plexuses go over into the mucous plexuses forming anastomoses with them. Throughout the entire *alimentary tract*, the lymphatic capillaries form extensive plexuses which are in many places divided into a superficial plexus in the mucosa and a deeper plexus in the submucosa. In portions provided with a peritoneal covering, there is a third rich subserous plexus. In the tongue and the small intestine the plexus in the mucosa sends out blind cul-de-sacs; in the tongue into the filiform papillæ; in the small intestine into the villi. Where muscle is present along the alimentary tract, the lymphatics pass between the muscle bundles, but form no plexuses around them. Lymphatics have been demonstrated in the pulp of the tooth (Schweitzer).

The lining of the *nasal*, *tracheal* and *bronchial passages* is supplied with a double plexus of lymphatic capillaries, a mucous and a submucous set, which vary in richness according to the looseness of the tissue. In the smaller bronchi but a single layer of capillaries is present, and no capillaries are present around the air cells (Miller). Plexuses surround the pulmonary arteries and veins. Under the *pleura* lie rich plexuses which connect with deeper lymphatics around the veins only in places where the veins reach the surface of the lung.

Concerning the arrangement of the lymphatic capillaries in the *glands* derived from the alimentary tract much remains to be learned. The *salivary glands* have been studied by Aagaard, who has found lymphatic capillaries accompanying the blood-vessels into the interior of the lobules, and forming here irregular plexuses.

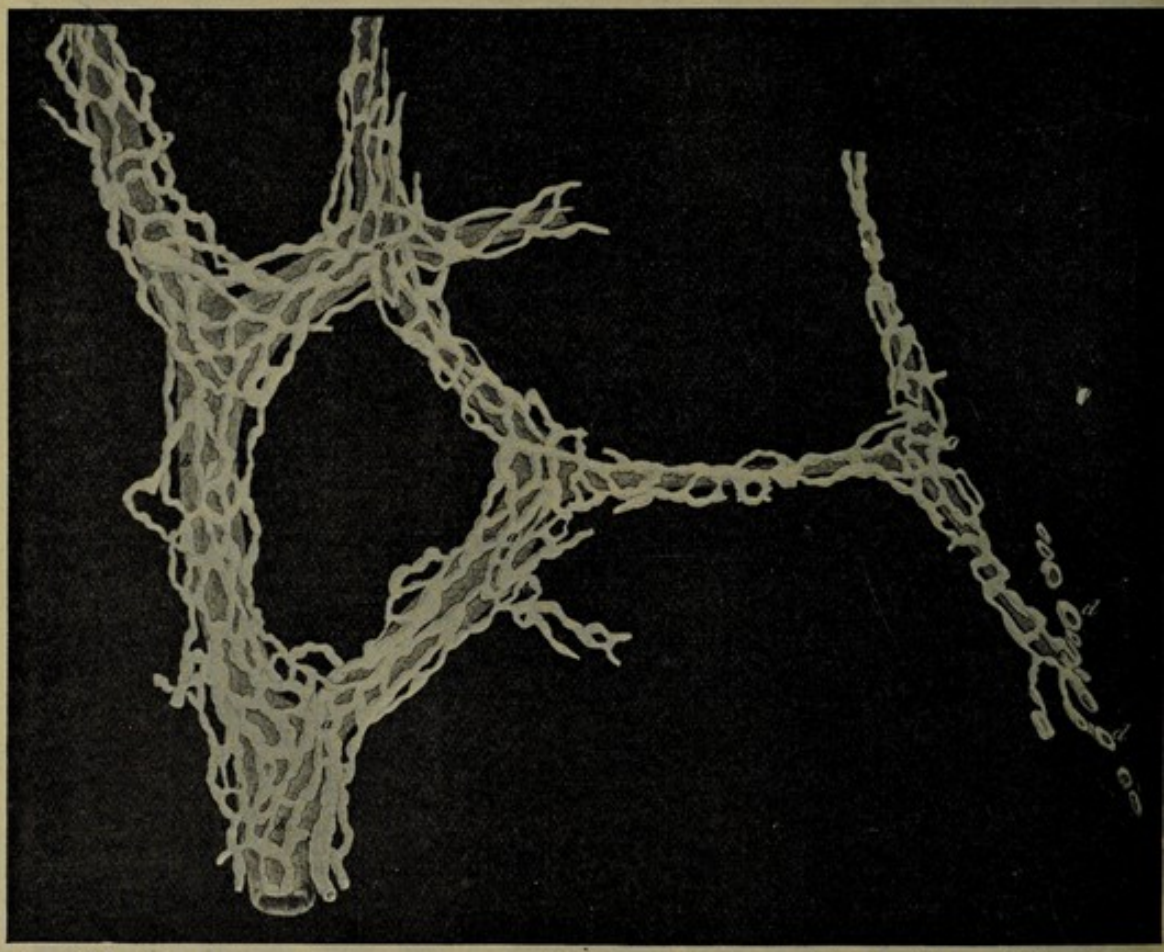

FIG. 624.—LYMPHATIC PLEXUS AROUND THE PORTAL VEIN IN AN ADULT MAN. (After Teichmann.)

The *thyroid gland* contains lymphatic plexuses which lie in relation to the colloid-containing alveoli. Direct connection between the lymphatics and the alveoli has been described by Matzunaga, but this observation needs verification. The lymphatics are apparently concerned in the absorption of the colloidal secretion, for traces of it have been found in the lymphatics draining the gland.

Concerning the lymphatics of the *parathyroids* nothing is known.

The course of the lymphatics draining the *thymus* has been described, but the nature of the capillaries in this gland is unknown. In the *spleen* lymphatics have been definitely found only in the capsule and the larger trabeculæ; not in spleen pulp.

The lymphatic capillaries of the *liver* are of great importance, for the lymph which flows from this organ forms a very considerable part of the total lymph which is collected into the thoracic duct. And yet very little is definitely known about the nature and distribution of the lymphatic capillaries in the interior of the organ. In the capsule there is a rich plexus, lying under the peritoneum, in which very large widenings have been described (called by Teichmann 'Lymphbehälter'). In the interior rich plexuses surround the branches of the hepatic artery and portal vein (fig. 624), and plexuses have been described accompanying the branches of the portal vein into the lobules. The path from blood-capillary to lymphatic in the perilobular spaces is more open than has been found in other organs, for Mall has found that if very finely

anular masses are used, and are injected through portal vein or hepatic artery under mild essure, the granules pass over into the lymphatics. Moreover, the lymph from the liver is her in proteins—more like the blood serum—than is the lymph from other organs.

The linings of the large *bile-ducts* and the *gall-bladder* are provided with a submucous network lymphatics (Sudler and Clermont). The gall-bladder has also a rich subserous plexus.

Concerning the lymphatic capillaries of the *pancreas* Bartels notes briefly that they form hly branched plexuses in the interlobular connective tissues, which surround larger or smaller rts of whole lobules, not the single gland elements.

The mucous lining of the *genitourinary tract*, wherever it has been carefully studied, has en found provided with plexuses of lymphatics. In the *bladder* they form a rich plexus of egular capillaries which lie immediately under the almost intraepithelial blood-capillaries. ney connect, through the muscular layer, with a subserous plexus. The lymphatic plexus of e *urethra* anastomoses with the capillaries of the base of the bladder, and in the male with those the glans penis. In the *prostate* (Camineti) the lymphatics form rich plexuses surrounding e glands, which connect with a very wide meshed subcapsular plexus, surrounding the entire and.

In the *testis* there is a rich superficial plexus, lying directly beneath the tunica albuginea. ncerning the deep lymphatics of the testis there has been much dispute. Ludwig and nomsa found the lymphatic capillaries going over into lacunæ, without endothelium. This s been disputed by Tommasi and Gerster, who find, in the septa, capillaries with endothelial all, which they consider the beginnings of the lymphatics.

In the female, lymphatic plexuses have been found in the mucosa of *vagina* and *hymen*, astomosing with those of the vulva. In the *uterus*, capillaries in the mucosa are very difficult demonstrate. Definite lymphatics, however, have been found passing through the mus- laris, and under the peritoneum a rich subserous plexus of capillaries is present. In the preg- nt uterus these subserous capillaries are much distended (Schick). The *Fallopian tubes* are ovided with lymphatics, but they have not been carefully described.

The *ovary* has a rich superficial lymphatic plexus. In the interior of the gland, according His, the capillaries form networks in the connective tissue framework. In the tunica externa the follicles there is a rich plexus.

The *kidney* has two sets of lymphatics, a superficial, capsular set, and a deep set. The cap- lar set is divided into two layers, one lying directly beneath the peritoneum made up of a wide eshed plexus, and the other in the fibrous capsule of the kidney, with finer capillaries and arrower meshes, which anastomose with the deeper capillaries. The lymphatic capillaries of e kidney parenchyma have been described by Kumita. He found rich plexuses in both rtex and medulla, surrounding the straight and convoluted tubules, the loops of Henle and e collecting tubules. He also found a plexus surrounding and accompanying the blood- ssels into the interior of the glomeruli.

The lymphatic capillaries of the *suprarenal* have also been described by Kumita. His sults agree with those of Stilling, who studied the lymphatics of the suprarenal of horse, cow nd calf. Like the kidney, the suprarenal possesses a superficial and a deep set. The superficial t is in two layers, as in the kidney, the outer lying in the looser tissue around the suprarenal nd the inner lying within and just under the capsule. The latter is made up of a rich lymphatic lexus, which anastomoses with the capillaries of the parenchyma. The parenchymatous mphatics are present in the form of plexuses which surround the groups of cells.

In spite of numerous investigations, endothelial-lined lymphatics have not been definitely und in the central nervous system, or in the peripheral nerves. The subarachnoid and similar paces, including the perineural spaces, do not form parts of the lymphatic system.

Rich plexuses of lymphatic capillaries are present in the *tendons* of *muscles* (Schweigger- eidel and Ludwig). In muscles, themselves, the question of the presence of lymphatics has ng been disputed, sometimes answered in the affirmative, more often in the negative. A tudy by Aagaard, however, would seem to place beyond doubt the presence of lymphatic capil- aries in *striated muscles*. By long continued injection, he was able to find lymphatics in the ntramuscular portions of the tendons, which extended out among the muscle-fibers themselves. He also found capillaries in the tongue musculature.

The *heart* is provided with a subpericardial plexus of lymphatic capillaries. A subendo- ardial plexus has also been described (Sappey, Rainer). Bock has found an extremely rich ymphatic network throughout the substance of the heart. According to his description, the ymphatic capillaries are more numerous than the blood-capillaries.

The *periosteum of bones* is provided with a rich plexus of lymphatic capillaries. They are resent in several layers, of which the outermost form the richest plexus. Lymphatic capillaries ave also been described accompanying the blood-vessels in the Haversian canals in bones Rauber, Schwalbe, Budge). Nothing is known concerning the lymphatics of the bone-mar- ow. *Cartilage* lacks both blood- and lymphatic capillaries.

The capsular membranes of *joints* are richly provided with lymphatic capillaries (Tillmanns). They are arranged in two layers—an inner layer made up of a rich plexus of wide capillaries, ying just outside the subendothelial blood-capillaries, and an outer layer, consisting of a rich lexus in the subsynovial tissue. The lymphatic capillaries have no open connection with the oint-cavity.

The membranes surrounding the *pleural*, *pericardial* and *peritoneal cavities* are richly sup- lied with lymphatic capillaries, which form here thick plexuses under the mesothelium. These lexuses are usually described with the underlying organ, as the subserous lymphatic capillaries f the intestine, etc. In the central tendon of the diaphragm the subperitoneal lymphatics are xtremely rich. They widen out here to form very large endothelial-lined cavities which, in the paces between the connective tissue bundles, lie directly in contact with the peritoneal pithelium. The existence of open connections between these capillaries and the peritoneal and leural surfaces (the 'stomata' of von Recklinghausen) has been disproven. The capillaries n the two surfaces of the central tendon communicate freely with one another.

2. THE LYMPHATIC VESSELS

The lymph which enters the lymphatic capillaries passes over into collecting vessels [vasa lymphatica] which carry it through the lymph-glands (nodes) to the large veins at the base of the neck. The general course of the lymphatic drainage from any given region is usually very similar to that of the corresponding venous drainage. The lymph-vessels course in the loose subcutaneous tissues, in the connective tissues between muscles and organs, often accompanying the arteries and veins, sometimes forming networks around them. An idea of their arrangement can be best obtained by glancing at the illustrations of the lymphatics of special regions. In general they are made up of numerous long, narrow vessels, rarely more than half or three-fourths of a millimeter in diameter, which occasionally communicate with one another, and which converge toward groups of lymph-glands placed in certain definite regions. In the lymph-glands (fig. 625)

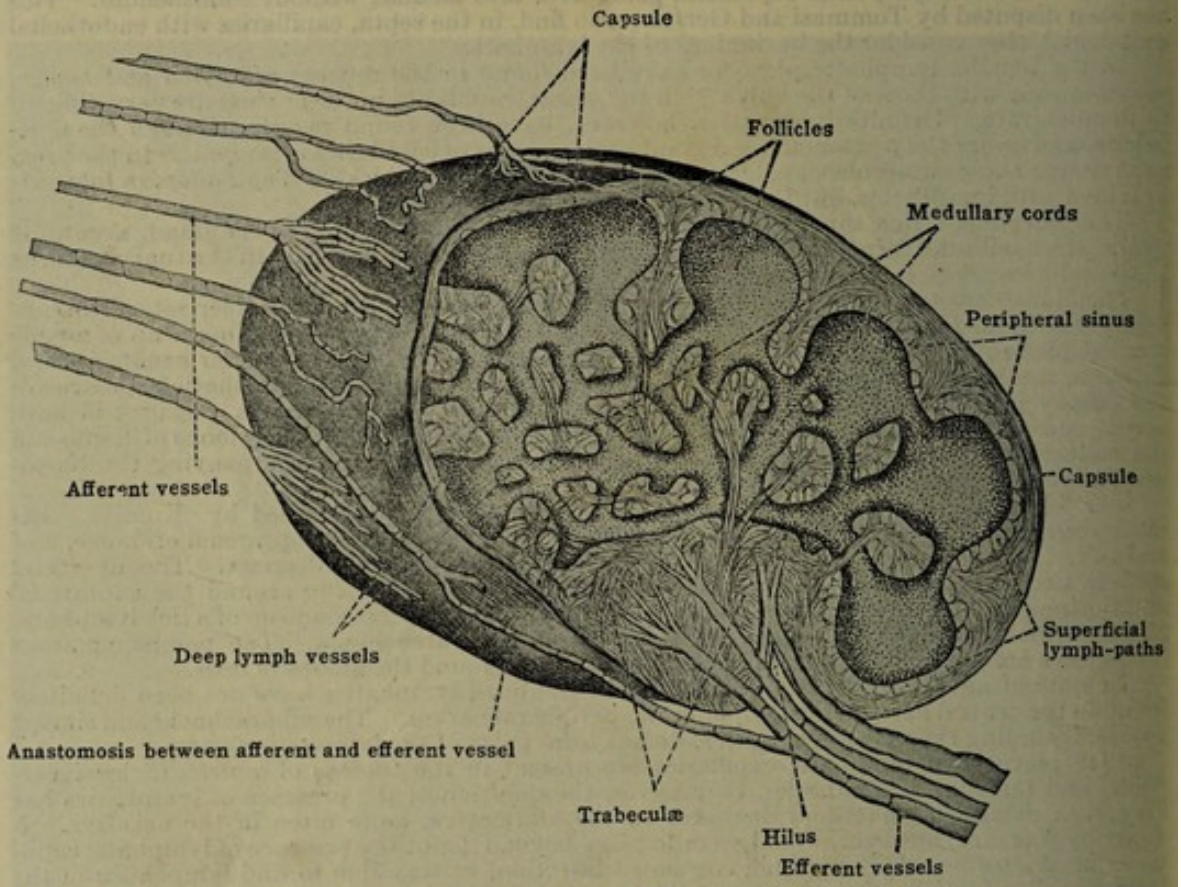

FIG. 625.—DIAGRAM OF A LYMPH-NODE. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

the afferent lymph-vessels break up into capillaries, which again collect into efferent vessels. Several of these efferents from each lymph-gland may pass to a second lymph-gland, where they undergo a second widening into capillaries. In this way the lymph, passing through one, two, three or more lymph-nodes in succession, eventually reaches the thoracic duct, or one of the short ducts, all of which empty into the large veins at the base of the neck. The thoracic duct which receives, at its lower end, the lymph from the lower half of the body, is the only lymphatic vessel which attains any considerable size (four to six mm. in diameter) and is usually the only one large enough to be seen readily without injection.

In *structure* the lymphatic vessels much resemble the veins. They possess an intima, a media and an adventitia, although the line of demarcation between the different layers is not sharp. In the thoracic duct, the endothelium of the intima is succeeded by a delicate layer of fibers, mainly elastic; outside of this is the media, made up mainly of circular smooth muscle-cells, interspersed with elastic and connective tissue fibers; then follows a layer of coarse elastic and connective tissue fibers, which is succeeded by the adventitia, containing longitudinal and transverse bundles of smooth muscle-cells, as well as blood-vessels and nerves. The other lymphatic vessels possess the three layers, which, however, toward the capillaries, grow thinner, and eventually reach a stage in which, outside the endothelium, there are found only single muscle-cells, or muscle-cells in groups of two or three.

The lymphatic vessels are characterized by their great richness in valves, which are present throughout their entire course, from their beginnings in the capillary region to their openings into the veins of the neck. The valves are bi- or tri-cuspid, and are always arranged so as to prevent the flow of lymph back to the capillaries. They thus aid indirectly in the *movement of the lymph*, in that any external pressure on the vessels must always force the lymph onward. The pressure of the surrounding organs and skeletal muscles, and the contraction of the smooth muscle in the walls of the lymph vessels, form important secondary factors in the movement of the lymph. The primary force, however, doubtless comes from the secretory or filtration phenomena of the lymphatic capillary walls.

Nerves of lymphatic vessels.—That the thoracic duct and the smaller lymphatic vessels are provided with nerves has been shown by several observers. According to Kytmanoff (in dogs) the nerves to the lymphatics are mainly non-medullated, and are both motor and sensory. They form four sets of plexuses—adventitial, supramuscular, intermuscular, and subendothelial. Sensory nerve-endings are found in adventitia and media, in the form of free-ending threads,

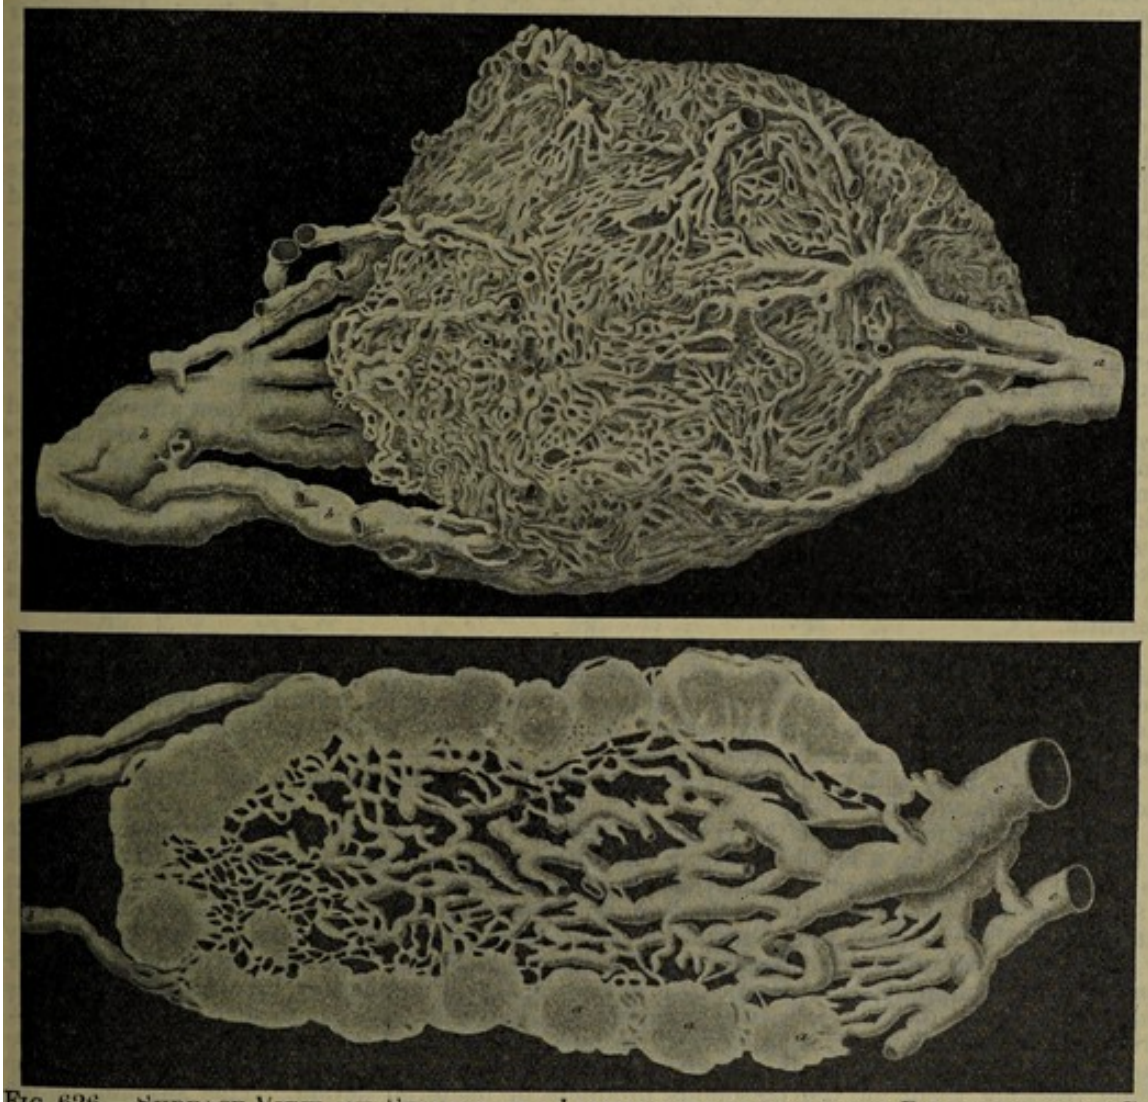

FIG. 626.—SURFACE VIEW AND SECTION OF A LYMPH-NODE SHOWING THE PERIPHERAL AND CENTRAL SINUSES. (After Teichmann.)

and bush-like endings. Motor endings are present in connection with the smooth muscle cells of the media. In the intima there is a plexus of extremely fine varicose threads. The physiological action of the nerves supplying the cisterna chyli has been tested by Camus and Gley who found in dogs a dilation of the cisterna as the result of electrical stimulation of the splanchnic nerve. Florey has observed spontaneous rhythmic contractions of mesenteric lymphatic vessels in guinea-pig and rat, but failed to find them in man and other mammals. In some animals they contracted as a result of stimulation of sympathetic nerves, and in all animals following direct mechanical stimulation.

3. *THE LYMPHOID ORGANS*

Closely associated with the lymphatic capillaries and vessels is a group of glandular structures known as lymphoid organs. They consist, essentially, of groups of round lymphoid cells, lying in a meshwork of reticulum fibers, and having often a definite relationship to the blood- or lymph-vessels. The group of lymphoid organs includes, in addition to the lymph-glands [lymphoglandulæ] or lymph-nodes (lymphonodi NK), which are particularly related to the lymphatic

vessels, the spleen, thymus and (in part) bone-marrow, which are also largely made up of lymphoid tissue. The thymus, however is considered separately with the GLANDS OF INTERNAL SECRETION (Section XIII).

In their most simple form, the lymphoid organs form mere irregular accumulations or patches of lymphoid cells, which have been termed lymphoid infiltrations. Such patches are frequent in mucous membranes especially along the intestinal tract and the air-passages in the lungs.

Larger accumulations of lymphoid cells produce definite round nodules, which may occur singly, as *solitary follicles* or in groups, as *aggregated follicles* (Peyer's patches) (fig. 623). In the solitary follicle the lymphoid cells are arranged concentrically, with a region in the center where the cells are less closely packed together. This is called the germinal center, and contains numerous cells undergoing mitotic division. The solitary follicle contains blood-capillaries. Lymph-capillaries, however, do not enter the follicle but form a rich plexus about it.

The **lymph-glands** or nodes (fig. 625) are larger lymphoid structures,which are developed along the course of the lymph-vessels. They vary much in size, shape, and color, and may occur singly or in small or large groups. The *size* varies from the size of a pin-head to that of an olive, or larger. In *shape* they may be spherical, oval, or flattened on one or more sides, according to their relations to other organs. Each gland has an indentation or hilus, where the arteries enter, and where the veins and efferent ducts emerge. Their *color* depends upon position and state of function. The glands along the respiratory tract are black, due to the presence of carbon granules. The mesenteric glands are milk-white during digestion, and other nodes are pale and translucent when their sinuses are filled with fluid, and pink or even red when red-blood cells are present in the sinuses. The lymph-gland is made up of four distinct elements: lymphoid elements, lymphatic capillaries, supporting structures, and blood-vessels.

The *lymphoid elements* (fig. 625) are arranged as follicles and as cell-strings. The follicles lie around the circumference of the gland, and form the cortex [substantia corticalis]. The cell-string or medullary cords are irregular cords of cells which extend from the follicles through the central or medullary portion [substantia medullaris] of the gland. The follicles and medullary cords are made up, as are the solitary follicles, of round lymphoid cells.

The *lymphatic vessels* (figs. 625, 626) enter the lymph-gland as several vasa afferentia, and leave it, at the hilus, as the vasa efferentia. The vasa afferentia spread out in the cortical portion of the gland into an extremely rich plexus of wide capillaries which surround the follicles, forming the peripheral sinus. The capillaries do not enter the follicle. This plexus continues, around the follicles, into the medullary portion where it forms again a rich plexus, the medullary sinus, in the spaces around the medullary cords. The medullary sinuses are broken up by naked reticulum fibers and cells, which are thus exposed directly to the lymph passing through the gland. At the hilus medullary capillaries collect into larger vessels and emerge as the vasa efferentia.

The *supporting structures* consist of a fibrous capsule surrounding the gland, from which trabeculæ or septa pass in, around and between the follicles and cords. From the septa, a fine reticulum passes into the follicles and cords, where it forms a rich dense meshwork, in the interstices of which lie the lymphoid cells. The capsule and trabeculæ are made up of white fibers, elastic fibers and smooth muscle-fibers.

The *blood-vessels*, which enter and leave at the hilus, send branches into the follicles and into the medullary cords.

The enormous widening of the lymph-stream in the lymph-node from the vasa afferentia to the capillaries—like a brook widening out into a pond—causes a very great diminution in the rate of flow of the lymph. Thus there is present in the gland a very slowly moving stream of lymph, which is separated from the lymphoid tissue outside by a single layer of flattened endothelial cells. There is thus possible an easy interchange of substances, and an opportunity for the passage, through the endothelium, of wandering cells. While the entire mode of functioning of the lymph-gland is not clear, it is known that lymphocytes, formed here, enter the lymph-stream and probably also the blood-stream, and that substances such as, for instance, carbon granules, or leucocytes laden with bacteria, are checked in their course by the lymph-gland. It is also known that lymph-glands become swollen as a result of the presence, in the lymph reaching them, of the poisonous products of bacterial action. This swelling of the lymph gland is an inflammatory process, and is not necessarily to be regarded as protective.

Lymphoid tissue is markedly reduced in amount during starvation (Jolly) and increased by rich feeding (Settles). The number of lymphocytes in the blood stream is increased during digestion.

Variations in lymphoid tissue according to age.—Lymphoid tissue—including lymph-glands, palatine and pharyngeal tonsils, aggregated and solitary follicles, the lymphoid portion of spleen and thymus—is much larger in amount in the child than in the adult (cf. p. 39). In fact, after an early period of relatively rapid growth there is a steady reduction in size, or atrophy, of lymphoid tissue both relative and absolute, which commences before adult life is reached. Miller believes that an exception is furnished by the lymphoid tissue in the lungs, due to the continuous irritation produced by carbon particles inhaled, which are taken up mainly by macrophages, and deposited largely around lymphoid accumulations.

Arrangement.—The lymph-glands are so arranged throughout the body that all the lymph which enters the lymphatic capillaries must pass through one or more lymph-glands on its way to the veins.

It is possible that this rule may have exceptions, although none have yet been definitely proved. Thus, some of the small lymphatics which join the thoracic duct may enter it without having passed through a gland. Moreover, there is often found (fig. 625) a direct anastomosis between an afferent and an efferent lymphatic vessel.

Most of the glands are collected in certain regions, where they form centers toward which the lymphatic vessels radiate. Such groups are termed regional glands. The glands forming such a group are connected with one another by numerous anastomoses, which are termed lymphatic plexuses. In addition to the regional glands there are many isolated glands which lie along the course of the lymph-vessels, and through which pass the vessels draining a much more limited capillary area. Such glands are termed *intercalated* glands.

4. *THE DEVELOPMENT OF THE LYMPHATIC SYSTEM*

Our knowledge of the lymphatic system has been very greatly increased during the past thirty years by studies on its mode of development. Previous to 1902 nothing definite was known about the primary development or the mode of growth of the lymphatic system. It was concluded by some (Budge, Gulland and Saxer) that the lymphatics arise from undifferentiated

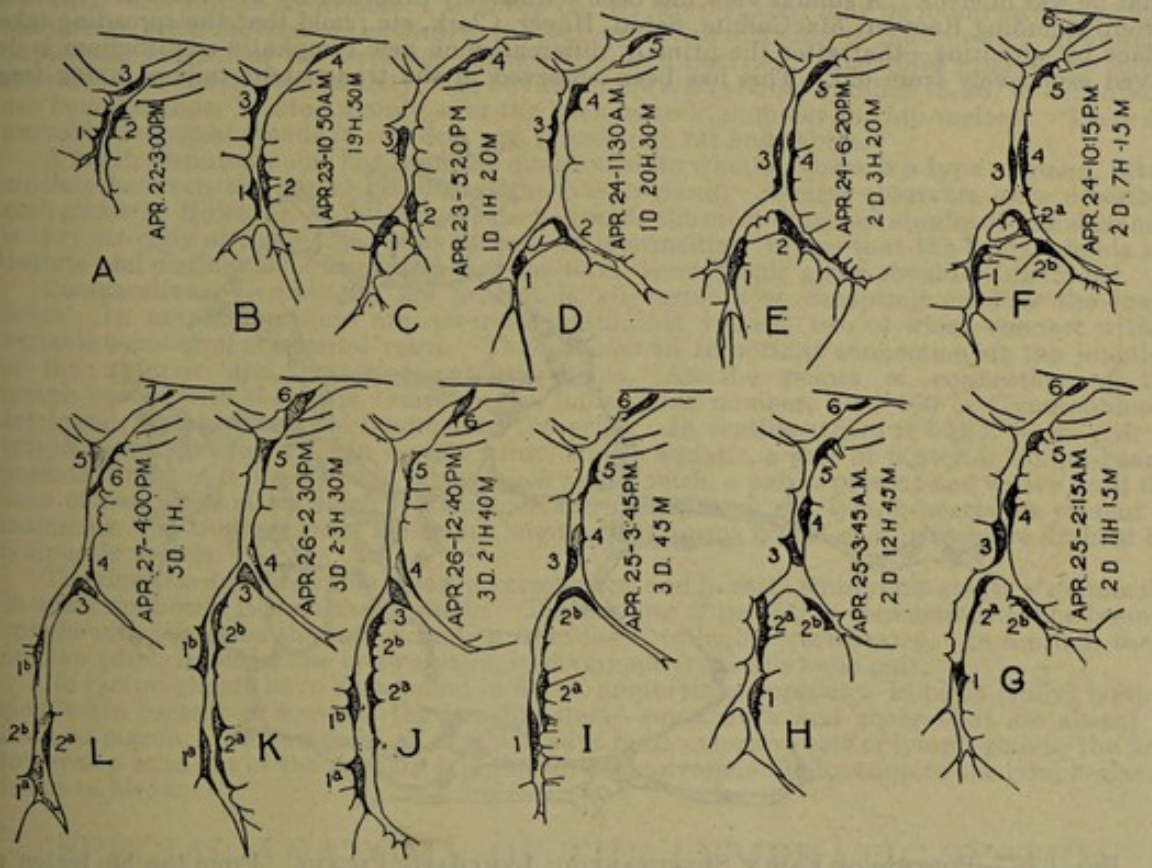

FIG. 627—THE GROWTH OF A LYMPHATIC CAPILLARY, AS SEEN IN THE TRANSPARENT TAIL OF A LIVING FROG-LARVA. Nuclear areas are dotted, and corresponding areas are numbered. (After E. R. Clark.)

mesenchyme cells; Ranvier believed that they arise from veins by budding of the endothelium; while Sala described them as arising partly from the mesenchyme and partly from venous endothelium. Regarding the mode of growth and spreading of the lymphatics, various theories were likewise held. Kölliker, His, Goethe and, later, Sala held that growth takes place by the successive addition of mesenchyme cells; Langer, Rouget, and Ranvier maintained that growth takes place by sprouting of the endothelium. S. Mayer thought that new lymphatics are derived from transformed blood-capillaries.

Miss Sabin, in 1902, gave the first clear picture of the mode of origin and growth of the lymphatic system, and our present knowledge has grown largely out of her discoveries. She showed, by injections of pig-embryos, that the lymphatics of the skin appear first in four regions of the body—two on each side at the base of the neck, and two in the inguinal region—in the form of sacs which are connected with the veins and spread out step by step over the skin of the entire body in the form of a richly anastomosing capillary plexus. Numerous studies have since been made on the mode of development of lymphatics, in many different animals, including man. The results of these studies leave many points still matters of controversy, and several divergent views have been developed, particularly as to the primary source of lymphatic endothelium. Miss Sabin first made the obvious conclusion that it is derived from venous endothelium by a process of sprouting, a view maintained by Hoyer and his pupils. F. T. Lewis described the first lymphatics as forming by the actual transformation of veins into lymphatics—a view which Miss Sabin later concurred in. Huntington and McClure at first also agreed with this view, but later gave it up in favor of the view that all lymphatic endothelium is derived from mesenchyme cells. This view has been supported chiefly by their pupils—Stromsten, Miller and West. E. R. and E. L. Clark failed to find any evidence for the trans-

formation of blood-capillaries into lymphatics. There is pretty general agreement that the earliest endothelium differentiates in certain definite regions, in the neighborhood of the veins. A recent study of the early lymphatics in chick-embryos, however, casts doubt upon the validity of this view. It was found that, in chick-embryos, if regions such as the posterior body-wall and the base of the posterior limb-bud are experimentally isolated from their supposed source of lymphatic supply, lymphatics develop *in loco*—but whether from blood-vessels or mesenchyme cells the authors were unable to determine. However, it has been found by all investigators that lymphatics have numerous connections with the veins, at early stages, particularly in certain regions, and that the number of connections is rapidly reduced, as the separated lymphatics grow together and anastomose, until, in most higher vertebrates, the only connections which persist are those at the right and left jugulosubclavian angles. The exact mode of origin is still in dispute and uncertain, largely on account of difficulties in technique.

The method by which lymphatics extend after their primary differentiation is also a matter of dispute. According to Huntington and McClure, lymphatic endothelium spreads chiefly by the continued differentiation of the indifferent mesenchyme cell into lymphatic endothelium. S. Mayer thought that spreading occurred by the continuous transformation of blood-vessels into lymphatics, although E. R. Clark, working on the same material, showed conclusively that he was in error. A similar view has been tentatively proposed by F. T. Lewis. Another group including Ranvier, MacCallum, Sabin, Hoyer, Clark, etc., hold that the spreading takes place by sprouting—that after the primary differentiation new lymphatic endothelium is derived exclusively from old. This has been observed in the transparent tails of living frog-

Fig. 628.—Portion of Early Subcutaneous Lymphatic Plexus. From the hip region of a chick embryo of 5 days, 7½ hrs. incubation, showing the character of the primitive plexus and the frequency of mitoses (marked X.) (After E. R. and E. L. Clark.)

larvæ (fig. 627). Studies of very early lymphatics in pig- and chick-embryos indicate clearly growth by sprouting (fig. 628). Growth by sprouting of mammalian lymphatics has been finally established by direct observation in the living, in artificial double-walled transparent chambers introduced into the rabbit's ear (Clark and Clark). There is therefore solid basis for the view that lymphatic endothelium, after its primary differentiation (the exact extent of which in time and place has not yet been entirely cleared up), becomes a specific, independent tissue, from which all lymphatic endothelium is derived.

The *lymphatic nodes* do not make their appearance until the system of vessels is well established. They are at first represented by masses of lymphoid tissue in the meshes of a lymphatic network. Later the lymphoid mass breaks up into smaller portions, into which the blood-vessels and branches from the surrounding network penetrate; and each mass, together with the portions of the network surrounding it, becomes enclosed in a connective tissue capsule. The original lymphoid tissue becomes transformed into the medullary cords and cortical nodules of the node, while the enclosing lymphatic capillaries form its peripheral lymph-sinus.

The earliest nodes appear in the places occupied by the primary lymphatic plexuses or sacs (Miss Sabin, F. T. Lewis, Jolly), and have been termed the 'primary nodes' (Miss Sabin). Secondary and tertiary sets of nodes develop later at places of confluence of many lymphatics (cf. A. H. Clark.)

Regeneration and new growth of lymphatic vessels and glands.—While blood-vessels are known to possess throughout life the capacity for regeneration and new growth, this process in lymph-vessels has been studied less fully. Coffin described newly-formed lymphatics in pleural adhesions, Evans in sarcomata, and E. R. and E. L. Clark have watched the process of regeneration and new growth in both the tail of the tadpole and the rabbit's ear. The process is similar to the new formation of blood-vessels, though appreciably slower.

The question as to whether lymph-glands may form anew is not yet entirely settled. The study of the problem is extremely difficult, because very small lymph-nodes may be normally present in a certain region, yet they may escape observation until they become hypertrophied under certain conditions. A. W. Meyer in a careful experimental study found no evidence of new-formation of lymph glands. On the other hand, there is considerable evidence for the new-formation of lymph-glands under pathological conditions.

The hemal nodes.—In addition to the lymph-nodes, there are present in certain animals (bovines, sheep and goats), and probably in man, a set of nodes somewhat similar to lymph-nodes in size, but related to the blood-vascular system, and without any connections with lymphatic vessels—the *hemal nodes* (hæmolymphonodi NK). Their structure resembles that of lymph-nodes, in that there are accumulations of lymphoid tissue, with peripheral and central sinuses, but the sinuses are filled with blood instead of lymph, thus giving them a red color. There is considerable resemblance, histologically, between hemal nodes and accessory spleens, and without doubt the two have frequently been confused. There is still some question as to the precise relationship between the sinuses and the arteries and veins. Some observers hold that arteries supply and veins drain the sinuses, others that the vascular connections of the sinuses are purely venous. Their function is unknown.

Their distribution is variable. In sheep (A. W. Meyer) they may be found anywhere near the viscera, from the base of the skull to the rectum, with a tendency to the following groupings: pararectal, lumbar or prevertebral, mediastinal, and cervical. The total number in sheep averages between thirty and forty. In bovines there is a variable number (2–36) of subcutaneous hemal glands, located mainly over the back in neck, shoulder and hip-regions. There are probably no hemal glands in cat, dog, pig, guinea-pig, rat and rabbit.

A much disputed point has been the question as to whether there is a type of gland, intermediate between the hemal gland and the lymph-gland. Several observers have described such glands. However, A. W. Meyer, who has made the most thorough studies of hemal glands, is very strongly of the opinion that there is no intermediary type—that the hemal glands are definite and distinct structures, and that the term 'hemolymph' gland should be discarded.

Comparative.—Lymphatics are present in all vertebrates, excepting possibly the lower fishes. In amphibia, there are several longitudinal vessels, two of which connect with a variable number of segmental veins. There is also an important connection at the junction of the anterior and posterior cardinal veins. At the points of connection of the lymph-vessels with the veins, lymph-hearts (in variable number, over 100 in Gymnophiona) are found, which pump the lymph into the veins. In reptiles, there is but a single pair of lymph-hearts (posterior). In certain birds, chiefly aquatic, a pair of posterior lymph-hearts persists throughout life, while in others, such as the chick, a pair is present and active until the time of hatching, after which it atrophies and disappears. No lymph-hearts are present in mammals. In the frog there are found large subcutaneous lymph-sacs, which are drained by lymphatic vessels.

The thoracic duct is double in lower vertebrates, and in early embryonic stages of mammals. In adult mammals it is normally single. The number of persistent connections of the lymph-vessels with the veins shows a reduction from lower to higher vertebrates. In reptiles, there are two pairs, in birds, one or two pairs, in mammals (typically) one pair.

No lymph-glands have been found in fishes, amphibia or reptiles. In birds (Jolly) lymph-glands are present in some of the lamellirosters—swan, duck and goose—but are absent in hen and pigeon. In mammals, all of which have more extensive sets of lymph-glands, the first to develop arise out of the primary lymph-sacs and correspond in location to the lymph-glands found in birds.

SPECIAL ANATOMY OF THE LYMPHATIC SYSTEM

The lymphatic system will be considered by regions as follows: A, head and neck; B, upper extremity; C, thorax; D, abdomen and pelvis; E, lower extremity.

A. THE LYMPHATICS OF THE HEAD AND NECK

The lymphatics of the head and neck may be divided into two sets. One set is superficial, draining the entire skin-surface, and has its nodes, for the most part, in the neck, the principal group lying along the external jugular vein. The other set is deeper and drains the mucous membrane of the upper part of the digestive and respiratory tracts, together with the deep organs, such as the thyroid gland, and the tendons of the muscles. The nodes of this set are deeply placed being situated along the carotid arteries, with outlying retropharyngeal nodes.

1. THE SUPERFICIAL NODES OF THE HEAD AND NECK

Lymph-nodes appear first in the neck in the process of development. In the pig the first node to appear develops from the lymph-sac, which is in the supraclavicular triangle behind the sternocleidomastoid muscle. From here vessels grow across the muscle and give rise to a chain of nodes along the external jugular vein. This chain is to be considered as the main chain of superficial nodes in the neck. From it lymphatic vessels grow over the back of the head, the side of the head, the face, and the front of the neck, and in their course groups of secondary

nodes develop. The nodes of the main chain are known as the superficial cervical nodes, and are from four to six in number. The secondary groups are—(1) the occipital; (2) the posterior auricular; (3) the anterior auricular; (4) the parotid; (5) the submaxillary, with the facial as a tertiary set, and (6) the submental

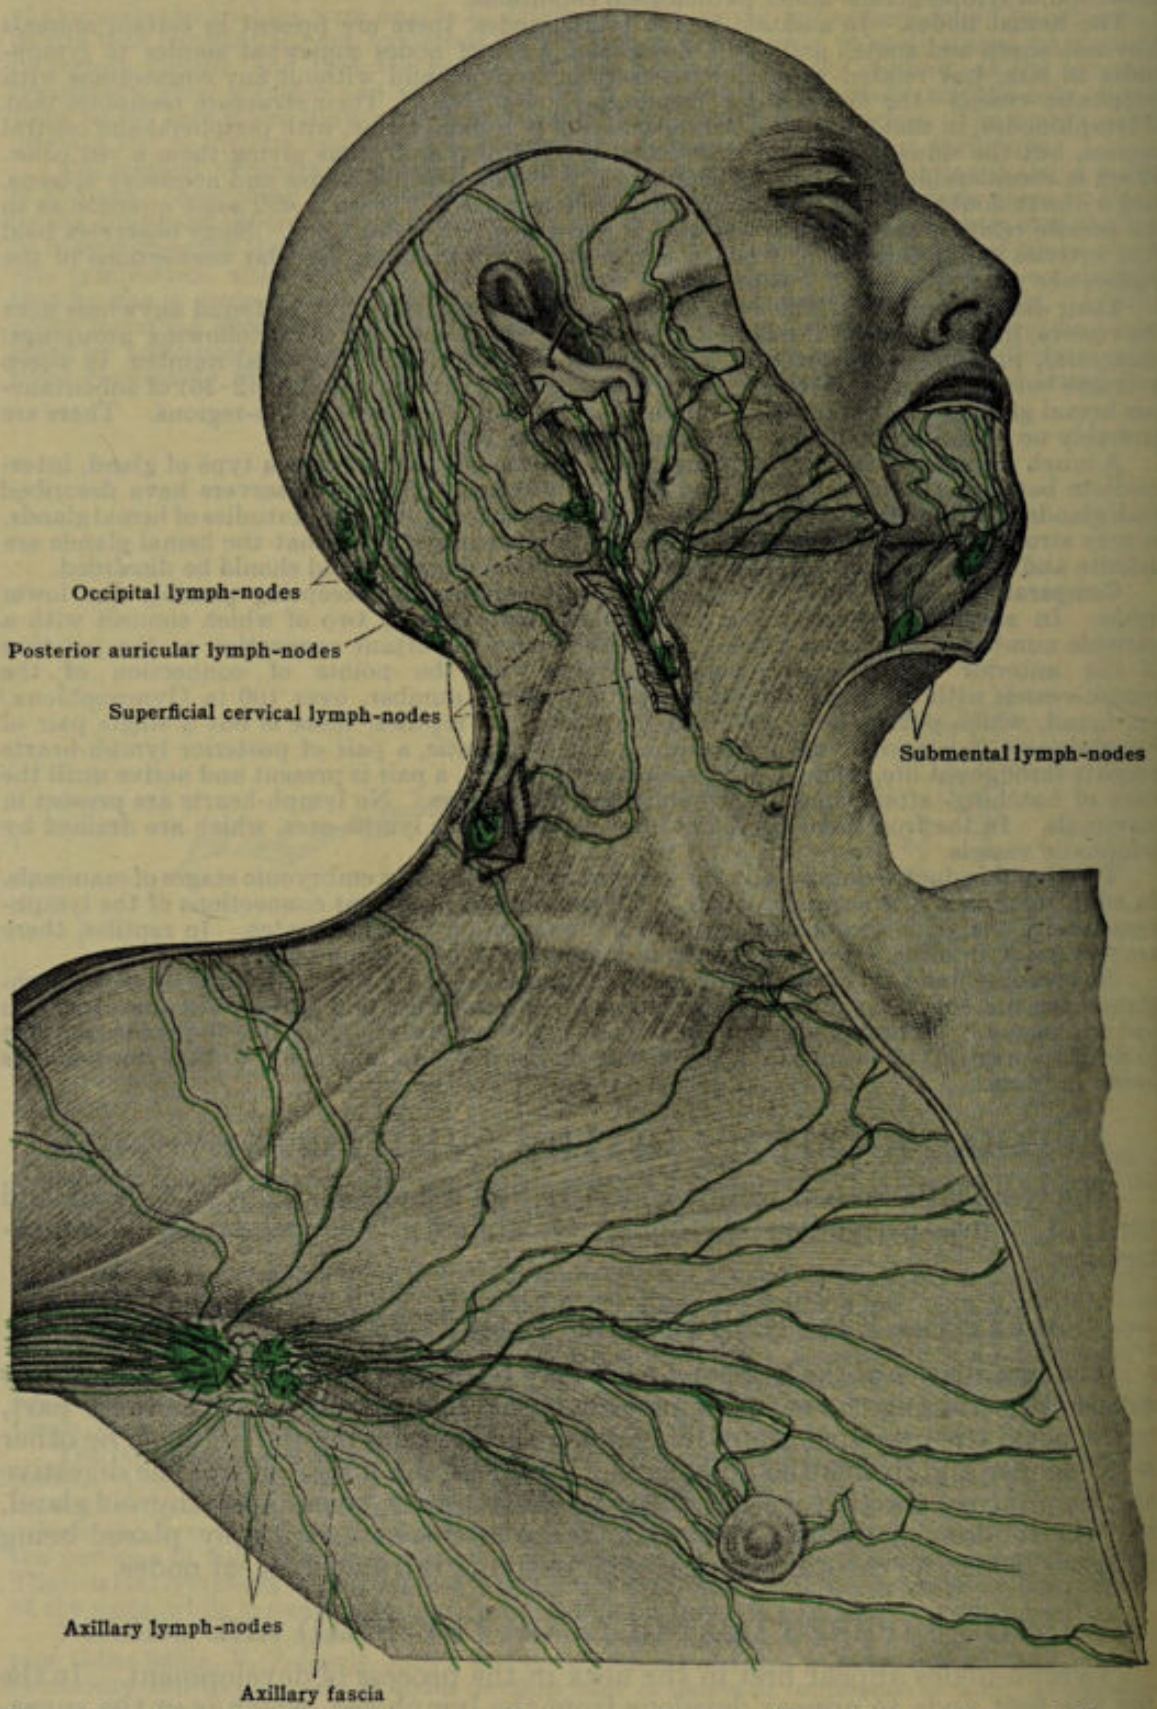

FIG. 629.—THE LYMPHATICS OF THE HEAD AND NECK. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

1. **The occipital nodes** [lymphoglandulæ occipitales].—The lymphatics of the scalp of the back of the head collect into a few trunks that either empty into from one to three small nodes near the occipital insertion of the semispinalis capitis

muscle, or pass by the secondary group and empty directly into the upper nodes of the main superficial cervical chain (figs. 629, 631).

2. The **posterior auricular nodes** [lgl. auriculares posteriores] (lymphonodi retroauriculares NK).—A portion of the temporal part of the scalp, together with the posterior surface of the auricle, except the lobule, and the posterior surface of the external auditory meatus, drain into two small nodes on the insertion of the sternocleidomastoid muscle. The efferent vessels of these nodes pass to the upper part of the superficial cervical chain (fig. 629).

3. The **anterior auricular nodes** [lgl. auriculares anteriores] are few in number—from one to three—and are situated immediately in front of the tragus. They receive vessels from the anterior surface of the auricle and the external auditory meatus, from the integument of the temporal region and the lateral

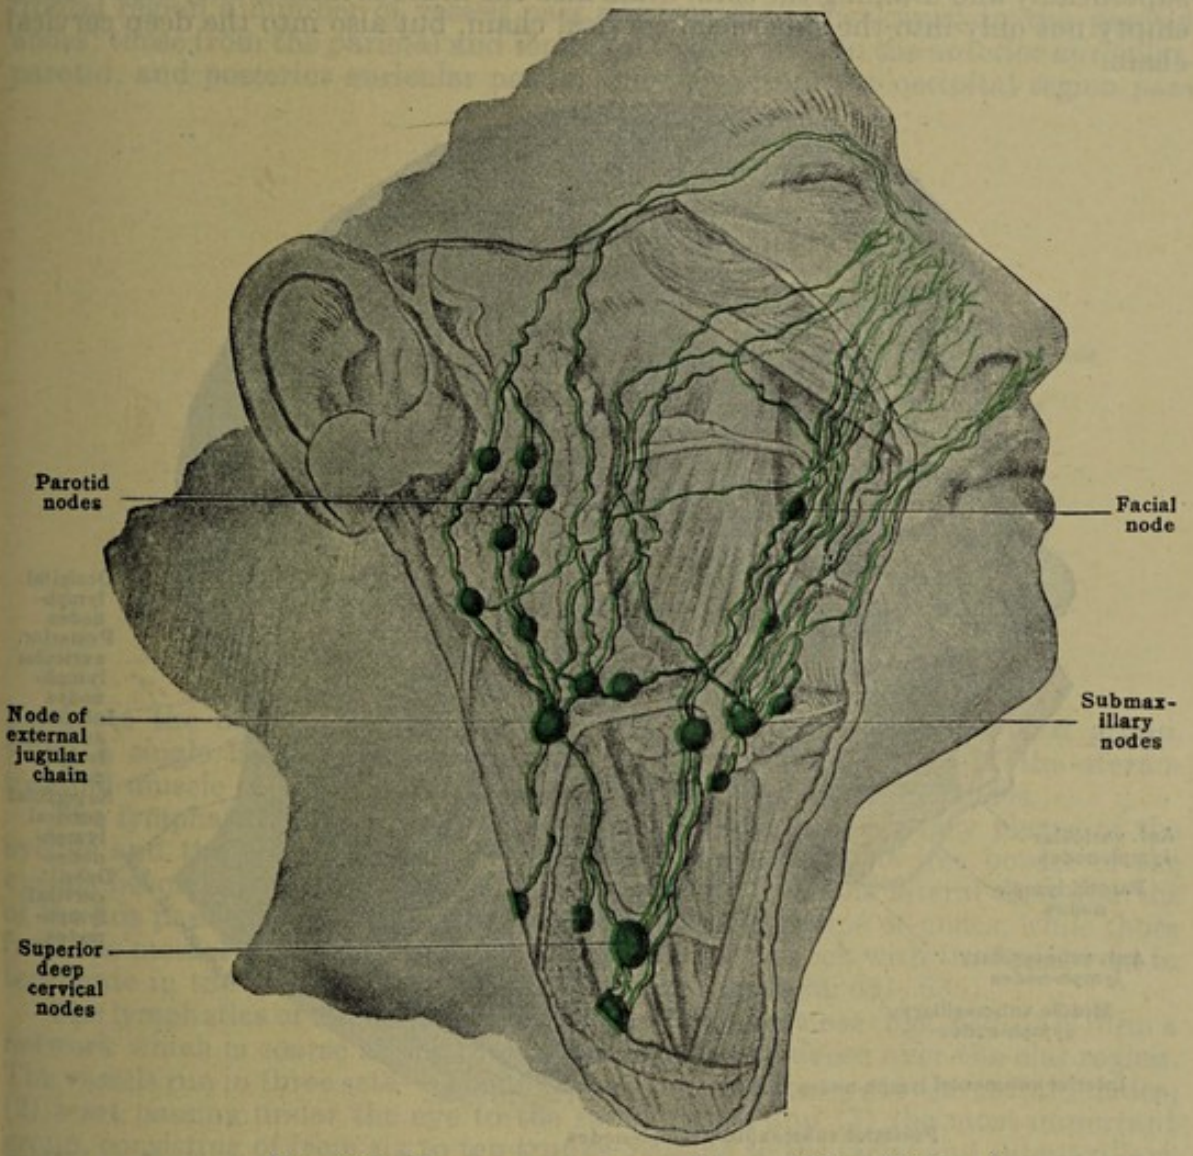

FIG. 630.—LYMPHATICS OF THE FACE. (After Küttner.)

portion of the eyelids. Their efferents pass to the parotid and superior deep cervical nodes (fig. 631).

4. **The parotid nodes** [lgl. parotideae].—The parotid group of nodes (figs. 630, 631, 635) is considerably larger than the two preceding, containing from ten to sixteen nodes, and the group drains a more complex area. It receives vessels from the adjacent surface of the external ear, the external auditory meatus, the skin of the temporal and frontal regions, and the eyelids and nose. The deeper nodes of this set receive vessels from the parotid gland.

In the embryo these nodes lie in the pathway of the lymph-vessels that grow to the scalp; many of these vessels, however, pass the parotid group and empty into the superficial cervical chain. The nodes of the parotid group lie embedded in the substance of the parotid gland, and their efferents pass to the submaxillary and the superior superficial and deep cervical nodes.

As 'inferior auricular nodes' (fig. 631), Bartels designates one or two small glands of the parotid group which lie below the ear, and receive afferent vessels from its lower part.

5. **The submaxillary and facial nodes.**—The submaxillary (lymphonodi submandibulares NK) group (figs. 630, 631, 635) consists of a chain of from three to six nodes, resting on the submaxillary (salivary) gland, along the inferior border of the mandible. They lie usually on the submaxillary gland, but may extend from the insertion of the anterior belly of the digastric to the angle of the jaw. They are about 5 mm. in diameter, and the largest is near the point where the external maxillary (facial) artery crosses the mandible. The submaxillary nodes, together with the next group, the facial, drain a complex area, including not only skin, but mucous membrane. They receive lymph-vessels from the nose, cheek, upper lip, the lateral part of the lower lip, together with almost all those from the gums and teeth and from the anterior third of the lateral portions of the tongue. In agreement with the fact that these nodes, though lying superficially and draining the skin, drain also the mucous membrane, their vessels empty not only into the superficial cervical chain, but also into the deep cervical chain.

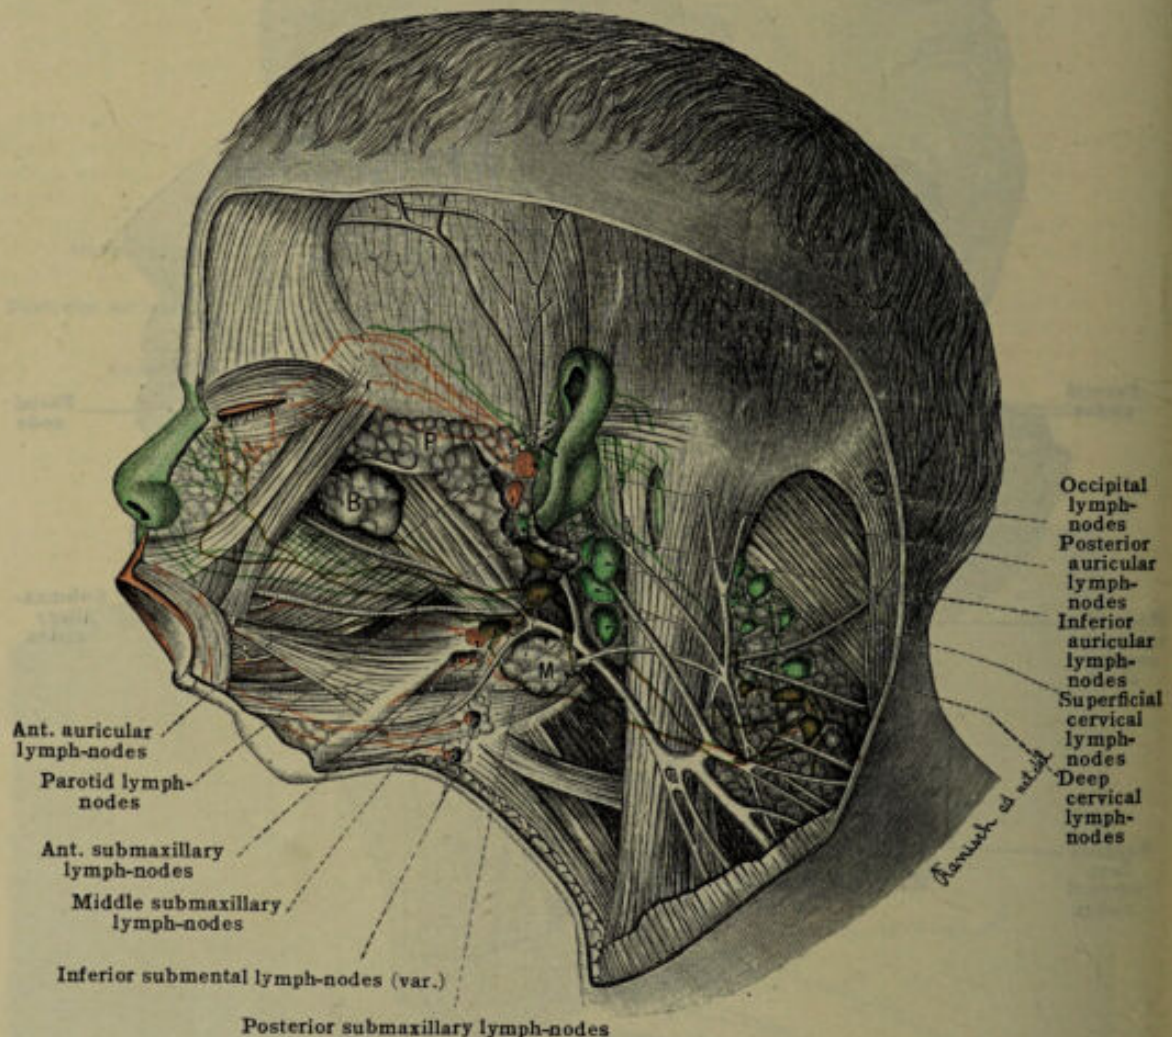

FIG. 631.—LYMPHATIC NODES AND VESSELS OF THE EAR, EYELIDS, NOSE AND LIPS. Newborn child. P, parotid. M, submaxillary gland. B, buccal fat ('sucking pad'). The dorsal deep cervical lymph-nodes are not labelled. (After Bartels.)

The **facial nodes** (lymphonodi faciales profundi NK) (figs. 630, 632) are evidently outlying nodes of the submaxillary group. They are in two main sets—(1) the **supramaxillary set,** which consists of from one to thirteen nodes, resting on the mandible near the point where it is crossed by the external maxillary (facial) artery; (2) the **buccinator set,** lying on the line connecting the lower margin of the ear and the angle of the jaw.

Of these latter nodes, some lie near the point where the parotid duct perforates the buccinator muscle; the others are further forward, between the external maxillary artery and the anterior facial vein. Additional nodes belonging to the group may occur near the nose and in the suborbital region. These facial nodes receive afferents from the outer surface of the nose, the lips, eyelids, cheek, temporal part of the face, the mucosa of the mouth, the teeth of the upper jaw, the gums, the tonsils, and the parotid gland. Their efferents pass to the submaxillary and parotid nodes.

6. The **submental nodes,** usually two in number, lie in the triangle bounded by the anterior bellies of the two digastric muscles and the hyoid bone (figs. 629, 631, 637). They are usually near the median line, and drain the skin of the chin, the skin and corresponding mucous membrane of the central part of the lower lip and jaw, the floor of the mouth, and the tip of the tongue. The efferent vessels pass either to the submaxillary nodes or to the deep cervical chain.

2. THE LYMPHATIC VESSELS OF THE FACE

The different parts of the face and their lymphatic relation to these groups of superficial nodes will now be considered.

The **lymphatics of the scalp** (figs. 629, 635) form a rich network in the neighborhood of the vertex, from which vessels pass in various directions. From the frontal region a number of vessels pass downward and backward to the parotid nodes; those from the parietal and temporal regions pass to the anterior auricular, parotid, and posterior auricular nodes; and those from the occipital region pass

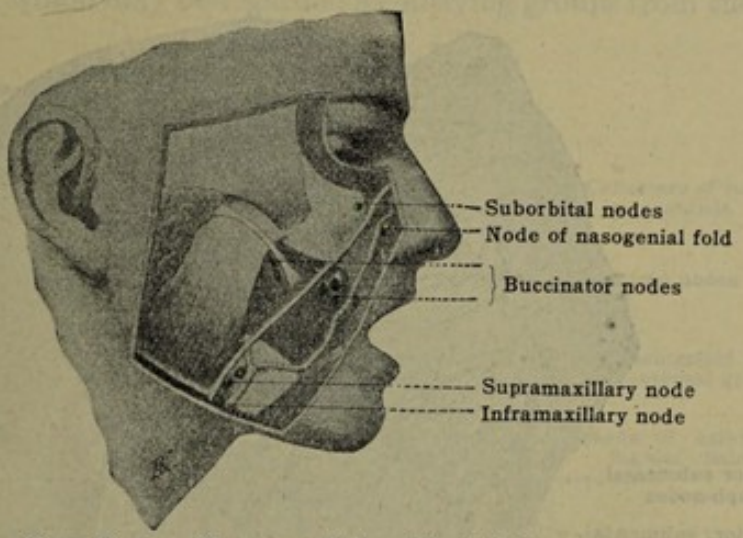

FIG. 632.—THE FACIAL NODES. (After Buchbinder.)

partly to the occipital nodes and partly to the superior deep cervical group, while a single large vessel descends along the posterior border of the sternomastoid muscle to terminate in one of the inferior deep cervical nodes.

The lymphatics of the eyelids and conjunctiva.—The capillary plexus of the eyelids and the conjunctiva is an abundant one, and at the free border of the eyelids becomes extremely close. The lymphatics from the lateral three-fourths of the lids pass to the anterior auricular and parotid groups of nodes, while those from the medial one-fourth pass obliquely across the cheek with the facial vein to terminate in the facial and submaxillary nodes (figs. 630, 631, 635).

The lymphatics of the nose.—The lymphatics of the nose (figs. 630, 631) form a network which is coarse at the root of the organ, but dense over the alar region. The vessels run in three sets—(1) one set passing over the eye to the parotid nodes; (2) a set passing under the eye to the same nodes; and (3) the most important group, consisting of from six to ten trunks, passing to the facial and submaxillary nodes. There are some anastomoses between the capillaries of the skin and those of the mucous membrane of the nose.

The lymphatics of the lips (figs. 633, 635).—The capillary plexuses of the skin and mucous membrane are continuous at the free border of the lips. The vessels of the upper lip, of which there are about four on each side, pass to the submaxillary nodes. From the lower lip the trunks from near the angle of the mouth pass to the submaxillary nodes, while those from the center of the lip pass to the submental nodes.

There are from two to four subcutaneous vessels and from two to three submucous vessels on either side. The collecting trunks passing to the submaxillary nodes do not anastomose, and the same is true of the submucous vessels of the lower lip. On the other hand, the subcutaneous vessels passing to the submental nodes anastomose freely, an important fact in connection with the extension of cancer of the lower lip.

The lymphatics of the auricle and external auditory meatus.—The lymphatic plexus in the auricle, external auditory meatus, and the outer side of the tympanic

membrane is an abundant one. An anastomosis has been described between a scanty plexus on the inner side of the tympanic membrane and the plexus on the outside. The collecting vessels pass to three sets of nodes:—(1) those from the external and internal surface of the auricle and the posterior part of the external auditory meatus pass to the posterior auricular nodes; (2) those from the lobule, the helix, a part of the concha and the outer portion of the external auditory meatus pass to the inferior auricular and superficial cervical chain; some of the vessels from the first and second areas also run to the deep cervical group; (3) an anterior group from the tragus and part of the external auditory meatus consisting of from four to six trunks, pass to the anterior auricular nodes, which are connected with the parotid nodes.

3. THE DEEP LYMPHATIC NODES OF THE HEAD AND NECK

The **deep cervical chain** (figs. 630, 631, 633–635) is the largest mass of nodes in the neck. It consists of from fifteen to thirty nodes, which lie along the entire

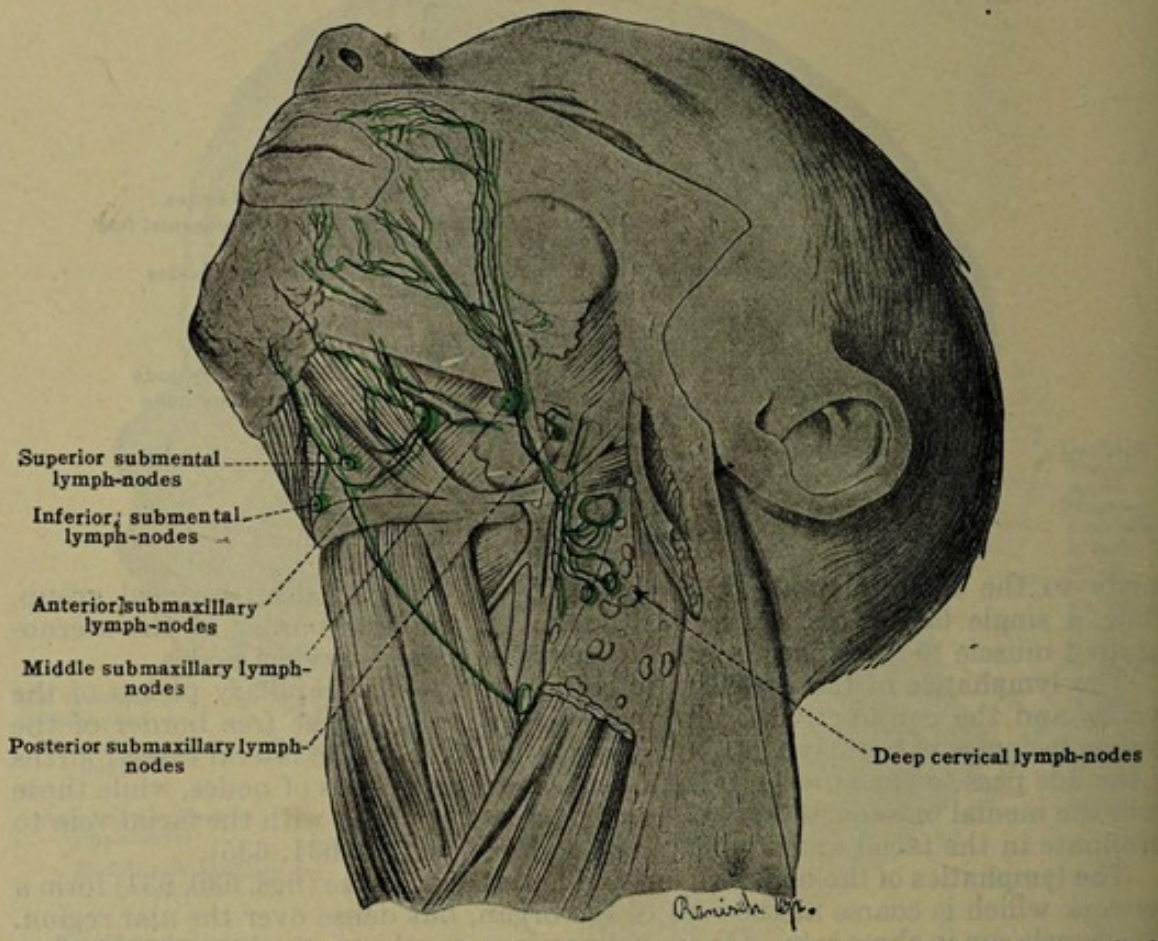

FIG. 633.—THE LYMPHATICS OF THE LIPS. Newborn child. (From Bartels after Dorendorf.)

course of the carotid artery and internal jugular vein. This chain receives vessels from all the superficial nodes, also directly from the skin, as well as from the entire mucous membrane of the respiratory and alimentary tracts in the head and neck. Thus it drains both the superficial and the deep structures.

For convenience of description this long chain, though usually continuous, is divided into two groups—(1) a superior group, lying above the level at which the omohyoid muscle crosses the carotid artery, and (2) an inferior or supraclavicular group, lying below that level.

(1) **The superior deep cervical nodes** [lgl. cervicales profundae superiores] extend from the tip of the mastoid process to the level at which the omohyoid muscle crosses the common carotid artery. The **dorsal** and smaller nodes of the chain lie on the splenius, levator scapulæ, and scalene muscles (fig. 631). They drain the skin of the back part of the head, both indirectly and directly, and receive (1) efferents from the occipital and posterior auricular nodes, (2) a large vessel from the skin of the occipital part of the scalp, (3) some trunks from the auricle, and (4) cutaneous and muscular vessels from the neck. The **ventral**

nodes of the chain lie on the internal jugular vein. They drain the face both directly and indirectly, as well as the deeper structures of the head and neck. They show especially well in fig. 637 in connection with the tongue. (See fig. 635.)

(2) The **inferior deep cervical** [lgl. cervicales profundae inferiores] or supraclavicular nodes lie in the subclavian triangle (fig. 635). In the upper part of the triangle the nodes rest on the splenius, the levator scapulæ, and the scalene muscles, while at the base of the triangle they are related to the subclavian artery and the nerves of the brachial plexus. They drain a wide area, receiving vessels from the head, neck, arm, and thoracic wall. They are connected with the superior deep cervical chain, and receive afferents from the axillary nodes, and, in addition, they receive vessels directly from the back of the scalp, from the skin of the arm, and from the pectoral region. Thus it will be seen that a large part of the lymph of the head and neck, as well as some from the arm and thorax, passes through these nodes. Their efferents unite to form the jugular trunk, which ends at the junction of the internal jugular and subclavian veins.

In the descriptions of the deep lymphatic vessels certain additional groups of nodes will be considered, which may be regarded as outlying groups from the deep cervical chain.

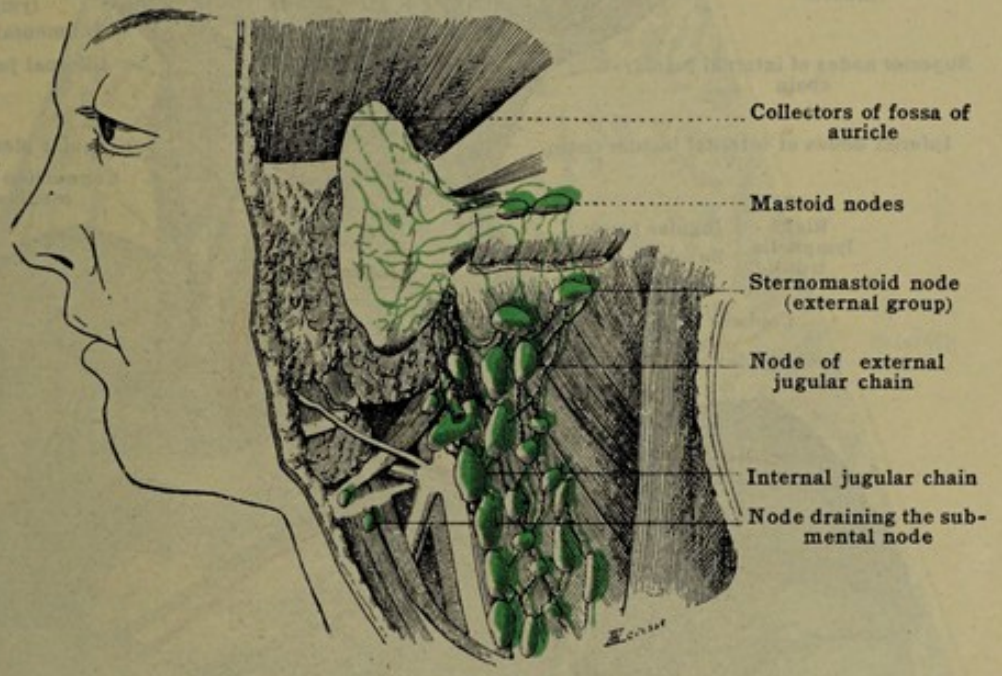

FIG. 634.—THE DEEP CERVICAL CHAIN. (After Poirier.)

4. THE DEEP LYMPHATIC VESSELS OF THE HEAD AND NECK

The lymphatics of the brain.—It is now recognized that there are no lymphatics in the brain and cord, so that the function of absorption must be accomplished by means of the veins. There is an abundant exudation of lymph around the nervous system into the subdural space, which is connected with the central canal of the nervous system, and which is to be considered as a zone in which the tissue-spaces are especially large. Along the arteries of the brain the adventitia is loose and open, possessing tissue-spaces which have received the confusing name of perivascular lymphatics. A better name would be perivascular tissue-spaces.

There is a continuous renewal of the fluid in the cerebral ventricle, chiefly derived from the choroid plexus. It passes into the subarachnoid spaces through the three foramina in the roof and at the sides of the fourth ventricle. Fluid is removed from the subarachnoid spaces chiefly by passing through the arachnoidal villi into the venous sinuses of the cranium.

The lymphatics of the eye.—No lymphatic vessels have as yet been discovered either in the eyeball or in the orbit. In both, however, there are abundant tissue-spaces, the most noteworthy of the orbit being the **interfascial space (space of Tenon)**, which communicates by a space between the optic nerve and its sheath with the subarachnoid spaces of the cranial cavity.

In the eyeball the tissue-spaces are abundant, aside from the vitreous and aqueous chambers. Numerous spaces exist in the choroid coat, especially in the lamina suprachoroidea, and in the sclerotic, both sets communicating by perivascular spaces surrounding the venæ vorticosæ with

the interfascial space. In the cornea there are abundant lacunæ, united by their anastomosing canaliculi, to form a network of lymph-spaces which come into close relation with the conjunctival lymphatics at the corneal margin.

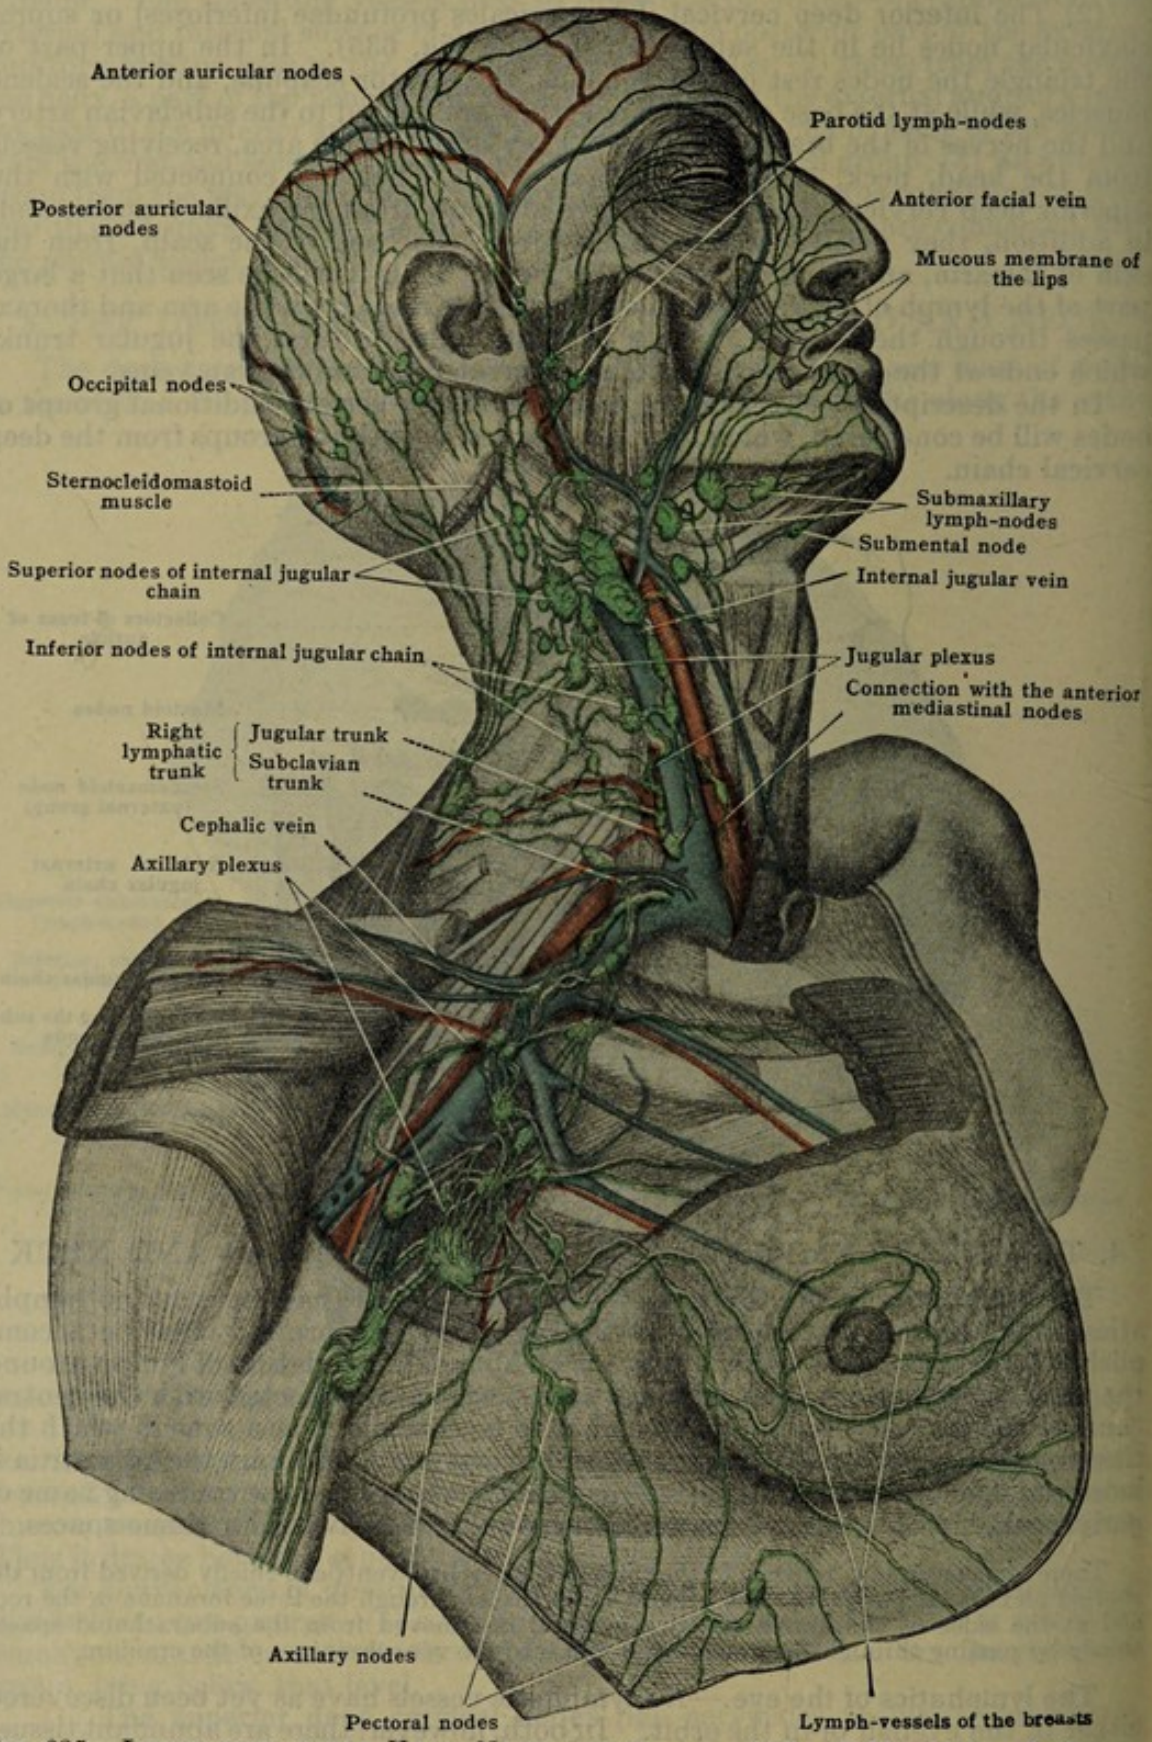

FIG. 635.—LYMPHATICS OF THE HEAD, NECK, AND AXILLA. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

The **conjunctiva,** however, being a portion of the integument, does possess lymphatic vessels (fig. 636), arranged in a double network whose collecting vessels accompany those of the eyelids, and terminate with them in the submaxillary, anterior auricular, and parotid nodes.

The Lymphatics of the Digestive Tract in the Head and Neck

The lymphatics of the gums and teeth.—The lymphatics from the mucous membrane of the gums pass to the submaxillary nodes. The capillary plexus is abundant; the collecting vessels arise from it on the inner surface of the gum, and pass between the teeth to reach a common semicircular collecting vessel on the outer surface. Lymphatics occur also in the pulp of the teeth (Schweitzer).

Both injections (Schweitzer) and clinical experience (Partsch and Ollendorff) indicate that the lymphatics which drain the pulp of the teeth of the upper jaw emerge through the infra-orbital foramen and pass chiefly to the middle and posterior submaxillary nodes, with exceptional drainage to the anterior submaxillary and parotid nodes. Those draining the teeth in the lower jaw pass along the mandibular canal to end chiefly in the middle submaxillary nodes, with occasional passage to the anterior or posterior nodes of this group.

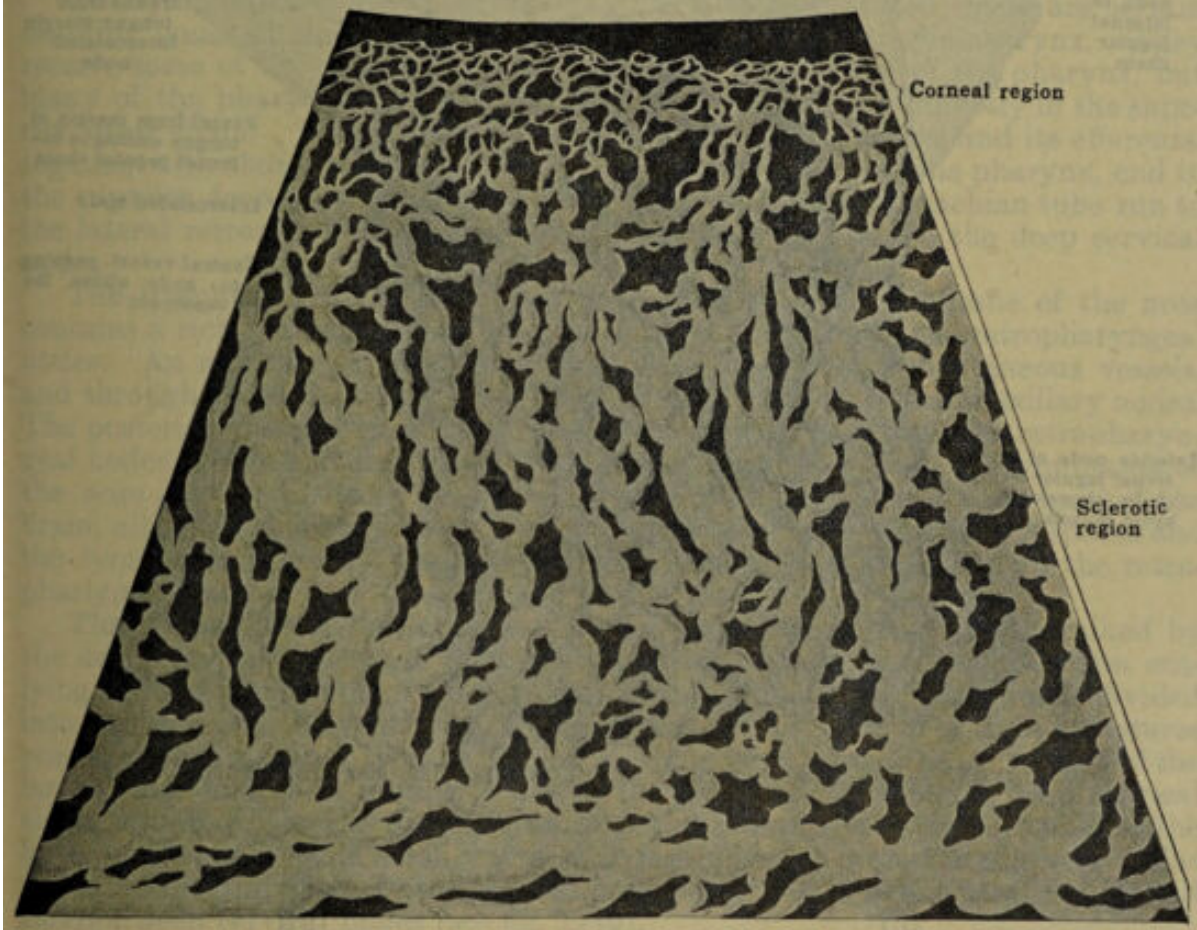

Fig. 636.—The Lymphatics of the Conjunctiva, Surface View. (After Teichmann.)

The lymphatics of the tongue (fig. 637).—There is a rich lymphatic plexus throughout the entire extent of the submucosa of the tongue, but that portion lying in the basal part of the tongue seems to be more or less independent of the rest. According to Aagaard the tongue muscles are provided with lymphatics which are drained by the vessels from the submucosal plexuses. There are four groups of collecting vessels—(1) apical, (2) marginal, (3) basal, and (4) central.

(1) The *apical vessels* are usually four in number, two on each side. One pair perforates the mylohyoid muscle and ends in a suprahyoid median node, while the other pair pass to the deep cervical chain. The latter are long, slender vessels, which run along the frenum of the tongue to the surface of the mylohyoid muscle, cross the hyoid bone just behind the pulley of the digastric and then run downward in the neck to a node of the deep cervical chain, just above the omohyoid. It will be noted in fig. 637 that the most anterior vessels end in the lowest nodes, while those from the back of the tongue end in higher nodes.

(2) The *marginal vessels* are from eight to twelve in number. They all pass to the superior deep cervical nodes, a part of them passing external to the sublingual gland, while the larger number pass internal to it. There is one large and constant node at the point where the digastric muscle crosses the jugular vein, to which a large number of the vessels converge.

(3) The *basal vessels* are seven or eight in number, and drain the basal portion of the tongue. Some end in the large node just mentioned, while others run backward close to the median line, where they anastomose, as far as the glossoepiglottidean fold, when they separate and join the tonsillar vessels to pass outward to the superior deep cervical nodes.

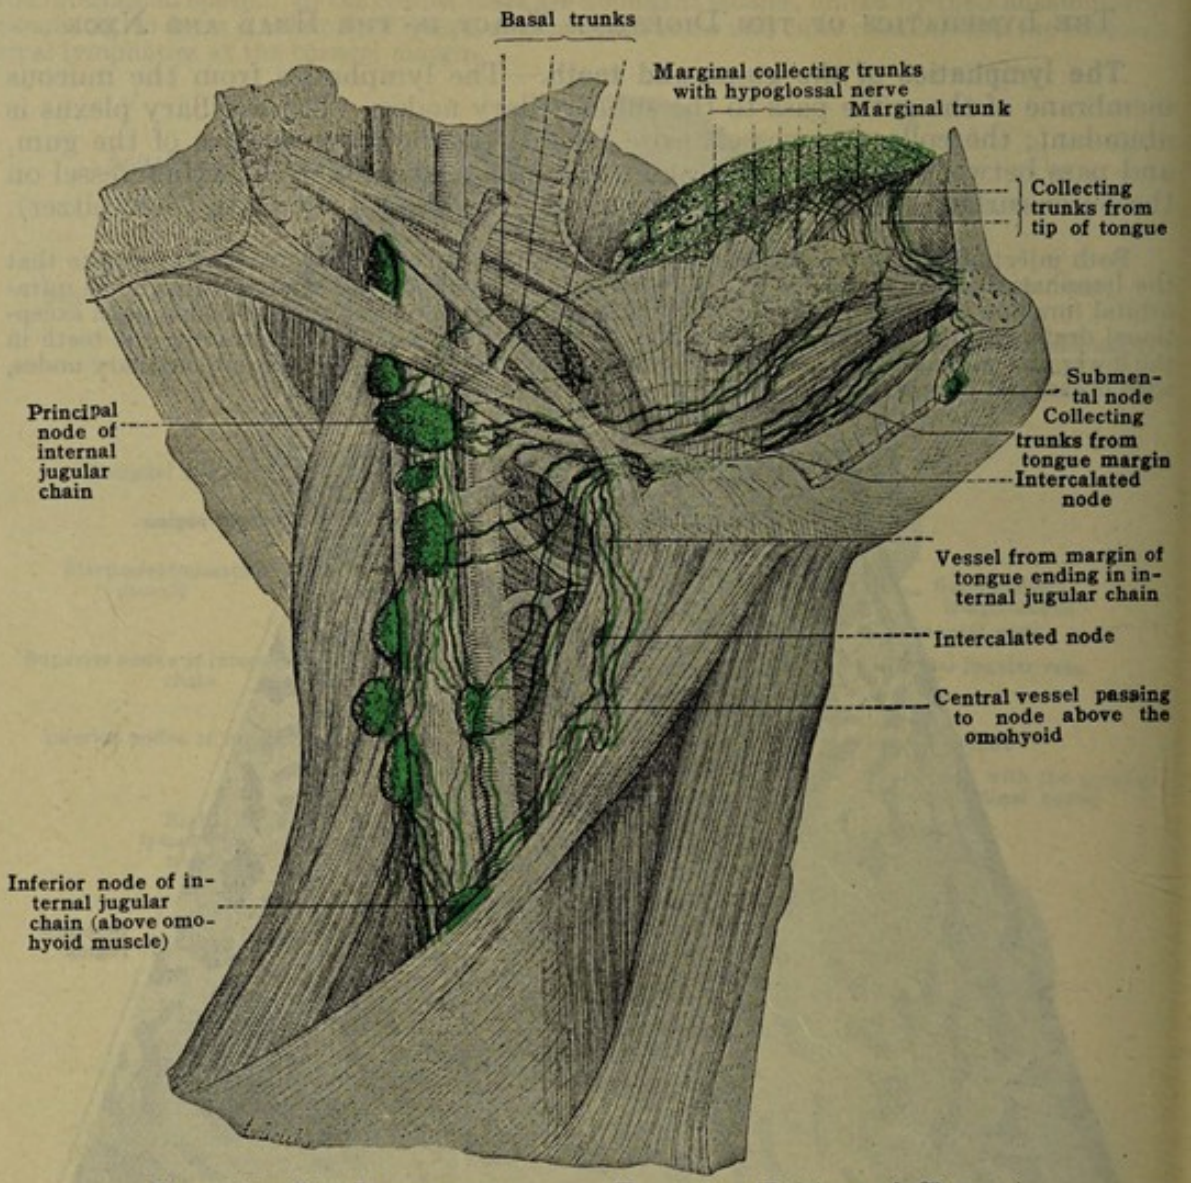

FIG. 637.—THE LYMPHATICS OF THE TONGUE. (Poirier and Charpy.)

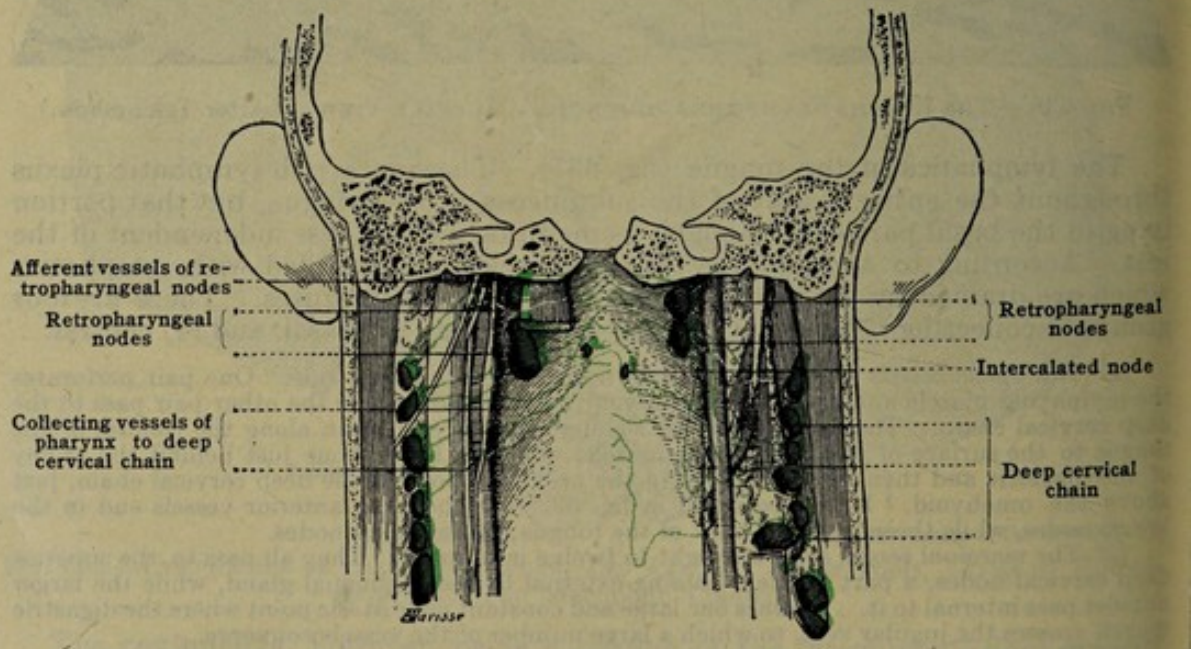

FIG. 638.—THE LYMPHATICS OF THE PHARYNX. (After Poirier and Cunéo.)

(4) The *central vessels*, arising from the central portion of the tongue, pass backward in the median line on the ventral surface of the tongue. They lie upon the mylohoyoid muscle, cross the hyoid bone, and end in the superior deep cervical chain.

The lymphatics of the palate.—The lymphatics from the palate pass to the deep cervical chain. The trunks from the hard palate run in the submucosa as far as the last molar tooth, where they pass in front of the anterior palatine arch (pillar) and end in the superior deep cervical nodes beneath the digastric muscle. In the soft palate the capillary plexus is very rich, reaching a maximum in the uvula. From the inferior surface of the soft palate and the palatine arches vessels pass directly to the superior deep cervical chain, but some of the vessels from the upper surface of the soft palate run forward with the pharyngeal vessels and end in the *retropharyngeal nodes*. It will be seen from fig. 638 that the retropharyngeal nodes are simply outlying nodes from the deep cervical chain.

The lymphatics of the pharynx.—As has just been stated, there are certain outlying nodes of the deep cervical chain which lie behind the pharynx. They receive some of the vessels from the submucosa of the roof of the pharynx, but many of the pharyngeal vessels pass by these nodes and end directly in the superior deep chain. The tonsil is especially rich in lymphatics, and its efferents, together with those from the middle and inferior portions of the pharynx, end in the superior deep cervical chain. The lymphatics of the Eustachian tube run to the lateral retropharyngeal lymph-nodes or, passing these, to the deep cervical nodes.

The lymphatics of the nasal cavities.—The mucous membrane of the nose contains a rich lymphatic plexus whose main trunks pass to the retropharyngeal nodes. An anterior set, however, anastomoses with the subcutaneous vessels, and through these their lymph is conveyed to the facial and submaxillary nodes. The posterior vessels run either to the deep cervical chain or to the retropharyngeal nodes. Key and Retzius have shown that an injection of the lymphatics of the nose may be made by injecting the subarachnoid spaces at the base of the brain, although there is presumably no direct connection between the spaces and the lymphatic vessels. The lymphatics of the nasal sinuses end in the retropharlyngeal nodes.

The lymphatics of the larynx.—The larynx is, for the most part, drained by the deep cervical nodes, although its lymph may also pass through certain outlying nodes situated upon its ventral surface. The mucous membrane is divided into two zones by the ventricular folds, the mucous membrane of these structures possessing but a scanty lymphatic plexus. The vessels from the upper part of the larynx, four or five in number, pass to the nodes of the superior deep cervical chain, situated near the digastric muscle; those from the lower part pass to the lower nodes of the same chain, some even descending as far as the supraclavicular nodes. The lymphatics of the trachea pass, on each side, to the paratracheal and inferior deep cervical nodes (see fig. 1149).

The lymphatics of the thyroid gland.—The lymphatics of the thyroid gland pass either to the small nodes situated in front of the larynx and trachea, or to nodes of the deep cervical chain, a part of them ascending and a part descending. The lymphatics of the thyroid region are shown in fig. 1149.

It will thus have been seen that the lymphatics of the mucous membrane of the head and neck all end in the deep cervical chain of nodes or in its outlying nodes. Some of the vessels pass by the outlying nodes, but since the nodes of the chain are so closely connected, the lymph must pass through several nodes before entering the veins. The palatine tonsils, the numerous lingual and pharyngeal tonsils, together with small lymph-follicles in the submucosa of the respiratory tract, represent lymph-nodes in the capillary zone.

B. THE LYMPHATICS OF THE UPPER EXTREMITY

1. THE LYMPHATIC NODES OF THE UPPER EXTREMITY

The lymph-nodes of the arm lie, for the most part, in the axilla, where there is a large group of nodes which receive almost the entire drainage of the arm and the thoracic wall. In addition, there is in the arm a set of outlying superficial nodes, the superficial cubital (supratrochlear), while small isolated nodes are often intercalated along the course of the deep lymphatic vessels which accompany the

radial, ulnar, anterior interosseus and brachial arteries, the cephalic vein, and the deep cubital vessels. The cubital nodes are shown in figs. 639 and 641.

(1) The **antibrachial nodes** are very small nodes (size of pin-head) intercalated along the deep lymphatics which accompany the radial, ulnar, anterior and posterior interosseus arteries.

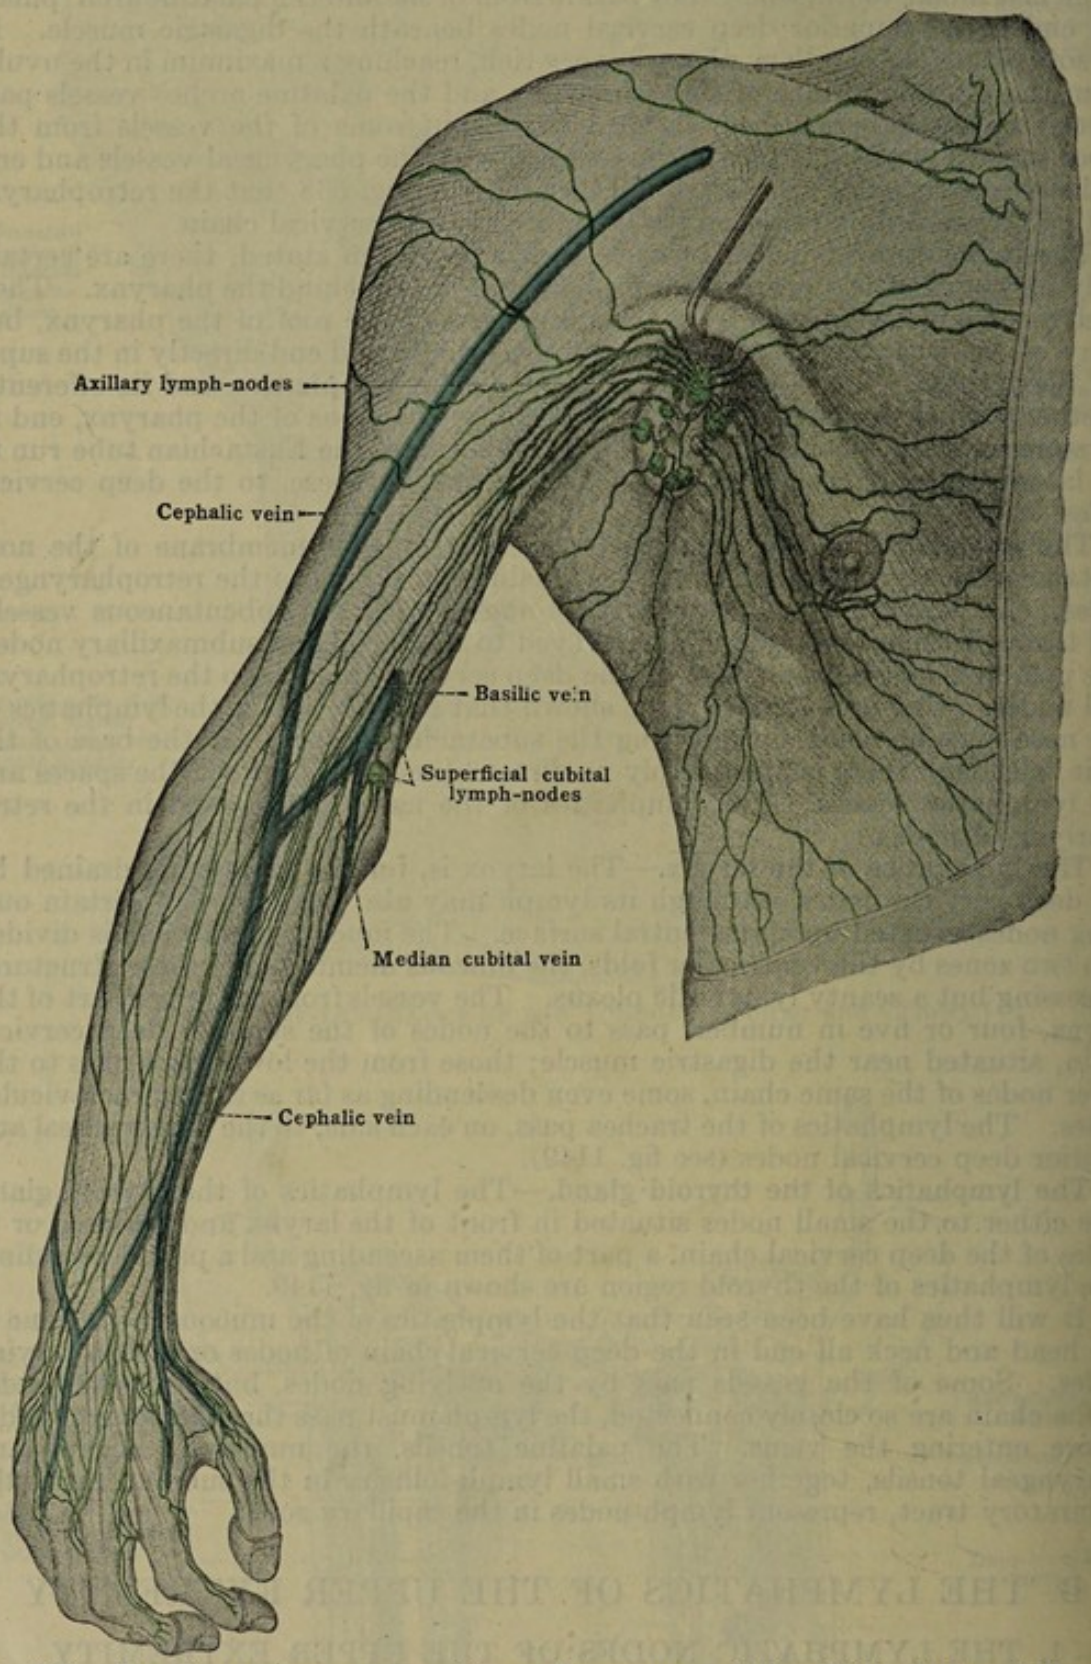

FIG. 639.—THE LYMPHATICS OF THE UPPER EXTREMITY. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

(2) The **deep cubital nodes** [lgl. cubitales profundæ] are also very small nodes, one or two in number, intercalated along the lymphatic vessels, near the deep vessels at the bend of the elbow.

(3) The **superficial cubital** (or supratrochlear) **node** [lgl. cubitalis superficialis] is situated three or four cm. above the medial epicondyle of the humerus. It lies in the superficial fascia on the medial side of the basilic vein near the place where it passes through the deep fascia. It is usually single, but may be absent or represented by a chain of from two to five nodes. Its efferents follow the basilic vein.

(4) The **deltopectoral nodes** are very small intercalated nodes, from one to three in number, and are situated in the groove between the deltoid and pectoral muscles. Their vessels follow the cephalic vein.

(5) The **axillary nodes** [lgl. axillares], from twelve to thirty-six in number, may be divided into groups according to the areas which they drain (figs. 639, 640). In addition to the upper extremity, they receive lymphatic drainage from the thoracic walls, including dorsal, lateral and ventral (mammary) regions.

(*a*) The *subclavian group* consists of four or five nodes, situated in the apex of the axillary fossa. They receive the efferent vessels of all the other groups, and their efferent vessels in turn unite to form a single trunk, the subclavian, which empties into the thoracic duct or subclavian vein on the left side and on the right side either into the vein directly or else after uniting with the jugular trunk. (See pp. 795, 796.)

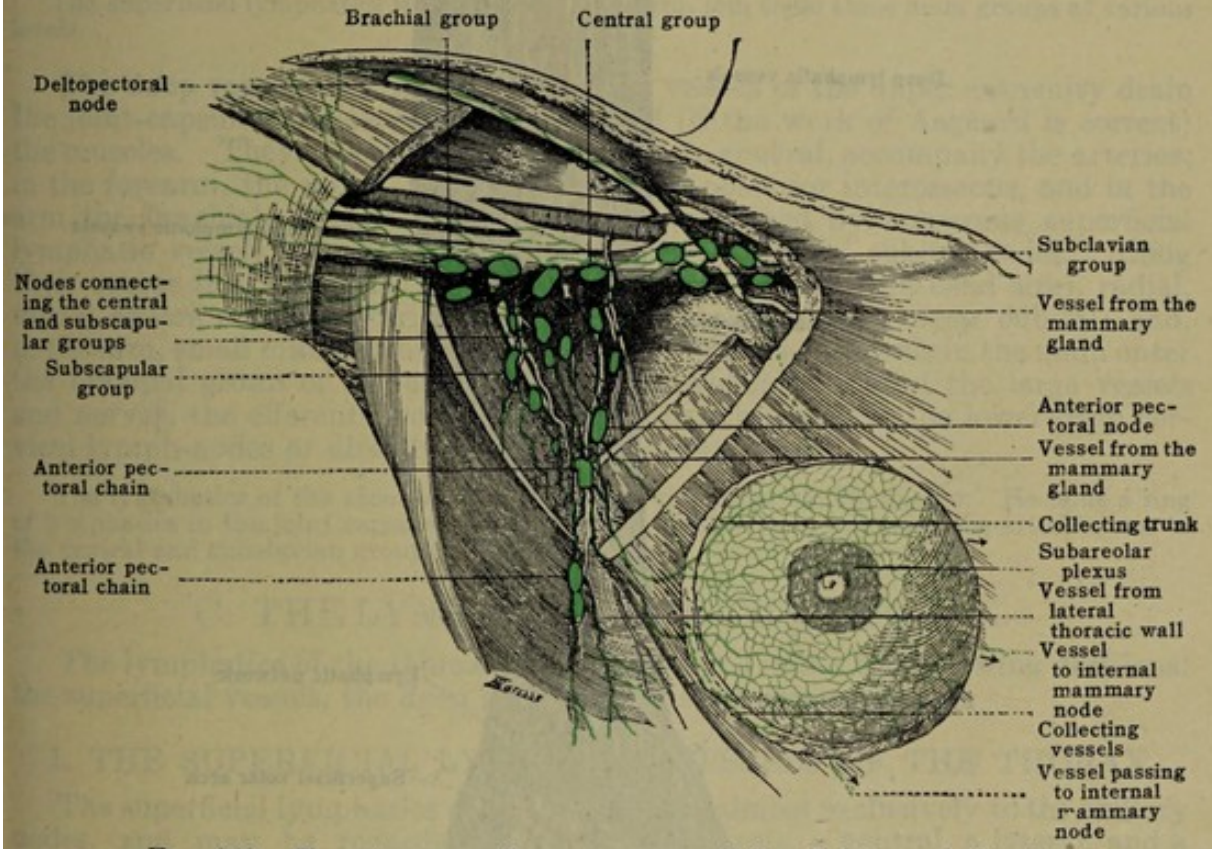

FIG. 640.—THE AXILLARY LYMPH-NODES. (After Poirier and Cunéo.)

(*b*) *The central group.*—A little lower along the axillary artery is a group of three to five nodes, which makes a second center for the vessels of the other groups, and sends its efferents to the subclavian group. It will be clear from fig. 640 that the separation of groups 1 and 2 is arbitrary.

(*c*) *The brachial group.*—This consists of four or five nodes, and, as its position toward the junction of the axillary and brachial arteries indicates, is the main station for the lymphatics of the arm proper. It receives almost all the superficial and deep lymphatics of the arm, and its efferents pass to the central and subclavian groups, although a few pass directly to the suprascapular group. Small, outlying nodes of this group may be intercalated along the vessels following the brachial artery throughout its course.

(*d*) *The subscapular group* [lgl. subscapulares].—In this group are six or seven nodes, which follow the subscapular artery and its branch, the circumflex (dorsal) scapular. Belonging to it there are usually two or three small nodes on the dorsal surface of the scapula, in the groove which separates the teres major and minor. This group receives vessels from the dorsal surface of the thorax, as well as from the arm, and its efferents pass to the brachial group.

(*e*) *The anterior pectoral group.*—This group consists of four or five nodes which lie along the lower border of the pectoralis major and drain the mammary gland and front of the chest. Their efferent vessels pass to the central and subclavian groups.

(*f*) The *posterior pectoral group* consists of small nodes situated on the inner wall of the axilla, along the course of the long thoracic artery. They receive afferents from the lateral integument of the thorax and drain into the nodes of the central group.

2. THE LYMPHATIC VESSELS OF THE UPPER EXTREMITY

The lymphatic vessels of the upper extremity are divided into two sets—a superficial and a deep set.

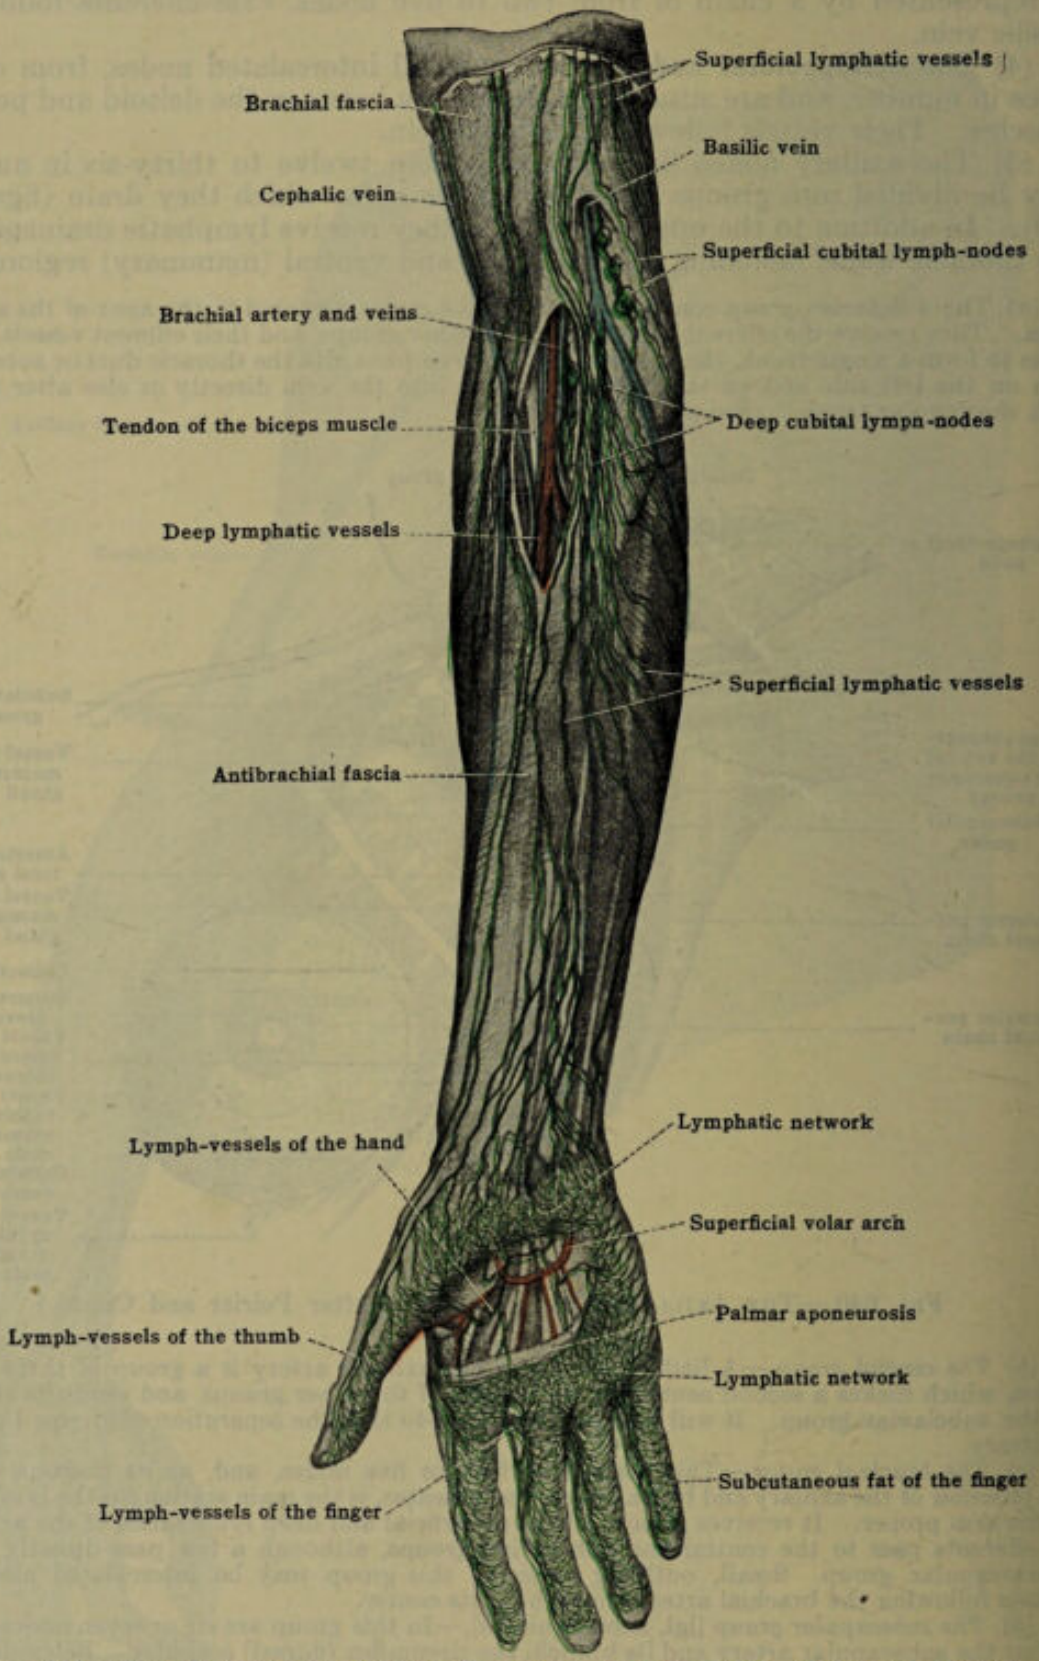

FIG. 641.—THE LYMPHATICS OF THE FOREARM. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

The superficial vessels.—The superficial lymphatic vessels of the arm course in two layers, the one quite subcutaneous, the other next to the deep fascia, with frequent anastomoses between the two sets. The majority of these vessels remain superficial throughout the arm, but some of them pass through the deep fascia in the upper arm especially where the basilic vein pierces the deep fascia,

to join the deep lymphatics accompanying the brachial artery. The general distribution of the superficial lymphatics and their relations with the lymph-nodes are shown in figs. 639 and 641.

The capillary plexus is most dense in the volar surfaces of the fingers, where the meshes are so fine that they can only be seen with a lens. On the dorsal surface of the fingers and hand the plexus is less dense. From the plexus on the palmar side of the fingers vessels come together at the base of the fingers where they pass dorsally to be joined by the dorsal vessels of the finger. They now follow two rather distinct curves: (1) those from the thumb and index finger and a part of the middle finger pass upward along the radial side of the forearm, course medially over the lower part of the biceps muscle, and empty into the axillary lymph-nodes. One or two vessels follow the cephalic vein and, after traversing the deltopectoral node, pierce the coastocracoid membrane to enter the subclavian nodes, or pass over the clavicle into the inferior deep cervical nodes. (2) Those from the rest of the fingers course for a short stretch on the dorsum of the forearm, when they turn toward the ulnar side, wind around to the volar side and either continue superficially along the upper arm to the axillary nodes, or pass into the superficial cubital node, or, joining the efferents from these nodes, pass through the deep fascia to unite with the deep lymphatics. (3) A set of vessels from the palm of the hand passes upward along the volar side of the forearm. Anastomoses are frequent between these groups of lymphatic vessels, particularly in the cubital region.

It will thus be seen that the superficial cubital nodes receive lymph from the ulnar digits and from the palm of the hand, but not from the thumb and forefinger.

The superficial lymphatics from the rest of the arm join these three main groups at various levels.

The deep vessels.—The deep lymphatic vessels of the upper extremity drain the joint-capsules, periosteum, tendons, and (if the work of Aagaard is correct) the muscles. They collect into vessels which, in general, accompany the arteries; in the forearm, the radial, ulnar, anterior and posterior interosseous, and in the arm the brachial. Above the elbow they are joined by numerous superficial lymphatic vessels including efferents from the superficial cubital nodes. Along their course in the forearm are intercalated small nodes (pin-head size), radial, ulnar, anterior and posterior interosseous (Mouchet) and deep cubital; and, in the arm, small brachial intercalated nodes. The deep vessels in the main enter the brachial group of axillary lymph-glands which lie behind the large vessels and nerves, the efferents from which nodes pass either into the lower deep cervical lymph-nodes or directly into the subclavian trunk.

The lymphatics of the *shoulder-joint* have been described by Tananesco. He finds a ring of lymphatics in the joint capsule, whose efferents, in the main, following the arteries, run to the central and subclavian groups of axillary nodes.

C. THE LYMPHATICS OF THE THORAX

The lymphatics of the thorax will be considered under the following divisions: the superficial vessels, the deep nodes, and the deep vessels.

1. THE SUPERFICIAL LYMPHATIC VESSELS OF THE THORAX

The superficial lymphatics of the thorax pass almost exclusively to the axillary nodes, and may be regarded as forming three sets, a ventral, a lateral, and a dorsal. The **ventral set** drains the thoracic integument, which extends from the median line and the clavicle over to the lateral border of the chest, and includes the vessels of the mammary gland, which will, however, be described separately. The majority of the vessels from this area end in the anterior pectoral group of axillary nodes, a few, which arise beneath the clavicle, passing to the supra-clavicular nodes, and a few perforating the intercostal spaces and ending in the chain of nodes along the internal mammary artery.

It has been shown that an injection into the subcutaneous plexus near the median line passes to the opposite side, and that, in addition to the anastomosis between the networks of the two sides of the thorax which this result manifests, there may also be a few collecting trunks crossing the median line, and, furthermore, anastomoses occur between the superficial networks of the anterior thoracic and abdominal walls. Thus while the main channel of lymphatic drainage is through the axilla, there are minor accessory channels (1) to the supraclavicular nodes, (2) to the axilla of the opposite side, (3) to the internal mammary chain, and (4) in isolated cases even to the inguinal nodes. These accessory channels may become more open in cases of obstruction to the main channels.

The **lateral set** of superficial thoracic lymphatics is much less extensive than the anterior, and its collecting vessels pass upward to open chiefly into the posterior pectoral group of axillary nodes.

The **dorsal set,** which occupies the subcutaneous tissue of the dorsal thoracic wall, sends its vessels to the subscapular group of axillary nodes.

The Lymphatics of the Mammary Gland (Figs. 640, 642)

The lymphatic network over the peripheral portions of the mammary gland is like that of the rest of the thoracic wall. In the areola, however, the capillaries are far more abundant, forming a double subareolar plexus. The superficial plexus is so dense that its meshes can be seen only with a lens. The deeper plexus not only drains the superficial plexus, but receives the vessels from the mammary gland itself, and from it arise usually two large trunks, one from the inferior and one from the superior part of the plexus. These two vessels pass to one or two of the nodes belonging to the anterior pectoral group of axillary nodes. In addition there may be—(1) one or two vessels passing to the nodes along the axillary artery; (2) in rare cases a vessel passing directly to the subclavian nodes. There is also a definite channel from the medial margin of the gland to the internal mammary nodes, the trunks following the perforating branches of the internal mammary

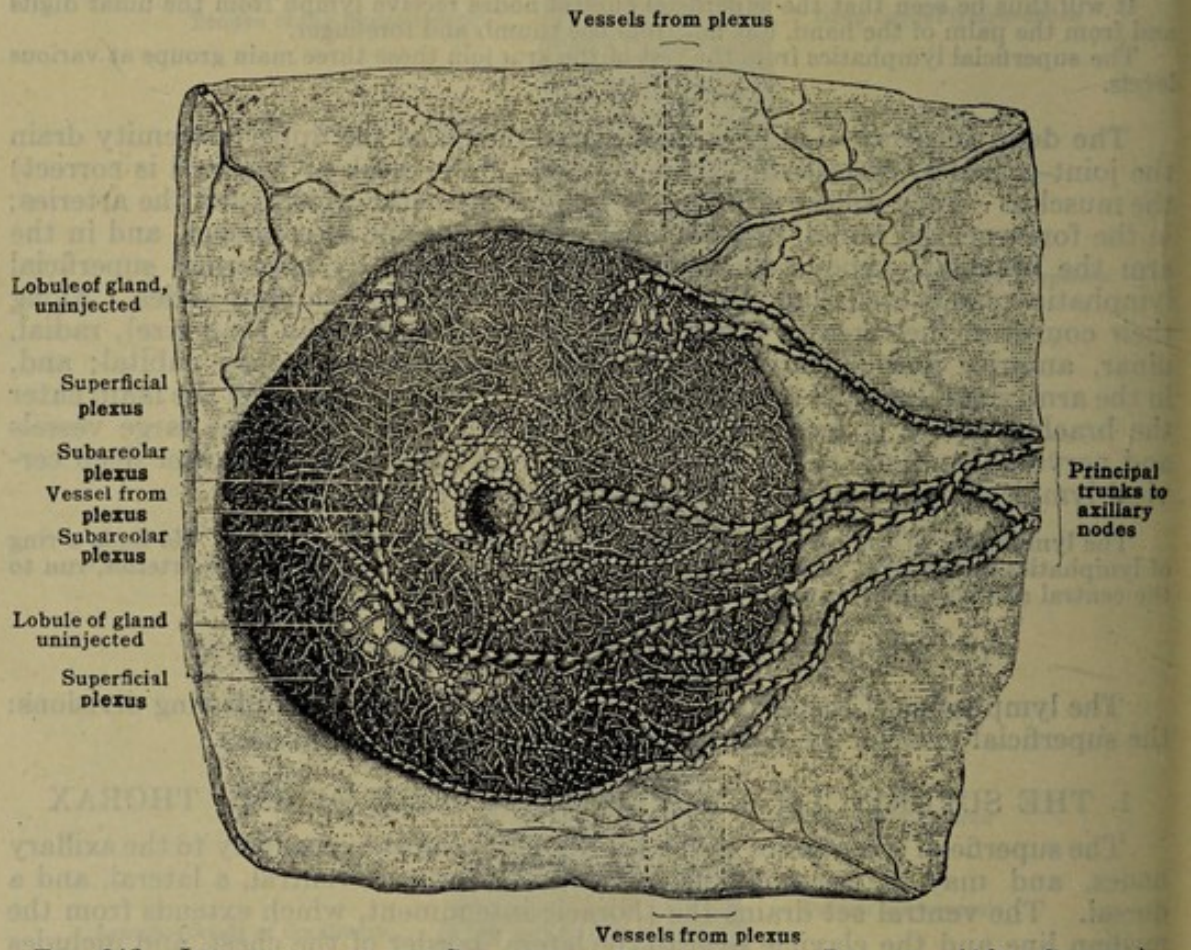

Fig 642.—Lymphatics of the Subareolar Plexus of the Breast. (After Sappey.)

vessels. It may also be noted that the crossed anastomosis and that with the abdominal network, mentioned in connection with the superficial thoracic vessels, may occasionally serve as channels for the mammary drainage.

There is also clinical evidence indicating that lymphatic vessels from the lower and medial aspect of the mammary gland may pass through the abdominal wall in the angle between the xiphoid process and the costal cartilages, establishing a communication with the lymphatics of the abdomen in the diaphragmatic region.

Lymphatics of the thoracic muscles.—The studies of Aagaard make it probable that muscles are provided with lymphatics. It is unquestioned that lymphatic vessels course through the pectoral muscles—some passing to the axillary, others to the subclavian, and still others to the internal mammary chain of nodes. This would suffice to explain the fact that cancer of the breast may extend into and through the pectoral muscles.

2. THE DEEP LYMPHATIC NODES OF THE THORAX

The lymphatic nodes of the thoracic cavity may be divided into the parietal and the visceral. The **parietal nodes** are arranged in two sets, the sternal

and the intercostal nodes. Along the internal mammary artery are from four to six small **sternal nodes** [lgl. sternales] which receive trunks from the anterior thoracic and the upper part of the abdominal walls, from the anterior diaphragmatic nodes which drain the liver, and from the medial edge of the mammary gland. The efferent vessels usually unite with the vessels of the anterior mediastinal and bronchial nodes, to form the bronchomediastinal trunk, which may join the thoracic duct on the left and the jugular or subclavian trunk on the right or may empty separately into the subclavian vein on either side or both (fig. 1149).

The **intercostal nodes** [lgl. intercostales] (fig. 644) lie along the intercostal vessels, near the heads of the ribs. There are usually one or two in each space. They receive afferents from the deeper part of the thoracic wall and costal pleura. Their efferents enter the thoracic duct, those from the nodes of the lower four or

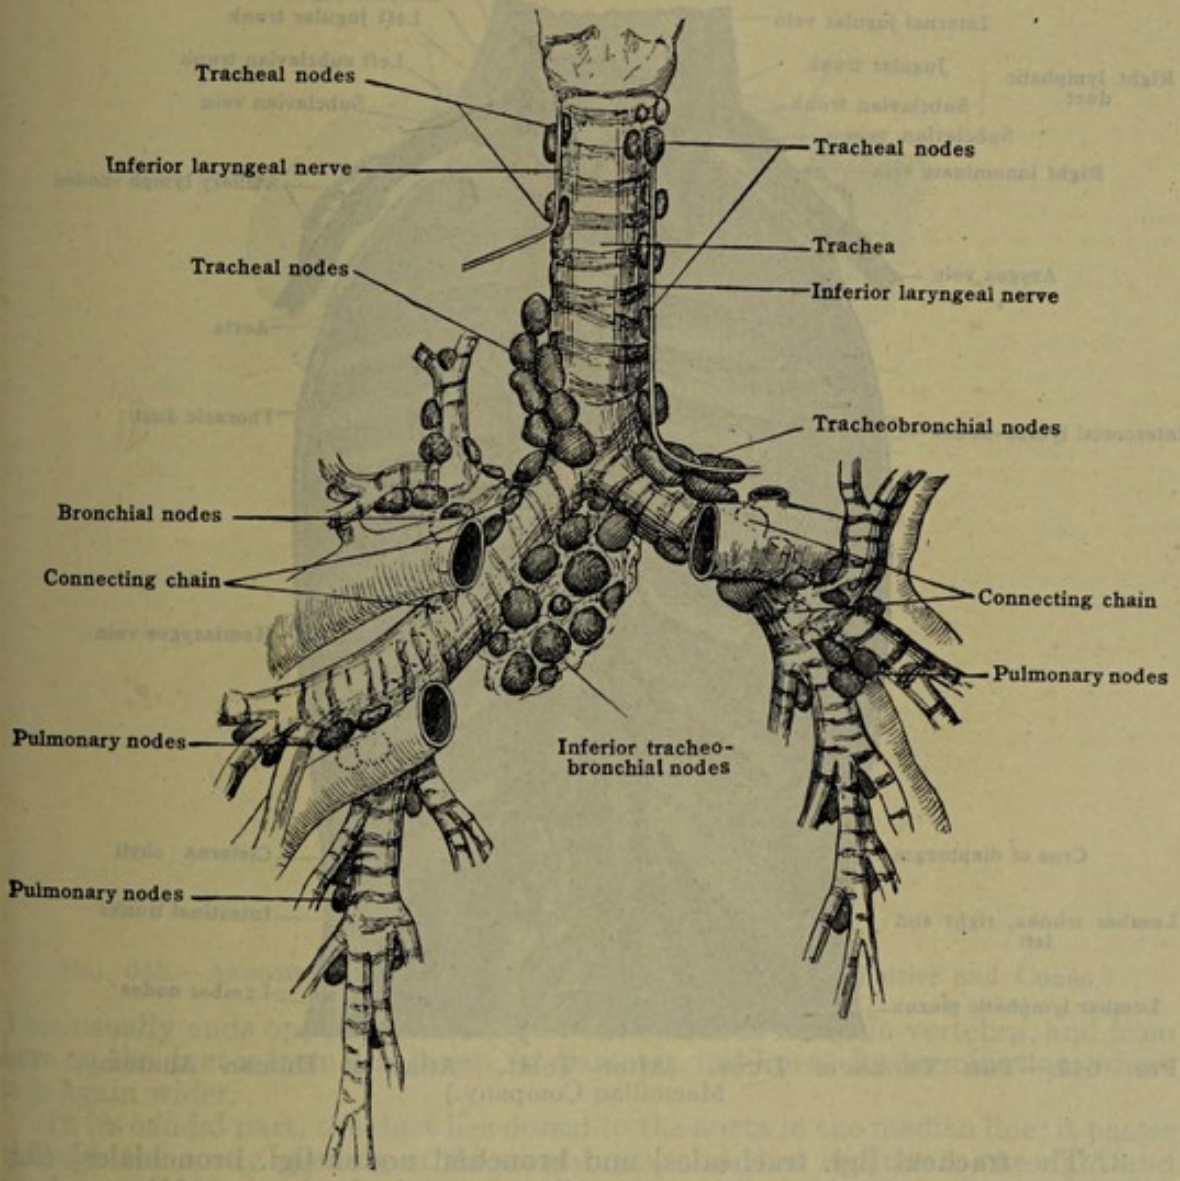

FIG. 643.—THE TRACHEAL AND BRONCHIAL NODES. (Sukiennikow.)

five interspaces uniting usually to form a common trunk on each side, but more marked on the left side, which descends to the cisterna chyli.

The efferent lymph-vessels from the upper intercostal nodes often unite into common trunks which drain several interspaces, and which may pass through a large gland near the thoracic duct before emptying into it. Occasionally such collecting vessels from the right side cross the midline behind the aorta to reach a large gland to the left of the aorta.

The **visceral nodes** of the thorax are arranged in three groups:

1. The **anterior mediastinal nodes** [lgl. mediastinales anteriores] (lymphonodi mediastinales ventrales NK) are situated, as their name indicates, in the anterior mediastinum, and are arranged in an upper and a lower set. The upper set (superior mediastinal group) is situated along the arch of the aorta, and consists of eight or ten nodes, which receive afferents from the pericardium and the

remains of the thymus gland. Their efferent vessels pass upward to join the bronchomediastinal trunk. The lower set consists of from three to six nodes, situated in the lower part of the anterior mediastinum. They receive afferent ducts from the diaphragm (for which reason they are sometimes termed the **diaphragmatic nodes**) and also from the upper surface of the liver. Their efferents pass upward to open into the upper anterior mediastinal nodes.

2. The **posterior mediastinal nodes** [lgl. mediastinales posteriores] eight or ten in number, are situated along the thoracic aorta, and receive vessels from the mediastinal tissue and from the thoracic portion of the esophagus. Their efferents open directly into the thoracic duct.

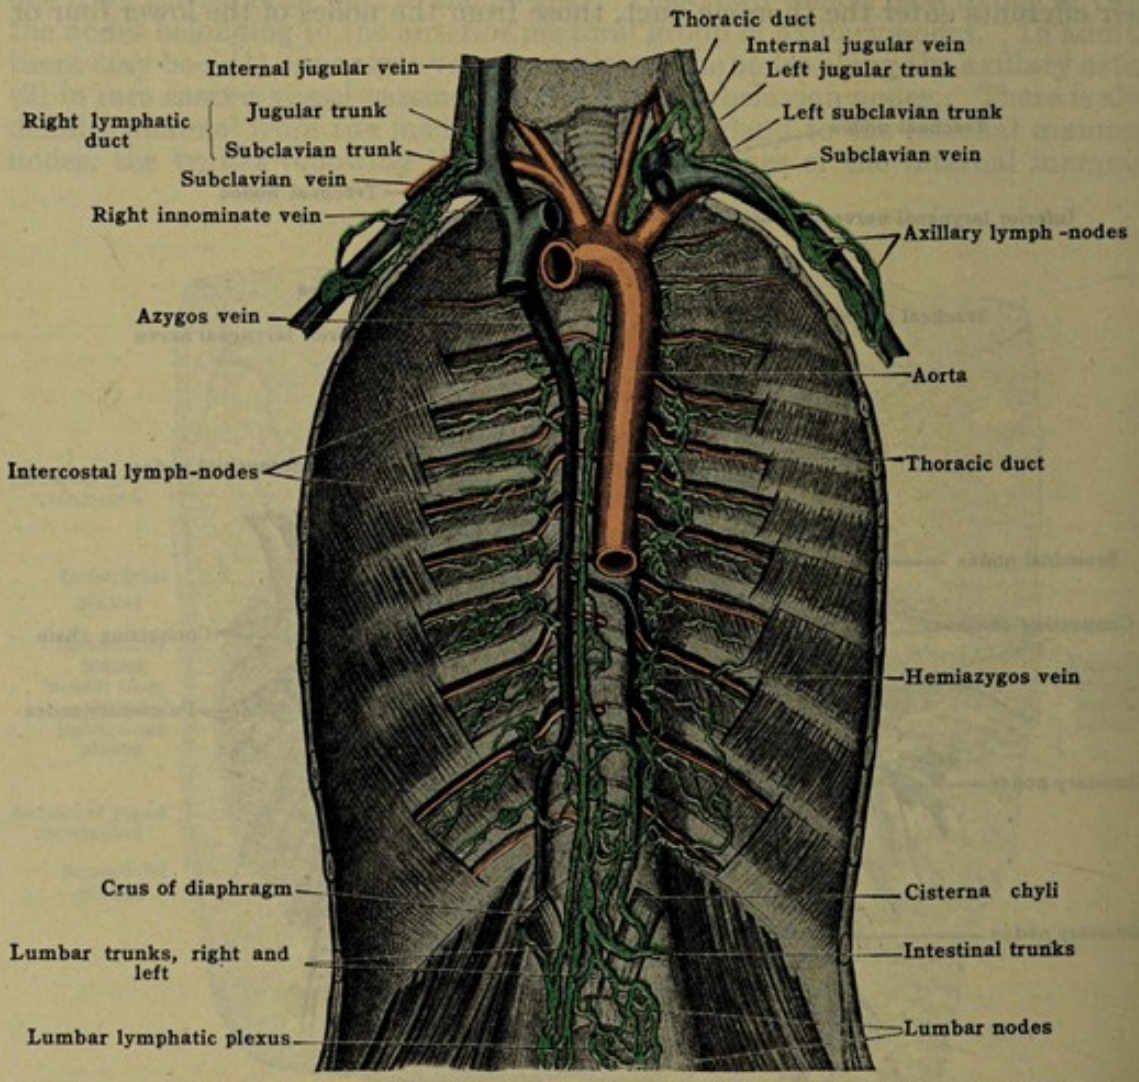

FIG. 644.—THE THORACIC DUCT. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

3. The **tracheal** [lgl. tracheales] and **bronchial nodes** [lgl. bronchiales] (fig. 643) form an extensive group lying along the sides of the lower part of the trachea, and along the bronchi as far as the hilus of each lung. According to their position they are termed tracheal (paratracheal), lateral tracheobronchial, inferior tracheobronchial (nodes of the bifurcation), and pulmonary nodes. The latter occur within the lung, at the bifurcation of the bronchial tubes. The groups receive the drainage of the lower part of the trachea, the bronchi, the lungs, part of the esophagus, and, to a small extent, the heart. Their efferent vessels unite with those from the upper anterior mediastinal and internal mammary nodes to form the bronchomediastinal trunk. (See also fig. 1149.)

3. THE DEEP LYMPHATIC VESSELS OF THE THORAX

The deep lymphatics of the thorax will be taken up in the following order: the thoracic duct; the right terminal collecting trunks; the parietal vessels; and the visceral vessels.

The Thoracic Duct

The **thoracic duct** [ductus thoracicus] (fig. 644), which is the main collecting trunk of the lymphatic system, extends from the second lumbar vertebra along the spinal column and course of the aorta to the junction of the left internal jugular and subclavian veins. It receives all the lymphatics below the diaphragm; the deep lymphatics from the dorsal half of the chest wall; and also, when joined by the left bronchomediastinal, subclavian and jugular trunks, from the remainder of the left half of the body, above the diaphragm. At the caudal end the duct is formed usually by the union of three collecting trunks, one from each of the lumbar groups of nodes, and an unpaired intestinal trunk. At its origin there is frequently a dilated portion known as the **cisterna chyli** (or receptaculum chyli).

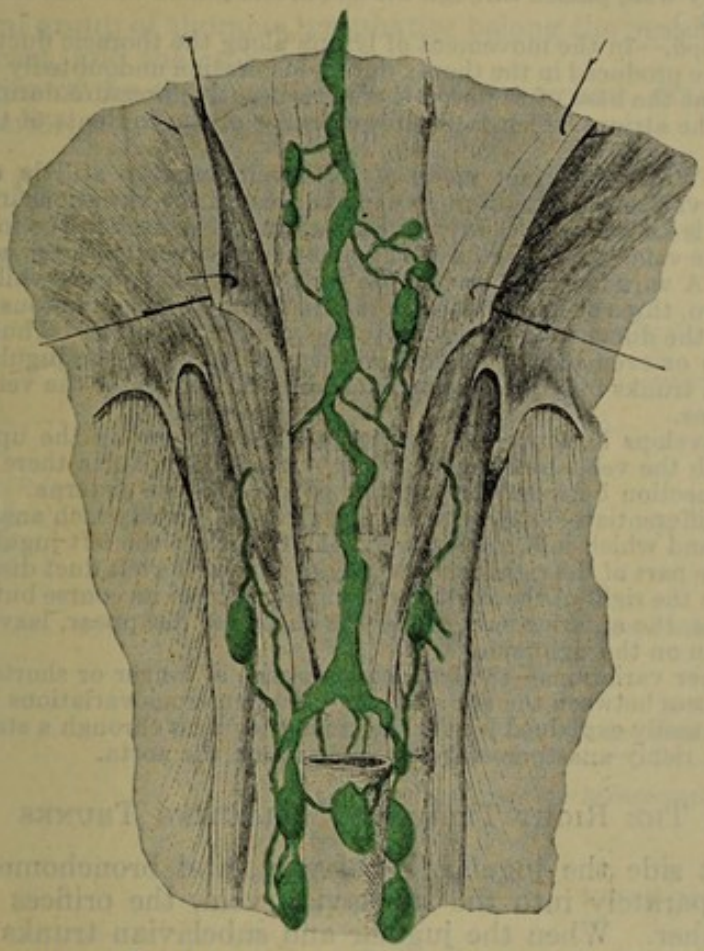

Fig. 645.—Abdominal Portion of the Thoracic Duct. (Poirier and Cunéo.)

This usually ends opposite the body of the eleventh thoracic vertebra, and from here on the duct is from 4 to 6 mm. in diameter, until near its termination, where it is again wider.

In its caudal part, the duct lies dorsal to the aorta in the median line; it passes through the aortic opening in the diaphragm, and then inclines to the right and passes upward between the aorta and the azygos vein to about the fourth, fifth, or sixth thoracic vertebra, where it bends to the left and passes, continuing upward, over the apex of the left lung to the medial side of the left subclavian artery, and in front of the root of the left vertebral artery and vein, and then curves downward to open into the left subclavian vein, close to its junction with the left internal jugular. The duct runs in the wall of the vein a short distance before ending. The termination of the duct is shown in figs. 644 and 1149.

Variations.—There is a wide range of variation from this usual course. The duct is frequently double throughout a part of its course, the two branches being connected by cross anastomoses, and finally uniting into a single trunk before joining the veins. It may be multiple, or a single trunk may pass in front of the aorta instead of behind. In a few instances it has been found emptying into the right instead of the left subclavian vein. There is also a wide range of variation in the height to which the duct ascends in the neck before curving downward to the vein. As regards the termination of the thoracic duct, variations are also frequent; it may bifurcate and end as two ducts. It often connects with the lowermost part of the internal jugular, or the beginning of the innominate. According to Henle, there is one un-

doubted case reported of a thoracic duct ending in the azygos vein near the sixth thoracic vertebra, the duct being obliterated above this point. At the terminal bend the thoracic duct receives the jugular trunk from the neck; it may also receive the subclavian and the bronchomediastinal trunks, but it is more usual for these last two to open either separately or together into the subclavian.

Variations are extremely numerous in the region of the cisterna chyli. Several observers state that, in the majority of cases in man, no definite receptaculum exists (cf. fig. 645). Bartels found one in only 25 per cent. of the cases studied. Instead, there is present a widening of each of the two lumbar trunks, with several anastomoses between them (55 per cent., Bartels), or a widening of these two stems without anastomosis (5 per cent.), or a much elongated widening arising from the growing together of the two lumbar trunks (10 per cent.). In cases where the lumbar trunks remain separate, the intestinal trunk joins the left one. One case has been described in which the thoracic duct ended at the level of the ninth thoracic vertebra. The lymphatics from the body below this point collected into a duct which became superficial just below the termination of the left saphena magna vein, passed cranialward in the subcutaneous tissue of the left body wall, passed through the axilla, and joined the venous system at the usual place. (E. R. Clark.)

Movement of lymph.—In the movement of lymph along the thoracic duct and into the vein, the negative pressure produced in the thorax during inspiration undoubtedly plays an important rôle. In the veins at the base of the neck there is a negative pressure during inspiration, with each relaxation of the atrium which facilitates entrance of the contents of the lymphatic ducts into the veins.

Development.—While the exact mode of its development is still in dispute, enough is agreed upon by the various investigators to explain most of the variations in the thoracic duct. As stated above, it is known that the lymphatics start in the neck in the form of a number of outgrowths from the veins in the region of the junction between the later internal jugular and subclavian veins. A variable number of these connections disappear, while the various combinations of one, two, three or four which are retained furnish the numerous variations in number and position of the ducts which empty into the vein in the adult. Thus the thoracic duct may have one, two or even three openings into the veins, while the jugular, subclavian and bronchomediastinal trunks may join the thoracic duct or may enter the veins separately or in various combinations.

The cisterna develops in connection with branches of veins in the upper lumbar region. All connections with the veins here are soon lost. Around the aorta there develops a plexus, which forms a connection between the anterior plexus and the cisterna. In this plexus two main vessels soon differentiate—the right and left thoracic ducts, which anastomose frequently with one another, and which join, respectively, the right and the left jugulosubclavian angle. Usually the cephalic part of the right and the caudal part of the left duct disappear, leaving the permanent vessel to the right of the aorta for the major part of its course but emptying into the left vein. However, the anterior part of the left duct may disappear, leaving the permanent duct to join the vein on the right side.

Most of the other variations—the frequent presence of longer or shorter doublings of the duct with anastomoses between the two parts and the numerous variations in the region of the cisterna chyli—are easily explained by the fact that they pass through a stage in development in which they form richly anastomosing plexuses around the aorta.

The Right Terminal Collecting Trunks

On the right side the jugular, subclavian, and bronchomediastinal trunks usually open separately into the subclavian vein, the orifices of the first two being near together. When the jugular and subclavian trunks unite, the common trunk is termed the right lymphatic duct [ductus lymphaticus dexter] (truncus lymphaceus dexter NK). This is an unusual form, and it is still more rare for the three ducts to unite to form a common stem (see figs. 644, 646, 1149).

These variations have the same explanation, embryologically, as was given for the corresponding variations on the left side. The subclavian trunk usually passes in front of the subclavian vein, but in some cases passes behind it.

The Deep Lymphatic Vessels

As with the nodes, the deep lymphatic vessels of the thorax may be divided into a parietal and a visceral group. To the former group may be assigned the lymphatics of the intercostal spaces and those of the diaphragm.

The **intercostal lymphatics** form plexuses in each intercostal space, which receive lymph from the periosteum of the ribs and from the parietal pleura, and from which the drainage is either ventral or dorsal. From the dorsal half of each space the drainage is to the intercostal nodes (fig. 644), while from the ventral half it is toward the internal mammary nodes.

The lymphatics of the diaphragm.—There is an exceedingly rich plexus of capillaries both on the thoracic and on the abdominal surface of the diaphragm, especially in the region of the central tendon. These plexuses lie in the subserous layer and are freely connected by vessels which perforate the muscle. There is, however, only slight communication between the plexuses of the right and left

sides of the diaphragm. The vessels lie between the coarse muscle-bundles, forming a very characteristic picture, in which the lymphatics stream outward radially, like the spokes of a wheel. The collecting vessels empty into three groups of small nodes on the convex thoracic surface.

The *ventral group* lies ventral to the central tendon. Two or three nodes in the center of this group receive afferents from the liver and none from the diaphragm, but the rest receive vessels from the ventral portion of the diaphragm and the efferents of all pass to the lower set of anterior mediastinal nodes.

The *middle group* consists of from three to six nodes, which lie, on the left side, near the point where the phrenic nerve enters the diaphragm; and on the right side, near the vena cava.

The *dorsal group* of four or five nodes is placed between the crura of the diaphragm. The vessels from the middle and dorsal groups pass to the posterior mediastinal nodes, and also to the upper celiac nodes, which likewise receive the drainage from the dorsal part of the abdominal surface of the diaphragm.

To the visceral group of thoracic lymphatics belong the vessels of the thymus, the lungs, the heart, and the esophagus.

The **lymphatics of the thymus,** according to Severeanu, drain into three sets of nodes, an anterior, a ventral and a dorsal group.

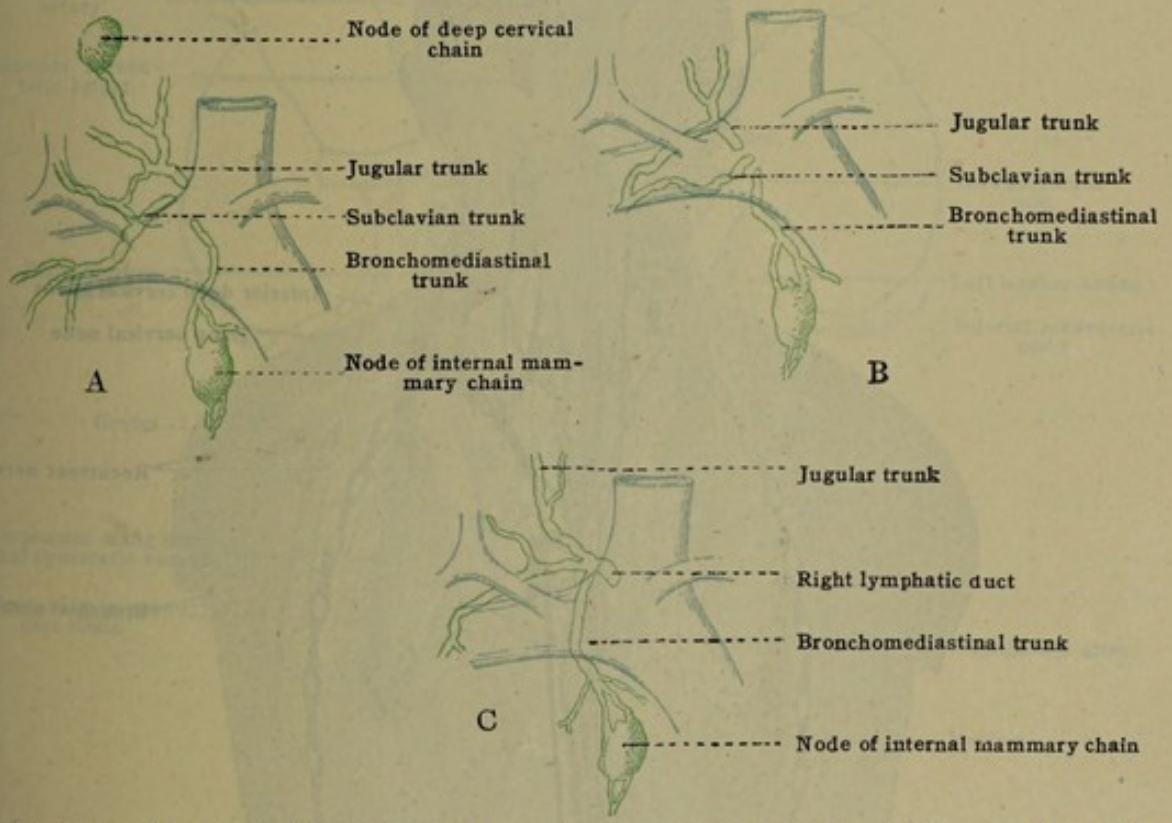

FIG. 646.—TERMINAL COLLECTING TRUNKS ON THE RIGHT SIDE. (Poirier and Cunéo.)

The *anterior* set, one gland on each side, lies lateral to the cephalic end of the thymus, and drains into the jugular or subclavian trunk. The *ventral* set includes 4–6 of the anterior mediastinal lymph-glands. The *dorsal* set, 2 on each side, is made up of anterior mediastinal glands lying between the thymus and the pericardium.

The **lymphatics of the lungs** are arranged in two sets, deep and superficial. The *deep lymphatics* fall into three groups: the lymphatics of (1) the bronchi; (2) the arteries; (3) the veins.

(1) The lymphatics of the bronchi take origin in plexuses which surround the bronchi and bronchioles, and accompany the bronchi to the hilus, communicating with the bronchial nodes (fig. 608). (2) The lymphatics of the arteries originate from the lymphatics of the terminal bronchus. Two branches, with numerous anastomoses, usually accompany each artery. (3) The lymphatics of the veins have an origin similar to that of the arteries, from the bronchial lymphatics, at the point where the smaller bronchioles divide. They accompany the veins to the hilus. An additional set of lymphatics, which have a deep origin, pass to the pleura, in company with the veins which go to the surface. There are no lymphatic capillaries surrounding the alveoli.

The *superficial lymphatics* consist of a rich plexus of vessels lying on the surface of the lung, beneath the pleura. They receive vessels from the deeper lymphatics, and are drained by vessels which pass directly, and independently of the other sets, to the lymph-nodes of the hilus (W. S. Miller).

In studying the development of the lymphatics to the lung, R. S. Cunningham has found that, in the pig, while the lymphatics to the anterior two-thirds of the lung are formed by outgrowths from the thoracic ducts, those to the posterior third are outgrowths from the retroperitoneal sac, and that there is persistent drainage of this portion of the lung into preaortic nodes and cisterna chyli. No such line of drainage has been found in man.

Clinical aspects.—When chronic adhesions form between visceral and the parietal pleura, lymphatic vessels grow across and connect the lymphatics of the lungs with those of the chest wall, diaphragm or pericardium. That the lymph from the lung then drains to unusual lymph glands is indicated by the accumulation of carbon, picked up from the pulmonary alveoli, in such glands as the axillary, internal mammary, intercostal or superior gastric. Whether there is also drainage in the opposite direction is not known.

Lymphatics of the heart.—The superficial (subepicardial) lymphatics of the heart collect to two main stems which accompany the main coronary vessels. The right stem accompanies the right coronary artery to its origin, passes on

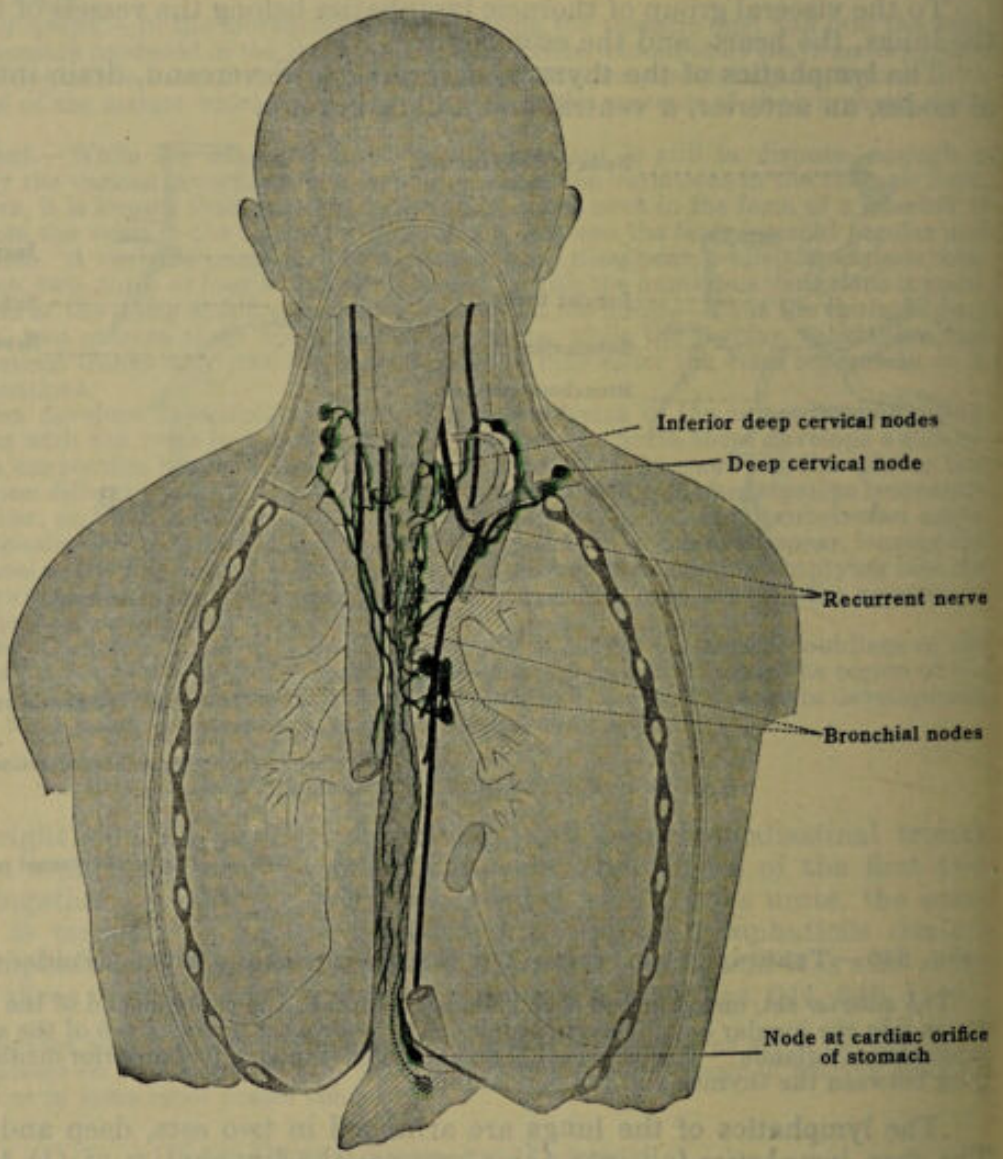

FIG. 647.—THE LYMPHATICS OF THE ESOPHAGUS. (After Sakata.)

over the arch of the aorta and empties into one of the anterior mediastinal lymph-nodes. The left stem, formed by two stems accompanying the circumflex and anterior descending branches of the coronary vein, passes behind the arch of the aorta to an anterior mediastinal lymph-gland. Two small subepicardial intercalated nodes have been described along these trunks.

Subendocardial lymphatics have been described, which connect by vessels passing through the musculature with the superficial lymphatics. Parenchymatous lymphatics have been demonstrated by Bock. The course of their efferent vessels has not yet been described.

The **lymphatic vessels of the esophagus** may be divided into three sets, of which the uppermost pass to outlying nodes belonging to the deep cervical chain, those from the thoracic portion of the tube pass to the bronchial and posterior

mediastinal nodes, while those from its lowermost part pass to the superior gastric nodes (fig. 647).

D. THE LYMPHATICS OF THE ABDOMEN AND PELVIS

In the following section there will be described successively the lymphatic nodes and vessels of the abdomen and pelvis, the lymphatic vessels of the abdominal walls, and the visceral lymphatic vessels.

1. THE LYMPHATIC NODES OF THE ABDOMEN AND PELVIS

The lymphatics which connect directly with the thoracic duct, though complicated, may be described briefly by saying that they follow the aorta and its branches. In the abdomen there are four main chains along the aorta—(1) the

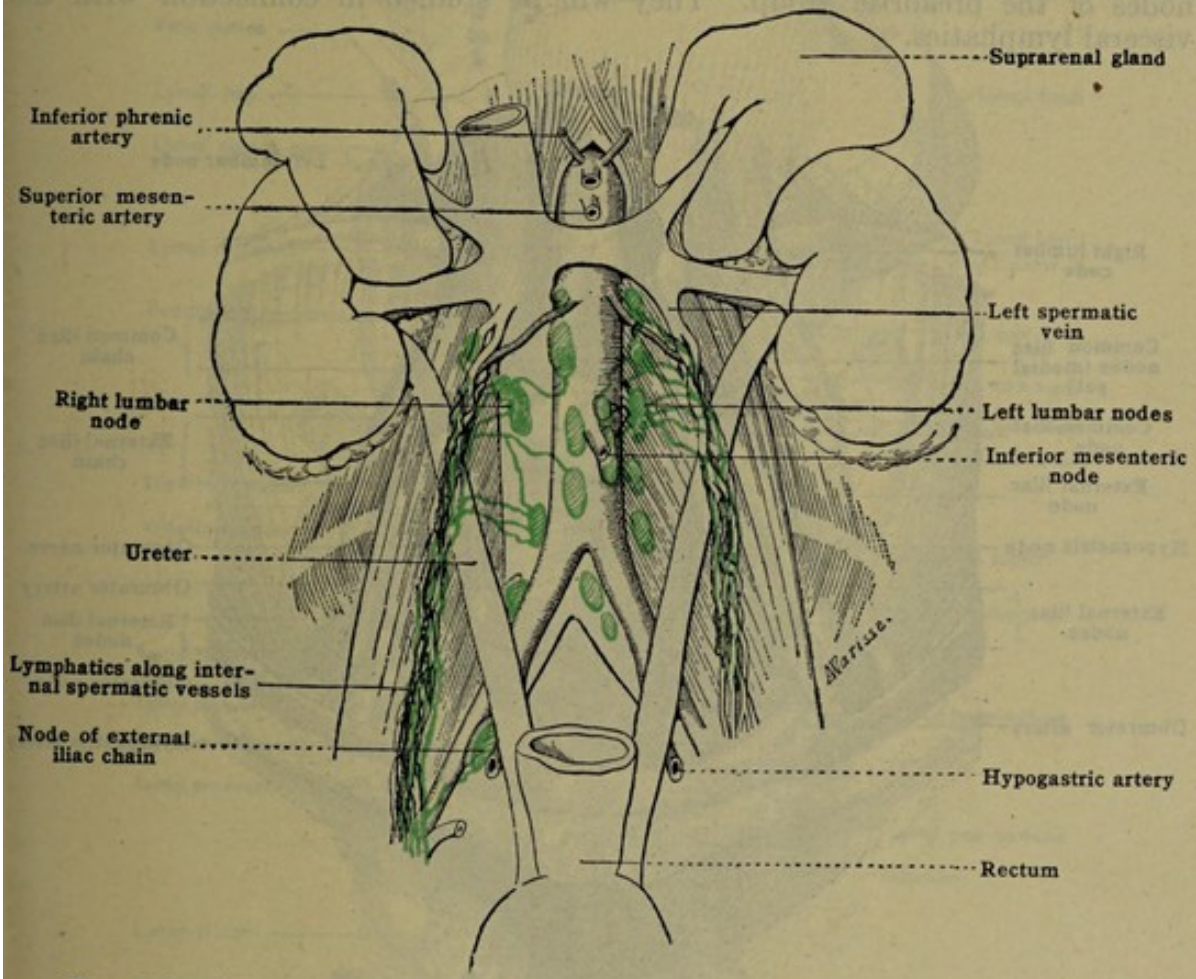

FIG. 648.—LOWER ABDOMINAL NODES IN THE NEWBORN. (Poirier and Charpy.)

left lumbar chain; (2) the right lumbar chain; (3) the preaortic chain; and (4) the postaortic chain.

The right and left lumbar nodes [lgl. lumbales], form an almost continuous chain along the abdominal aorta (fig. 648), resting upon the psoas muscles, some of those on the right side being ventral and some dorsal to the inferior vena cava. They receive: (1) the efferent lymphatics of the common iliac nodes, and hence drain the lower limb and external genitalia; (2) the efferent lymphatics that follow the lumbar arteries and thus drain the abdominal wall; (3) the efferents that follow the paired visceral aortic branches, namely, those from the kidneys, suprarenal, and internal reproductive organs. On the right side, the lymphatics from the reproductive organs pass to the nodes ventral to the vena cava; those of the abdominal walls pass to the dorsal set, while those from the kidney pass to both sets. The efferent vessels of the lower lumbar nodes pass to higher ones and so on up the chain, the vessels from the uppermost nodes uniting to form a single **lumbar trunk** on each side. These trunks pass to the thoracic duct, forming two of the so-called trunks of origin of that vessel (fig. 644).

The **preaortic nodes** (cf. fig. 650) of the lumbar chain are arranged in three groups at the root of each of the three unpaired visceral branches of the aorta—

the celiac, the superior mesenteric, and the inferior mesenteric arteries. The **celiac nodes** [lgl. coeliacæ] are from one to three in number, and are in reality parts of chains of nodes extending along the branches of the artery and constituting the **hepatic** [lgl. hepaticæ], **gastric** [lgl. gastricæ superiores et inferiores], and **splenic** [lgl. pancreaticolienales] nodes. They drain the stomach, duodenum, liver, pancreas, and spleen. For nodes of the gastric region, see fig. 652.

The **superior mesenteric** group is larger, and is continuous with the **mesenteric nodes** [lgl. mesentericæ] lying in the root of the mesentery. This group drains the remainder of the small intestine, the cecum and appendix, the ascending and transverse colons, and the pancreas.

The **inferior mesenteric** group (fig. 648) usually has two nodes, one on either side of the artery. It drains the rectum and descending and sigmoid colons. All the nodes in the mesentery and intestinal walls may be considered as outlying nodes of the preaortic group. They will be studied in connection with the visceral lymphatics.

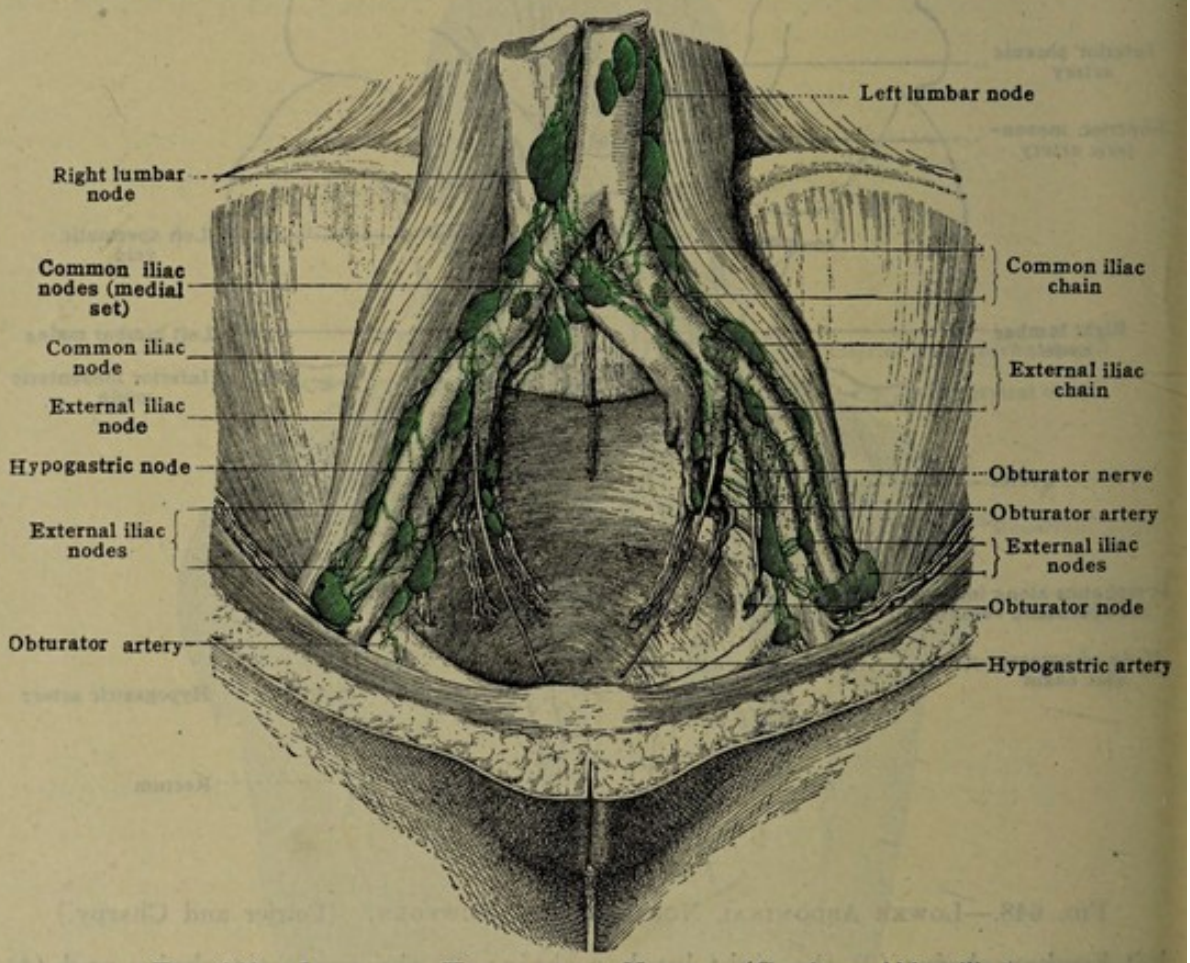

FIG. 649.—ILIAC AND HYPOGASTRIC NODES. (Cunéo and Marcille)

The inferior mesenteric nodes drain into the neighboring lumbar nodes, and also directly upward to the superior mesenteric nodes, and then again to the celiac nodes. From the last a single stem, the **intestinal trunk** [truncus intestinalis] (fig. 644), arises and passes either to the right lumbar trunk or directly to the thoracic duct, forming the third of the so-called trunks of origin of the duct.

The **postaortic nodes** are not true regional nodes, but receive vessels from the lumbar and preaortic chains.

Below the bifurcation of the aorta there are three large chains, the common iliac, the external iliac, and the hypogastric.

The **common iliac nodes** [lgl. iliacæ], are in three groups (fig. 649). The *lateral* set consists of about two nodes, which are in reality a part of a continuous chain extending along the side of the aorta, common iliac, and external iliac arteries. A second set of two to four *posterior nodes* lies behind the artery. These two groups receive the efferent vessels of the external iliac and hypogastric chains. The *medial* set usually consists of two nodes which rest upon the

promontory of the sacrum. They receive vessels from the sacral nodes, together with most of those from the pelvic viscera, namely, from the prostate, neck of the bladder, neck of the uterus, the vagina, and part of the rectum. The efferent lymphatic vessels of the common iliac nodes pass to the lumbar (aortic) chain.

External iliac nodes (figs. 649, 657–660).—These are likewise in three sets—lateral, intermediate, and medial. The *lateral* chain consists of three or four nodes, the lowest one being behind the crural arch. They receive: (1) some

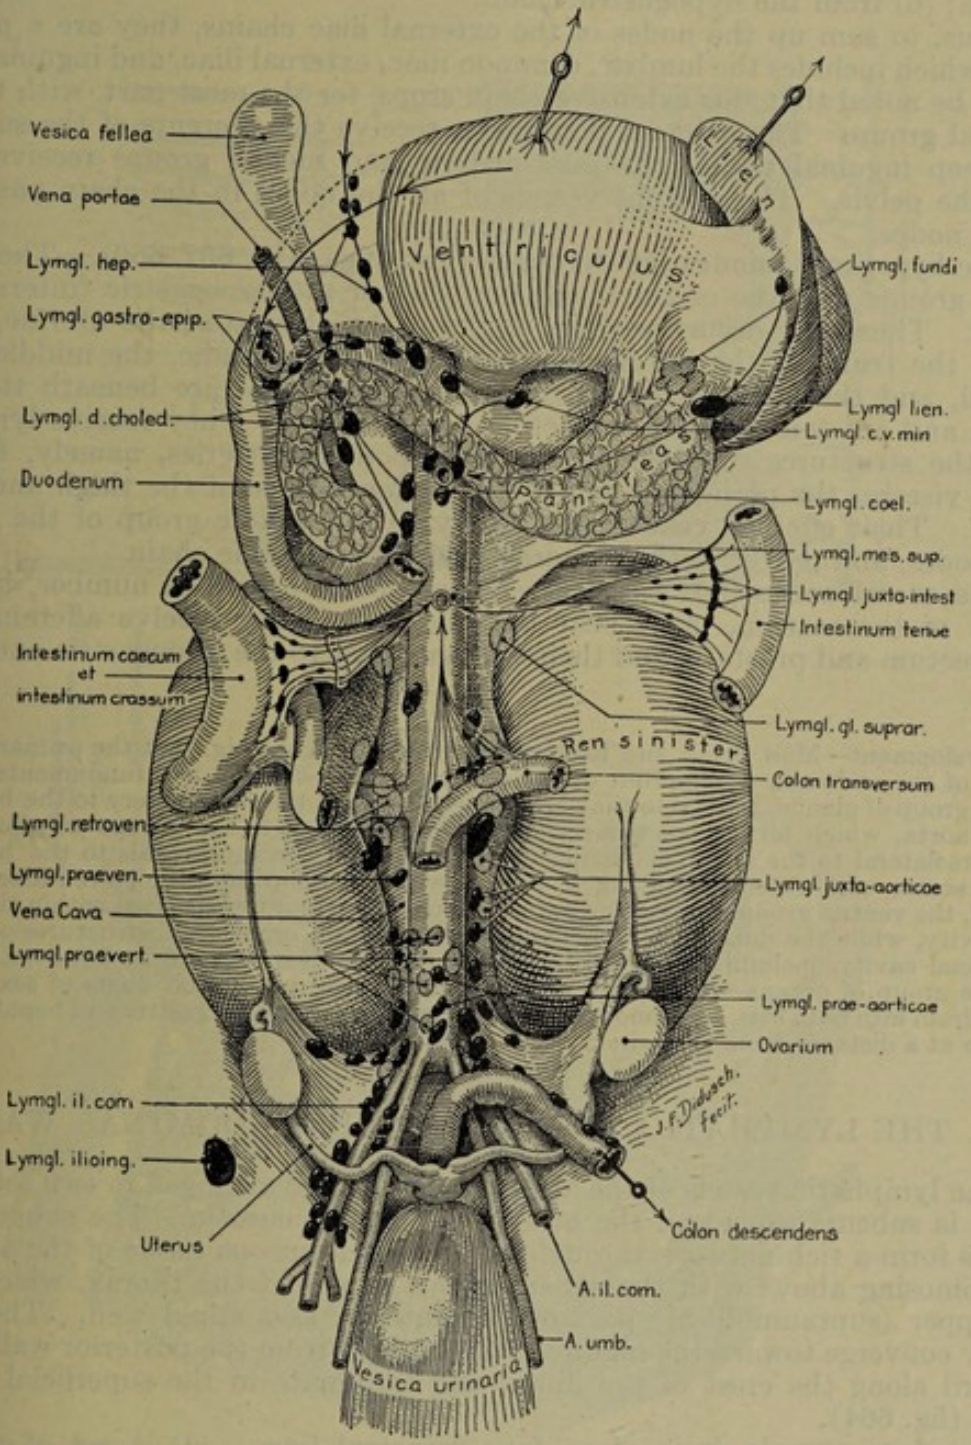

FIG. 650.—ABDOMINAL LYMPH-NODES OF A 20 CM. PIG FETUS. Solid black: derivatives of the retroperitoneal sac; stippled: derivatives of the iliac sac. (After Reichert.)

of the vessels of the superficial and deep inguinal nodes; (2) vessels from the glans or clitoris, which come through the inguinal canal; (3) vessels from the part of the abdominal wall supplied by the deep epigastric and deep circumflex arteries, along which there may be a few outlying nodes—the **epigastric nodes** [lgl. epigastrical].

The *intermediate* chain consists of two or three nodes behind the artery. When there are three, the lowest ('retrocrural') is likewise near the femoral ring. It

receives vessels from the bladder, prostate, neck of the uterus, and upper portion of the vagina. The *medial* chain consists of three or four nodes, and is the continuation of the deep inguinal nodes. Its lowest nodes are likewise near the femoral ring, while the next node is large and constant, and usually lies within the pelvis. This chain receives many vessels: (1) from the superficial and deep inguinal nodes; (2) from the glans and clitoris through the femoral canal; (3) from the abdominal wall; (4) from the neighborhood of the obturator vessels; (5) from the neck of the bladder, the prostate, and membranous part of the urethra; (6) from the hypogastric chain.

Thus, to sum up the nodes of the external iliac chains, they are a part of a chain which includes the lumbar, common iliac, external iliac, and inguinal nodes. It will be noted that this extensive chain stops, for the most part, with the deep inguinal group. The external iliac nodes receive the efferents of the superficial and deep inguinal nodes; the intermediate and medial groups receive vessels from the pelvis. The efferent vessels of all the nodes in the chain pass to the higher nodes.

The **hypogastric nodes** [lgl. hypogastricæ] (figs. 649, 657–660).—These nodes are in groups near the origin of the branches of the hypogastric (internal iliac) artery. Thus they occur near the origin of the obturator, the uterine, or prostatic, the trunk of the inferior gluteal (sciatic) and pudic, the middle hemorrhoidal, and the lateral sacral arteries. All the nodes are beneath the pelvic fascia, and are connected by numerous anastomoses. They receive lymphatics from the structures supplied by the corresponding arteries, namely, from the pelvic viscera, the perineum, and the posterior surface of the thigh and gluteal region. Their efferent vessels pass partly to the middle group of the common iliac nodes, and partly to the posterior nodes of the same chain.

The sacral nodes [lgl. sacrales].—These nodes, 5 or 6 in number, lie in the hollow of the sacrum, in or near the mid-line. They receive afferent vessels from rectum and prostate, and their efferents pass to the hypogastric and lumbar nodes.

Development—Miss Sabin and Reichert have shown, in the pig, that the primary lymph-glands of the abdomen develop out of the primary lymph-sacs, in two fundamental groups: (1) the group of glands, ventral to the aorta, extending from the celiac artery to the bifurcation of the aorta, which form from the retroperitoneal sac, and (2) the groups of glands dorsal and dorsolateral to the aorta, extending from the level of the suprarenals to the bifurcation of the aorta, with extensions along the iliacs, which develop from the paired iliac sacs. In general, the ventral group receives the drainage from the structures situated within the abdominal cavity, while the dorsal and dorsolateral groups drain organs and structures outside the abdominal cavity, including body-wall and lower extremities. There is, however, an intermediate group of organs—diaphragm, kidney, suprarenal, ureter, and ducts of sex glands—which drain into both sets. Secondary sets, such as the mesenteric, gastric and hepatic glands, develop at a distance from the primary sets (cf. fig. 650).

2. THE LYMPHATIC VESSELS OF THE ABDOMINAL WALLS

The lymphatic vessels of the abdominal walls are arranged in two sets, one of which is subcutaneous and the other deep or aponeurotic. The **subcutaneous** vessels form a rich network through all the subcutaneous tissue of the abdomen, anastomosing above with the subcutaneous plexus of the thorax, which drains the upper (supraumbilical) part of the anterior abdominal wall. The vessels chiefly converge toward the inguinal region, those from the posterior wall curving forward along the crest of the ilium, and terminate in the superficial inguinal nodes (fig. 664).

The **deep** vessels drain along four principal lines. (1) A set of collecting vessels follows the line of the deep epigastric artery to terminate in the lower external iliac nodes; (2) a second set follows the deep circumflex iliac vessels to the same nodes; and (3) a third set follows the lumbar vessels to terminate in the nodes of the lumbar chain; (4) the upper part of the anterior abdominal wall drains into the sternal nodes, following the superior epigastric vessels.

A group of small **epigastric nodes**, which may be regarded as offsets from the iliac chain, occur on the lymph-vessels which accompany the deep epigastric vessels, not far from their termination, and a second less constant group of usually three small **umbilical nodes** occurs in the vicinity of the umbilicus in the network covering the posterior layer of the sheath of the rectus abdominis muscle.

3. THE VISCERAL LYMPHATICS OF THE ABDOMEN AND PELVIS

The lymphatics to the viscera follow along the course of the blood-vessels. At the point where the artery of an organ branches from the aorta there is a group of nodes which represents the main regional group, and a second chain of nodes extends along the artery. The final arrangement of nodes and vessels varies with each organ. The lymphatics (vessels and nodes) of the alimentary tract, suprarenal gland, urinary and reproductive tracts will be successively considered.

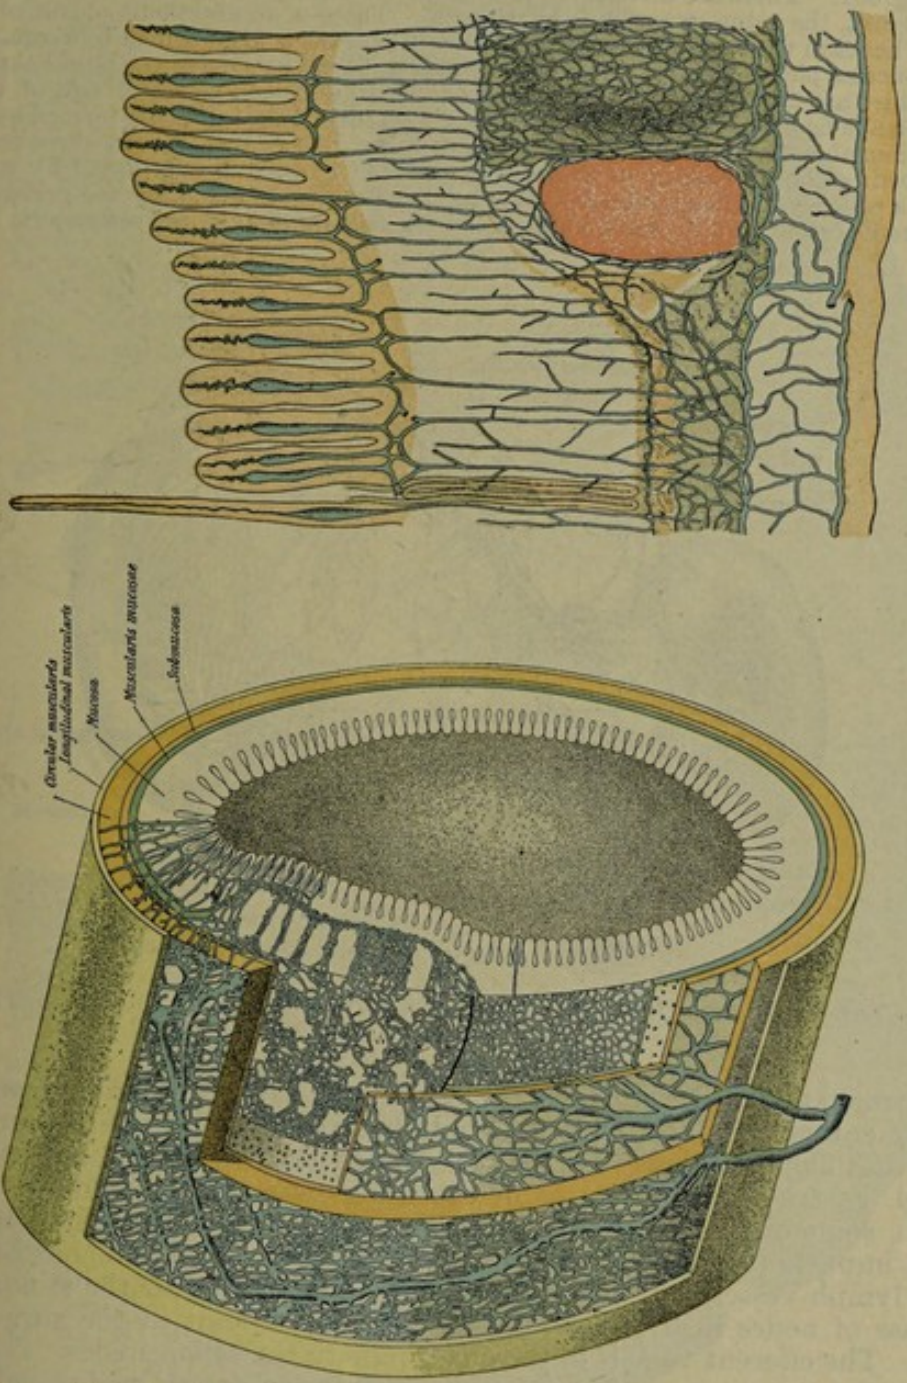

FIG. 651.—THE LYMPHATIC VESSELS OF THE INTESTINE. (After Mall.)

In almost all organs there is a peripheral or capsular lymphatic plexus, which anastomoses with the parietal lymphatics, these anastomoses being particularly well developed in the case of the liver. In addition there are one or two deep plexuses in the great majority of the organs which drain partly directly to their regional nodes and partly by way of the peripheral plexus.

THE LYMPHATICS OF THE ALIMENTARY TRACT

The lymphatics of the mouth, pharynx, and esophagus have already been described (pp. 785, 798). In general, throughout the abdominal part of the alimentary canal, the distribution of nodes is as follows: (1) There are primary

regional nodes situated at the roots of the arteries (celiac and the superior and inferior mesenteric arteries); these nodes drain large segments of the intestine (2) groups of definite and constant nodes placed along the branches of the arteries within the mesentery; these drain a definite smaller segment of the intestine (3) chains of nodes along the anastomotic loops of the arteries, close to the intestinal wall; these are of the type called 'intercalated nodes'; (4) solitary or compound follicles, situated within the submucosa or capillary zone of the lymphatics.

What may be taken as the typical arrangement of the lymphatic vessels in the intestine may be seen in fig. 651. There are three zones in which the capillary plexuses are spread out, namely in the subserosa, the submucosa, and the mucosa. There is an abundant plexus of large capillaries just beneath the serosa; in the submucosa the plexus is also formed by large capillaries while the mucosal plexus is finer. The lymph-follicles lie in the zone of the mucosal plexus, and it is from this that the central chyle vessels of the villi arise. The spiral tips of the central lacteals shown in fig. 651 are probably artefacts. The collecting vessels are formed by the union of vessels from the submucous and subserous plexuses. They traverse the three sets of nodes just described. The movement of chyle from the villi is undoubtedly aided by spontaneous contractions of the villi (King, Versar). Its further progress is aided, by the peristaltic movements of the intestine, and, in some animals, by the contractions of the mesenteric lymphatics (Florey).

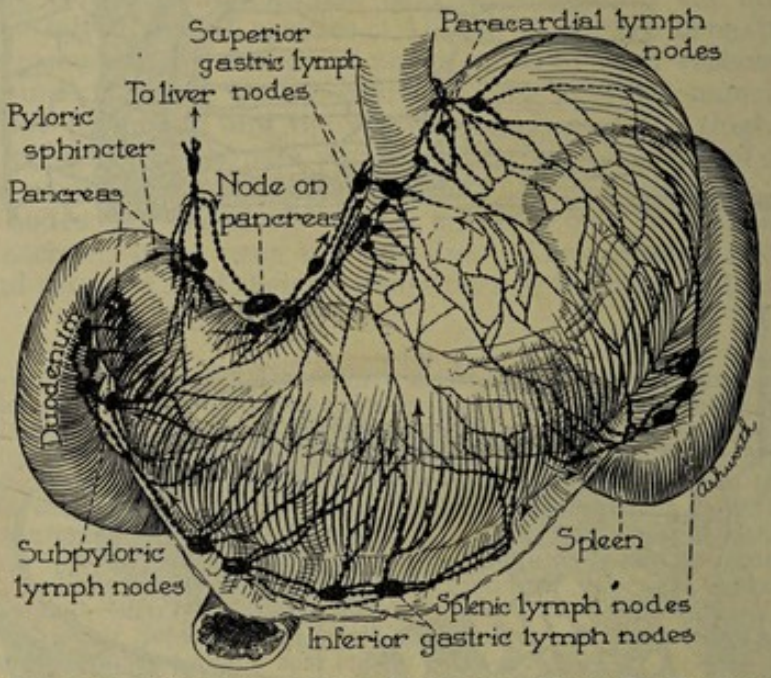

FIG. 652.—THE LYMPHATIC DRAINAGE OF THE STOMACH. (From Dr. Horton, in The Proceedings of the Staff of the Mayo Clinic, 1927, Volume 2.)

The lymphatics of the stomach (fig. 652).—The stomach differs from the rest of the alimentary canal in its blood-supply in having a ventral anastomotic loop, namely, that along the lesser curvature. Along this loop is the **superior gastric chain** [lgl. gastricæ superiores] of nodes, lying between the folds of the lesser omentum, some of them being on the posterior surface of the stomach. This is the most important group of nodes draining the stomach, and it has been shown that the lymph-vessels from the pylorus run obliquely across the stomach to the main mass of nodes near the cardia, an important point in the surgery of the pylorus. The efferent vessels of the chain pass to the celiac nodes. The vessels of the greater curvature pass to a group of **inferior gastric nodes** [lgl. gastricæ inferiores], situated along the right gastroepiploic artery, while those of the fundus follow the short gastric and left gastroepiploic vessels to the nodes which lie along the splenic artery [lgl. pancreaticolienales], both these sets of nodes also draining to the celiac group. There is a zone half-way between the lesser and greater curvatures, in which the lymphatics are scanty. The lymphatics of the cardia connect with those of the esophagus, and the mucosal plexus of the pylorus is continuous with that of the duodenum.

The lymphatics of the duodenum.—The lymphatics of the duodenum depart somewhat from the type, owing to its relations with the pancreas and the bile-ducts. The collecting vessels end: (1) in nodes ventral to the pancreas, which

follow the pancreaticoduodenal artery to the hepatic chain; (2) in nodes dorsal to the pancreas, which follow the superior mesenteric artery to the superior mesenteric nodes. There are anastomoses between the lymphatics of the duodenum and those of the pylorus, of the pancreas, and of the chain along the common bile-duct.

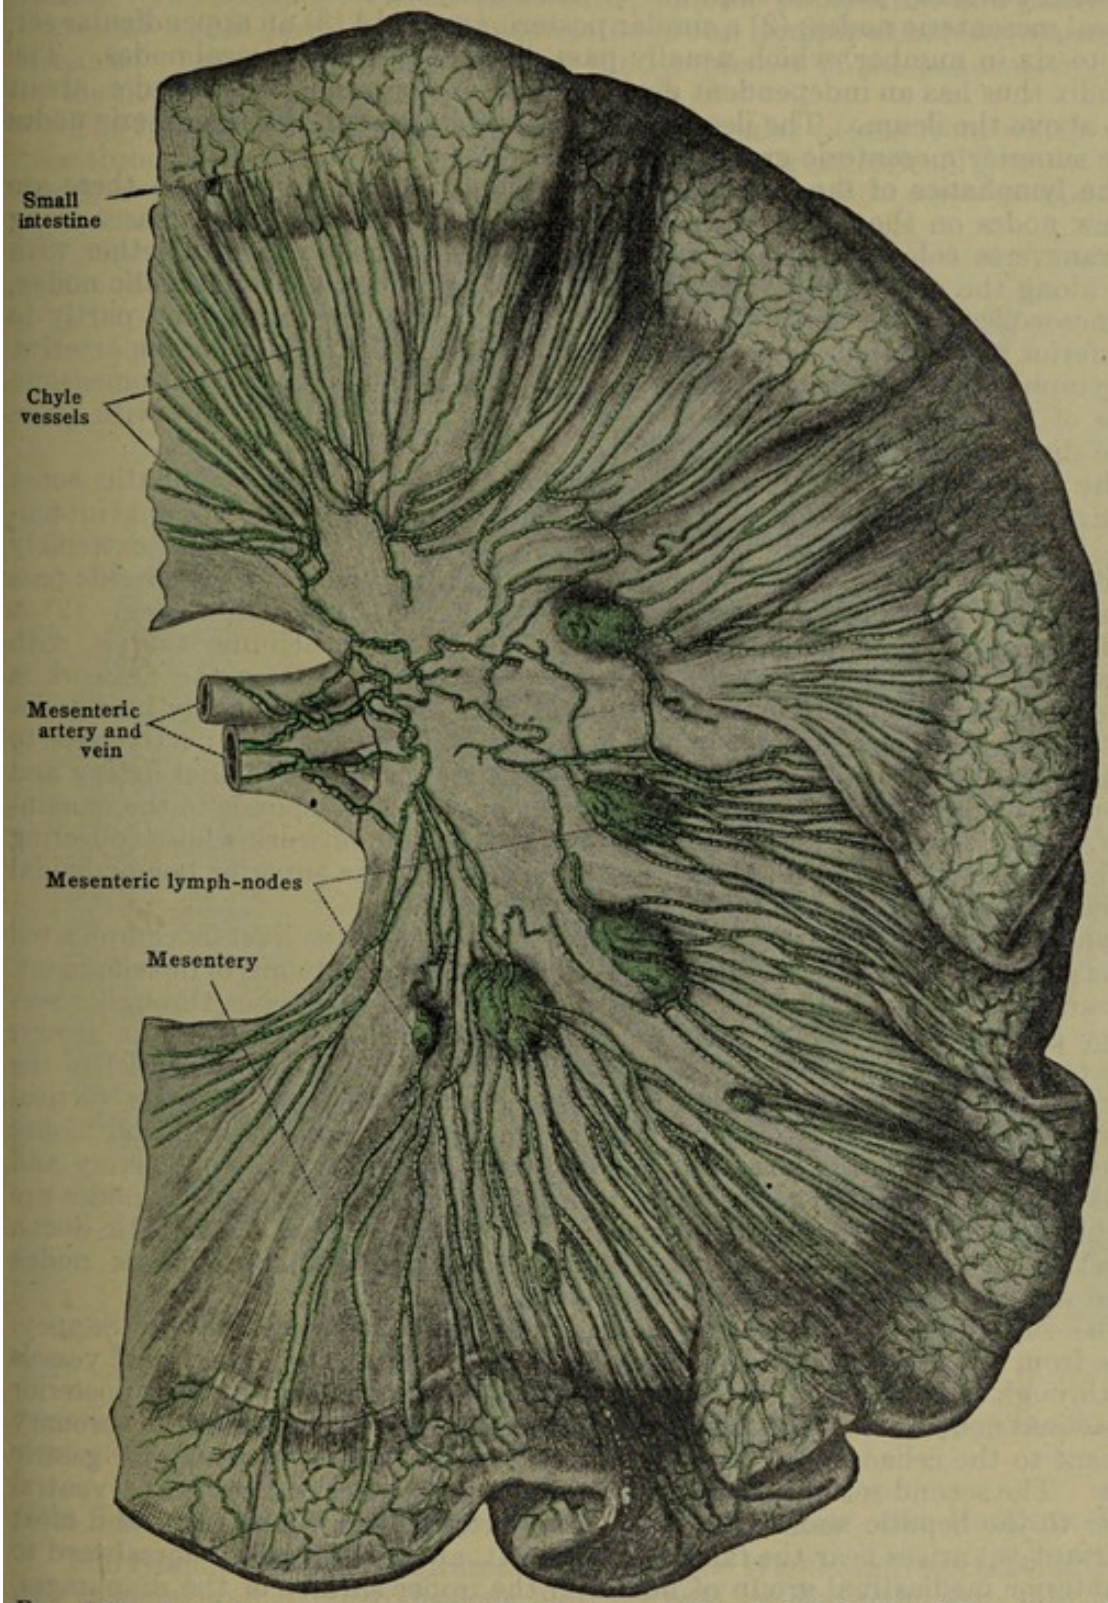

FIG. 653.—LYMPHATICS OF THE SMALL INTESTINE. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

The **lymphatics of the jejunoileum** (fig. 653) have already served as the type of the arrangement of the intestinal lymphatics (see above). During the absorption of fats from the intestines, the mesenteric lymphatics contain the chyle and appear milk-white in color. The group of **mesenteric nodes** to which the lymphatics of the small intestine pass is the largest and one of the most important in the body, its individual nodes numbering from 130 to 150.

The lymphatics of the ileocecal region (figs. 654, 655).—The surgical importance of the lymph-nodes in connection with the vermiform process (appendix) warrants a detailed description of them, in which the observations of Brödel will be followed. The drainage of the cecum and appendix is along the ileocolic artery, and is carried on by three sets of collecting vessels—(1) an anterior cecal set, which generally pass through one or more outlying nodes before reaching the ileocecal mesenteric nodes; (2) a similar posterior set; and (3) an appendicular set, three to six in number, which usually pass directly to the ileocecal nodes. The appendix thus has an independent drainage into one or two ileocecal nodes, about 3 cm. above the ileum. The ileocecal chain drains through the mesenteric nodes to the superior mesenteric group.

The lymphatics of the large intestine.—Along the ascending colon there are but few nodes on the terminal vascular arches, but the number increases along the transverse colon, especially at its two angles. These nodes, together with those along the descending and sigmoid colons, are termed the **mesocolic nodes,** [lgl. mesocolicæ] and they drain partly to the superior mesenteric and partly to the inferior mesenteric nodes, their efferents following the corresponding arteries. The lymphatics of the transverse colon connect with those of the great omentum. Those of the descending colon are more scanty, and connect below with those of the sigmoid colon and rectum.

The lymphatics of the rectum and anus.—There are three lymphatic zones of the rectum and anus. (1) An **inferior zone,** corresponding to the anal integument, in which the capillary networks, both superficial and deep, are extremely abundant, and from which from three to five collecting vessels on either side pass to the inguinal region and end in the medial superficial inguinal nodes. (2) A **middle zone,** corresponding to the transition zone of epithelium—that is, with the mucous membrane below the columns of Morgagni. Here the network is coarse, and has its meshes arranged vertically; its ducts drain partly into nodes situated along the inferior and middle hemorrhoidal arteries, and partly pass to nodes in the mesorectum, situated along the superior hemorrhoidal artery and known as the **anorectal** nodes. (3) The **superior zone** corresponds to the remainder of the rectal mucous membrane, and contains a rich network whose collecting vessels pass to the anorectal glands, and thence along the superior hemorrhoidal arteries to the mesocolic and inferior mesenteric nodes.

Lymphatics of the liver.—The lymphatic drainage of the liver is complicated and has great need of being entirely restudied from the standpoint of development. Its course is mainly to the celiac nodes, but on the way it passes through a secondary group of three to six **hepatic nodes,** situated along the hepatic artery. Some of these nodes are along the horizontal part of the artery, parallel to the superior border of the pancreas, while the rest follow the artery in its vertical course along with the portal vein, and become continuous at the portal fissure with two distinct chains of nodes, one of which follows the hepatic artery and portal vein, and the other the cystic and common bile-ducts. These nodes are variable, but one constant node is at the junction of the cystic and hepatic ducts. A part of the drainage of the liver is also through the **diaphragmatic nodes** of the anterior and posterior mediastinal groups.

The superficial lymph-vessels of the liver have been studied by Sappey. Those from the superior surface include three sets. From the dorsal part vessels pass through the diaphragm with the vena cava, and end in the adjacent posterior mediastinal nodes. Some of these vessels from the right lobe pass in the coronary ligament to the celiac nodes, and some from the left lobe to the superior gastric nodes. The second set of vessels from the superior surface runs over the ventral border to the hepatic nodes situated in the portal fissure. The third and most important set arises near the falciform ligament, and passes partly dorsalward to the anterior mediastinal group of nodes on the upper surface of the diaphragm, and to the nodes around the vena cava, and partly ventralward to the hepatic nodes of the portal fissure.

The collecting vessels of the inferior surface of the liver pass to the nodes situated in the portal fissure, either along the artery or the bile-ducts.

The lymphatics of the **gall-bladder** join the hepatic nodes along the cystic and common bile-ducts, and also the superior pancreatic nodes.

Lymphatics of the pancreas.—The lymph-vessels which drain the pancreas fall, according to Bartels, into four groups: left, anterior (upper), right and

posterior (lower). (1) The left group drain the tail of the pancreas and pass to the splenic lymph-nodes, at the hilus of the spleen. (2) Anteriorly lymphatics pass to the superior pancreatic, superior gastric and hepatic nodes. (3) To the right, lymphatics pass to the pancreaticoduodenal lymph-nodes. (4) Posteriorly lymphatics pass to the aortic, mesenteric, mesocolic, and inferior pancreatic nodes. The splenic, superior pancreatic, inferior pancreatic, and pancreaticoduodenal nodes form a closely associated group [lymphoglandulæ pancreaticolienales]. Anastomoses exist between the lymphatics of the pancreas and those of the duodenum.

The **lymphatics of the spleen** form a subcapsular plexus from which vessels pass through the hilus to the **splenic nodes** (of the pancreaticolienal group). These nodes are variable in number and are situated along the course of the splenic

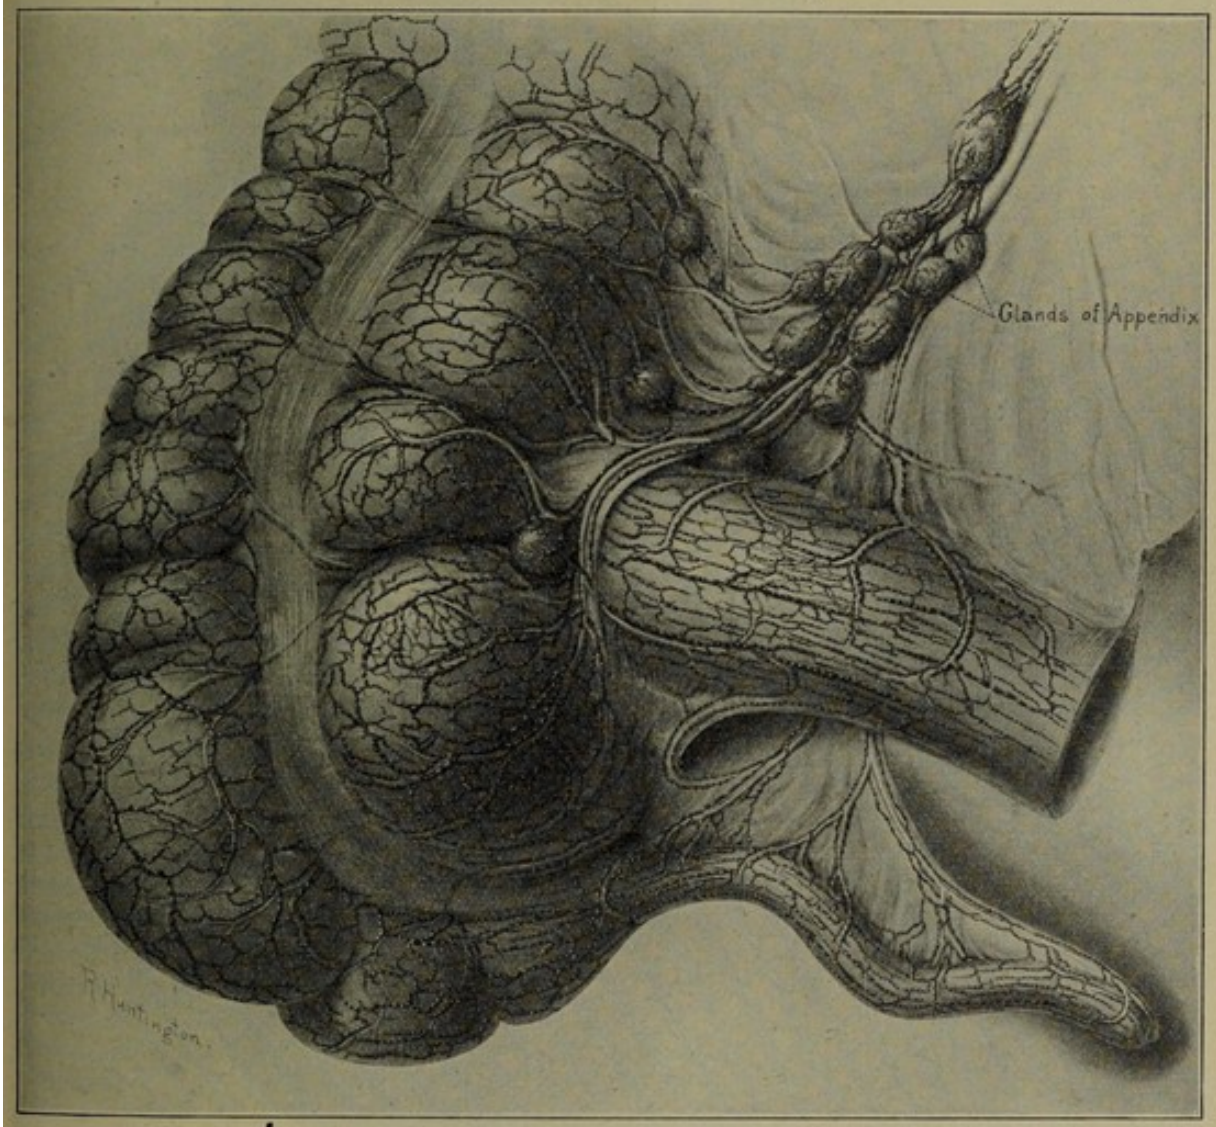

FIG. 654.—THE LYMPHATICS OF THE ILEOCECAL REGION, ANTERIOR VIEW. (After Kelly.)

vessels. In addition to the spleen, they drain the fundus of the stomach and a part of the pancreas.

THE LYMPHATICS OF THE SUPRARENAL GLAND AND OF THE URINARY TRACT

The lymphatics of the suprarenal gland.—The lymphatic vessels coming from the capsular and parenchymatous plexuses pass, on the right side, into two or three anterior para-aortic nodes, and a small retrovenous gland, near the crus of the diaphragm; on the left side, into para-aortic nodes, and, in part, through the diaphragm, in company with the splanchnic nerve, to a posterior mediastinal gland, lying between the ninth thoracic vertebra and the aorta. Anastomoses occur with the lymphatics of the kidney.

In addition to the capsular lymphatics proper, Kumita describes a subserous plexus, which is present over both kidney and suprarenal, which anastomoses with the lymphatics of the liver and diaphragm. The efferents of this plexus collect, on the right side, to a gland placed

to the right of the inferior vena cava, anterior to the right renal vein, and on the left side to a gland anterior to the left renal vein.

The lymphatics of the kidney.—The lymphatic vessels from the deep capsular and parenchymatous lymphatics of the kidney run to the nodes of the lumbar chain (fig. 656). On the right side, part of the nodes concerned lie ventral and part dorsal to the renal vein; one of the nodes lies as far caudalward as the bifurcation of the aorta; and one or two vessels may pass to preaortic nodes. On the left side the vessels end in four or five nodes of the lumbar group. The efferents of these nodes end in the thoracic duct.

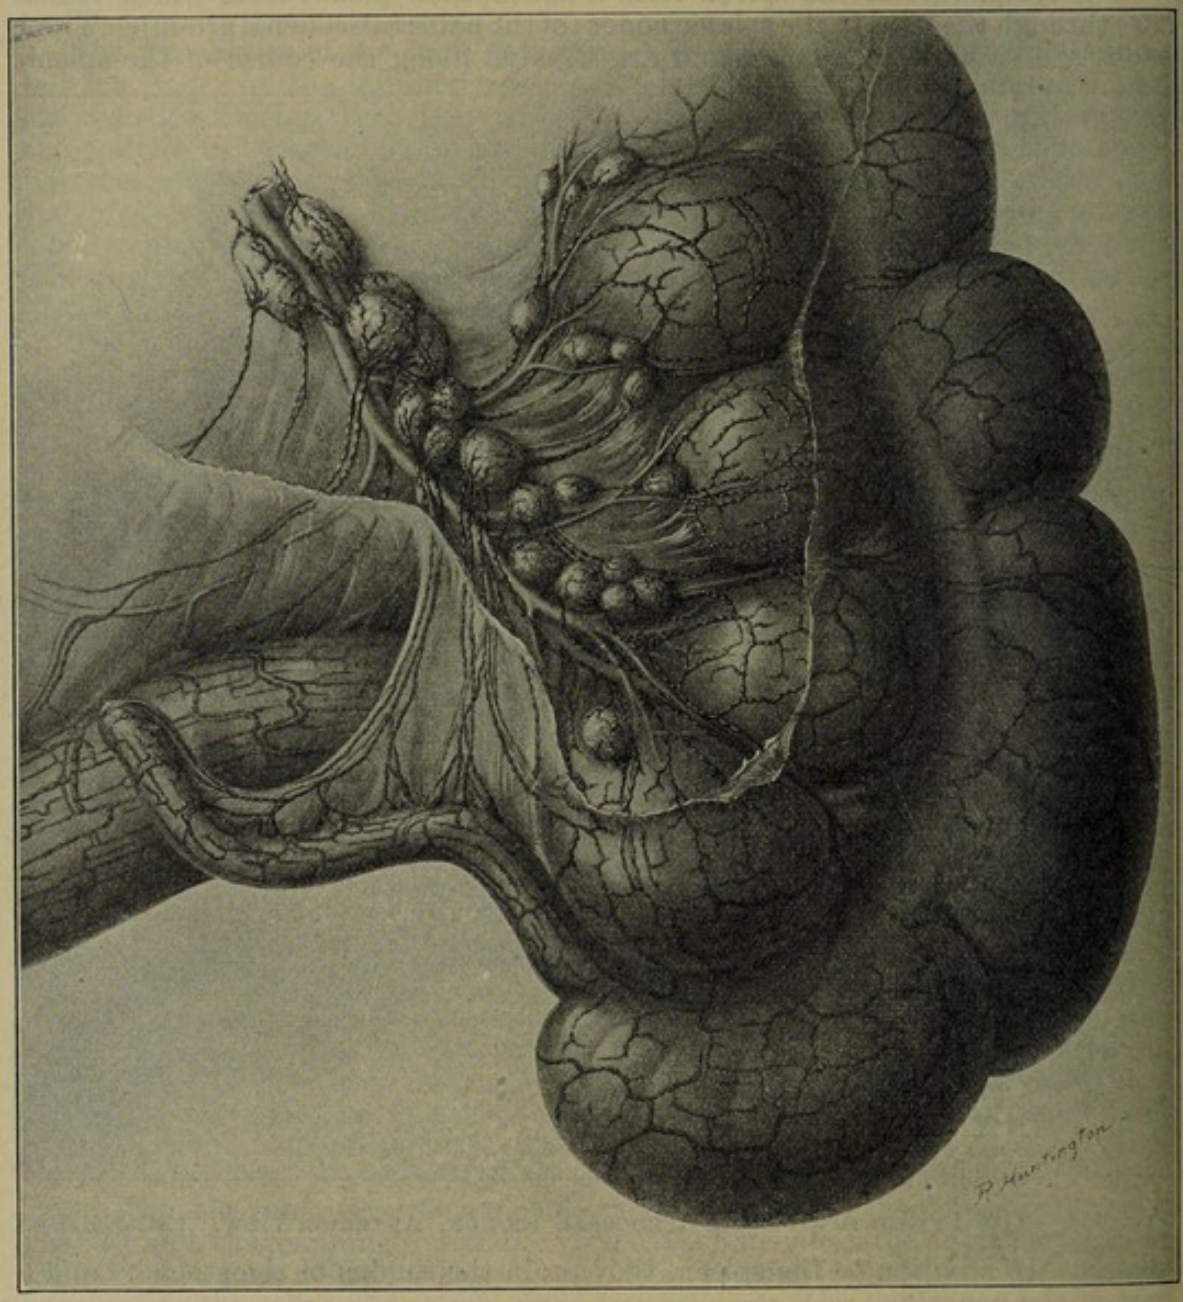

FIG. 655.—THE LYMPHATICS OF THE ILEOCECAL REGION, POSTERIOR VIEW. (After Kelly.)

The lymphatics of the ureter.—According to Sakata, the lymphatics of the ureter fall into three groups: (1) An anterior (upper) group, which run to the anterior lumbar nodes, or join the renal lymphatics; (2) a middle group which pass to the posterior lumbar and interiliac nodes; (3) a posterior (lower) group which pass to hypogastric nodes and which anastomose with lymphatics of the bladder.

The lymphatics of the bladder (fig. 657).—The collecting vessels from the anterior part of the inferolateral surface pass to a node of the external iliac group, situated near the femoral ring; those from the upper part of the inferolateral surface and anterior part of the superior surface pass to the middle node of the middle group of the external iliac chain; and those from the rest of the superior

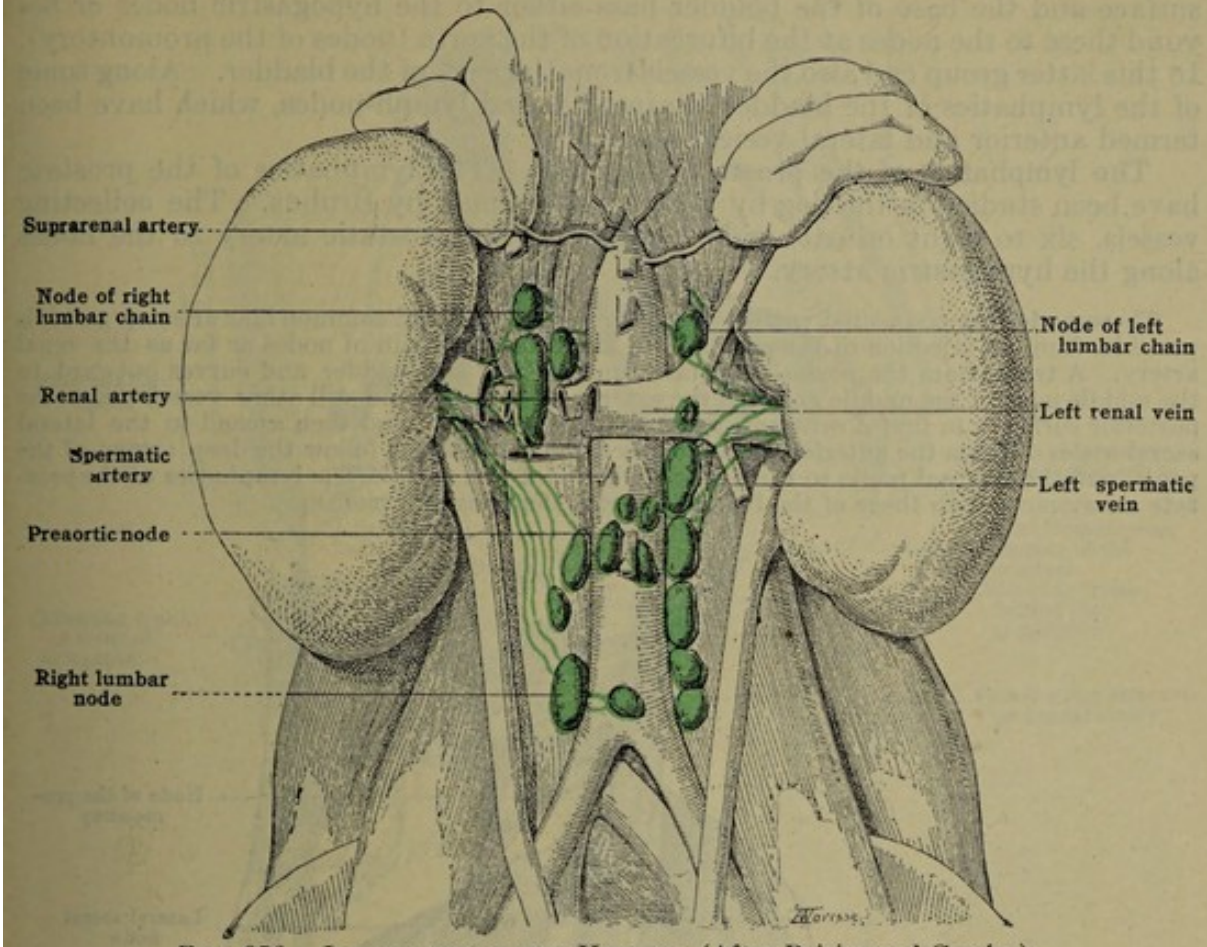

FIG. 656.—LYMPHATICS OF THE KIDNEY. (After Poirier and Cunéo.)

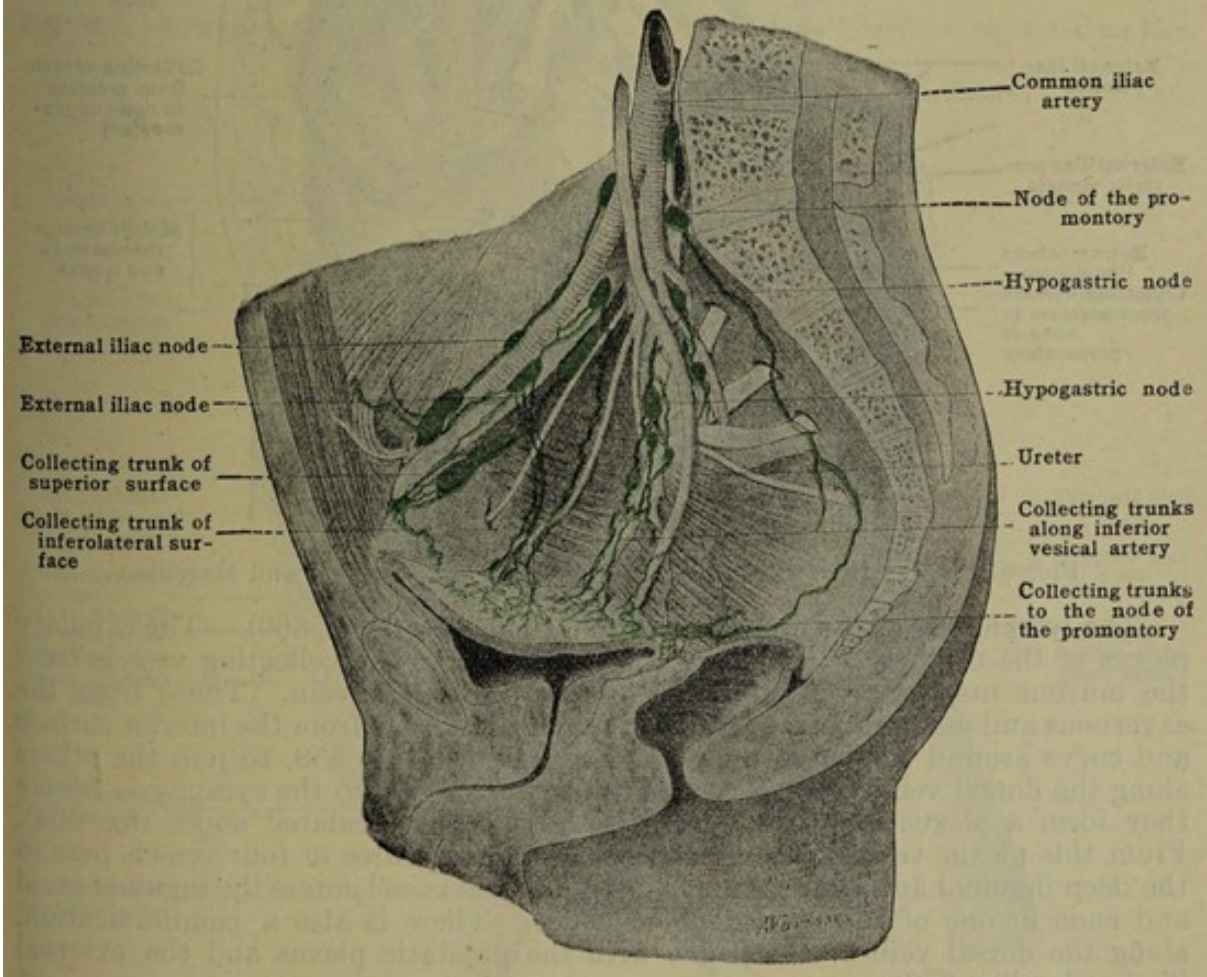

FIG. 657.—LYMPHATICS OF THE BLADDER. (After Cunéo and Marcille.)

surface and the base of the bladder pass either to the hypogastric nodes or beyond these to the nodes at the bifurcation of the aorta (nodes of the promontory). In this latter group end also the vessels from the neck of the bladder. Along some of the lymphatics of the bladder are intercalated lymph-nodes, which have been termed anterior and lateral vesical nodes.

The lymphatics of the prostate (fig. 658).—The lymphatics of the prostate have been studied in the dog by Walker and in man by Bruhns. The collecting vessels, six to eight on each side, pass along the prostatic artery to the nodes along the hypogastric artery.

These nodes are connected with those along the external and common iliac arteries, and it is possible, from an injection of the prostate, to fill the entire chain of nodes as far as the renal artery. A trunk from the posterior surface runs up over the bladder and curves outward to the middle node of the middle group of the external iliac chain, and still other vessels from the posterior surface run first downward, pass around the rectum, and then ascend to the lateral sacral nodes. From the anterior surface a descending trunk may follow the deep artery of the penis, and the internal pudic to the hypogastric nodes (fig. 658). The lymphatics of the prostate anastomose with those of the bladder. ductus deferens and rectum.

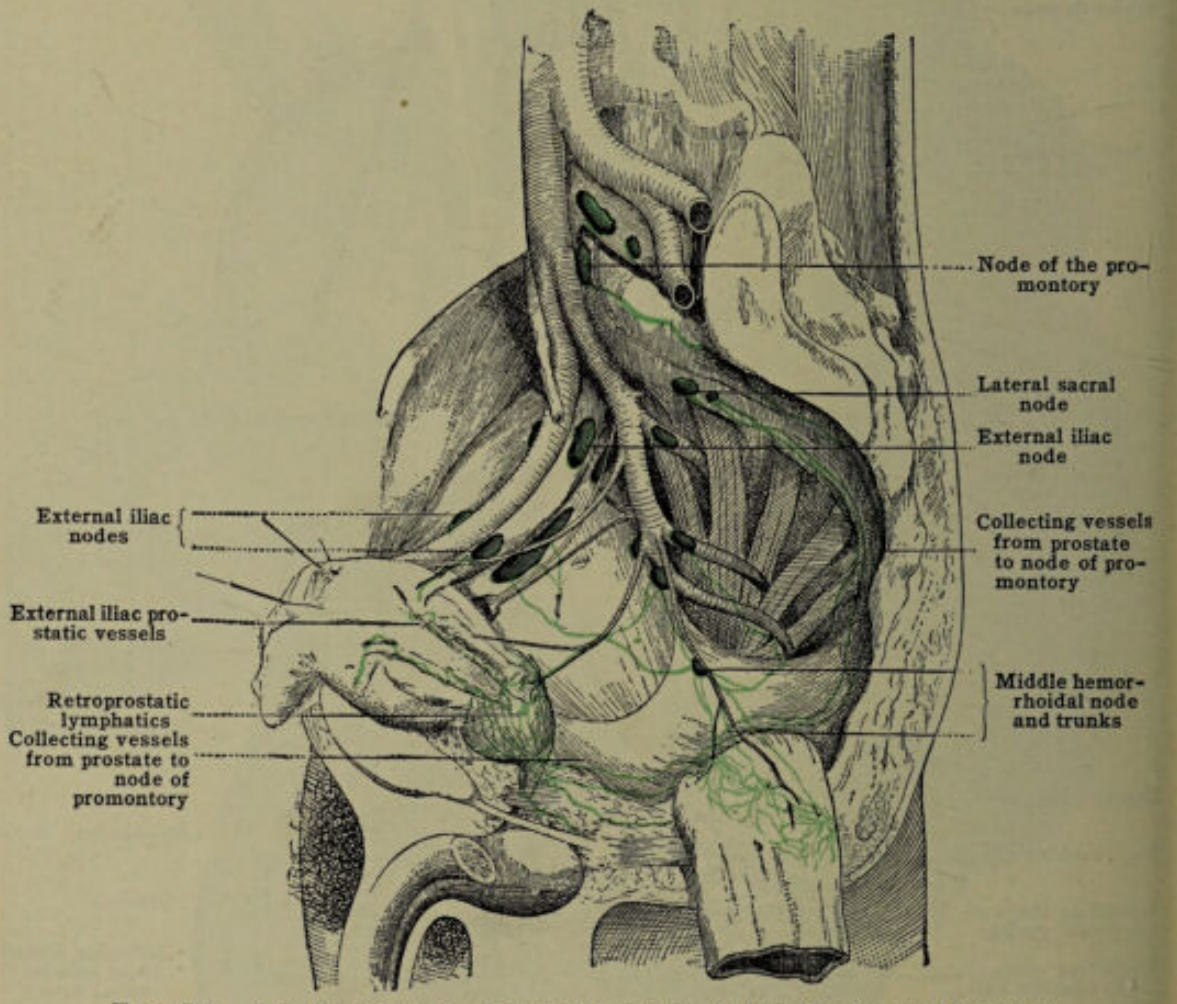

FIG. 658.—THE LYMPHATICS OF THE PROSTATE. (After Cunéo and Marcille.)

The lymphatics of the urethra.—1. *In the male* (figs. 659, 660).—The capillary plexus of the urethra is in the mucous membrane. The collecting vessels from the mucous membrane of the glans follow the dorsal vein. Those from the cavernous and membranous portions of the urethra start from the inferior surface and curve around the corpora cavernosa, as seen in fig. 659, to join the others along the dorsal vein. These vessels run with the vein to the symphysis, where they form a plexus in which there may be some intercalated nodes (fig. 660). From this plexus vessels pass in various directions: Three or four vessels pass to the deep inguinal and external iliac nodes, and one vessel enters the inguinal canal and ends in one of the external iliac nodes. There is also a communication, along the dorsal vein of the penis, with the prostatic plexus and the external iliac nodes (fig. 659).

The vessels from the membranous portion either follow the internal pudic artery, or pass to the symphysis and end in the external iliac nodes, or pass

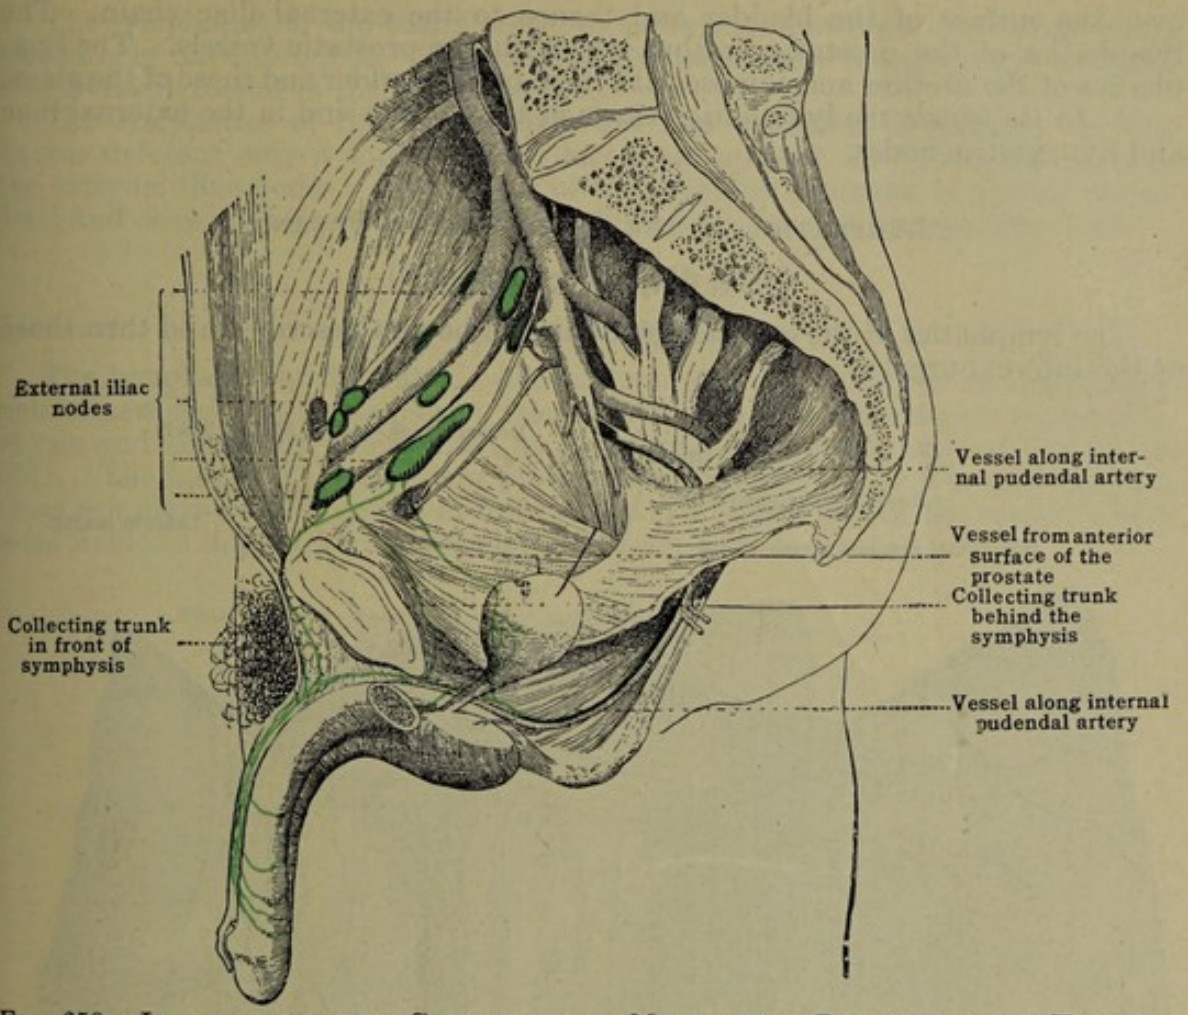

FIG. 659.—LYMPHATICS OF THE CAVERNOUS AND MEMBRANOUS PORTIONS OF THE URETHRA. (After Cunéo and Marcille.)

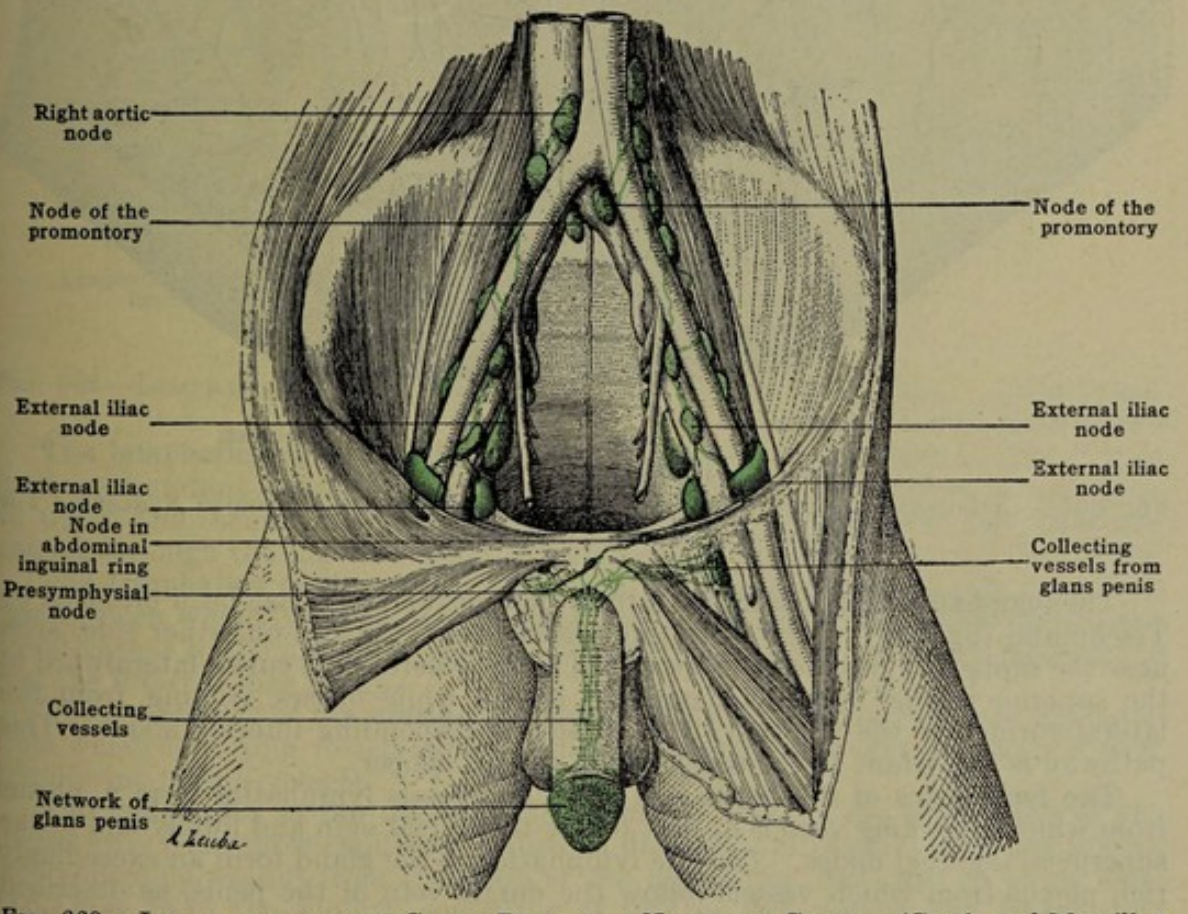

FIG. 660.—LYMPHATICS OF THE GLANS PENIS IN A NEW-BORN CHILD. (Cunéo and Marcille.)

over the surface of the bladder and thence to the external iliac chain. The lymphatics of the prostatic urethra run with the prostatic vessels. The lymphatics of the urethra anastomose with those of the bladder and those of the glans.

2. *In the female* the lymphatic vessels of the urethra end in the external iliac and hypogastric nodes.

Lymphatics of the Reproductive Organs

In the Male (Figs. 658–660)

The lymphatics of the external genitalia will be first described and then those of the internal organs.

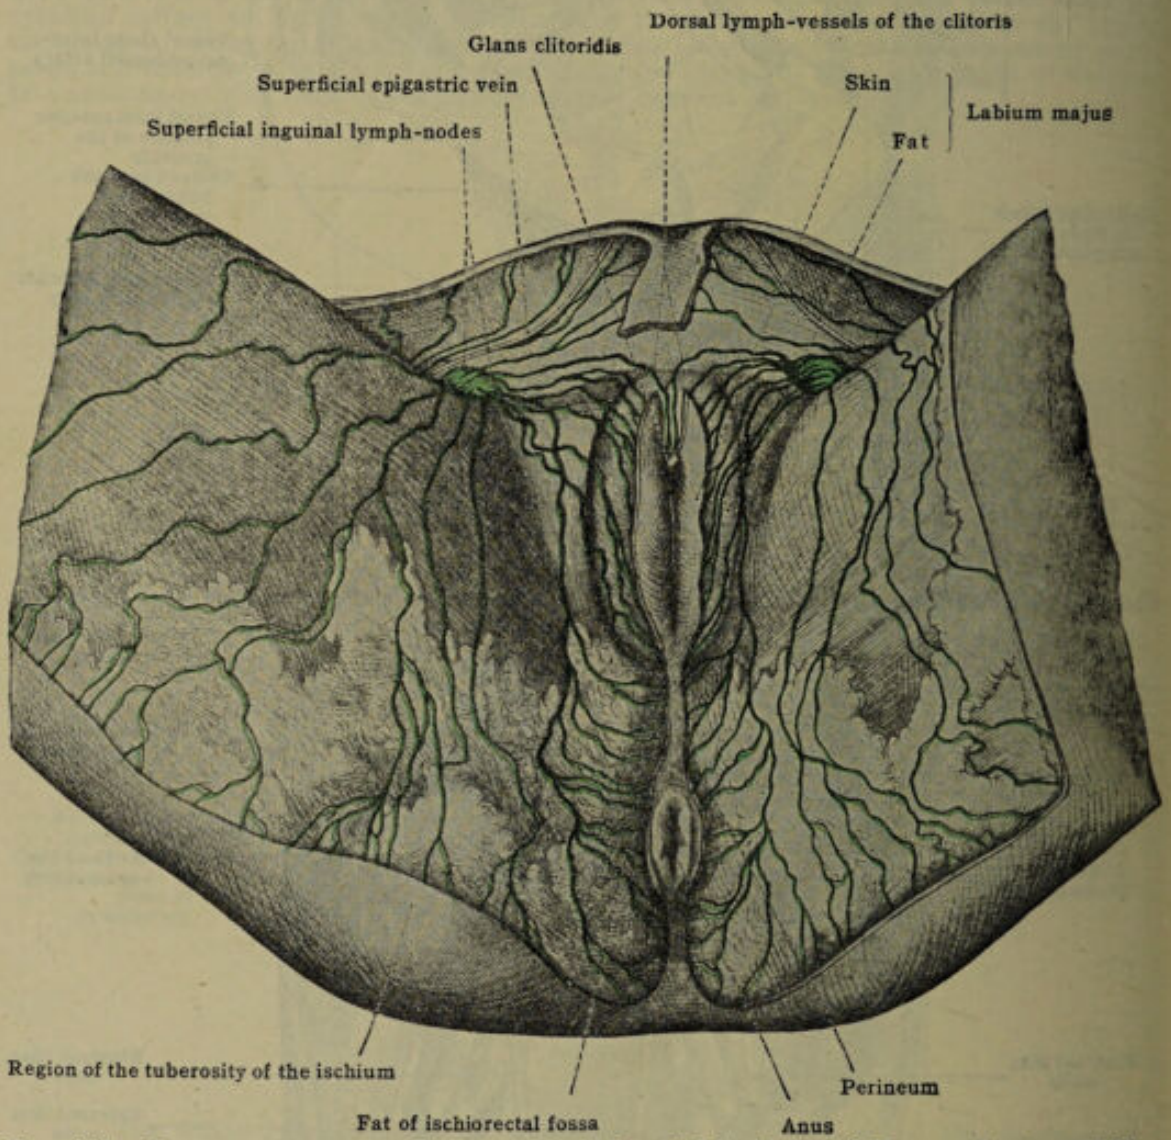

Fig. 661.—Lymphatics of the Perineum. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

The lymphatics of the scrotum form a rich plexus which has been pictured by Teichmann (fig. 622). The collecting vessels, ten to fifteen on either side, arise near the raphe and pass to the root of the penis, where some curve lateralward to the superior medial superficial inguinal nodes; while others, coming from the lateral surface of the scrotum, pass to the corresponding inferior nodes. This pathway is important in the extension of scrotal cancer.

The lymphatics of the penis.—(1) The cutaneous lymphatics form a plexus from which collecting vessels at first follow the dorsal vein and finally end in the superficial inguinal nodes. (2) The lymphatics of the gland form an exceedingly rich plexus from which vessels follow the dorsal vein of the penis, as described under the urethra, and end in the deep inguinal and external iliac nodes (fig. 660). (3) The lymphatics of the erectile structures are little known.

The **lymphatics of the testis** are both superficial and deep, the latter being exceedingly hard to inject. The collecting vessels follow the spermatic cord and blood-vessels to end in the lumbar nodes.

The lymphatics of the ductus deferens and vesiculæ seminales.—In the ductus deferens only a superficial set has been injected, and its vessels pass to the external iliac nodes. The plexus of the vesiculæ seminales is double, superficial and deep, and its vessels pass to the external iliac and hypogastric nodes.

Lymphatics in the Female

(Figs. 661–663)

The lymphatics of the vulva.—Throughout the vulva there is an exceedingly rich, superficial lymphatic plexus, from which collecting vessels pass to the symphysis and there turn lateralward to the medial superficial inguinal nodes (fig. 661). The fact that the capillary plexus is continuous from side to side and that there is a plexus of the vessels in front of the symphysis makes the nodes of both sides liable to infection from a unilateral lesion.

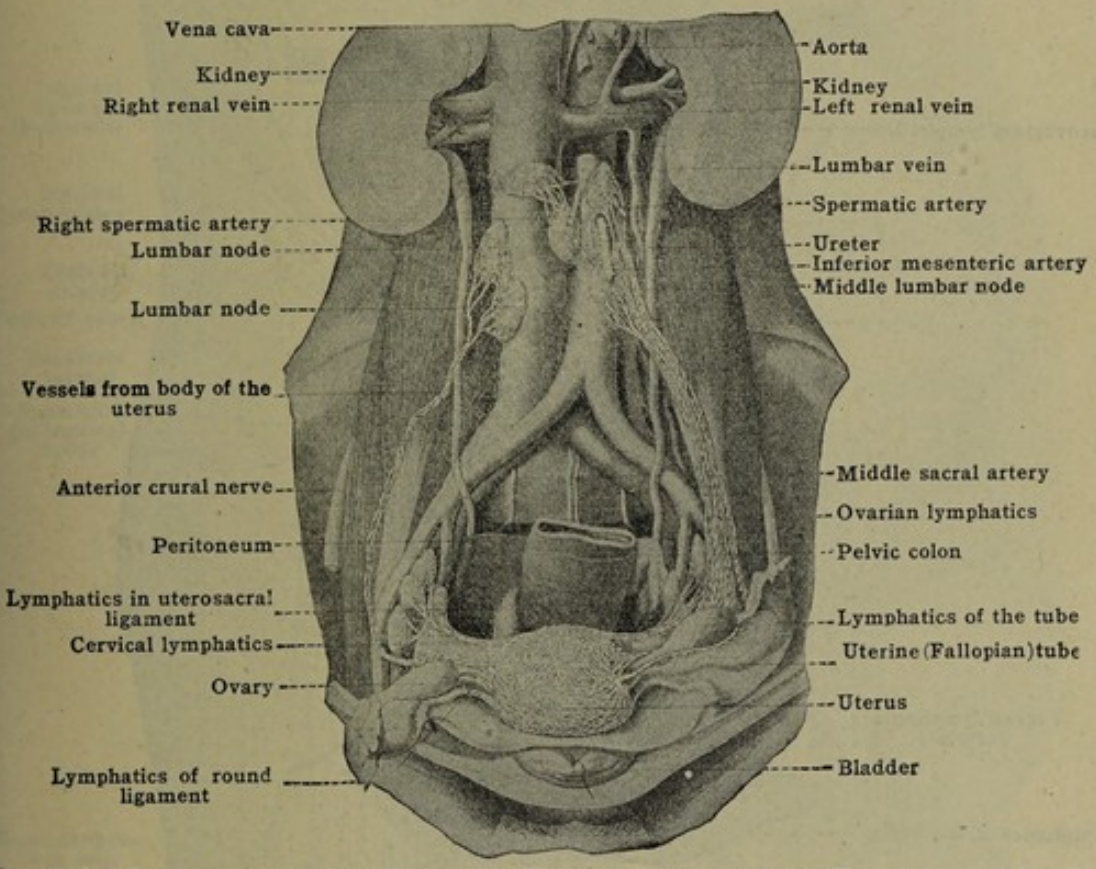

FIG. 662.—LYMPHATICS OF THE INTERNAL GENITAL ORGANS IN THE FEMALE. (After Poirier.

The lymphatics of the clitoris.—The lymphatics of the glans of the clitoris form an abundant network from which collecting vessels pass toward the symphysis pubis, and thence principally to the deep inguinal nodes, one or two, however, passing through the inguinal canal to terminate in the lower external iliac nodes.

The lymphatics of the ovary.—The ovary has a remarkably rich lymphatic plexus, from which from four to six vessels leave the hilus and follow the ovarian blood-vessels to the lumbar nodes. One vessel may run in the broad ligament to join the internal iliac group.

The **lymphatics of the uterine (Fallopian) tube** form three capillary networks from which collecting vessels run in part with those of the ovary, and in part with the uterine lymph-vessels.

The lymphatics of the uterus.—According to Poirier, the lymphatics of the uterus arise from three capillary plexuses, a mucous, a muscular, and a peritoneal. The collecting vessels from the *body of the uterus* (fig. 662) are in three sets: (1) Those from the fundus, consisting of four or five vessels, run lateralward through the broad ligament and the suspensory ligament of the ovary and follow the ovarian vessels to the lumbar and preaortic nodes. They anastomose with

the lymphatics from the ovary opposite the fifth lumbar vertebra; (2) some small vessels from the fundus follow the round ligament of the uterus and terminate in the inguinal nodes; and (3) others from the body of the uterus pass laterally with the uterine vessels and terminate in the iliac nodes.

The collecting vessels from the *cervix* (figs. 662, 663), five to eight in number, form a large lymphatic plexus just after leaving the cervix. From this plexus run three sets of vessels. Two or three vessels pass lateralward with the uterine artery in front of the ureter, and end in the external iliac nodes; a second set passes behind the ureter and ends in a node of the hypogastric group; and a third set from the posterior surface runs downward over the vagina and then backward and upward to end in the lateral sacral nodes and node of the promontory of the sacrum.

The lymphatics of the vagina (fig. 663).—There are two lymphatic plexuses in the vagina, a superficial and deep—the latter, the mucosal plexus, being exceedingly rich. The collecting vessels are in three groups. The superior set

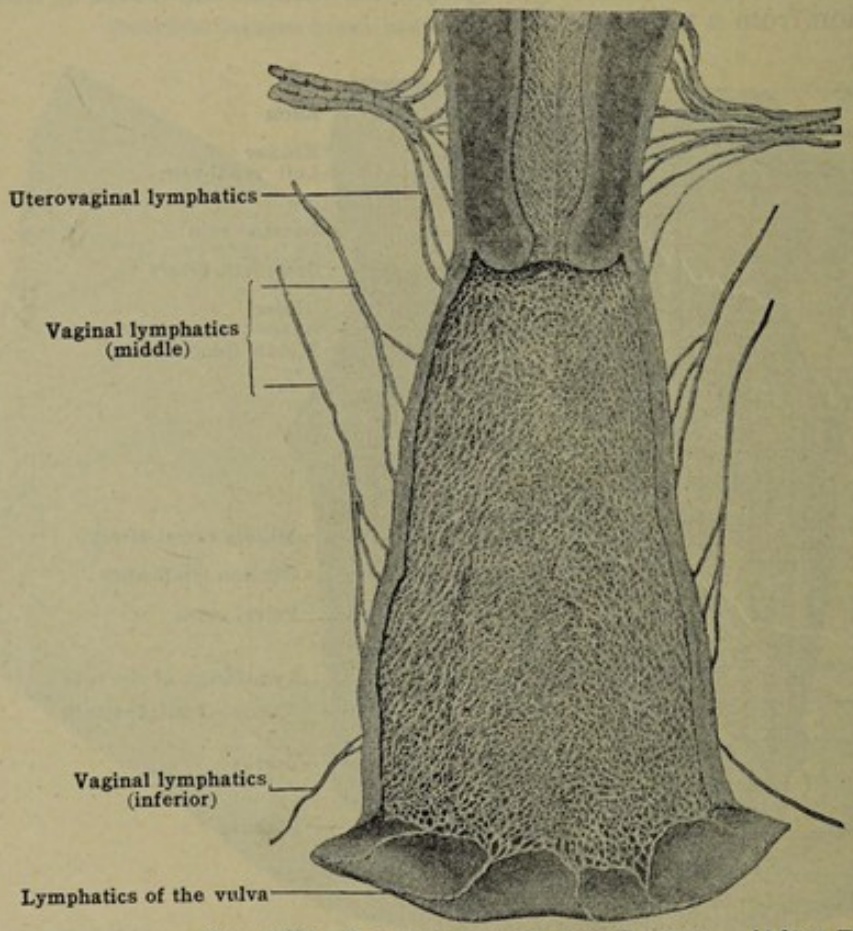

FIG. 663.—LYMPHATICS OF THE VAGINA. (After Poirier.)

(uterovaginal) drains the upper third of the vagina and takes the same course as those from the lower cervical portion of the uterus; the middle set follows the vaginal artery to the hypogastric nodes; and the inferior set runs to the lateral sacral nodes and to those of the promontory. The capillary network of the lower part of the vagina is continuous with the plexus of the vulva, which drains to the inguinal nodes.

E. THE LYMPHATICS OF THE LOWER EXTREMITY

1. THE LYMPHATIC NODES OF THE LOWER EXTREMITY

The principal group of nodes of the lower extremity is situated in the inguinal region, and hence is known as the **inguinal group** (figs. 664, 665). It is in many respects similar to the axillary group, although it is not quite equivalent to it developmentally. The nodes composing it are divisible into a superficial and a deep group, the former containing many more and larger nodes than the latter. Furthermore, it is convenient to divide each of these groups into an upper and a

lower set, the dividing line being an arbitrary line drawn horizontally through the point where the saphenous vein pierces the fascia of the fossa ovalis. The nodes above this line are termed collectively the **inguinal nodes** [lgl. inguinales], while those below it are known as the **subinguinal nodes** [lgl. subinguinales).

The superficial inguinal nodes lie along the base of the femoral trigone immediately below Poupart's ligament, superficial to the fascia lata. In thin

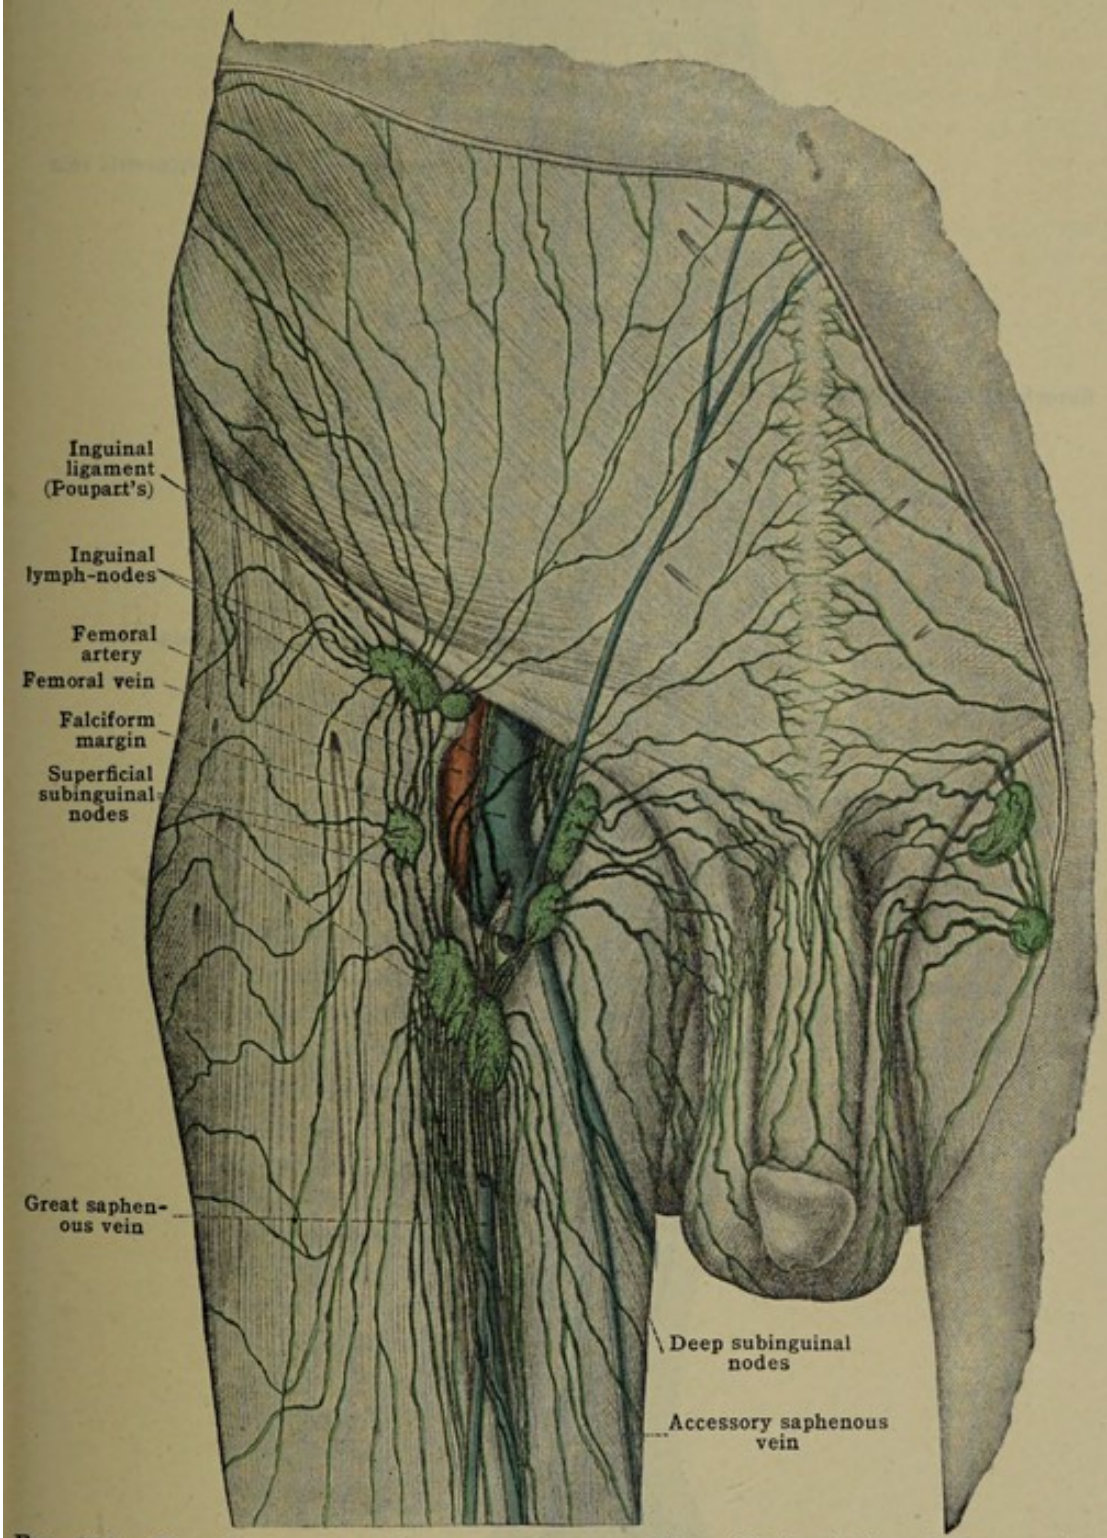

FIG. 664.—THE SUPERFICIAL INGUINAL NODES. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

persons, they are often palpable. Their number varies from ten to twenty. They receive the subcutaneous drainage of the anterior and lateral abdominal walls, the gluteal region, the external genitalia and the perineal region. Their efferents descend to the fossa ovalis, which they perforate along with the saphenous vein and terminate in the lower external iliac nodes.

The **superficial subinguinal nodes** occupy the lower part of the femoral trigone and receive the entire superficial drainage of the lower extremity, as well as

a few vessels from the gluteal region and from the perineum. Their efferents pierce the fossa ovalis and pass partly to the deep subinguinal nodes and partly directly to the lower external iliac nodes.

The deep inguinal nodes.—The deep nodes are small, and vary from one to three. They lie medial to the femoral vein, the highest one (*node of Cloquet or of Rosenmüller*) being placed in the femoral ring and being of especial surgical

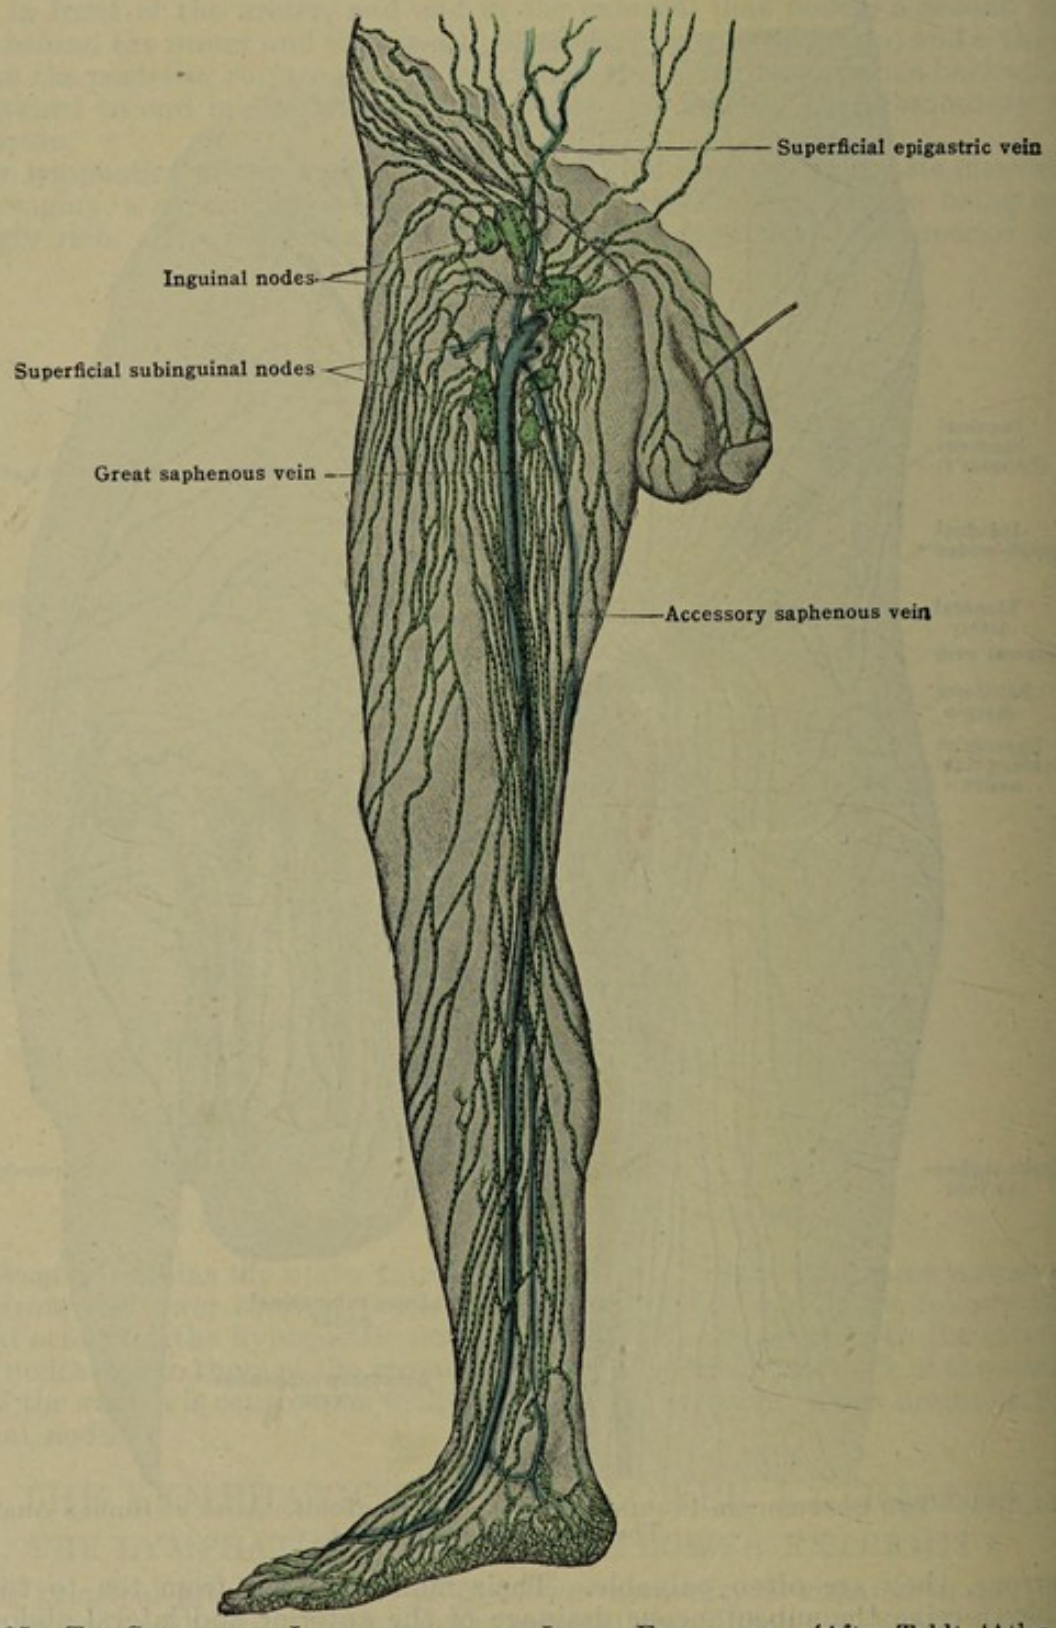

FIG. 665.—THE SUPERFICIAL LYMPHATICS OF THE LOWER EXTREMITY. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

interest in that, when enlarged, it may simulate a strangulated hernia. The lowest node is below the point where the great saphenous joins the femoral vein. These deep nodes receive the deep lymphatics of the lower extremity, also vessels

from the glans penis or clitoris, and some of the vessels from the superficial subinguinal nodes. Their efferent vessels enter the external iliac nodes.

In addition to the inguinal group of nodes there are some other nodes in the lower limb situated along the course of the deep vessels. Thus there is an inconstant node in the course of the anterior tibial vessels below the knee, and

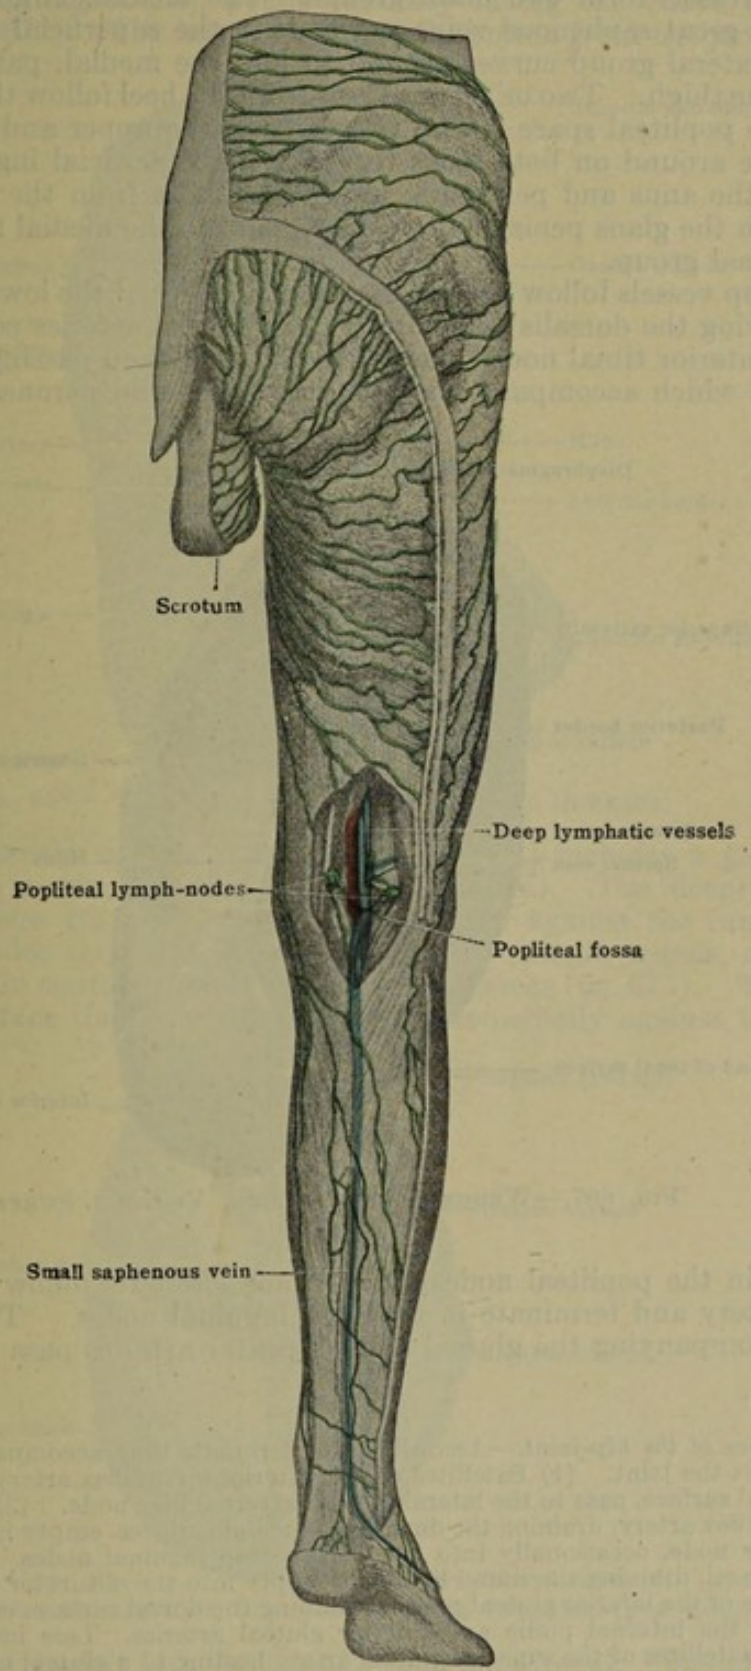

FIG. 666.—THE LYMPHATICS OF THE BACK OF THE LOWER EXTREMITY. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

there is a small group of **popliteal nodes** [lgl. popliteæ], in the popliteal space (fig. 666), which receive the lymphatics accompanying the lesser saphenous vein, also those which accompany the posterior tibial and peroneal vessels, and those which drain the knee-joint.

2. THE LYMPHATIC VESSELS OF THE LOWER EXTREMITY

As in the upper extremity, the subcutaneous capillary plexus of the lower varies greatly in complexity, being most abundant in the soles of the feet. The collecting vessels form two main groups. The medial, larger group (fig. 665) follows the great saphenous vein, and ends in the superficial subinguinal nodes, while the lateral group curves around to join the medial, partly in the leg and partly in the thigh. Two or three vessels from the heel follow the lesser saphenous vein to the popliteal space. The vessels from the upper and dorsal part of the thigh curve around on both sides to reach the superficial inguinal nodes. The vessels of the anus and perineum, as well as those from the external genitalia, except from the glans penis or the clitoris, pass to the medial nodes of the superficial inguinal group.

The deep vessels follow the course of the arteries of the lower extremity, those accompanying the dorsalis pedis and anterior tibial arteries coming into relation with the anterior tibial node (when present), and then passing backward to join the vessels which accompany the posterior tibial and peroneal arteries. These

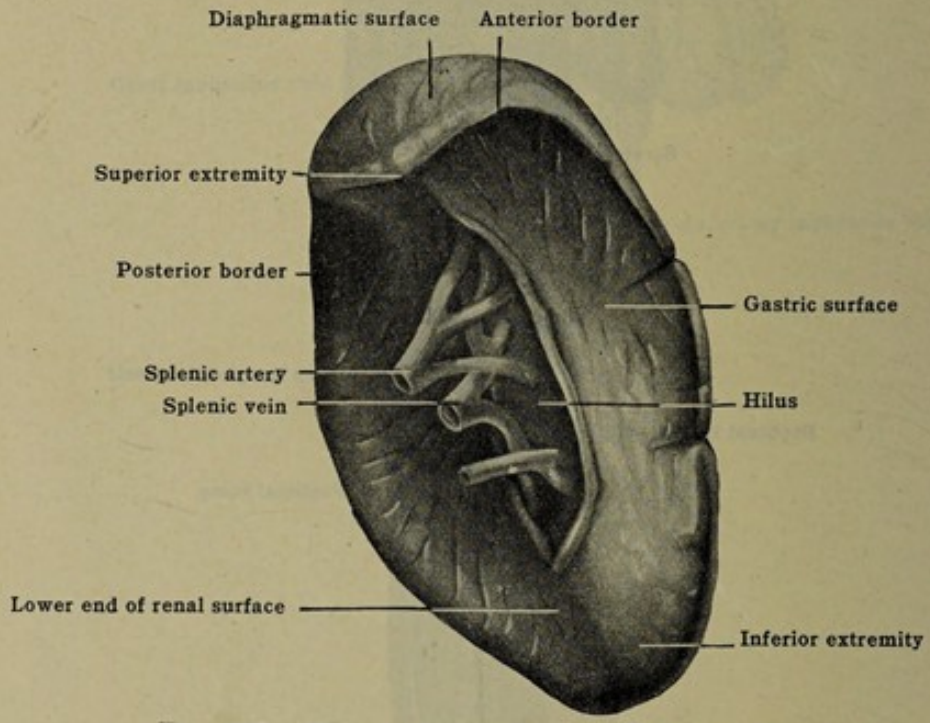

FIG. 667.—WEDGE-SHAPED SPLEEN, VISCERAL SURFACE.

terminate in the popliteal nodes, from which efferents follow the course of the femoral artery and terminate in the deep inguinal nodes. The deep lymphatic vessels accompanying the gluteal and obturator arteries pass to the hypogastric nodes.

Lymphatics of the hip-joint.—According to Clermont, they accompany, in the main, the arteries about the joint. (1) Satellites of the anterior circumflex artery, draining almost the entire ventral surface, pass to the lateral inferior external iliac node. (2) Satellites of the posterior circumflex artery, draining the dorsal and medial surfaces, empty into the medial inferior external iliac node, occasionally into one of the deep inguinal nodes. (3) Satellites of the obturator vessel, draining the round ligament, empty into the obturator or hypogastric nodes. (4) Satellites of the inferior gluteal vessels, draining the dorsal surface, empty into three small nodes along the internal pudic and inferior gluteal arteries. Less important ('accessory') vessels are: satellites of the superior gluteal artery leading to a gluteal node; vessels from the dorsal surface which cross the lateral border of the pectineus to reach the medial inferior external iliac node; and vessels from the ventral surface, crossing parallel to the cotyloid notch, passing under the psoas to the lateral inferior external iliac or one of the deep inguinal nodes.

Lymphatics of the knee-joint.—According to Tanasesco the lymphatics draining the structures around the knee-joint in the main follow the arteries about the joint and pass largely to the more deeply placed of the popliteal nodes. Some (superficial) follow the great saphenous vein to the subinguinal nodes, and sometimes deep vessels pass the popliteal nodes and, accompanying the femoral artery, run to the deep inguinal or inferior external iliac.

SPLEEN

The **spleen** [lien] has approximately the shape of an elongated, ovoid body, or that of a slightly curved wedge (figs. 667, 668), with three (or four) surfaces, and three rounded borders. Its largest surface is the convex, **diaphragmatic surface** [facies diaphragmatica], posterolaterally facing the curve of the diaphragm (figs. 671, 672). The latter separates the spleen from the pleural cavity

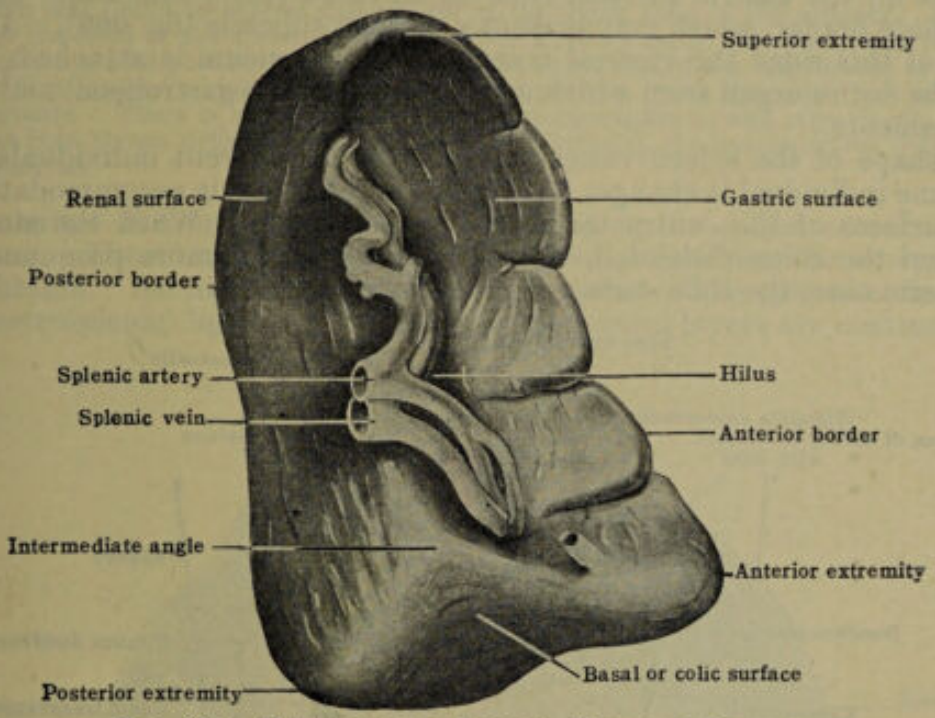

FIG. 668.—TETRAHEDRAL SPLEEN, VISCERAL SURFACE.

and ribs. The visceral surface (facies visceralis NK) includes a gastric (pars gastrica NK) and a renal portion (pars renalis NK). The deeply concave, **gastric surface** [facies gastrica] rests ventro-medially against the fundus of the stomach. It includes the **hilus,** which receives the splenic vessels, and behind which the spleen is in contact with the tail of the pancreas (fig. 671). The slightly concave, **renal surface** [facies renalis] rests posteromedially against the convex,

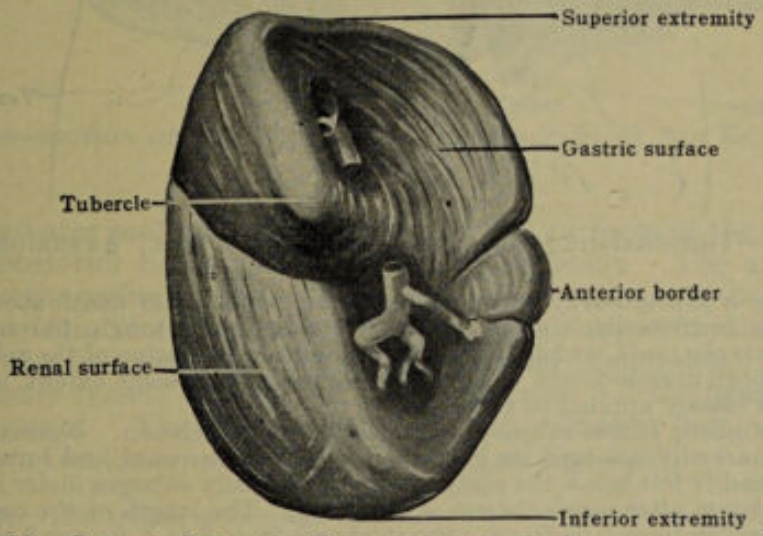

FIG. 669.—SPLEEN SHOWING TUBERCLE ON THE INTERMEDIATE BORDER.

anterior surfaces of the left kidney (fig. 672) and suprarenal. The more caudal portion of this area touches, to a variable extent, the left colic flexure. An enlarged basal or **colic surface** often gives the spleen a more tetrahedral shape (figs. 668, 670).

The spleen has an **anterior** and a **posterior border.** The anterior border [margo anterior] (margo acutus NK) forms a rather sharp, considerably convex line, on which sometimes slight serrations (lobulations) are noticeable. The

posterior border [margo posterior] (margo obtusus NK) is almost straight and less prominent than the anterior margin. The anterior border touches the fundus of the stomach, the posterior the lumbar region of the diaphragm. In the tetrahedral spleen, an **inferior** border separates the colic from the diaphragmatic surface. The spleen also shows a **superior** (extremitas vertebralis NK) and an **inferior extremity** (extremitas ventralis NK), the latter occupying a more ventral position. Between the gastric and renal surfaces of the spleen, usually somewhat on the gastric surface, runs an elevated ridge, sometimes called the intermediate border, which may present a distinct tubercle (fig. 669). Along the margins of this ridge the visceral layer of the peritoneum is attached. It surrounds the entire organ from which it is reflected as the gastrolienal and phrenolineal ligaments.

The **shape** of the spleen varies considerably in different individuals. Even in the same individual it changes its shape to some extent in accommodating itself to the surfaces of the contracted or distended viscera. When the stomach is empty and the colon distended, the tetrahedral form is more pronounced. In the opposite case, the colic surface may disappear entirely.

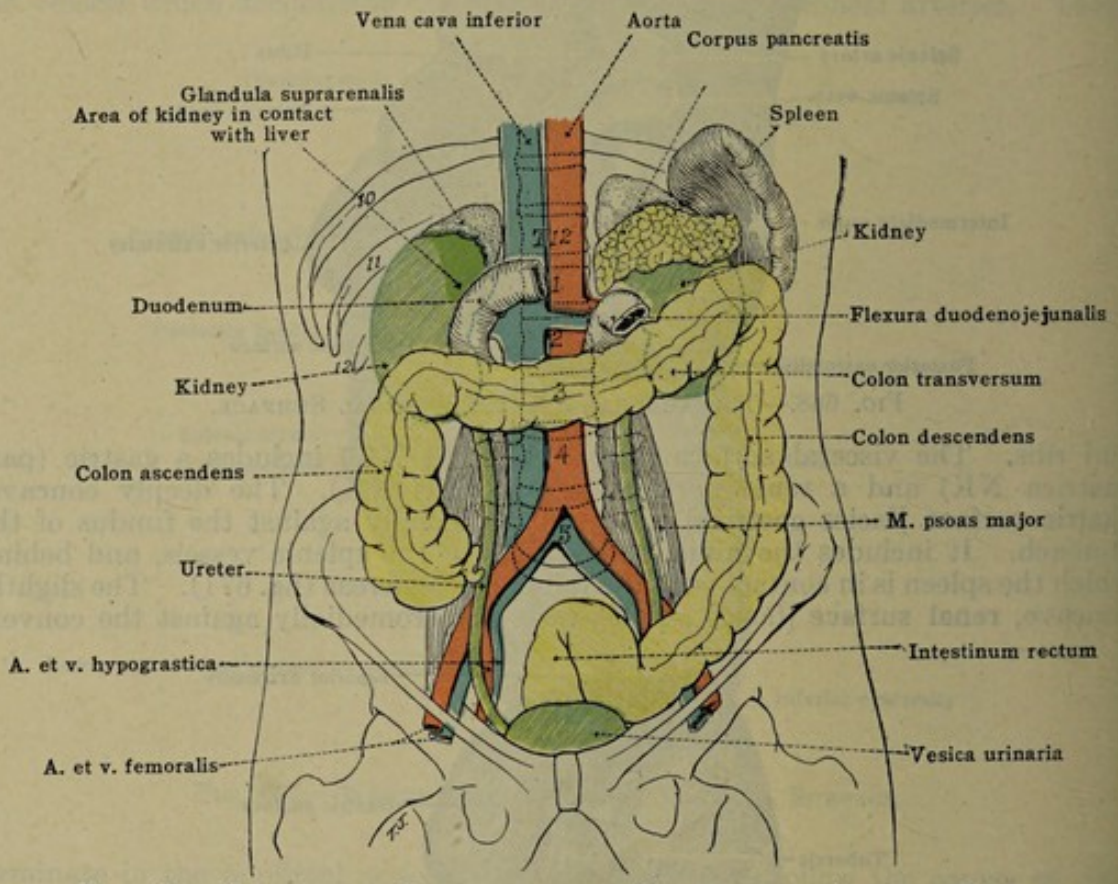

FIG. 670.—TOPOGRAPHIC RELATIONS OF THE SPLEEN, ETC. ANTERIOR VIEW.

The spleen has a rather dark, brownish red **color**, which after death soon changes to a purplish tint. Its **consistency** is soft. It is surrounded by a tough, fibrous capsule, containing many elastic elements, which allow for considerable expansion of the splenic substance, and numerous smooth muscle-fibers. The latter are present, to some extent, in the trabeculæ. The peritoneum is closely applied to the capsule.

The size of the spleen is also subject to great individual variation. Normally it cannot be palpated, but if markedly enlarged its lower end extends downward and forward toward the umbilicus and is readily felt below the costal margin. It easily enlarges under increased blood-pressure. A few hours after meals its size is increased. The length of the organ varies from 10 to 14 cm.; the width from 6 to 10 cm.; the thickness from 3 to 4 cm.; and the weight varies from 80 to 300 grams or more. After the age of 40 years, a slight involution of the spleen sets in.

Topography.—The spleen lies obliquely in the left hypochrondiac region (fig. 1032), its cranial end sometimes reaching into the epigastric region. It is situated in a shallow excavation, formed dorsally by the kidney and suprarenal, laterally by the costal part of the diaphragm, cranially by the dome of the diaphragm, caudally by the left colic flexure and phrenocolic ligament (fig. 983), ventromedially by the stomach. The long axis of the organ runs about parallel with the tenth rib (fig. 670), the spleen lying laterally to a line drawn from the left sternoclavicular

articulation to the tip of the eleventh rib. The upper extremity lies in the region of the costal angle, the lower nearly reaches the midaxillary line. The width of the spleen extends through the 9th and 10th intercostal spaces.

Moody and Van Nuys have made a roentgenographic study of the size and position of the spleen in living, healthy young adults. They find that, in the erect posture, the length of the shadow cast by the spleen varies, in 80% of males, from 11.0 to 15.0 cm., the extreme range being 9.0 to 17.0 the figures for females being 1 cm. less; while the width of this shadow is most commonly from 6.0 to 7.0 cm. in males, and 5.0 to 6.0 cm. in females. The caudal pole of the spleen was found to extend much lower in the living than in the cadaver. Instead of stopping at the level of the eleventh thoracic vertebra, as usually described, they found that the range of the caudal pole of the spleen is from the upper half of the first lumbar to the upper half of the fifth lumbar vertebra, the most frequent position being the upper half of the third lumbar vertebra. There is evidence that the spleen diminishes in size after death, and also, that, as has been shown definitely in cats and dogs (Barcroft), the human spleen diminishes in size after exercise

Ligaments.—Nowhere, except near the hilus, is the spleen attached to the peritoneum. Therefore, it easily slides in its bed and follows the movements of the diaphragm. An important suspensory ligament of the spleen is the **gastrolienal** (gastrosplenic) **ligament** (fig. 981); its peritoneal layers are continued from

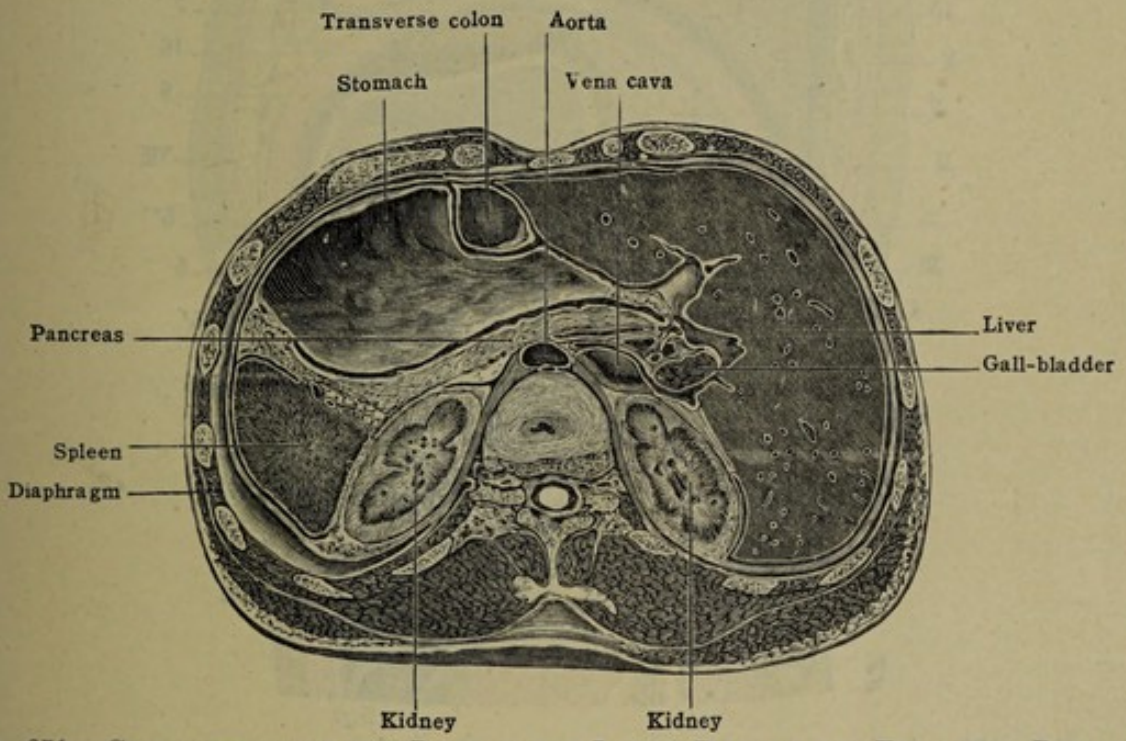

FIG. 671.—CROSS-SECTION OF THE BODY AT THE LOWER PART OF THE EPIGASTRIC REGION. (Rüdinger.)

the anterior (greater sac) and posterior (lesser sac) surfaces of the stomach to the anterior and posterior borders of the hilus, respectively. The anterior layer is continued over the entire surface of the spleen, and then meets the posterior layer to be reflected from the hilus of the spleen to the adjacent surface (fig. 979). This double reflection forms the short **phrenolienal** (lienorenal) ligament which carries the splenic vessels and the tail of the pancreas. This ligament is variable in form and extent. The **phrenocolic** ligament, although not attached to the spleen, supports the lower extremity of the organ (fig. 983).

Blood-supply.—The *splenic artery* and *vein* run in the phrenolienal ligament to the hilus. The artery is rather tortuous, especially in older persons, and lies above the vein. It branches several (about six) times into the vessels of the superior and inferior group before reaching the organ. The splenic vein is likewise formed outside the hilus by several tributaries.

At the hilus some *lymph-vessels* are found which send a few branches into the capsule and larger trabeculæ. No lymph-vessels go through the splenic tissue proper. About 8 or 10 lymph-nodules, connected with these vessels, are found near the hilus, between the layers of the gastrolienal ligament (splenic nodes), and some along the superior border of the pancreas (pancreaticosplenic nodes).

Nerve-supply.—Nerve-fibers from the median and anterior parts of the celiac plexus form a dense network, the *splenic plexus* and follow the splenic artery into the organ. Fibers from the right vagus can also be traced in. The few medullated fibers are probably sensory

Development.—The spleen develops in the mesenchyma of the dorsal mesogastrium. A diffuse accumulation of leucoblasts is noticeable at the beginning of the second fetal month (8 to 10 mm. embryos). This area very soon becomes considerably vascularized, especially the veins forming loose capillary plexuses. Later, angioblasts are carried into this zone, and the spleen begins to assume its hemopoietic function. During fetal life, red as well as white blood-cells are formed in the spleen. After birth the formation of erythrocytes ceases. For further details on the development of the spleen, see p. 39.

Variations.—Sometimes *lobulated spleens* are found, in which the above-mentioned notches along the anterior border are exaggerated. Deep incisions may appear also on the diaphragmatic surface and on the posterior border so that the entire organ seems to be divided up into lobes. Such a spleen probably represents an atavistic type, the organ being lobated in the lower vertebrates and even in some mammals.

Another, not uncommon, abnormality is the formation of *accessory spleens*. These usually are small nodules in the neighborhood of the main organ. Sometimes their number is quite excessive. In man over 400 have been counted in a single individual, widely distributed through the peritoneal cavity; in dogs and cats, over 800. Occasionally, a group of such small

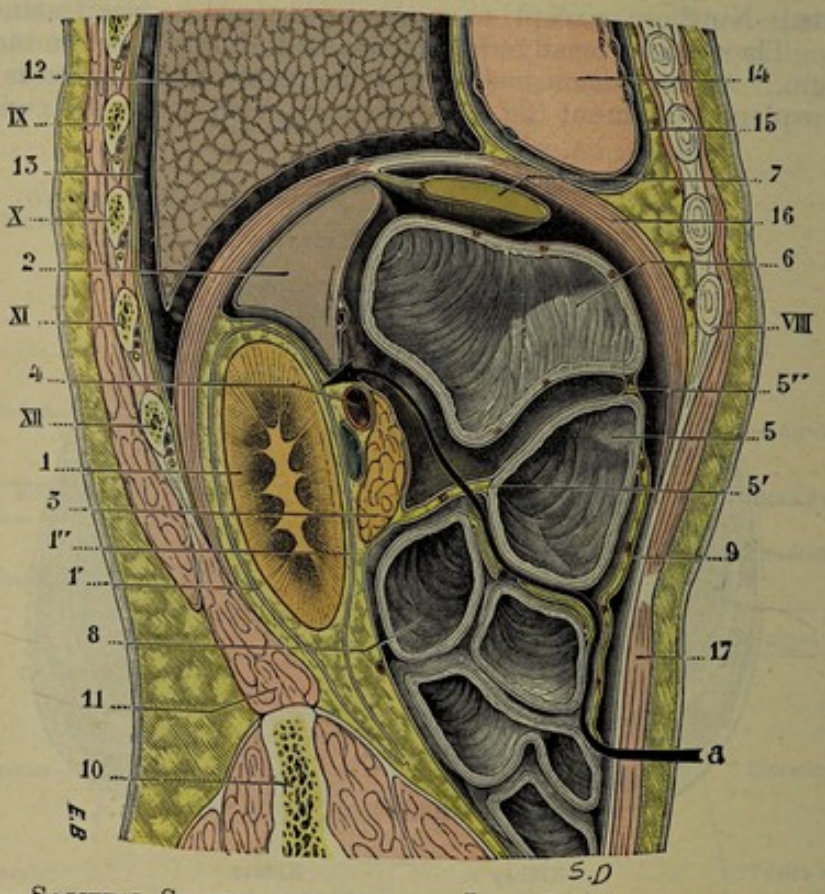

FIG. 672.—SAGITTAL SECTION THROUGH THE LEFT SIDE OF THE BODY, SHOWING THE RELATIONS OF THE SPLEEN. Line *a* indicates inferior surgical route. (Testut and Jacob.)

nodules (isolated lobules) takes the place of the main organ. Whether in the above mentioned cases all these numerous nodes actually represent *accessory spleens* or *hemal nodes*, is still an open question. It is difficult to make a differential diagnosis of very small nodules. There is, however, no doubt that the body of the spleen can break up into its units. A congenital absence of the spleen is extremely rare.

Comparative.—In fishes, turtles and frogs the spleen exists as an elongated body developed in the mesentery parallel and in close proximity to the digestive tube, along the upper, middle, or lower part of the intestine. This distribution has led to the suggestion that the spleen is to be thought of as originally an organ extending along the entire course of the digestive tube, different portions of which are suppressed in different animals. In urodeles, reptiles, birds and most mammals it forms a compact sometimes lobulated body near the stomach.

SECTION VIII

THE NERVOUS SYSTEM

By IRVING HARDESTY, A.B., Ph.D., D.Sc.

PROFESSOR OF ANATOMY, THE TULANE UNIVERSITY OF LOUISIANA

THE nervous system of man, both anatomically and functionally, is the most highly developed and extensively distributed of all the organ-systems of the body. It consists of an aggregation of peculiarly differentiated tissue-elements, so arranged that through them stimuli may be transmitted from and to the functional apparatuses of all the other organ systems of the body. It is a mechanism with parts so adjusted that stimuli affecting one tissue may be conveyed, controlled, modified, and distributed to other tissues so that the appropriate reactions result. While protoplasm will react without nerves, while muscle will contract without the mediation of nerves, yet the nervous system is of the most vital importance to the higher organisms in that the stimuli required for the functioning of the organs are so distributed throughout their component elements that the necessary harmonious and coordinate activities are produced. For this purpose the nervous system permeates every organ of the body; nerve cell-bodies, accumulated into groups, give rise to the nerves which ramify and divide into smaller and smaller branches till the division attains the individual nerve-fibers of which the nerves are composed, and even the fibers bifurcate repeatedly before their final termination upon their allotted tissue elements from which they receive stimuli and to which they trasmit impulses. So intimate and extensive is the distribution throughout that could all the other tissues of the body be dissolved away, still there would be left in gossamer its form and proportions—a phantom of the body composed entirely of nerves.

The parent portion or **axis** of the system, known as the central nervous system, extends along the dorsal midline of the body, surrounded by bone and, in addition, protected and supported by a series of especially constructed membranes or meninges, the outermost of which is the strongest. The cephalic end of the axis, the **encephalon,** is remarkably enlarged in man, and is enclosed within the largest portion of the bony cavity, the cranium, while the remainder of the central axis, the **spinal cord,** continues through the foramen magnum and lies in the vertebral canal.

The intimate connection of the axis with all the parts of the body is attained by means of forty-six pairs of nerves, which are attached to the axis at somewhat regular intervals along its extent. They course from their segments of attachment through the meninges and through their respective foramina in the bony cavity to the periphery. Of these *craniospinal nerves*, fifteen pairs pass through the cranium and are attached to the encephalon, and thirty-one pairs to the spinal cord. Some of the cranial nerves and all of the thirty-one pairs of spinal nerves contain both *afferent fibers*, which convey impulses from the peripheral tissues to the central axis, and *efferent fibers*, which convey impulses from the axis to the peripheral tissues. The different pairs of nerves possess the two varieties of fibers in varying proportions.

Close to the spinal cord, each spinal nerve is separated into two roots—its posterior or *dorsal root* and its anterior or *ventral root.* The afferent fibers enter the axis by way of the dorsal roots, which are, therefore, the sensory roots, and the efferent fibers leave the axis by way of the ventral or motor roots.

As usually studied, the nervous system is considered in two main **divisions**:—

(1) The *central nervous system*, composed of—(*a*) The spinal cord, or medulla spinalis, and (*b*) the brain or encephalon.

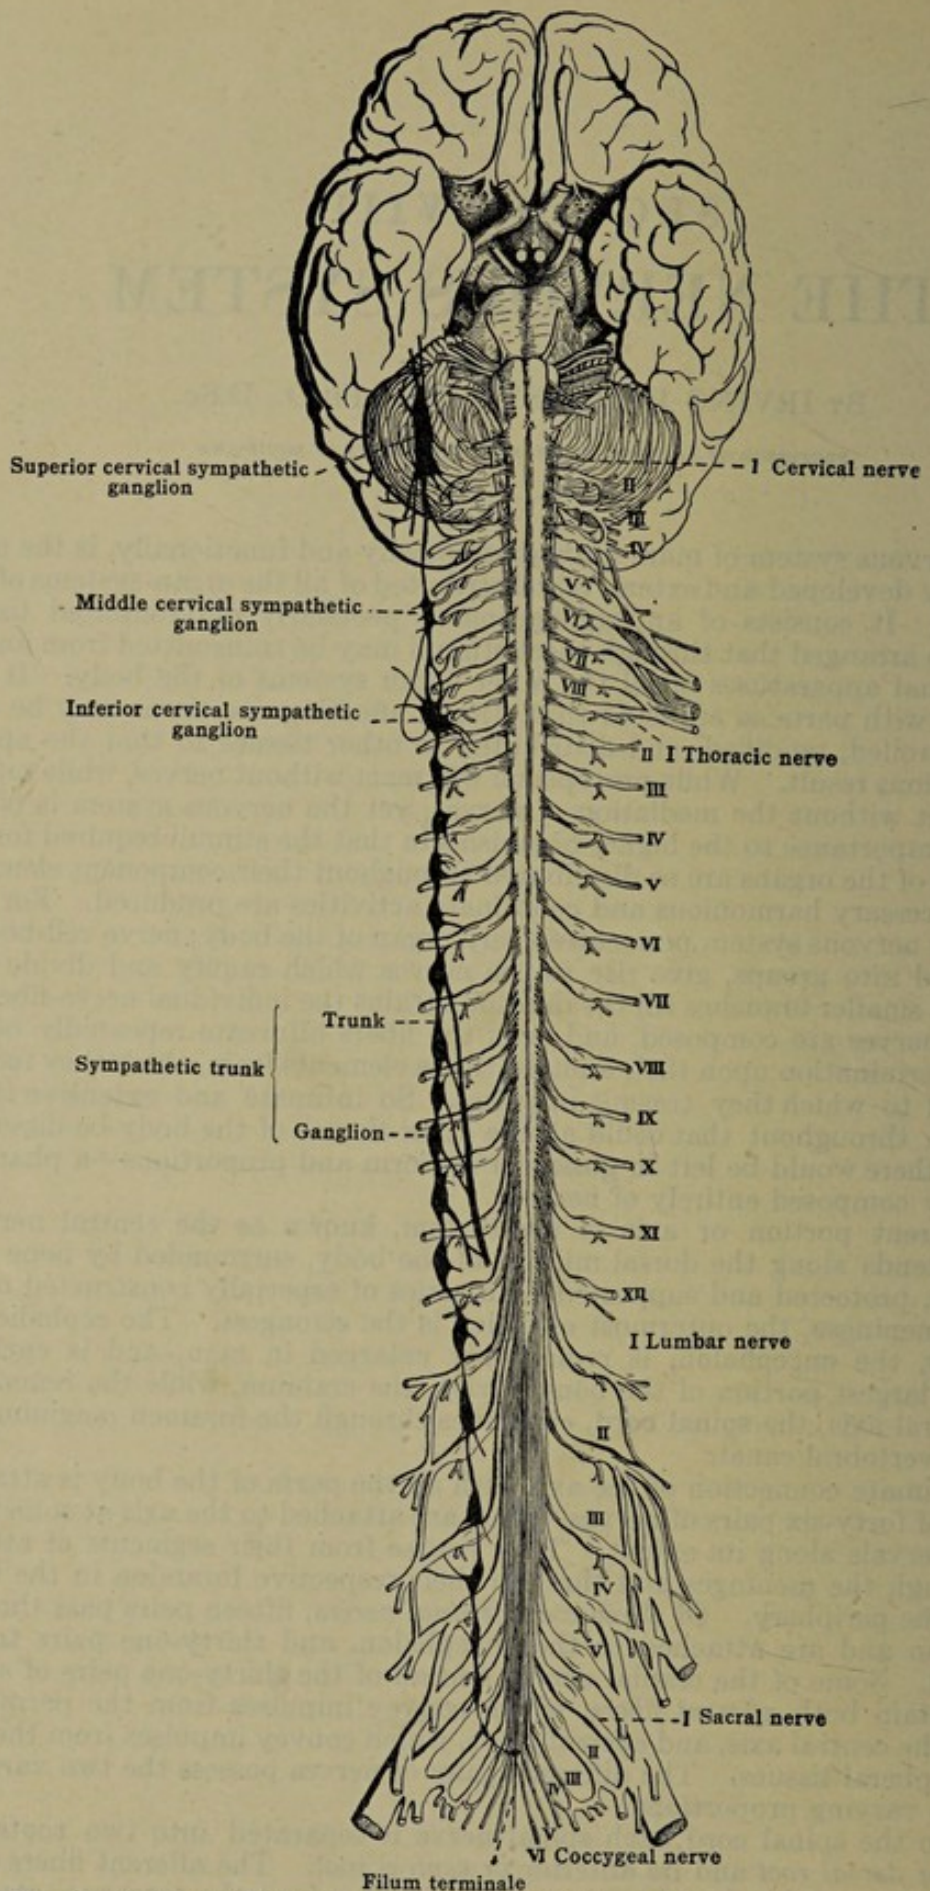

FIG. 673.—SHOWING THE VENTRAL ASPECT OF THE CENTRAL NERVOUS SYSTEM, WITH THE PROXIMAL PORTIONS OF THE CRANIOSPINAL NERVES ATTACHED AND THE RELATION OF THE PROXIMAL PORTION (SYMPATHETIC TRUNK) OF THE SYMPATHETIC NERVOUS SYSTEM. THE ENCEPHALON OR BRAIN IS STRAIGHTENED DORSALWARD FROM POSITION WITH REFERENCE TO THE SPINAL CORD. THE SPINAL GANGLIA AND THE DORSAL AND VENTRAL ROOTS OF THE SPINAL NERVES MAY BE NOTED.

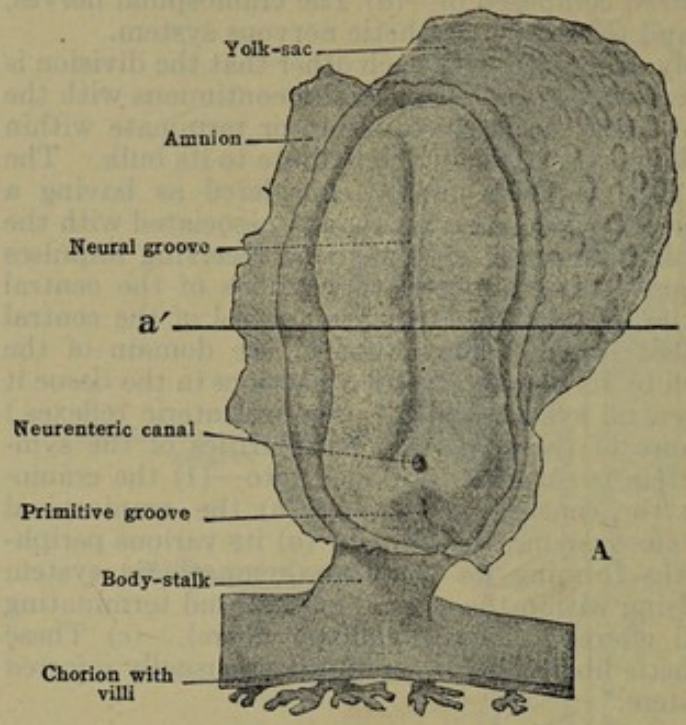
(Composite drawing in part after Allen Thomson from Rauber—modified.)

(2) The *peripheral nervous system*, composed of—(*a*) The craniospinal nerves, with the organs of special sense and (*b*) the sympathetic nervous system.

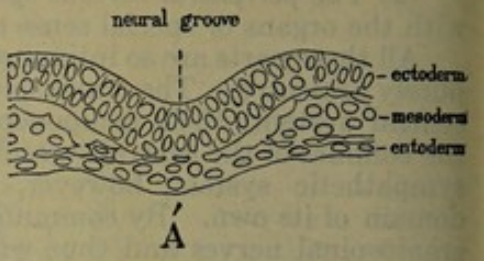
All these parts are so intimately connected with each other that the division is purely arbitrary. The craniospinal nerves are anatomically continuous with the central system; their component fibers either arise within or terminate within the confines of the central system, and thus actually contribute to its bulk. The sympathetic system, however, may be more nearly considered as having a domain of its own. By communicating rami, it is intimately associated with the craniospinal nerves and thus with the central system, both receiving impulses from the central system and transmitting impulses to portions of the central structure. But, while its activities are largely under the control of the central system, it is thought possible that impulses may arise in the domain of the sympathetic system and, mediated by its nerves, produce reactions in the tissue it supplies without involving the central system at all. (See myenteric reflexes.) For this reason, as well as because of the structural peculiarities of the sympathetic system, the nervous system is sometimes divided into—(1) the craniospinal system, consisting of (*a*) the central system and (*b*) the craniospinal nerves; (2) the sympathetic nervous system, consisting of (*a*) its various peripheral ganglia and their outgrowths forming its plexuses (sympathetic system proper) and (*b*) efferent fibers arising within the central system and terminating in sympathetic ganglia (visceral efferent or preganglionic fibers). (*c*) These visceral efferent and the sympathetic fibers proper combined are usually referred to as the 'autonomic nervous system.'

Within and closely proximal to the central system or axis are grouped the parent cell-bodies whose processes comprise the nerve-fibers of the craniospinal nerves. Other groups of nerve cell-bodies, distributed in the periphery without the bounds of the central system, give rise to the fibers, nerves and plexuses of the sympathetic proper. Any group of such cell-bodies situated in the periphery, whether belonging to the craniospinal or sympathetic system, is known as a *ganglion*. A group of cell-bodies situated within the central system and giving origin to a given bundle of nerve-fibers is known as a *nucleus*.



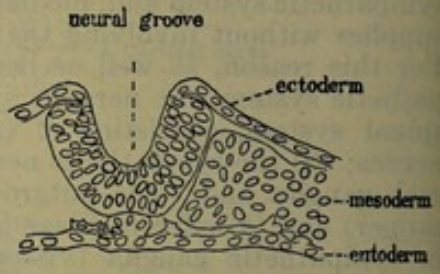
THE DEVELOPMENT OF THE NERVOUS SYSTEM

The essential elements of the nervous system, the nerve cell-bodies and the essential portion of all nerve-fibers, central, craniospinal and sympathetic, develop from one of the embryonic germ layers, the ectoderm, and all, except the olfactory ganglion cells, arise from a given region of that germ layer. Further a portion of the supporting tissue of the nervous system, the neuroglia, is considered as of the same origin.



In its development the nervous system is precocious. It is the first of the functional apparatuses to begin differentiation and is the first to acquire its form. The first trace of the embryo appears on the developing ovum as the *embryonic area*, and the rapidly proliferating cells of this area shortly become arranged into the three germinal layers:—the outer layer or *ectoderm*, the middle layer or *mesoderm*, and the inner layer or *entoderm*. Early in the process of this arrangment there is formed along the axial line of the embryonic area a thickened plate of ectodermal cells, the *neural plate*. In the further proliferation of these cells, the margins of the neural plate, which lie parallel with the long axis of the embryonic area, rise slightly above the general surface, forming the *neural folds*, and the floor of the plate between the folds undergoes a slight invagination, the process resulting in the *neural groove* (fig. 674, A, A′ and B, B′). As development proceeds and the embryonic area assumes the form of a distinct embryo, the neural folds or lips of the groove gradually converge, and beginning at the oral end, finally unite. Thus the groove is converted into the *neural tube*, extending along the dorsal midline and enclosed within the body of the embryo by the now continuous ectoderm above (fig. 674. C′ and D, D′).

For a time the neural tube remains connected with the inner surface of the general ectoderm along the line of fusion by a residual lamina of ectodermal cells. This lamina is known as the *ganglion-crest* (neural crest). It is a product of the proliferation of the ectoderm during the process of fusion, consists of the cells which composed the transition between the closing lips of the original groove and the general ectoderm, and whose fusion aided in the closure of the tube. The ectoderm soon becomes separated from the ganglion crest and the cells of the crest become distinctly differentiated from the cells of the neural tube. The essential elements of the entire nervous system together with the neuroglia are derived from the cells of the neural tube and the cells of the ganglion-crest.



Before the caudal extremity of the tube is entirely closed, its oral end undergoes marked enlargement and becomes distended into three vesicular dilations, the anterior, middle, and posterior primary *brain-vesicles*. The anterior of these primary vesicles gives off a series of secondary vesicles. These are followed by further dilations, flexures of its axis, and by localized thickenings of its walls. The portion of the tube included in the three primary vesicles develops into the encephalon or brain. The remainder of the tube becomes the spinal cord. This latter portion retains the simpler form. By the proliferation and migration laterally of the

cells lining this portion of the tube, there results a comparatively even, bilateral thickening of its walls so that the mature spinal cord retains a cylindrical form throughout its length.

The proliferating and migrating cells of the wall of the neural tube are known as *germinal cells*. Their cell-boundaries are soon lost and the entire wall becomes a syncytium. The products of their division are apparently indifferent at first, but later they become differentiated into two varieties: (1) *spongioblasts*, or those nuclei which will control the development of neuroglia, and (2) *neuroblasts*, or those which will increase in size, acquire individual cytoplasm, give off processes and become nerve cell-bodies. As described below, the processes given off by a neuroblast are of two general characters: (1) a long process or axone which goes to form nerves, nerve-roots, and nerve-fasciculi, and (2) dendritic processes which are numerous, branch much more frequently and extend but a short distance from the cell-body. An adult cell-body with all its processes is known as a *neurone* and the neuroblasts of the developing system become transformed into the neurones of the varying sizes, shapes, and arrangements of processes

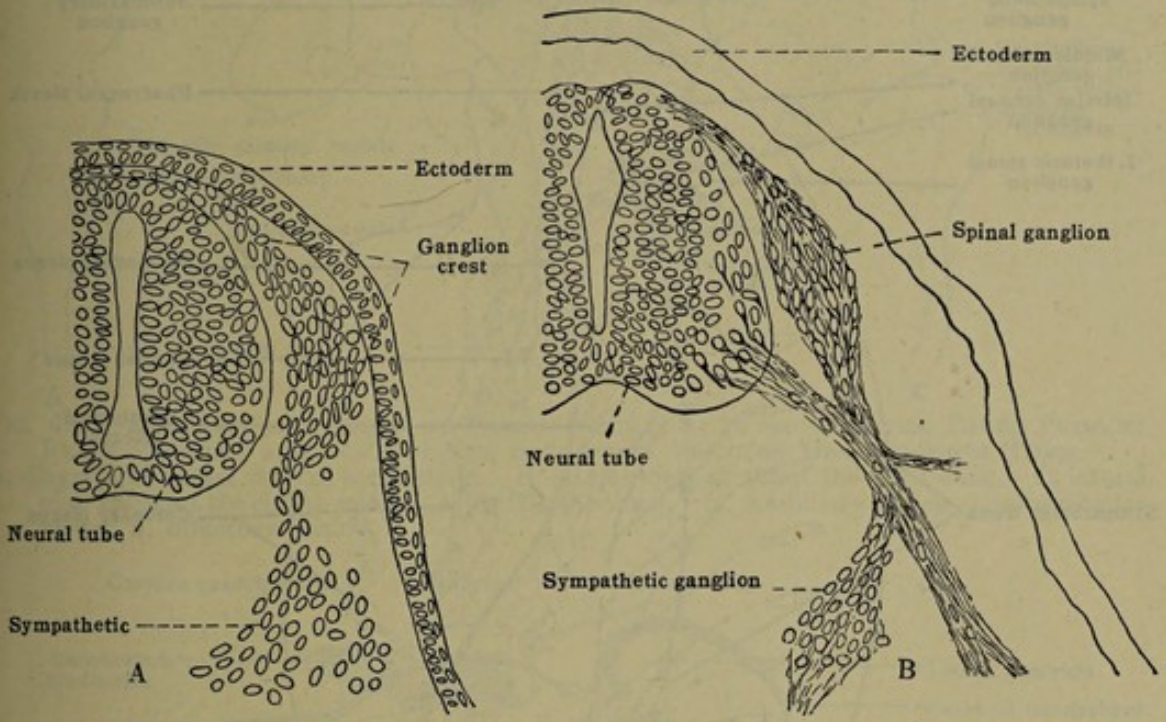

FIG. 675.—DIAGRAMS OF TRANSVERSE SECTIONS OF EMBRYONIC SPINAL CORDS SHOWING THE MIGRATION OF THE ELEMENTS OF THE GANGLION CREST TO FORM THE SPINAL AND SYMPATHETIC GANGLIA AND THE ORIGIN OF THE DORSAL AND VENTRAL ROOTS OF THE SPINAL NERVES.

A, a stage following D′ of fig. 674. B, a later stage in which the ganglia and the components of the nerve are assuming their form resulting from the further migration and from processes being given off by the neuroblasts.

characteristic of different divisions and localities of the nervous system. Usually the first process to be noted is that which will become the axone or nerve-fiber.

Neurones whose cell-bodies belong to the peripheral nervous system are not elaborated within the walls of the neural tube or central nervous system. These, comprising the spinal ganglion neurones and those of the sympathetic system, are derived from the cells of the ganglion-crest. The wedge-shaped lamina of cells, comprising the ganglion-crest, through rapid cell division, gradually extends outward and ventralward over the surface of the neural tube along either side. Soon the proliferation becomes most active in regions proximate to the mesodermic somites or body segments and this activity, together with the stress of the growing length of the body, results in the ganglion-crest (originally a continuous lamina) becoming segmented also. The segments or localized ganglion-masses thus formed are the beginning not only of the spinal ganglia, but also of the ganglia of the entire sympathetic system. The elements of the segmented crest assume a more lateral position, and then occurs a separation of their ranks. A portion of them remain in a dorsolateral position near the wall of the neural tube and develop into the neurones of the *spinal ganglia* (the sensory neurones of the spinal nerves), but others wander further out into the periphery and become the neurones of the

sympathetic. Certain of those in this more nomadic group settle within the vicinity of the vertebral column and by sending out their processes, form the *sympathetic trunk* or the proximal chain of sympathetic ganglia (vertebral ganglia); others migrate further, but in more broken rank, and become the ganglia of the *prevertebral plexuses* or *collateral ganglia* (as the cardiac, celiac and hypogastric plexuses), or the scattered intermediate chain of ganglia; while still others wander into the very walls of the peripheral organs and occur singly or in groups in such plexuses as those of Auerbach and Meissner, within the tunics of the walls of the alimentary canal. These latter groups comprise the *terminal ganglia* of the sympathetic. Scattered along between these proximal, intermediate, and distal groups there are to be found small straggling

ganglia, many of which contain so few cell-bodies that they are indistinguishable with the unaided eye. All these sympathetic neurones, however, are probably directly anatomically associated with and under the control of the neurones of the central system through *visceral efferent fibers* passing to them by way of the rami communicantes or by way of the peripheral distribution of the spinal and cranial nerves. It should be mentioned here that independent or intrasympathetic (myenteric) reflexes are claimed (see Sympathetic System).

The ganglia of the sensory portions of all those cranial nerves attached to the inferior of the three main divisions of the brain and all the sympathetic ganglia of the head have an origin similar to that of the spinal and sympathetic ganglia in the remainder of the body.

The behavior of the walls of the three primary vesicles, into which the oral end of the neural tube is converted, is much more complex than in case of the spinal cord. Their walls do not thicken uniformly and, to give rise to the form of the adult brain, the anterior and the posterior of the three vesicles give off secondary vesicles.

The walls of the posterior primary vesicle give rise to the posterior of the main divisions of the brain, the hindbrain or *rhombencephalon*, the cerebellum developing from the anterior portion only of its dorsal wall, and the medulla oblongata and pons from its ventral wall. Its cavity persists and enlarges into the fourth ventricle of the adult, while the posterior portion of its dorsal wall does not develop functional nervous tissue but persists as a thin roof-membrane known as the *choroid tela of the fourth ventricle*. The cells which form the ganglia of the cochlear and vestibular nerves arise probably from the dorsolateral regions of this vesicle.

From the middle primary vesicle comes the midbrain or *mesencephalon*, the corpora quadrigemina [colliculi] developing from its entire dorsal wall and the *substantia nigra* from its ventral wall, which wall later is also occupied by the *cerebral peduncles*. The constriction between the middle and posterior vesicles becomes the *isthmus* of the rhombencephalon.

The anterior or first primary vesicle undergoes greater elaboration than either of the other two. At an early period it gives off a series of secondary vesicles or diverticula. First, two ventrolateral outpouchings occur, the *optic vesicles*, which later become the optic stalks and optic cups of the embryo. A medial protuberance becomes evident in its anterodorsal wall and from each side of this quickly starts a lateral diverticulum. The two lateral diverticula thus arising from the protuberance are the beginning of the two *cerebral hemispheres* or the *telencephalon*, and the vesicular cavities contained persist as the two *lateral ventricles* of the brain. Soon, each of these vesicular rudiments of the hemispheres gives off ventrally from its anterior part a narrow tube-like diverticulum, each continuous into the larger cavity of the parent primary vesicle. These are the olfactory vesicles which are transformed into the

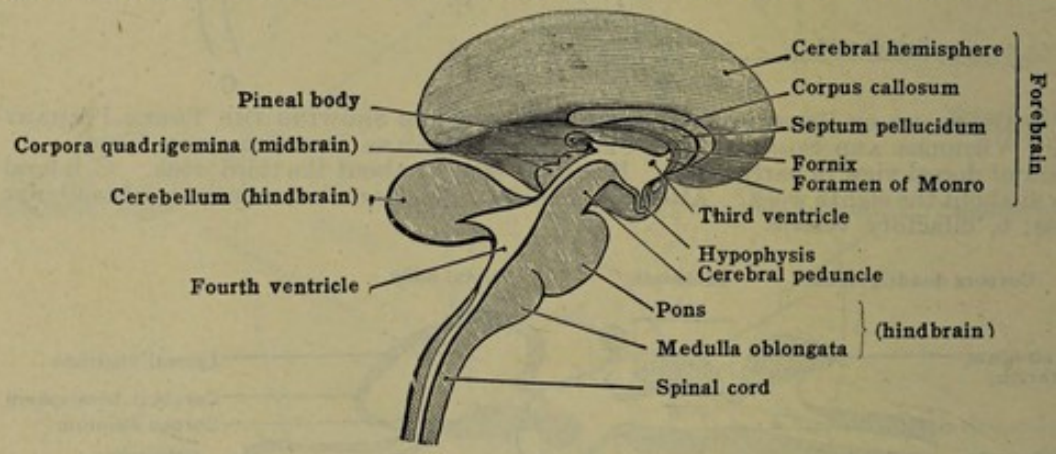

FIG. 680.—DIAGRAM OF MESIAL SECTION OF THE HUMAN BRAIN SHOWING THE SEGMENTS AND THE FLEXURES AND EXPANSION OF THE CEREBRAL HEMISPHERES OVER THE OTHER PORTIONS OF THE BRAIN. THE OLFACTORY VESICLE AND THALAMUS ARE NOT SHOWN.

olfactory bulbs and *olfactory tracts* of the adult encephalon. (See fig. 677, B. and C.) As development proceeds, the cavities of the olfactory vesicles become occluded in man. However, in many of those animals in which the olfactory apparatus attains greater relative development than in man, these cavities persist as the olfactory ventricles. The cavities of the optic vesicles never persist as ventricles in the adult. They form stalks which represent the future courses of the *optic nerves*, while from their dilated extremities are developed the retinæ, pigmented portions of the ciliary bodies and portions of the iris of the ocular bulbs.

In addition to that which forms the cerebral hemispheres, the remaining portion of the anterior primary vesicle becomes the *diencephalon* or interbrain. The lateral walls of this part of the vesicle thicken to form the *thalami*, the posterior end of its dorsal wall gives off a secondary vesicle which becomes the *pineal body* (*epiphysis*), and from its ventral wall projects the infundibular recess which becomes the posterior lobe of the *hypophysis* with its infundibulum and tuber cinereum.

The adult human brain is characterized by the preponderant development of the cerebral hemispheres. The secondary vesicles forming these expand till, held within the cranial cavity, the hemispheres come to extend posteriorly completely over the diencephalon and the mesencephalon and even overlap the cerebellum to its posterior border. Their cavities, which persist from their origin from the anterior primary vesicle, are correspondingly large (the lateral ventricles) and comprise two of the *four ventricles* of the adult brain. The *third ventricle* becomes a narrow cavity situated between the two thalami. It represents the original cavity of the anterior primary vesicle from which the structures above mentioned arose as secondary vesicles. It remains continuous with the lateral ventricles by the two *interventricular foramina*, known also as the *foramina* of *Monro*, one into each cerebral hemisphere. The *fourth ventricle* of the adult represents the cavity of the posterior primary vesicle and comes to lie between the cerebellum and the pons and medulla oblongata, since the cerebellum likewise extends posteriorly from its region of origin. The cavity of the middle primary vesicle becomes the *cerebral aqueduct*, or aqueduct of Sylvius, passing under the corpora quadrigemina and connecting the fourth or posterior ventricle with the third ventricle of the adult.

Development of the nerve-fibers.—All axones begin as outgrowths or processes of the cytoplasm of neuroblasts. Most of such processes are sent out at a very early stage in the development of the nervous system and extend to the tissues they are to innervate when these tissues

are as yet quite near the neural tube and incompletely differentiated. Then, as the structures of the body elaborate and assume their final forms and positions more remote from the central nervous system, the axones terminating in them must necessarily grow and be drawn out with the structures. At need, later axones are sent out by neurones developing later to supply the growth demands. Such axones follow the general paths made by those already extending to the tissues requiring them. Being processes of the cytoplasm of the cell-body, the growth and life of all axones (and dendrites) is under the control of the nucleus in the cell-body. They grow by absorbing nourishment, or having added to them substances, from the lymph in the tissue stroma through which they pass, which stroma may be either ectodermal or mesodermal in origin.

The great majority of axones in the central nervous system and all in the peripheral system, with the exception of the olfactory nerves, have isolating sheaths about them. The sheath is an acquired structure and is not added till a relatively late period of development. These sheaths are of two general varieties, sheaths consisting merely of a fibrous coat with the nuclei belonging to it, and sheaths in which there has been added a coating of fat or myelin, *medullary sheaths*. A *nerve-fiber* consists of an axone and its sheath whether medullated or non-medullated.

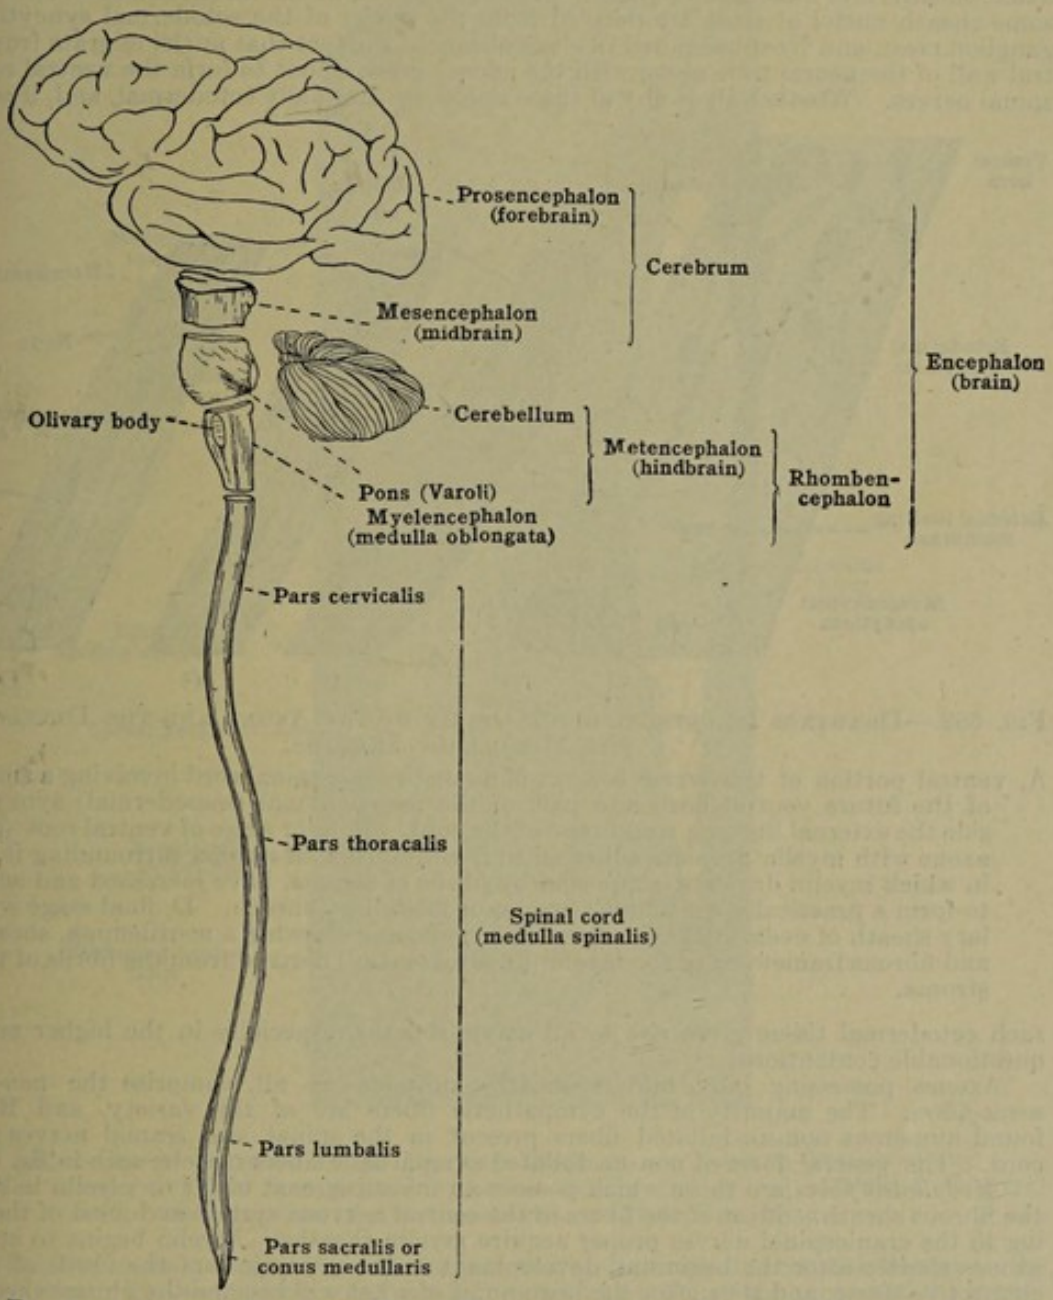

FIG. 681.—DIAGRAM ILLUSTRATING THE GROSS DIVISIONS OF THE CENTRAL NERVOUS SYSTEM.

In the embryo, axones are given off from the developing neurones at a time when the entire ectodermic neural tube and embryonic ganglia and the mesodermic tissue surrounding them are each void of definite cell boundaries, each being a continuous mass of nucleated protoplasm, a *syncytium*. From these syncytia are developed the fibrous connective tissues of the later framework supporting the nervous system. Of this, the fibrous tissue, *neuroglia*, is derived from the ectodermal syncytium, while the white and elastic fibrous tissues are derived from the mesodermal or mesenchymal syncytium. Before any connective tissue fibrils are developed in either syncytium, before and at the time of the ingrowth of blood-vessels into the developing ganglia and the neural tube from the mesenchyme about them, there occurs an invasion of the mesenchymal syncytium into the ectodermal syncytium. This invasion occurs both as inde-

pendent ingrowths and fusions at the periphery of the neural tube and by the mesenchymal tissue being carried in by the ingrowing blood-vessels. After the mixture of the nuclei resulting from this fusion of the syncytia from the two sources, nuclei of mesodermal origin cannot be distinguished from those of ectodermal origin. Further, axones outgrowing from the embryonic ganglia and neural tube carry with them adhering portions of the ectodermal syncytium into the surrounding mesenchymal syncytium (figs. 682, A and 683).

As development proceeds further, each syncytium becomes resolved into a reticulum of granular endoplasmic processes, containing the nuclei, with transparent exoplasm occupying its meshes. Fibers soon form in the exoplasm and from these develop the connective-tissue fibers, whether neuroglia within the central nervous system or mesenchymal fibrous tissue both without and within it. Certain of these fibrils of course surround the axones imbedded among them and from condensations of such fibrils are derived the fibrous sheaths of the axones, the sheath nuclei being acquired from the adjacent nuclei of the original syncytium. These sheaths become more dense or pronounced as the axones extend and the fibrous tissue increases with growth, but there are always present fine marginal fibrils by which the sheaths grade into the looser fibrous tissue about them. It is generally believed that the tissue giving rise to these axone sheaths is of mesodermal origin. However, in amphibian larvæ, Harrison has shown that some sheath nuclei at least are derived from the nuclei of the ectodermal syncytium of the ganglion crest, and Neal has noted in elasmobranchs the fact that nuclei migrate from the ventral wall of the neural tube along with the axones growing out to form the ventral roots of the spinal nerves. Whether all or any of these nuclei are originally ectodermal, and, if so, whether

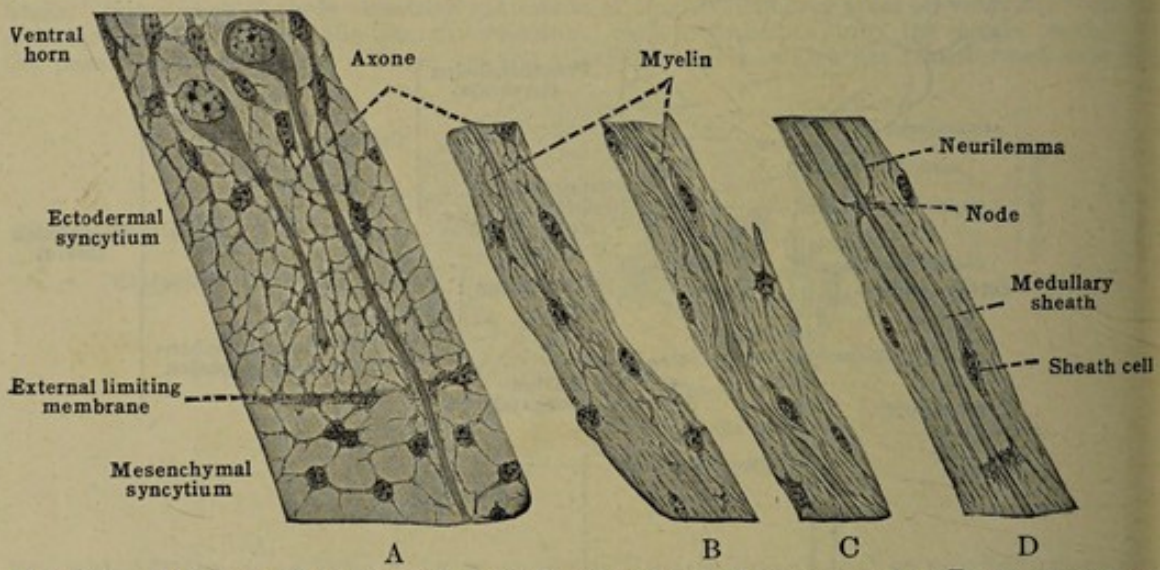

FIG. 682.—DRAWINGS ILLUSTRATING THE ORIGIN OF THE AXONE AND THE DEVELOPMENT OF THE MEDULLARY SHEATHS.

A, ventral portion of transverse section of an embryonic spinal cord involving a small portion of the future ventral horn and part of the mesenchymal (mesodermal) syncytium outside the external limiting membrane of the cord. B, later stage of ventral root (peripheral) axone with myelin droplets adhering to it and fibrillated stroma surrounding it. C, stage in which myelin droplets, supported by fibrils of stroma, have increased and accumulated to form a practically continuous myelin or medullary sheath. D, final stage with medullary sheath of even thickness, showing a node, and showing a neurilemma, sheath nucleus and fibrous framework of the myelin ('neurokeratin') derived from the fibrils of the original stroma.

such ectodermal tissue gives rise to all axone sheaths, especially in the higher animals, are questionable contentions.

Axones possessing only fibrous sheaths, or none at all, comprise the *non-medullated nerve-fibers*. The majority of the sympathetic fibers are of this variety, and Ranson has found numerous non-medullated fibers present in the spinal and cranial nerves and spinal cord. The general form of non-medullated sympathetic fibers may be seen in fig. 689, C.

Medullated fibers are those which possess an investing coat of fat or myelin in addition to the fibrous sheath. Most of the fibers in the central nervous system and most of those belonging to the craniospinal nerves proper acquire myelin sheaths. Myelin begins to appear upon axones shortly after the beginning development in the syncytium of the fibrils of the fibrous connective tissue, and thus after the beginnings of what will become the fibrous sheaths. The fibrous portions of the sheaths in the central nervous system develop less rapidly and are far more scant than those of the medullated fibers of the peripheral nerves. Probably because of this, it has been claimed that myelin begins to appear on the axones of the central system before the appearance of the fibrous sheath. In man, the first appearance of myelin occurs at about the fourth month, but myelinization is not completed till after birth. The craniospinal nerves contain completely medullated fibers before the central system does.

Myelin first appears as small droplets adhering to the axone at irregular intervals. These droplets increase in size and number and gradually accumulate to form a practically continuous sheath of fat immediately investing the axone. They probably result from the coalescence of finer droplets floating in the surrounding fibrillated stroma. However, collecting upon the axone, the myelin retains the form of an emulsion, and as it increases in amount it incloses the adjacent fibrils which serve as a framework supporting the droplets of the emulsion in its meshes.

Thus supported, the increasing myelin does not inclose the adjacent nuclei and endoplasm of the original syncytium. Probably because of the fibrous support of the myelin thus obtained, medullating fibers may be often seen presenting the beaded appearance shown in fig. 682, C, instead of an even distribution of the emulsion after it has become continuous along the axone. The 'beads' probably reflect the uneven beginning of the accumulation indicated in B of this figure. Increasing further, the myelin becomes a cylinder of even thickness, the adjacent nuclei being pressed away against its surface and the adjacent fibrils also condensed upon it. Thus, there is good reason to believe that the fibrous portion of the sheath, the *primitive sheath* or *neurilemma*, of the medullated axone arises as a condensation of the fibrils of the surrounding stroma during development, that the sheath cells represent certain of the nearest nuclei incorporated from the original syncytium, and that the so-called *neurokeratin* of the myelin

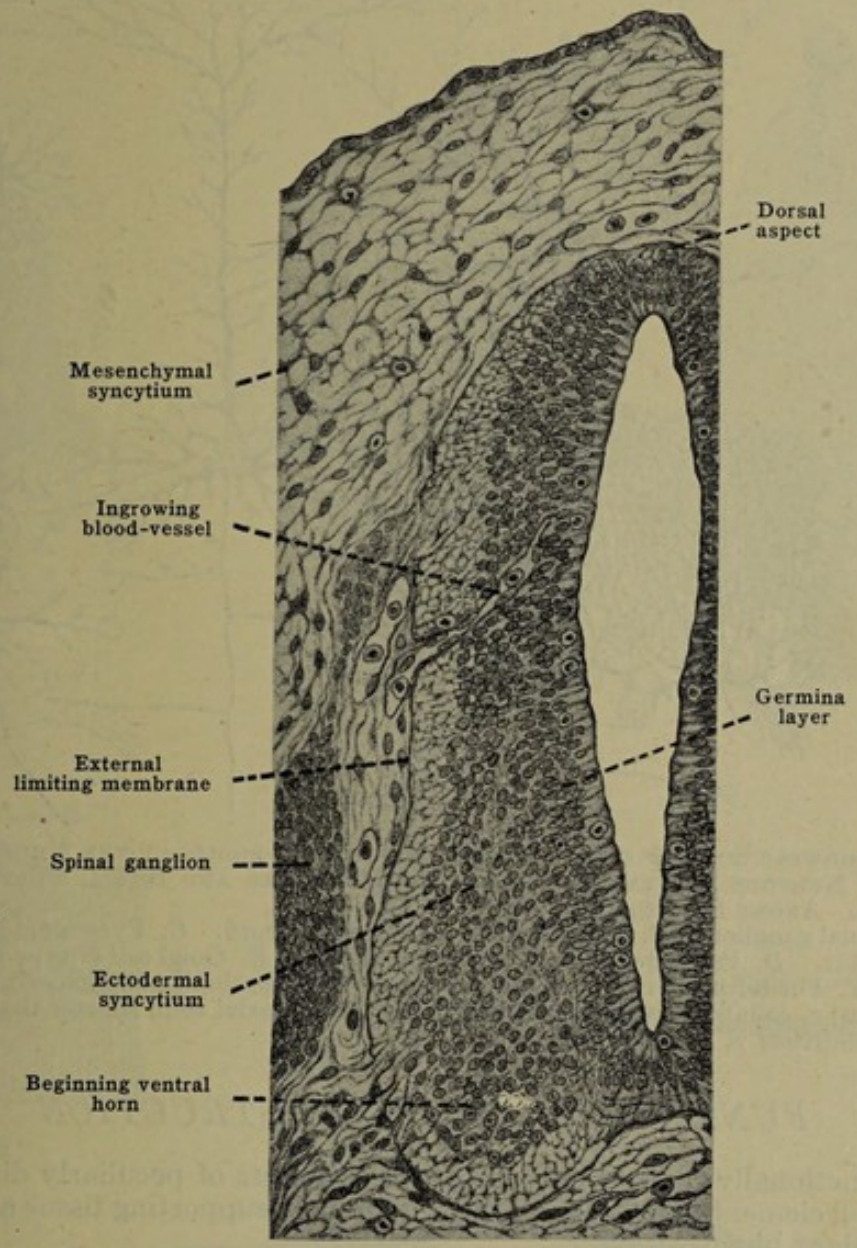

FIG. 683.—CROSS-SECTION OF THE NEURAL TUBE IN AN EMBRYO PIG OF 9 MM. Showing the ectodermal and mesodermal syncytia during the period of their fusion and before the formation of either neuroglia or connective tissue.

represents the fibrous framework of the myelin inclosed by it during its accumulation upon the axone. The theory that the myelin arises as a differentiated portion of the axone and the theory that it is formed by the neurilemma have been advanced. That it is accumulated from already synthesized fat droplets in the immediately surrounding fluid of the stroma and adheres to the axone, added droplets coalescing there, in preference to other tissue elements because of some biotaxic physical or chemical peculiarity of the axone, is more probably correct.

As the medullary sheath approaches completeness, constrictions may be observed at more or less regular intervals at which the myelin emulsion is absent. These are the *nodes of Ranvier*. The process by which they arise is not clearly understood. While the fiber is growing in length, new myelin is added at the nodes. The internodal segments of the sheath increase in length with age, and each segment may possess from one to several sheath nuclei.

In adolescence, fibers whose medullary sheaths are in various stages of completeness may be found both in nerve bundles in the central system and in the craniospinal nerves, and in both, the sheaths of some axones certainly never acquire myelin. Also, in the adult, fibers

whose medullary sheaths present the beaded appearance may be observed, probably repre senting cases of arrested accumulation of myelin. According to Westphal there is a slight in crease in the thickness of the sheath with age. Larger axones acquire thicker sheaths of myeli than smaller ones. For the craniospinal fibers, in transverse sections, the area of the section o the medullary sheath averages equal to the area of the section of the axone (Donaldson an Hoke.) Some fibers of the sympathetic system are medullated but in such the myelin sheath i relatively thinner than in the craniospinal system. Beaded sheaths are frequent in sympa thetic rami, though non-medullated fibers are most abundant.

FUNDAMENTALS OF CONSTRUCTION

The functionally mature nervous system consists of peculiarly differentiated essential cell elements held in place by two forms of supporting tissue and supplied with abundant blood-vessels.

The nervous element is distinguished from all other units of the structure of organs in that its cell-body gives off outgrowths or processes of peculiarly great length and characteristic form. Knowledge of the possible lengths and complexity of these processes is comparatively recent and, to include them together with their parent cell-body, which has long been known as the *nerve-cell*, the term neurone is used. The **neurone,** therefore, may be defined as the nerve cell-body with all its processes, however numerous and far reaching they may be. As a class of tissue elements, all neurones possess characteristics distinguishing them from other tissue elements, but the varieties within this class vary greatly. They vary in form both according to function and according to their locality in the nervous system. They vary in different animals, those in the higher animals being more complex in form. Fig. 684 gives illustrations of the external form of the cell-body of a few of the types found in the human nervous system.

The cell-body of the neurone gives off two general types of processes, dendrites and the axone:

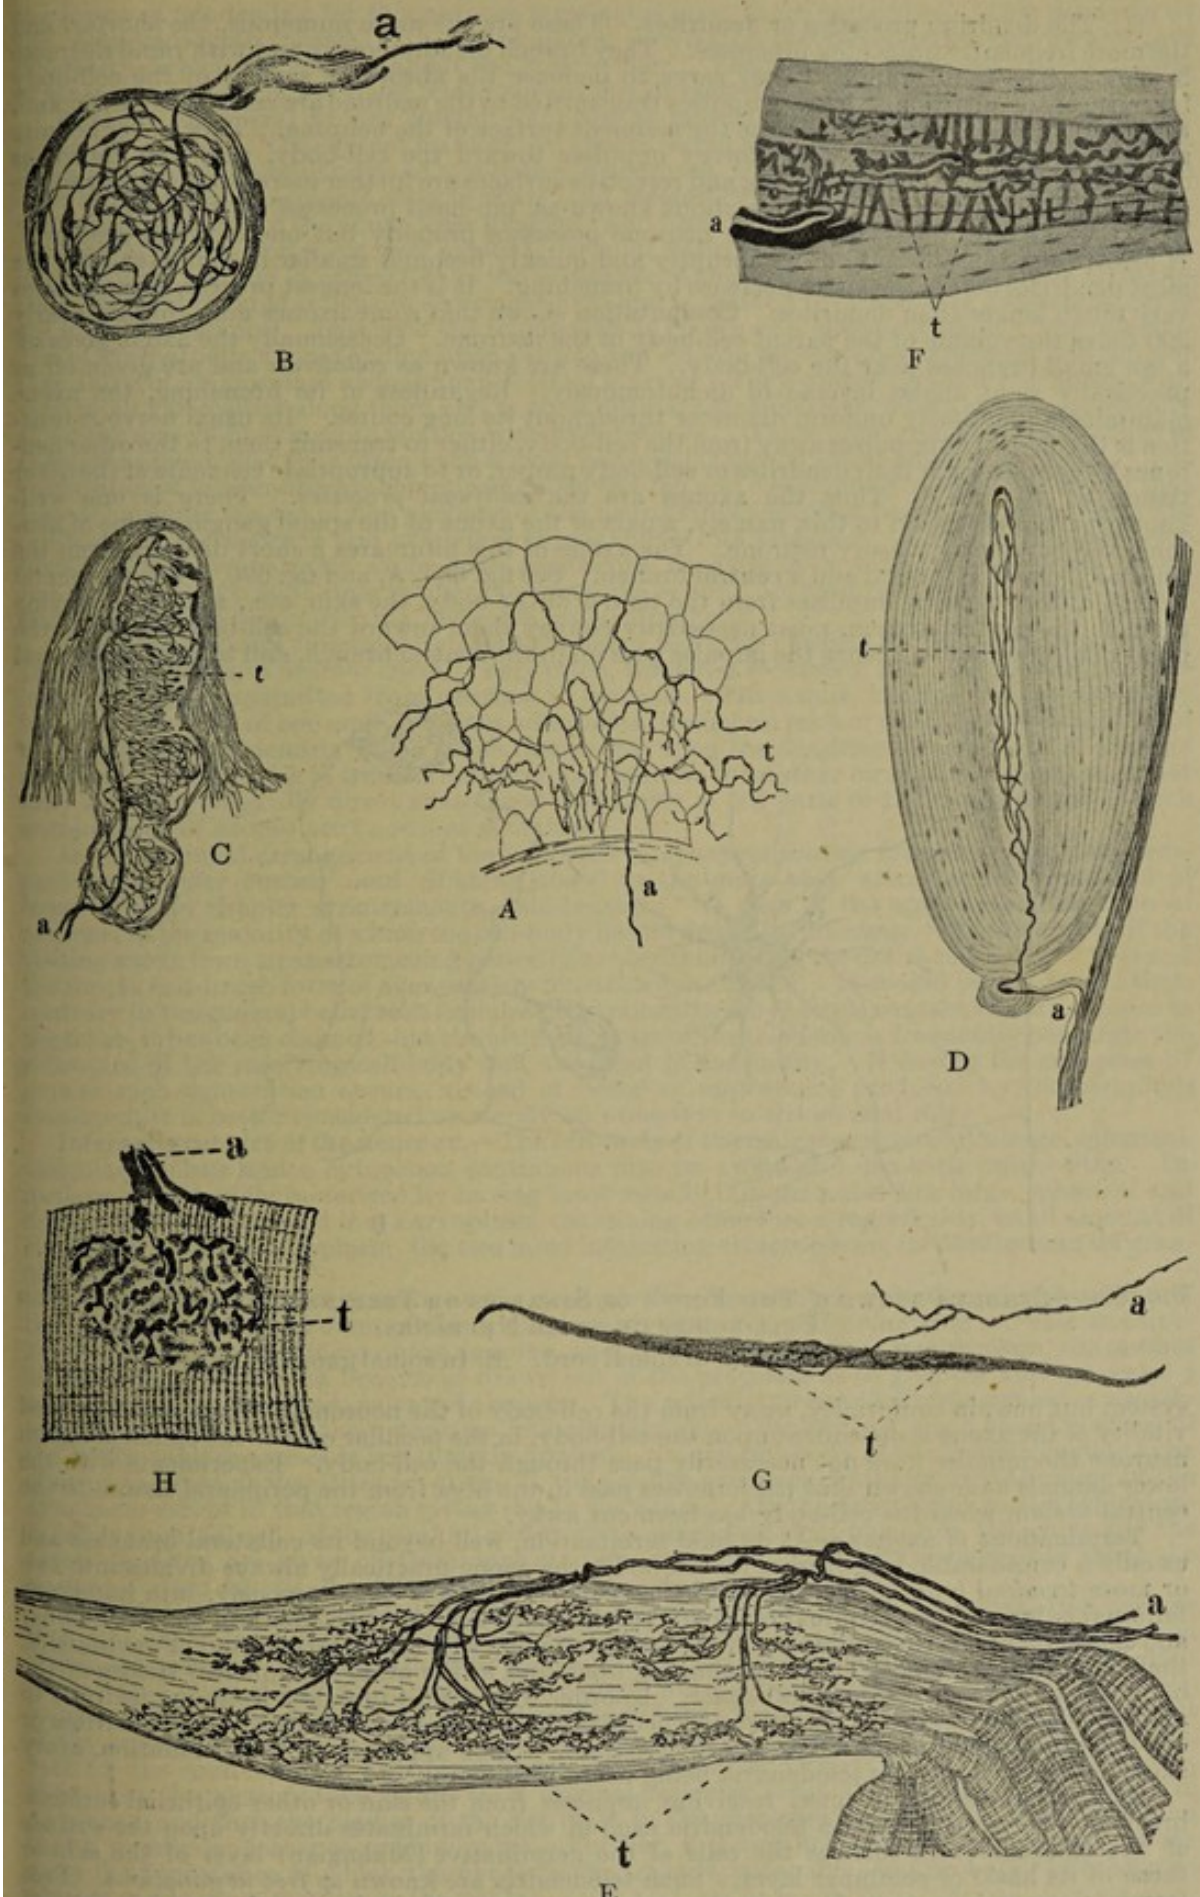

FIG. 685.—SHOWING SOME VARIETIES OF PERIPHERAL TERMINATIONS OF AXONES.

A. 'Free termination' in epithelium (after Retzius). B. Krause's corpuscle from conjunctiva (after Dogiel). C. Meissner's corpuscle from skin (after Dogiel). D. Pacinian corpuscle (after Dogiel). E. Termination upon tendon sheath (Huber and DeWitt). F. Neuromuscular spindle (after Ruffini). G. Motor termination upon smooth muscle-fiber. H. Motor 'end-plate' on skeletal muscle fiber (after Böhm and von Davidoff). a, axone; t, telodendria.

(1) The dendritic processes or **dendrites.** These are the more numerous, the shorter, and the more frequently branching processes. They branch dichotomously and with rapid decrease in diameter as they branch. They serve to increase the absorbing surface of the cell-body for purposes of nutrition. Nerve impulses transmitted to the neurone are received by them and, therefore, they also serve to increase the recipient surface of the neurone. They never acquire medullary sheaths. Since they convey impulses toward the cell-body, they are known as *cellipetal processes.* Their absorbing and receptive surfaces are further increased by the presence of thickly placed, very minute projections known as 'pin-head processes' or *gemmules.*

(2) The **axone** (neuraxis). Each neurone possesses properly but one of these processes. It arises from the cell-body more abruptly and quickly becomes smaller in diameter than are most dendrites before the latter decrease by branching. It is the longest process, in most cases very much longer than dendrites. Computation shows that some axones may contain nearly 200 times the volume of the parent cell-body of the neurone. Occasionally the axone gives off a few small branches near the cell-body. These are known as *collaterals* and are given off at practically right angles instead of dichotomously. Regardless of its branching, the axone maintains a practically uniform diameter throughout its long course. Its usual nervous function is to convey the impulses away from the cell-body, either to transmit them to the other neurones by contact upon their dendrites or cell-body proper, or to appropriate elements of the other tissues of the body. Thus the axones are the *cellifugal processes.* There is one well-known partial exception to this, namely, a part of the axone of the spinal ganglion type of neurone, the peripheral sensory neurone. The axone of this bifurcates a short distance from the cell-body into a peripheral and a central branch. See fig. 684, A, and fig. 690. The peripheral branch collects sensory impulses from the tissues of the body, the skin, etc., and, in conveying them to the central system, must necessarily convey them toward the cell-body as far as the point of bifurcation. Thence the impulse goes on in the central branch, still toward the central

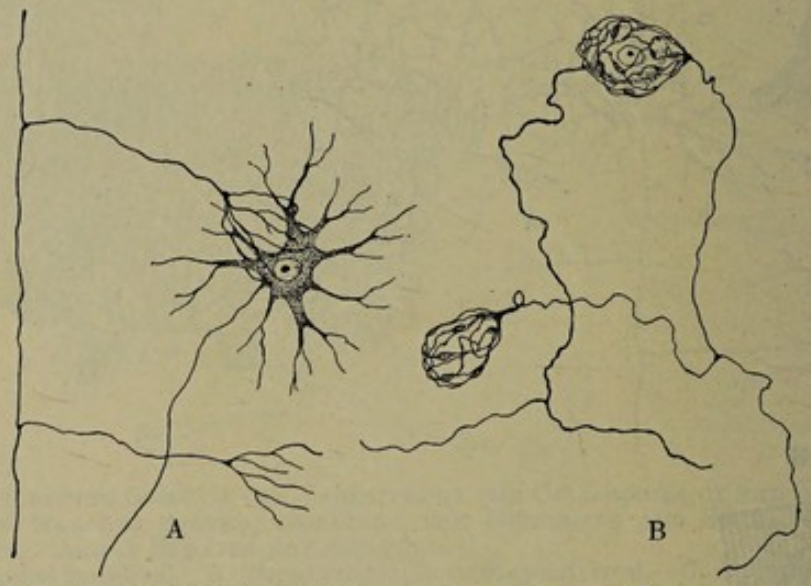

FIG. 686.—SCHEMES SHOWING TWO FORMS OF SYNAPSES OR TERMINATIONS OF AXONES UPON CELL-BODIES OF OTHER NEURONES.
A. In ventral horn of spinal cord. B. In spinal ganglia.

system but now, in conformity, away from the cell-body of the neurone. While the continued vitality of the axone is dependent upon the cell-body, in the peculiar case of the spinal ganglion neurone the impulse does not necessarily pass through the cell-body. Experiments with the lower animals have shown that the impulses pass in the fiber from the peripheral tissues to the central system when the cell-body has been cut away.

Terminations of axones.—At its final termination, well beyond its collateral branches and usually a considerable length from its cell-body, the axone practically always divides into two or more *terminal branches,* and each of these breaks up, now dichotomously, into numerous terminal twigs. These terminal twigs are known as *telodendria.* Telodendria vary in number and character of form according to the tissues in and upon which they terminate. Functionally, they are of three classes: Those terminating upon and in the other (peripheral) tissues of the body are either (1) *sensory* or (2) *motor.* In order to transmit impulses from one neurone to another, telodendria of the axone of one neurone are placed in contact with the dendrites or cell-body of another neurone forming (3) *synapses.* Upon approaching its termination, every axone loses its sheath, its telodendria being necessarily bare.

Afferent or sensory axones, receiving impulses from the skin or other epithelial surfaces break up into very numerous telodendria each of which terminates directly upon the surface of the epithelial cell, such as the cells of the germinative (Malpigian) layer of the skin or those of its basal or columnar layer. Such telodendria are known as *free terminations.* Free terminations are also to be found in the connective tissues of the body. A second variety of peripheral termination of afferent axones is the *encapsulated form.* These are known as 'end organs' and 'corpuscles' and are named according to their complexity and position. Three of the different forms of them are shown in fig. 685, B, C, and D. These are always situated in fibrous connective tissue from which their capsules are derived. Their most elaborate form is the lamellated or Pacinian corpuscle. Besides the motor axones terminating upon the fibers of voluntary or skeletal muscle, sensory impulses are carried from this tissue and one of

the forms of telodendria for this purpose terminates upon the muscle-fiber. This is known as the 'neuromuscular spindle.' In it, the axone penetrates the sarcolemma and breaks into telodendria which coil spirally about the muscle-fiber. The most extensive and elaborate form of sensory telodendria are those which spread out in plate-form upon tendons sheaths.

Efferent peripheral axones convey impulses to muscle and the secretory cells of glands (secretory axones). The efferent craniospinal axones terminate upon skeletal (voluntary) muscle-fibers and upon the cell-bodies of sympathetic neurones, the axones of which latter terminate upon cardiac muscle, smooth muscle-fibers, and (secretory) in glands. Upon skeletal muscle, the terminal branch of the axone loses its sheath and breaks up into numerous telodendria which themselves branch and show very evident, irregular varicosities, the whole of which spread out in plate-form, and lie in contact with the substance of the muscle-fiber. In man and all mammals, the area covered is usually somewhat oval and is marked by a granular differentiation of the muscle substance. This with the telodendria is known as a *motor end-plate*. The telodendria of sympathetic axones ending upon cardiac and smooth muscle-fibers are fewer and simpler than those of craniospinal axones upon skeletal muscle. They consist of a few fine fibrils, with very small varicosities along them and at their ultimate terminations, which run longitudinally along the muscle-fiber in close relation with its substance. Those upon gland-cells are similar in character except that they often form a loose pericellular plexus about and upon the cell. The varicosities of telodendria are sometimes called *end-feet* and closer study of them has shown that they themselves consist of fine plexuses of the neurofibrils described below as contained in the cell-body of the neurone and extending throughout all its processes. Boek and Agduhr have found that a sympathetic axone may sometimes accompany a craniospinal axone to an end-plate on a skeletal muscle-fiber, presumably serving to maintain muscle tone. Tower claims that these accompanying fibers are not sympathetic.

Synapses.—Every functionally complete nerve pathway consists of two or more neurones arranged in series, a *neurone chain*. Very often, the series consists of many more than two, the impulses being transmitted from neurone to neurone. The axone, bearing the impulse away from the cell-body of one neurone, gives off terminal branches, each of which loses its sheath and breaks up into telodendria which twine themselves upon the dendrites or cell-body of another neurone. The impulse is transferred from one neurone to another by means of contact rather than by embryologically direct anatomical continuity of the parts of the two neurones. Such terminations of axones are known as synapses.

In the terminal arrangement of the telodendria, synapses assume forms varying from compact *'pericellular baskets'* and *'climbing fibers'* to the more open arborizations composed of fewer twigs in simpler arrangements, *'end-brushes.'* In case of the spinal ganglion type of neurone, in the majority of which the cell-body has no dendritic processes, the telodendria of the visiting axone form an anastomosing pericellular plexus inclosing the entire cell-body. This and the simple end-brush form of synapses are illustrated in fig. 686. It should be mentioned that, contrary to the general belief that impulses are transmitted by simple contact of the neurones in the series, it has been claimed that the ultimate twigs of the telodendria frequently penetrate the substance of the receiving cell-body and are fused in continuity. If during the processes of growth such penetration occurs, instead of being an appearance produced by the technique employed, it is better considered as merely an exception to the general rule.

Internal structure of the neurone.—The cell-body of the neurone consists of a large, spherical, vesicular nucleus and a cytoplasm continuous into its axone and dendritic outgrowths. Its nucleus is further characterized by having most usually but one nucleolus, large, spherical and densely staining, situated in a karyoplasm containing otherwise a remarkably small amount of chromatin. Of the cytoplasm, the two most interesting structures are its fibrillar and its granular components.

The **fibrillar structure,** known as the *neurofibrillæ*, represents a growth and elaboration of the spongioplasmic reticulum of the original embryonal cell. The filaments increase in thickness during the development of the neurone, and, in the sending out of its processes, the meshes of the original reticulum become so drawn out in the processes as to give the appearance of a more or less parallel arrangement of threads. The reticular or net-like arrangement is usually more nearly retained in the cytoplasm immediately about the nucleus, since here the stress of the outgrowing processes is less directly applied. In the cell-body of the spinal ganglion type of neurone, when no dendrites are given off, the net-like arrangement is apparent throughout the cytoplasm except in that region giving rise to the axone. On the other hand, in the typical so-called 'pyramidal cell' of the cerebral cortex, from which two chief processes, the axone and the apical dendrite, are given off from opposite poles, the more reticular arrangements about the nucleus if often practically obliterated by the opposing growth stress.

So manifest does the parallel appearance of the neurofibrillæ in the processes often become that it has been interpreted as a series of individual and independent fibrils. In the application of gold chloride and similar methods to the neurones of lower forms, the reduced reagent is often precipitated upon the fibrils in parallel, seemingly independent lines. And, assuming the existence of independent fibrils, it has been contended that the neurone is not the functional unit of the nervous system but is itself composed of numerous functional units, individual fibrils, each for the conduction of nerve impulses. More recent and trustworthy methods, however, show that the neurofibrillæ retain their original reticular form, the threads anastomosing in all planes, and that the meshes of the net may, in the processes, be so drawn in one direction that a parallel appearance predominates. Further, it is now held that the neuroplasm, or the more fluid substance in which the fibrils lie throughout, is capable, and probably fully as capable, of conducting impulses as the fibrils.

Of the **granules** in the cytoplasm, the most interesting are those first described in detail by Nissl. These are the most abundant of those in the cell-body and are known as *tigroid masses* or *Nissl bodies*. They consist of numerous basophilic granules collected into clumps or masses of varying size. They are known to disappear during fatigue of the nervous system and they are more abundant in animals after a period of rest. They are distributed throughout the cytoplasm of the cell-body with the interesting exception that they are not found in the axone nor in

the immediate vicinity of its place of origin from the cytoplasm, leaving a free region known as the *axone hillock*. As accumulated masses, they show characteristic shapes and arrangement which are interpreted as signifying the shapes and arrangement of the spaces or meshes they occupy in the reticulum of the neurofibrillæ. In cell-bodies of the varieties found in the ventral

horns of the spinal cord or in the cerebral and cerebellar cortex, for example, the masses situated immediately about the nucleus are smaller, more numerous and of irregular shape. Nearer and in the beginnings of the dendrites, they are larger and mostly of fusiform or diamond shape. Farther out in the dendrites, they become more and more thin and attenuated; and in the distant reaches of the dendrites they are invisible or absent. In the cell-body of the spinal ganglion they are of irregular shape, smaller and more numerous throughout the cytoplasm, being slightly

smaller and more thickly placed in the immediate vicinity of the nucleus. In all neurones several hours postmortem, they appear in fewer and larger masses and it was in this condition that Nissl originally described them in man. Closely examined, the masses of all sizes are found to be accumulations of finer granules. Functionally they are supposed to be of nutritive significance, substances in unstable chemical equilibrium, energy stored in the cytoplasm, capable at need of being split into simpler forms usable in the activities of the neurone. The fact that tigroid masses are absent from the axone hillock, the axone, and the distant reaches of the dendrites may signify that the substance is chiefly present here only in the split and usable form. Also, in the axone especially, the neurofibrillæ are so closely arranged that the meshes of their net here are too small to contain masses of appreciable size. Close examination of the axone hillock and longitudinal sections of the axone in deeply stained preparations usually discloses a few very minute basophilic granules.

A second form of granules described for the neurone is that included within the name, *mitochondria*. These granules are chemically different from the tigroid masses and are thought to be present in all protoplasm, animal and plant. They are considered composed of a phospholipin combined with a small amount of albumin, and, like tigroid masses, to represent a form of stored energy.

Pigment-granules also are found in nerve cells, probably representing an insoluble form of the waste products of the cell metabolism.

Sheaths of the axone.—The great majority of axones acquire sheaths about them which isolate and protect them in their course through other tissues or isolate them from other axones.

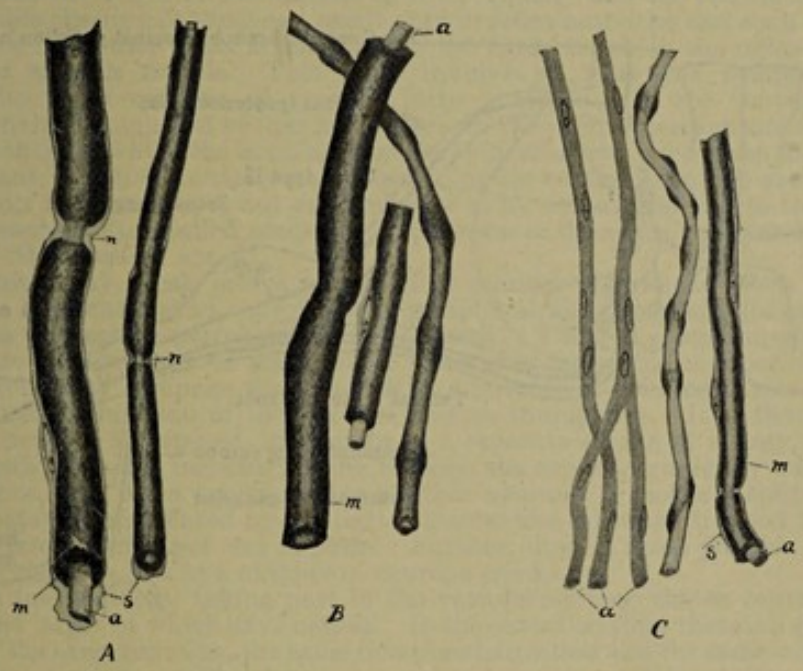

FIG. 689.—SHOWING PIECES OF AXONES.

A. From a craniospinal nerve. *B*. From the spinal cord. *C*. From the sympathetic. *a*. axones; *m*, medullary sheath; *n*, node of Ranvier; *s*, neurilemma or sheath of Schwann with occasional sheath-nuclei.

A *nerve-fiber* is an axone together with its sheaths. In transverse sections, the axone comprises the central portion of the nerve-fiber or its so-called 'axis-cylinder.' It is of course the essential portion of the fiber. As noted above in describing their development, nerve-fibers are classified according to the character of the sheaths. Those which possess sheaths of myelin, a peculiar form of fat, are known as *medullated fibers*, and those in which the sheaths are merely membranes of condensed fibrous tissue, void of myelin, are *non-medullated fibers*. A medullated fiber also possesses a fibrous membrane outside its myelin sheath, known as the *neurilemma* or sheath of Schwann. The neurilemma is of the same origin and general structure as the sheath of the non-medullated fiber, and both possess scattered nuclei of fibroblasts. Medullated fibers, at more or less regular intervals, show constrictions at which the myelin sheath ceases, but over which the neurilemma continues. These constrictions are the *nodes of Ranvier*. The myelin is in the form of an emulsion, whose fat droplets are supported in a fine fibrous reticulum (neurokeratin), while the neurilemma without serves to hold it in place. The neurilemma possesses from one to three or four sheath-nuclei between adjacent nodes of Ranvier.

There is no sharp line of separation between medullated and non-medullated fibers, for in any division of the nervous system there may be found axones in all degrees of medullation. Most of the fibers belonging to the sympathetic system (processes of sympathetic neurones) are non-medullated, but both partially medullated and completely medullated sympathetic fibers may be found. (See fig. 689.) The myelin sheaths of completely medullated sympathetic fibers are always thinner and less well developed than those of medullated craniospinal fibers. Most of the fibers belonging to the craniospinal nerves and to the central nervous system are medullated, but among the fibers belonging to either there are to be found numerous non-medullated fibers. As indicated in fig. 689, nodes of Ranvier are absent in the medullated fibers of the central system.

In all the higher vertebrates, the myelin sheath always begins on the axone a short distance from its parent cell-body. The neurilemma of the medullated and the fibrous membrane of

the non-medullated fiber are each faintly continuous with the fibrous connective tissue sur rounding it, and, in the craniospinal and sympathetic ganglia, in which each cell-body of th neurone has a fibrous capsule about it, the fibrous membrane or the neurilemma, as the cas may be, is directly continuous into the capsule of the cell-body. Upon approaching its fina termination, in other tissues or upon the dendrites or cell-body of other neurones, the nerve fiber always loses its sheath, the telodendria of the axone always being bare when placed i contact with the other element. In losing the sheath, the myelin sheath, if present, alway ceases and the fibrous membrane becomes continuous with the tissue investing the receivin element, whether the capsule of the ganglion cell, the sarcolemma of the skeletal muscle fiber the corium of the skin, or the connective tissue capsule of the encapsulated terminal corpuscle

The **connective tissue** of the nervous system is of two main varieties—*white fibrous connec tive tissue* and *neuroglia*. White fibrous tissue alone supports and binds together the periphera system, and it is the chief supporting tissue of the central system. As connective tissues, thes two varieties are quite similar in structure, each consisting of fine fibrillæ, either dispersed or i bundles, among which are distributed the nuclei of the parent syncytium. In both tissues nuclei of fibroblasts are frequently found possessing varying amounts of cytoplasm which ha not yet been sacrificed in producing the essential fibrils.

In addition to its enveloping membranes, the three meninges, which are of white fibrou tissue, the white fibrous tissue supporting the central system within is quite abundant. It is al sent in from without, either as ingrowths of the developing pia mater, the innermost of the

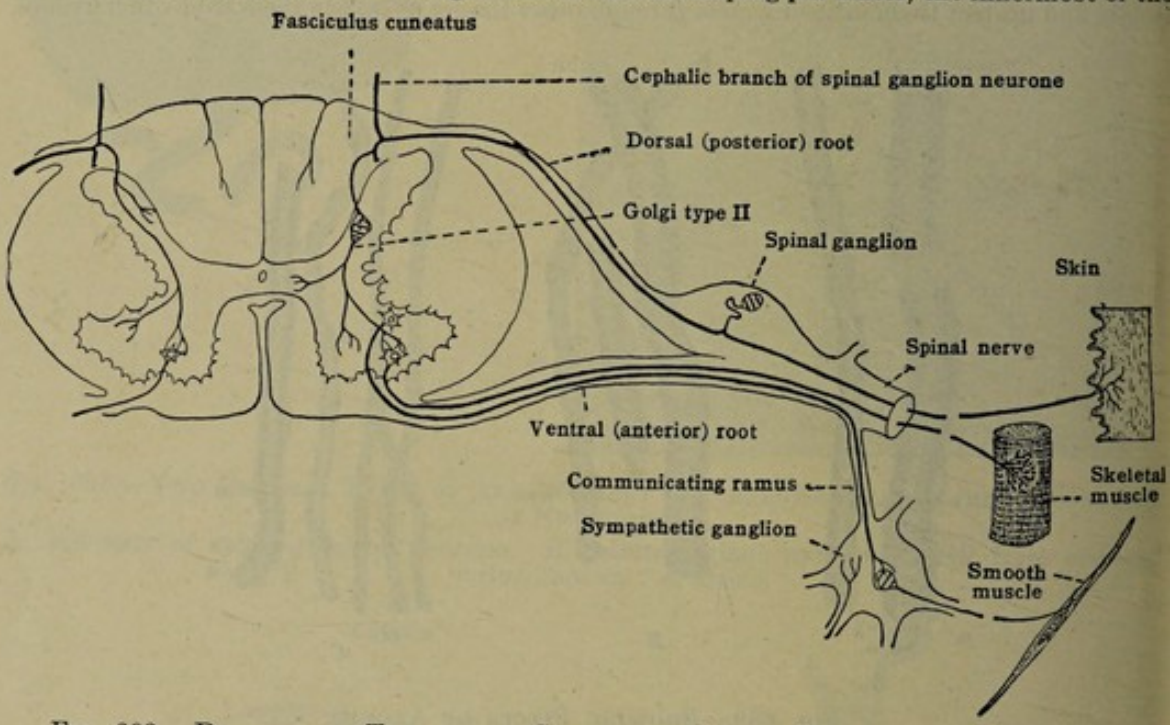

FIG. 690.—DIAGRAM OF TRANSVERSE SECTION OF SPINAL CORD WITH ROOTS OF SPINAL NERVE AND NEIGHBORING GANGLIA ATTACHED, ILLUSTRATING SIMPLEST FORMS OF NEURONE CHAINS. TWO VISCERAL EFFERENT FIBERS ARE SHOWN TERMINATING IN THE SYMPATHETIC GANGLION.

membranes, or is carried in with the blood-vessels, of the walls of which it is an abundant component (fig. 683). The neuroglia as a connective tissue differs from white fibrous tissue in origin and in its chemical or staining properties. Based upon the latter, there are methods of technique by which the two may be distinguished. The epithelioid lining the central canal of the spinal cord and the ventricles of the encephalon, with which the canal is continuous, is the remains of the mother tissue of the neuroglia, and in the adult is the only vestige representing its origin. The cells of this lining are known as *ependymal cells*, and they are usually classed as a variety of neuroglia. They retain in large part the original syncytial form.

Axones, with their medullated or non-medullated sheaths (nerve-fibers) comprise all nerves in the periphery and all nerve tracts in the central system.

White substance [substantia alba] ('white matter') consists of portions of nervous tissue in the central nervous system in which medullated fibers predominate. The myelin sheaths, being in the form of a fat emulsion, reflect the entire spectrum and thus appear white.

Gray substance [substantia grisea] ('gray matter') is an aggregation of nervous tissue in which medullated axones do not so predominate. Thus sympathetic ganglia and sympathetic nerves may be gray, though the term is usually applied to gray portions of the central system, such as the cerebral cortex, the gray column of the spinal cord, etc. Such gray regions contain more cell-bodies of neurones than other regions, though at least half of their volume may consist of neuroglia, white fibrous connective tissue, blood-vessels, and axones of both varieties.

Neurone chains.—As noted above, the numerous neurones comprising the nervous system are functionally and anatomically related to all the other tissues of the body and to each other. A functionally complete *nerve pathway* extends from the tissue in which the nerve impulse is aroused to the tissue in which a resultant reaction occurs. It is known that the simplest possible of such paths necessarily comprises at least two neurones. The great majority involve a greater number. The axone of one neurone bearing impulses from a peripheral tissue transfers the impulses to the dendrites or cell-body of another by synapsis, and the axone of this, in the same way, transfers them to another and so on till the final or efferent neurone receives the impulses and the telodendria of its axone transfer the impulse to the tissue element which reacts in response to the stimulus brought. Neurones are thus linked together in chains. A neurone chain may be defined, therefore, as a number of neurones associated with each other in series to form a functionally complete nerve pathway. Examples of the simplest forms of neurone chains as contained in the spinal cord are illustrated in fig. 690. An impulse aroused in the skin is borne by the spinal ganglion neurone to the spinal cord where, in the left half of the figure, telodendria of one of the terminal branches of its axone form synapses with a neurone in the ventral horn, and the axone of this bears the impulse out of the spinal cord to transmit it probably direct to skeletal muscle. This arrangement involves but two neurones and is supposed to be relatively rare. In the right half of the figure, a third neurone is seen interposed. This is a neurone, numerous in gray substance everywhere, whose axone is relatively short and branches frequently, making possible several synapses in the near neighborhood of its parent cell-body. Its type is referred to as the *Golgi neurone of type II*. This interposed, gives a chain of three neurones between the origin of the impulse in the periphery and the contraction of muscle in response. Simple chains like these can result only in reflex activities and such chains are often called *reflex arcs*. Another chain is indicated in the figure in which the reflex action involves involuntary or smooth muscle. This must involve at least one sympathetic neurone, and, should the Golgi neurone of type II form synapses with the ventral horn neurone involved, the chain is composed of four neurones. In the more extensive and complex neurone chains, such as those in which the impulse from the skin, as above, ascends to the cerebral cortex and the resultant muscular contraction is thrown under cerebral control, each of the several neurones or links in the series is not only referred to by name according to the position of its cell-body, but each is often called according to its order in the series, as 'neurone of first order,' 'second order,' 'third order,' etc.

A given axone may break into a considerable number of branches each of which forms synapses with a different second neurone, or, if peripheral, the telodendria of each branch may terminate upon a separate peripheral tissue element. Thus, a given impulse aroused in a peripheral tissue element may be transmitted to an ever increasing number of neurones, and the initial neurone may comprise the first link in a number of neurone chains. Such is quite general in the structural plan of the nervous system throughout. It is thought possible to consider each neurone interposed in a chain as a separate source of energy, a sort of relay in the nerve path; that the impulse passing through the axone is gradually weakened in overcoming resistance, but, when transferred to another neurone, it incites a splitting into usable form of the substance represented by the tigroid masses and mitochondria and thus a liberation of energy or a reinforcement of the impulse. Further, thus is made possible the economy of one neurone serving as a link in a number of neurone chains.

The axones (nerve-fibers) taking part in the various neurone chains course in bundles of varying size, the larger of which have names. In the central system there is a general tendency with axones of the same function, the same functional direction and the same origin to course in company with each other. A fiber bearing impulses from the peripheral tissues to the central system is an *afferent fiber* or sensory fiber. A fiber bearing impulses out of the central system to peripheral tissues is an *efferent fiber* or motor fiber. Efferent fibers which bear impulses to skeletal muscle are known as *somatic efferent fibers*, while those which terminate upon the cell-bodies of sympathetic neurones and thus bear impulses destined for smooth muscle, cardiac muscle and glands (secretory) are *visceral*, or *splanchnic, efferent fibers*.

A nerve is a closely associated aggregation of parallel nerve-fibers coursing in the *periphery*. It may be spinal, cranial or sympathetic according to its attachment or according to the origin of the majority of its fibers. It may contain several functional and structural varieties of fibers. The spinal nerves contain all structural varieties. **Nerve-roots** are those bundles of fibers which join to form a nerve. Most of the cranial nerves have but one root. Nerve-roots, in their turn, are formed by the junction of smaller *root-filaments*. *Nerve-branches* result from the divisions of the nerve, the separation of its component fibers into separate bundles. Some branches are of sufficient size and significance to be called nerves and given separate names. The smaller branches are called *rami*, twigs, etc.

In the *central system*, a given bundle of fibers of similar origin and functional direction is called a **fasciculus**, while two or more adjacent fasciculi coursing parallel with each other, but often of different origins and functional directions, comprise a **funiculus**, a bundle of bundles. The central nervous system is bilaterally symmetrical throughout its length. Bundles of fibers arising from cell-bodies situated on either side and crossing the mid-line transversely and within the level of their origin to terminate in the opposite side form a **commissure**. The commissures vary greatly in size and contain fibers crossing in both directions. Even scattered fibers which so cross the mid-line are called *commissural fibers*. In distinction, companion bundes of fibers of the same origin, functional direction and significance which arise and course one on either side of the mid-line and then cross the mid-line to terminate in levels different from the levels of their origin are said to *decussate* and their crossing is known as a **decussation**. In further distinction from commissures, the direction of the crossing in decussations usually is oblique rather than transverse. Fibers of varying length, arising from cell-bodies situated in one locality of the central system which do not cross the mid-line, but terminate in other localities of the same side, above and below the level of their origin or in a different region of the same level, form **association fasciculi**. The shortest association fasciculi, largely confined within the bounds of a given division of the central system, are known as **fasciculi proprii**.

The cell-bodies of neurones whose axones go to form certain nerve roots, fasciculi and certain commissures show a tendency to accumulation in localized masses. In the *peripheral* system, such an accumulation of cell-bodies is known as a **ganglion**; in the *central system* such is distinguished as a **nucleus**. Thus, there are the *sympathetic ganglia* which give rise to sympathetic nerves and sympathetic roots of nerves; and on the beginning of each spinal nerve there is a *spinal ganglion* which gives rise to the afferent fibers of its dorsal root and in its nerve trunk. There are *ganglia of* the *cranial nerves* which give rise to the afferent or sensory axones in them and which are of the same significance as the spinal ganglia. Every ganglion, therefore, has connected with it bundles of nerve-fibers. Some of these fibers bear impulses from the central system and transfer them to the cell-bodies of the ganglion; others arise from the cell-bodies in the ganglion and bear impulses to the central system or, in case of the sympathetic, to the tissues of the peripheral organs. Necessarily, the larger the ganglion, the larger will be the bundles of fibers connected with it.

Nuclei may be considered in two general classes: (1) Recipient nuclei or nuclei of termination, and (2) Nuclei of origin. (See fig. 691.)

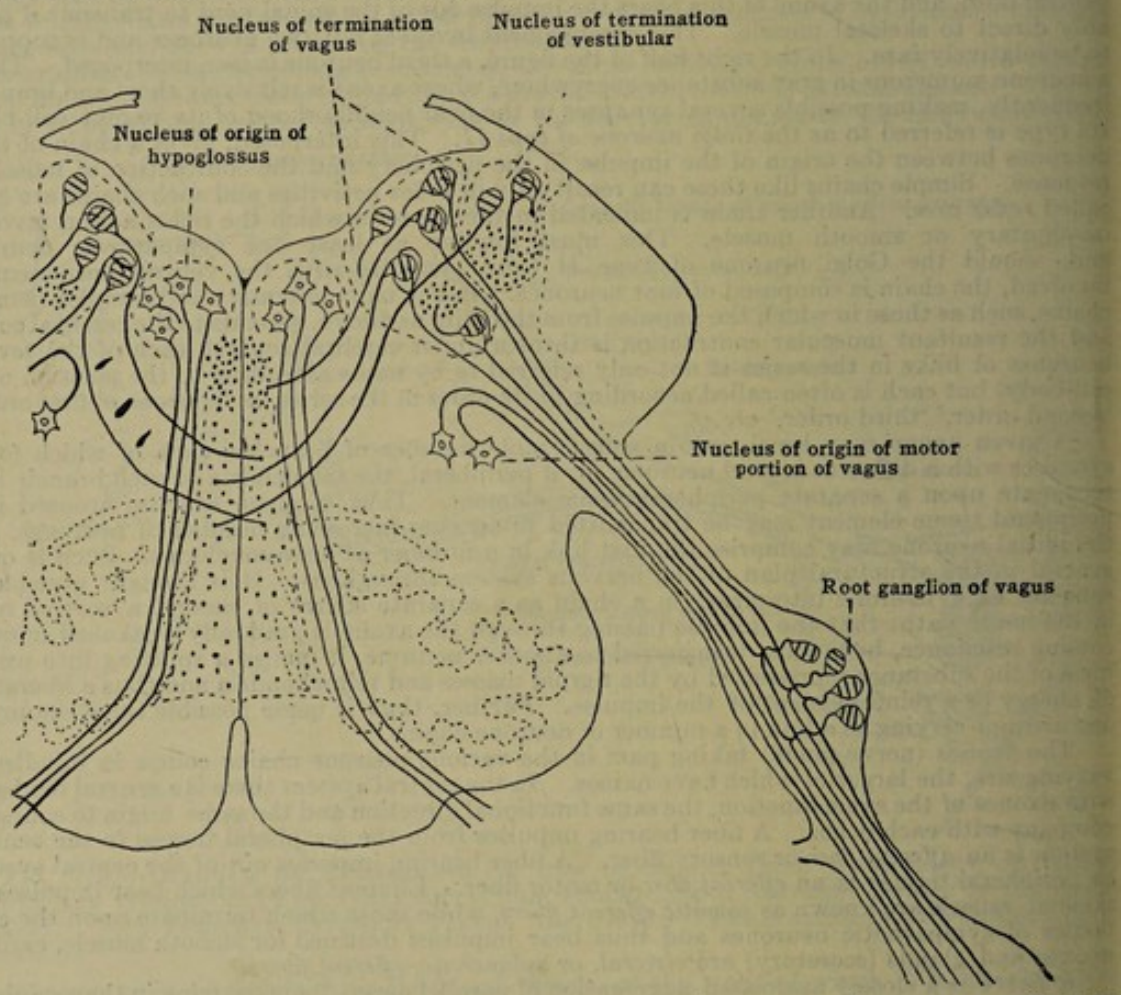

FIG. 691.—DIAGRAM OF TRANSVERSE SECTION OF MEDULLA OBLONGATA, ILLUSTRATING NUCLEI OF TERMINATION AND NUCLEI OF ORIGIN.

A nucleus of termination is an accumulation of cell-bodies in which the axones of a given fasciculus or of a nerve-root terminate, that is, cell-bodies which, by synapses, receive the impulses borne by the terminating axones. In most cases the impulses transferred to a nucleus so named are sensory in character. The nucleus may be considered as a defined region in which neurones of the next order are interpolated in a given nerve pathway or system of neurone chains. Fasciculi in the spinal cord which bear impulses to the brain have their terminal nuclei chiefly in the medulla oblongata and thalamus, and the sensory or afferent axones of the cranial nerves find their nuclei of termination upon entering the central system.

A nucleus of origin is an accumulation of cell-bodies of neurones which give origin to the axones going to form a given nerve-root or a fasciculus. Strictly speaking, a nucleus of termination for one nerve-tract is the nucleus of origin for another, the next link in the neurone chain. However, the term is commonly used to distinguish a group of cell-bodies giving rise to a motor nerve tract. Thus each motor cranial nerve has its nucleus of origin within the central system. The gray substance of the spinal cord is in the form of a column continuous throughout the length of the cord and so the cell-bodies in the ventral horns of this column which give rise to the motor or efferent roots of the spinal nerves are not considered as grouped into nuclei of origin, one for each of the motor roots.

The dorsal root of each spinal nerve is afferent or sensory in function and its axones arise as processes of cell-bodies comprising the spinal ganglion of the nerve. The afferent or sensory fibers of the cranial nerves arise as processes of cell-bodies comprising the ganglia of the cranial nerves, which ganglia are, in development and character, with the exception of the optic and olfactory, exactly homologous to the spinal ganglia.

The ventral root of each spinal nerve is efferent or motor in function and its fibers arise as processes of cell-bodies situated in the ventral horn of the gray substance of the spinal cord. The efferent or motor fibers of the cranial nerves arise as processes of cell-bodies accumulated as nuclei of origin in the gray substance of the encephalon, and homologous with those cell-bodies of the ventral horns of the spinal cord which give origin to the ventral-root fibers.

The general relation of the cerebrum (which includes the mesencephalon) to the remainder of the nervous system is a *crossed relation*. Neurone-chains from the general body to the cerebrum, via the spinal nerves and cord and via the cranial nerves and medulla oblongata and pons of one side, cross the mid-line to terminate in the opposite side of the cerebrum. Axones, and neurone chains, arising in response in one side of the cerebrum, likewise nearly always decussate in descending to terminate in the respective regions of the opposite side.

Many of the names given nervous structures, prior to 1850 especially, instead of suggesting something of their functional or anatomical significance, indicate nothing more than active imaginations for accidental resemblances between the various structures of the nervous system and objects in ordinary domestic environment. Also, quite often the name given a structure is merely the name of some anatomist associated with it. The much needed elimination of these old non-descriptive names is proving a very slow process. Attempts have often increased the difficulty by making necessary the use of several names for a given structure instead of one. The most recent and concerted attempt, the nomenclature known as the BNA (anatomical names chosen by a commission appointed for the purpose which convened in Basle in 1895), has been adopted by modern text-books. It is here used in the form of the English equivalents of the Latin terms, except in cases of those Latin terms which have become so commonly used as to be considered words incorporated into the English language. The BNA has retained many of the old names and, since a name should indicate something of the locality and significance of the structure to which it is applied, it is not yet wholly satisfactory throughout. In applying the names of a few fasciculi, the BNA in the following pages is slightly modified by so compounding the name that the first word in the compound indicates the locality of origin of the faciculus and the second, the locality of its termination. Thus, '*Dorsal spinocerebellar fasciculus*' indicates the more dorsally coursing of the fasciculi which arise from cell-bodies in the spinal cord and terminate in the cerebellum. This principle applies to many of the BNA names without change, as '*lateral cerebrospinal fasciculus*.' Some changes recommended by the NK are also indicated.

THE CENTRAL NERVOUS SYSTEM

The central nervous system [systema nervorum centrale], or organ, is an aggregation of nuclei, fasciculi and commissures—a large axis of gray and white substance—situated in the dorsal midline of the body, and the bundles of fibers connecting it with the tissues of other systems and with the peripheral ganglia are of necessity correspondingly large. So numerous are the axones connecting it and so intimately are its neurones associated that a disturbance affecting any one part of the system may extend by way of its neurone chains to influence all other parts. The enlarged cephalic extremity of this central axis, the brain or **encephalon,** is a special aggregation of nuclei and masses of gray and white substance, many of which are much larger than any found in the peripheral system.

In the study of the central nervous system its enveloping membranes or meninges are met with first, and logically should be considered first, but since a comprehensive description of these membranes involves a foreknowledge of the various structures with which they are related, it is more expedient to consider them after making a closer study of the entire system they envelop.

For convenience of study, the central nervous system is separated into the gross divisions, spinal cord and brain (encephalon) as illustrated in figure 691. Each of these divisions will be subdivided and considered with especial reference to its anatomical and functional relations to the other divisions and to the interrelations of its component parts.

I. THE SPINAL CORD

The spinal cord [medulla spinalis] is the lower (caudal) and most attenuated portion of the central nervous system. It is approximately cylindrical in form and terminates conically. Its average length in the adult is 45 cm. (18 in.) in the male and 42 cm. in the female. Divested of its outer meninges, it weighs from 26 to 28 grams or about 2 per cent. of the entire central nervous system.

After birth it grows more rapidly and for a longer period than the encephalon, increasing in weight more than sevenfold, while the brain increases less than half that amount. Its specific gravity is given as 1.038.

The line of division between the spinal cord and the medulla oblongata is arbitrary. The outer border of the foramen magnum is commonly given, or, better, a transverse line just below the decussation of the pyramids. Lying in the vertebral canal, the adult cord usually extends to the upper border of the body of the second lumbar vertebra. However, cases may

be found among taller individuals in which it extends no farther than the last thoracic vertebra. With increase in stature, its actual length increases, but the extent to which it may descend the vertebral canal decreases. Up to the third month of intrauterine life it occupies the entire length of the vertebral canal, but owing to the fact that the vertebral column lengthens more rapidly and for a longer period than does the spinal cord, the latter, being attached to the brain above, soon ceases to occupy the entire canal. At birth its average extent is to the caudal margin of the body of the second lumbar vertebra.

External Morphology of the Spinal Cord

In position in the body, the spinal cord conforms to the curvatures of the vertebral canal (fig. 681). In addition to the bony wall of the vertebral canal, it is enveloped and protected by its three membranes or meninges, which are continuous with the like membranes of the encephalon: first, the **pia mater,** which closely invests the cord and sends ingrowths into its substance, contributing to its support; second, the **arachnoid,** a loosely constructed, thin membrane, separated from the pia mater by a considerable **subarachnoid space;** third, the **dura mater,** the outermost and thickest of the membranes, separated from the arachnoid by merely a slit-like space, the **subdural space.**

The intimate association of the central system with all the peripheral organs is attained chiefly through the spinal cord, and this is accomplished by means of thirty-one pairs of spinal nerves, which are attached along its lateral aspects. The nerves of each pair are attached opposite each other at more or less equal intervals along its entire length, and in passing to the periphery they penetrate the meninges, which contribute to and are continuous with the connective tissue sheaths investing them. Each nerve is attached by two roots, an afferent or **dorsal root,** which enters the cord along its posterolateral sulcus, and an efferent or **ventral root,** which makes its exit along the ventrolateral aspect.

With its inequalities in thickness and its conical termination the spinal cord is subdivided into four parts or regions:—(1) The **cervical portion,** with eight pairs of cervical nerves; (2) the **thoracic portion,** with twelve pairs of thoracic nerves; (3) the **lumbar portion,** with five pairs of lumbar nerves; and (4) the **conus medullaris,** or sacral portion, with five pairs of sacral and one pair of coccygeal nerves. From the termination of the conus medullaris, the pia mater continues below in the subarachnoid space into the portion of the vertebral canal not occupied by the spinal cord, and forms the non-nervous, slender, thread-like terminus, the *filum terminale.* This becomes continuous with the dura mater at the lower extremity of the filum.

In the early fetus the spinal nerves pass from their attachment to the spinal cord outward through the intervertebral foramina at right angles to the long axis of the cord, but, owing to the fact that the vertebral column increases considerably in length after the spinal cord has practically ceased growing, the nerve-roots become drawn caudad from their points of attachment, and, as is necessarily the case, their respective foramina are displaced progressively downward as the termination of the cord is approached, until finally the roots of the lumbar and sacral nerves extend downward as a brush of parallel bundles considerably below the levels at which they are attached. This brush of nerve-roots is the **cauda equina.** The dura mater, being more closely related to the bony wall of the canal than to the spinal cord, extends with the vertebral column and thus envelops the cauda equina, undergoing a slightly bulbous, conical dilation which decreases rapidly and terminates in the attenuated canal of the coccyx as the coccygeal ligament [filum duræ matris spinalis] (fig. 692).

The enlargements.—Wherever there is a greater mass of tissue to be innervated, the region of the nervous system supplying such must of necessity contain a greater number of neurones. Therefore, the regions of the spinal cord associated with the skin and musculature of the regions of the superior and inferior limbs are thicker than the regions from which the neck or trunk alone are innervated. Thus in the lower cervical region the spinal cord becomes broadened into the *cervical enlargement,* and likewise in the lumbar region occurs the *lumbar enlargement.* The spinal nerves attached to these regions are of greater size than in other regions.

The **cervical enlargement** [intumescentia cervicalis] begins with the third cervical vertebra, acquires its greatest breadth (12 to 14 mm.) opposite the lower part of the fifth cervical vertebra (attachment of the sixth cervical nerves), and

extends to opposite the second thoracic vertebra. Unlike the lumbar enlargement, its lateral is noticeably greater than its dorsoventral diameter.

The **lumbar enlargement** [intumescentia lumbalis] begins gradually with the ninth or tenth thoracic vertebra, is most marked at the twelfth thoracic vertebra

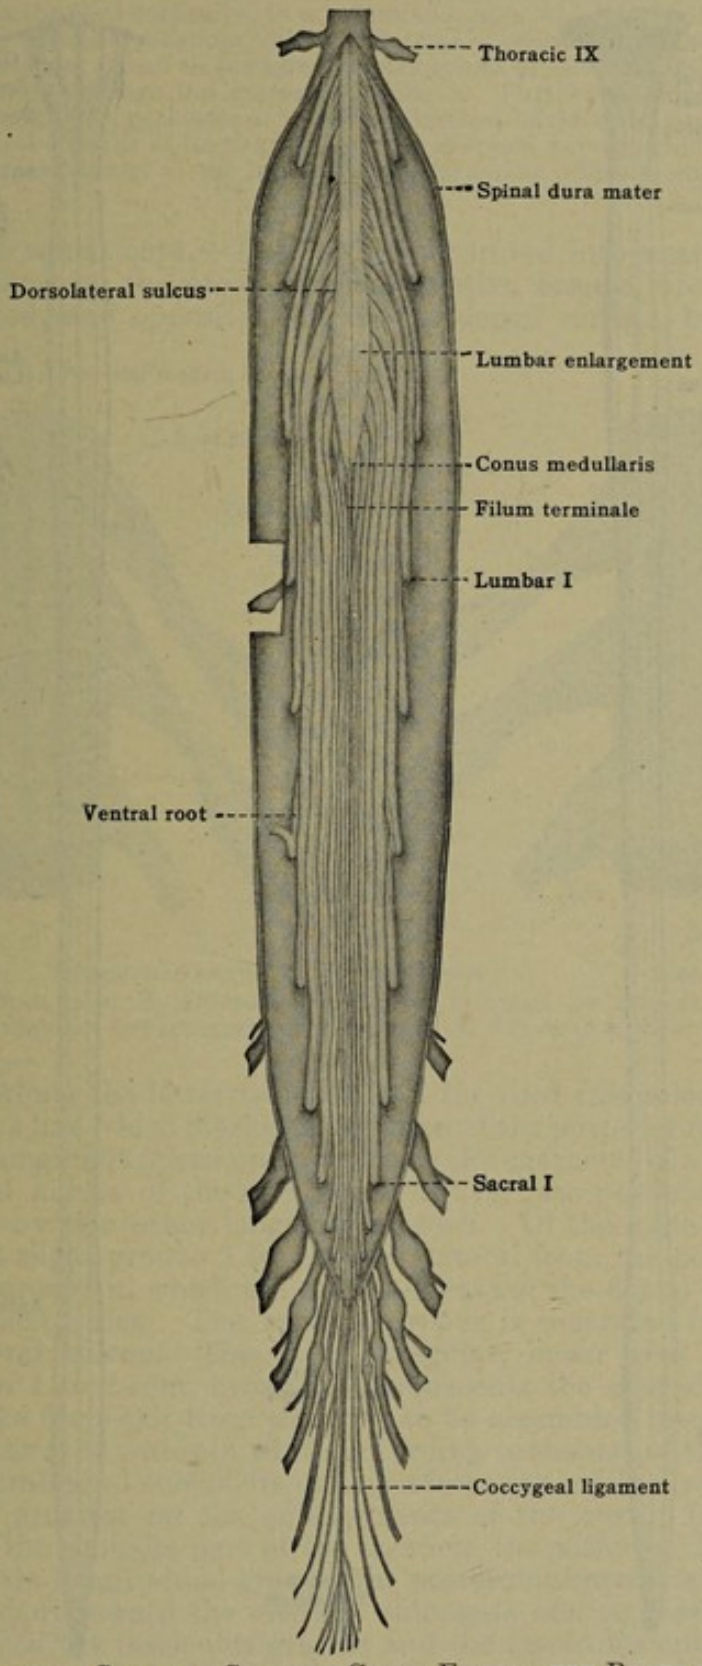

FIG. 692.—DRAWING FROM SPECIMEN SHOWING CAUDA EQUINA, THE ROOTS OF CERTAIN OF THE SPINAL NERVES WHICH FORM IT, AND ITS ACCOMPANYING DURA MATER. (Dorsal aspect.)

(attachment of the fourth lumbar nerves), and rapidly diminishes into the conus medullaris.

Both the lumbar and thoracic regions are practically circular in transverse section. Neither diameter of the lumbar is ever so great as the lateral diameter of the cervical enlargement.

The thoracic part attains its smallest diameter opposite the fifth and sixth thoracic vertebra (attachment of the seventh and eighth thoracic nerves).

The enlargements occur with the development of the upper and lower limbs. In the embryo they are not evident until the limbs are formed. In the orang-utan and gorilla the cervical enlargement is greatly developed; the ostrich and emu have practically none at all.

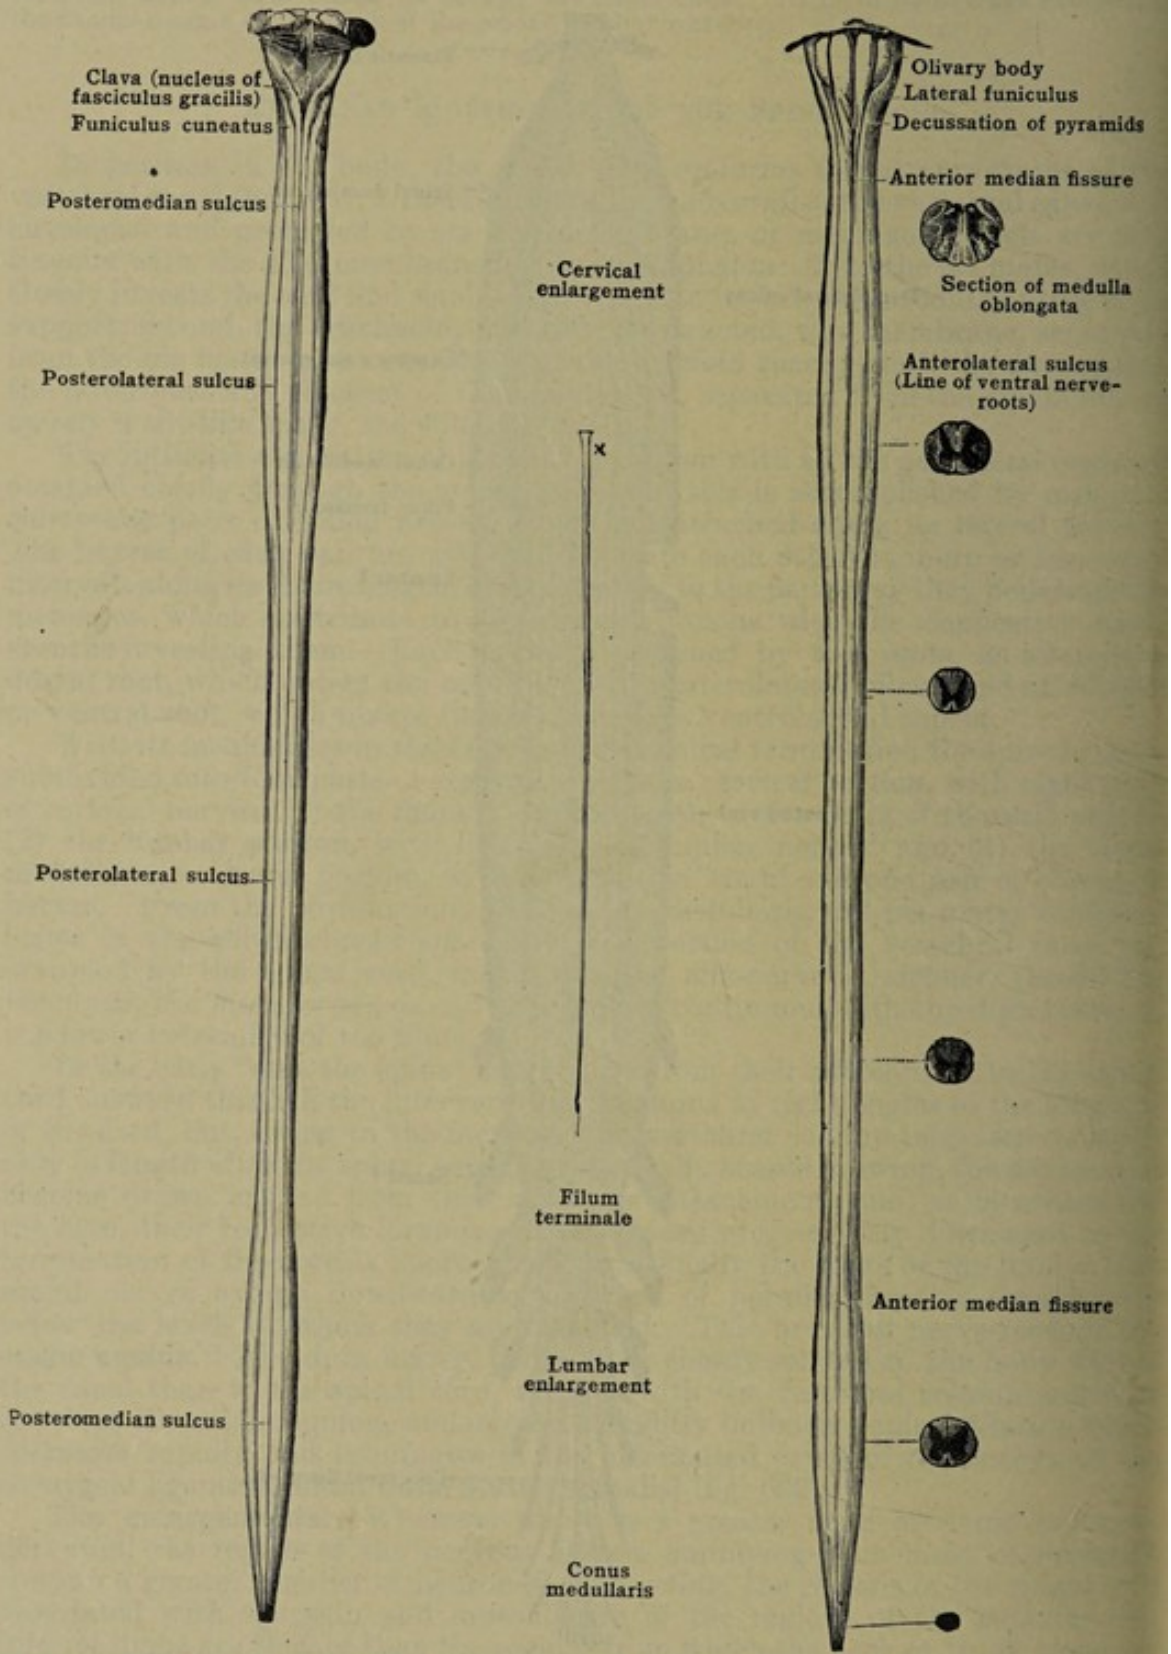

FIG. 693.—POSTERIOR AND ANTERIOR VIEWS OF THE SPINAL CORD. (Modified from Quain.)

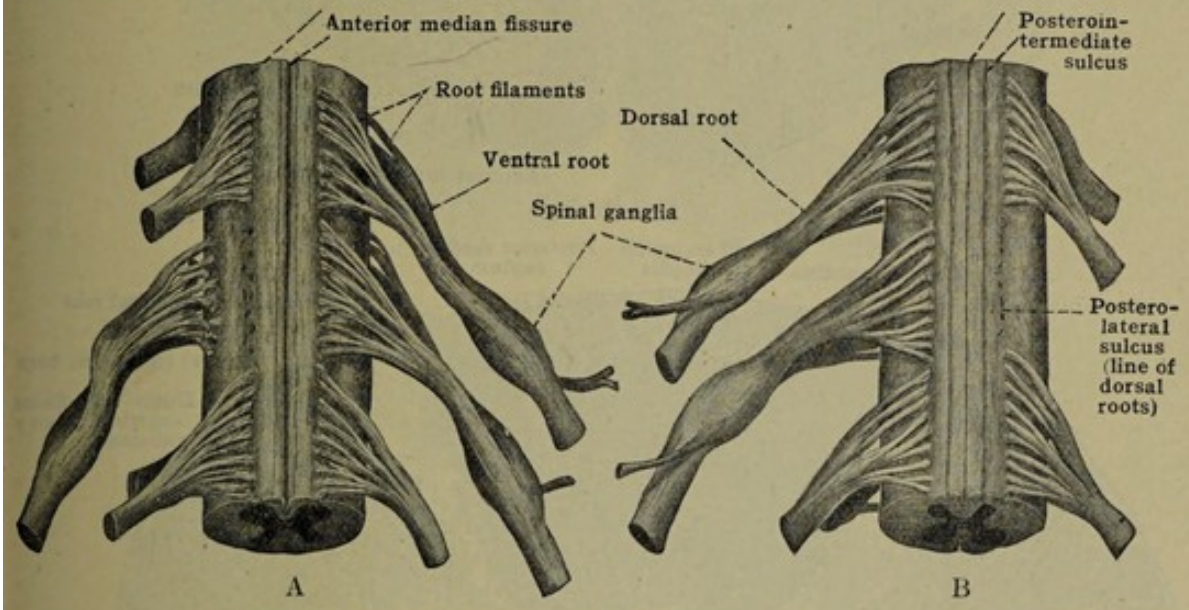
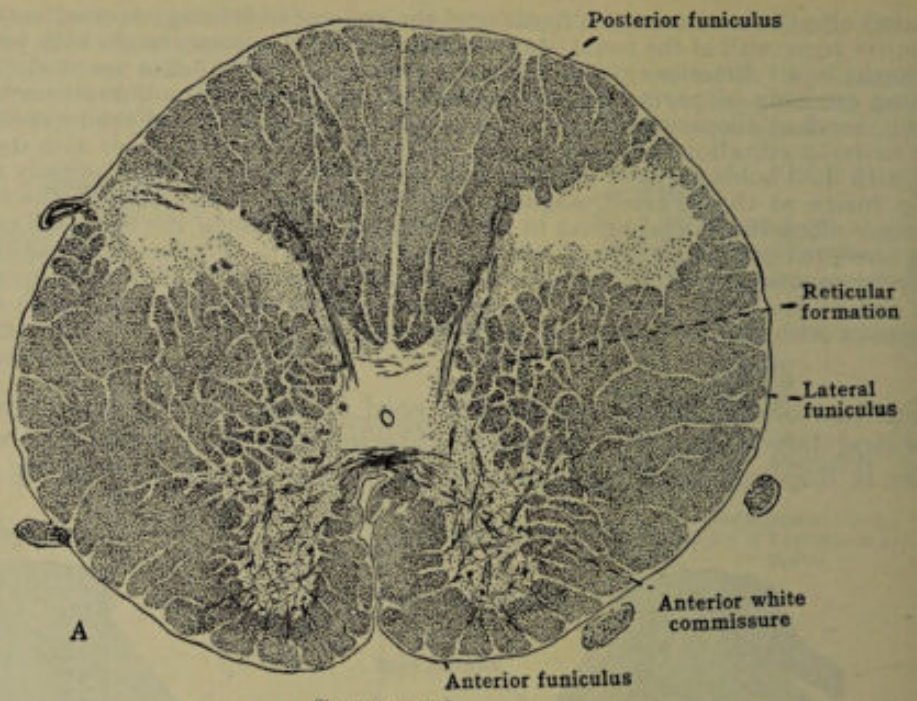
Protection of the spinal cord.—The chief provisions for protection of the cord are the bony walls of the vertebral canal, the meninges of the cord, the curvatures of the vertebral column, and the fact that the vertebral canal in which the cord lies is of much greater diameter than the cord and is filled with a cushion of cerebrospinal fluid. The parts of the vertebral column most exposed to injury are the cervical and the lumbar regions—regions joining less mobile parts, the head and pelvis. The cervical region is especially affected by violence exerted on the

head and also the lumbar region because of the amount of leverage exerted on that part. The protective bony wall of the canal consists of a number of separate bones with joints which allow movement in all directions without serious weakening. The bones are of the spongy variety, allowing crushing of parts without fracture of the whole. The curvatures of the vertebral column, cervical, thoracic and lumbar, and the cushion structure of the intervertebral disks all serve to damp vibrations and absorb jars. The very tough dura mater with its subdural space filled with fluid holds the cord suspended in a voluminous sack which is firmly fixed in position (1) by fusion at the foramen magnum with the internal periosteum of the cranium, (2) by adherence along its ventral aspect to the internal periosteum of the vertebral canal, and (3) by being anchored caudally through the coccygeal ligament. Further the cord is slung laterally by the ligamenta denticulata, processes of the dura attached to the closely investing pia of the cord, and by the dural sheaths of its thirty-one pairs of spinal nerves, which sheaths also are continuous with the periosteum in the intervertebral foramina. (See meninges of the spinal cord.)

Surface of the spinal cord.—The cord is separated into nearly symmetrical right and left halves by the broad **anterior median fissure** into which the pia mater is duplicated, and opposite this, on the dorsal surface, by the **posterior**





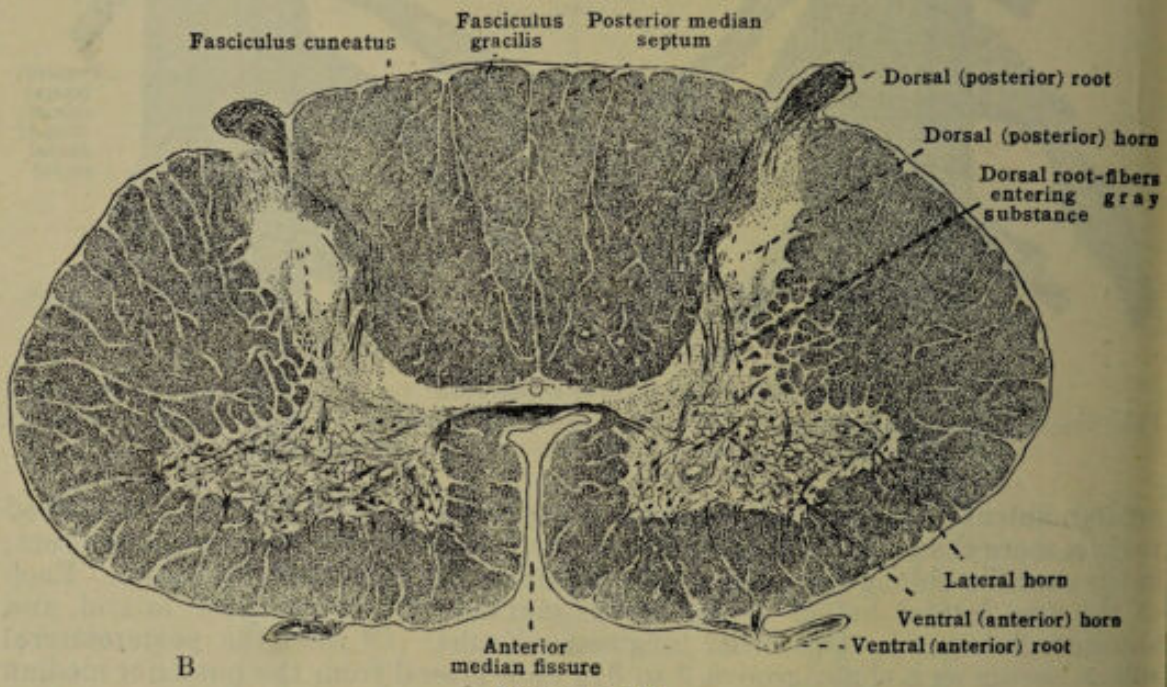


FIG. 694.—A, VENTRAL, AND B, DORSAL, VIEWS OF PORTION OF SPINAL CORD SHOWING MODES OF ATTACHMENT OF DORSAL AND VENTRAL ROOTS.

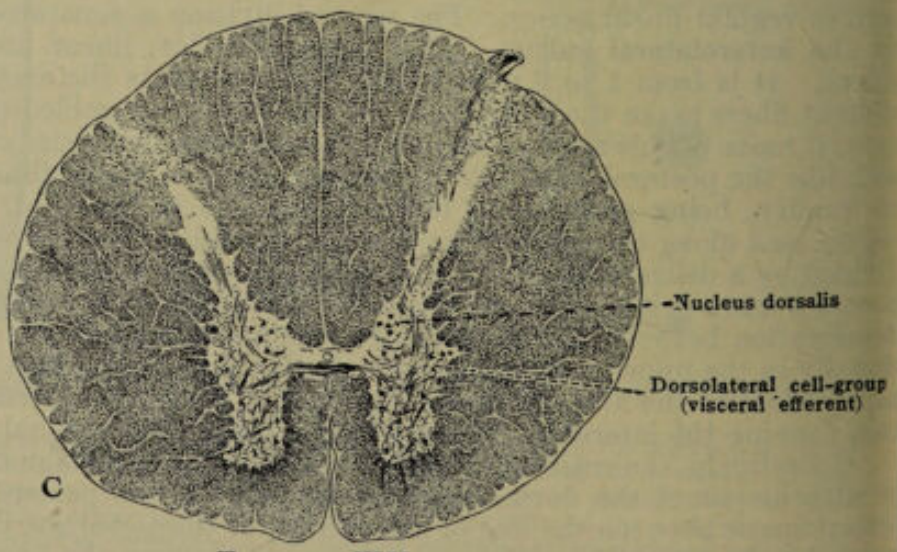
median sulcus. Along the lower two-thirds of the cord this sulcus is shallowed to little more than a line which marks the position of the posterior median septum; in the medulla oblongata it opens up and attains the character of a fissure. Each of the two lateral halves of the cord is marked off into posterior, lateral, and anterior divisions by two other longitudinal sulci. Of these, the **posterolateral sulcus** occurs as a slight groove 2 to 3½ mm. lateral from the posterior median sulcus, and is the groove in which the root filaments of the dorsal roots enter the cord in regular linear series. The ventral division is separated from the lateral by the **anterolateral sulcus.** This is an irregular, linear area rather than a sulcus. It is from 1 to 2 mm. broad, and represents the area along which the efferent fibers make their exit from the cord to be assembled into the respective ventral roots. This area varies in width according to the size of the nerve-roots, and, like the posterolateral sulcus, its distance from the midline varies according to locality, being greatest on the enlargements of the cord. In the cervical region, and along the cephalic part of the thoracic, the posterior division is subdivided by a delicate longitudinal groove, the **posterointermediate sulcus,** which becomes more evident toward the medulla oblongata and represents the line of demarcation between the fasciculus gracilis and the fasciculus cuneatus. Occasionally in the upper cervical region a similar line may be seen along the ventral aspect close to the anterior median fissure. This is the **anterointermediate sulcus,** forming the lateral boundary of the ventral cerebrospinal fasciculus.



Collectively, the entire space between the posterior median sulcus and the line of attachment of the dorsal roots is occupied by the **posterior funiculus;** the lateral space between the line of attachment of the dorsal and that of the ventral roots, by the **lateral funiculus;** and the space between the line of attachment of

COCCYGEAL

the ventral roots and the anterior median fissure, by the **anterior funiculus.** Each of these funiculi is subdivided within into its component fasciculi.

The dorsal and ventral nerve-roots are not attached to the cord as such, but are first frayed out into numerous thread-like bundles of axones which are distributed along their lines of entrance and exit. These bundles are the **root-filaments** [fila radicularia] of the respective roots. The fila of the larger spinal nerves are fanned out to the extent of forming almost continuous lines of attachment, while in the thoracic nerves there are small intervals between the root-filaments belonging to adjacent roots. Throughout, the intervals are less between the fila of the ventral than between those of the dorsal roots.

By reflected light masses of medullated axones appear white when fresh, and such masses are known as **white substance.** The spinal cord consists of a continuous, centrally placed column of gray substance surrounded by a variously thickened tunic of white substance. The closely investing pia mater sends

numerous ingrowths into the cord, bearing blood-vessels and contributing to it internal supporting tissue. The volume of white and of gray substance varie both absolutely and relatively at different levels of the cord. The absolut amount of gray substance increases with the enlargements. The absolut amount of white substance also increases with the enlargements coincident wit the greater amount of gray substance in those regions. The relative amount o white substance increases in passing from the conus medullaris to the medull oblongata, as explained later.

The gray substance.—All the nerve-cells of the gray substance are derived fron the cells forming the neural tube in the embryo, and in the adult the column o gray substance, though greatly modified in shape, still retains its position abou the central canal. In transverse section the column appears as a gray figure o two laterally developed halves, connected across the mid-line by a more attenu ated portion, the whole roughly resembling the letter H. The cross-bar of the H is known as the **gray commissure.** Naturally, it contains the **central canal** which is quite small and is either rounded or laterally or ventrally oval in section according to the level of the cord in which it is examined. The canal continues upward, and in the medulla oblongata opens out into the fourth ventricle. Downward, in the extremity of the conus medullaris, it widens slightly and forms the rhomboidal sinus or **terminal ventricle,** then is suddenly constricted into an extremely small canal extending a short distance into the filum terminale, and there ends blindly. The gray commissure always lies somewhat nearer the ventral than the dorsal surface of the cord, and itself contains a few medullated axones which vary in amount in the different regions of the cord. The medullated axones crossing the midline on the ventral side of the central canal form the ventral or **anterior white commissure**; those, usually much fewer in number, crossing on the dorsal side of the central canal, form the dorsal or **posterior white commissure.** These two commissures comprise fibers crossing in the gray substance as distinguished from others which cross in the white substance dorsal and ventral to them, namely, the **dorsal cornucommissural tract** and the **ventral commissural bundle.** The axones of these four commissures serve chiefly in functionally associating the two lateral halves of the gray column.

Each lateral half of the gray column presents a somewhat crescentic or comma-shaped appearance in transverse section, which also varies at the different levels of the cord. At all the levels each half presents two well-defined horns, themselves spoken of as columns of gray substance. The **dorsal horn** [columna posterior] extends posteriorly and somewhat laterally toward the surface of the cord along the line of the posterolateral sulcus. It is composed of an **apex** (crista columnæ dorsalis NK) and a **neck** [cervix columnæ posterioris].

In structure the apex is peculiar. The greater portion of it consists of a mass of small nerve-cells and neuroglia tissue, among which a gelatinous substance of questionable origin predominates, giving the horn a semi-translucent appearance. This is termed the **gelatinous substance of Rolando,** to distinguish it from a similar appearance immediately about the central canal, **the central gelatinous substance.** The apex of the dorsal horn is widest in the regions of the enlargements, especially the lumbar, and the gelatinous substance of Rolando is most marked high in the cervical region. In these regions the cervix shows a slight constriction of the dorsal horn between the apex and the line of the gray commissure. In the thoracic region, however, the base of the cervix is the thickest part of the dorsal horn. This thickness is due to the presence there of the **nucleus dorsalis,** or Clarke's column—a column of gray substance containing numerous nerve-cells of larger size than elsewhere in the dorsal horn, and extending between the seventh cervical and third lumbar segments of the cord. Tapering finely at its ends, this nucleus attains its height in the lower thoracic or first lumbar segment. About the ventrolateral periphery of the nucleus dorsalis are scattered nerve-cells of the same type as those contained in it. These cells are sometimes distinguished as **Stilling's nucleus,** though Clarke's column was also described by Stilling. They are more numerous about the lower extremity of the nucleus dorsalis, and they continue still more numerous in line with it below its termination in the lumbar region.

It must be noted that the dorsal horn throughout contains numerous cell-bodies of neurones, mostly of small size (nuclei of the dorsal horns). These are especially numerous in the margins of the horn where they are referred to as the *stratum zonale.* Their significance will be given below in connection with the nerve-tracts with which they are concerned (fig. 698).

The **ventral horn** [columna anterior] of each lateral half of the gray figure is directed ventrally toward the surface of the spinal cord, pointing toward the anterolateral sulcus. It contains the cell-bodies which give origin to the efferent or ventral root axones, and these axones make their emergence from the spinal cord along the anterolateral sulcus. The ventral horns vary markedly in shape

in the different regions. In certain segments each ventral horn is thickened laterally and thus presents its two component columns of gray substance: the **lateral horn** [columna lateralis], a triangular projection of gray substance into the surrounding white substance, in line with or a little ventral to the line of the gray commissure; and the **ventral horn proper** [columna anterior], projecting ventrally. In the midthoracic region the lateral horn is absent except its dorsolateral part, and the ventral horn is quite slender; in the cervical and lumbar enlargements both horns are considerably enlarged.

The gray substance is not sharply demarcated from the white. In the blending of the two there are often small fasciculi of white substance embedded in the gray, and likewise the gray substance sends fine processes among the axones composing the white substance. Such processes or gray trabeculæ are most marked along the lateral aspects of the gray figure and present there the appearance known as the **reticular formation.** The reticular formation of the spinal cord is most evident in the cervical region (fig. 695).

Minute structure.—The large cell-bodies of the ventral horn as a whole are divisible into four groups, only three of which are to be distinguished in the midthoracic region of the spinal cord:—(1) A *ventral group* of cells, sometimes separated into a ventrolateral and a ventromedial portion (see figs. 695, 698), occupies the ventral horn proper, is constant throughout the entire length of the cord, and contributes axones to the ventral root, most of which probably supply the muscles adjacent to the vertebral column; (2) a *dorsomedial group* of cells, situated in the medial part of the ventral horn, just below the level of the central canal, gives origin to axones some of which go to the ventral root of the same side, some of which cross the midline viâ the anterior white commissure, either to pass out in the ventral root of the opposite side or (mostly) to enter the white substance of that side and course upward or downward, associating with other levels of the cord. Some of its axones terminate among the cells of the ventral horn in the same level of the opposite side; (3) a *lateral group* of cells, which is separated into a dorsolateral and a ventrolateral portion, occupies the lateral column or horn, and is best differentiated in the cervical and lumbar enlargements. Most of the axones arising from its larger cells are contributed to the ventral root of the same side, and most of such axones supply the muscles of the extremities. Some of those from its ventral portion are distributed to the muscles of the body-wall. The dorsolateral portion is that part of the lateral column which persists throughout the cord, and is considered as supplying the visceral efferent ('autonomic') fibers in the ventral roots. It is usually referred to as the dorsolateral cell group of the ventral horn, the only lateral group in the midthoracic region. It is called the *intermediolateral* group when all the cell groups of both horns are collectively considered. (4) An *intermediate group*, occupying the middorsal portion of the ventral horn. Axones arising from its cells are in part contributed to the ventral root as visceral efferent fibers, but most of them course wholly within the central nervous system. Some pass to the opposite side of the cord, chiefly viâ the anterior and possibly the posterior white commissure, to terminate either in the same or different levels of the gray column. Others of longer course pass to the periphery of the cord, join one of the spinocerebellar fasciculi, and pass upward to the cerebellum.

Furthermore, there are scattered throughout the gray substance many small cell-bodies of neurones. These give rise to axones of shorter course, either **commissural** or **associational** proper. Of such axones many are quite short, coursing practically in the same level as that in which their cells of origin are located, and serve to associate the different parts of the gray substance of that level. Others course varying distances upward and downward for the association of different levels of the gray column.

It is evident from the above that in addition to the various nerve-cells it contains, there is also to be found a felt-work of axones in the gray substance. Many of these axones are medullated, though not in sufficient abundance to destroy the gray character of the substance The felt-work is composed of four general varieties of fibers:—(1) Axones arising from the cells of the spinal ganglia which enter the cord as dorsal root-fibers and form synapses with the cell-bodies of the gray substance; (2) The terminal branches of axones entering from the fasciculi of the white substance and forming end-brushes (synapses) about the various cell-bodies in the gray substance (partly medullated); (3) axones given off from the cells of the gray substance and which pass into the surrounding white substance either to enter the ventral roots or to join the ascending and descending fasciculi within the spinal cord (partly medullated); (4) axones of Golgi neurones of type II, which do not pass outside the confines of the gray substance (non-medullated). Some axones of any of these varieties may cross the midline and thus become commissural. In general all fibers of long course acquire medullary sheaths a short distance from their cells of origin, and lose them again just before termination. From the cell groups of the dorsal horn, especially the stratum zonale, arise fibers of long course which decussate in the ventral commissure and ascend to the brain in bundles known as the 'spinal lemniscus.'

The white substance of the spinal cord.—The great mass of the axones of the spinal cord course longitudinally and form the thick mantle surrounding the column of gray substance. This mantle is divided into right and left homolateral halves by the anterior median fissure along its ventral aspect, and along its dorsal aspect by the posterior median septum, which is for the most part a connective tissue partition derived from the pia mater along the line of the posterior median sulcus. The mantle is supported internally by interwoven

neuroglia and white fibrous connective tissue, the latter derived from the mesoderm via the pia mater, closely investing it without.

The axones of the white substance belong to three general neurone systems:— (1) The *spinal association* and *commissural system* of axones which serve to correlate the different levels and the two sides of the spinal cord and which are proper to the spinal cord, i.e., they do not pass outside its confines. (2) The *spinocerebral and cerebrospinal system*, which consists of axones of long course one set ascending and another descending, forming links in the neurone chain between the cerebrum and the peripheral organs. The ascending axones of this system collect the general bodily sensations which are conveyed through synapse to the cerebrum, the cerebral cells contributing axones which descend the cord conveying efferent or motor impulses in response. (3) The *spinocerebellar and cerebellospinal* system consists of conduction paths, one set ascending and another descending, which are links between cerebellar structures and the gray substance of the spinal cord. To this might be added a fourth system of neurones (spinobulbar) connecting and correlating the spinal cord and the medulla oblongata.

The second, third and fourth systems increase in bulk as the cord is ascended. The ascending axones of each system are contributed to the white substance of the cord along its length, and therefore accumulate upward; the axones descending from the encephalon are distributed to the different levels of the cord along its length, and therefore diminish downward.

The mass of the first system of axones varies according to locality (figs. 695, 701). Wherever there is a greater mass of neurones to be associated, as there is in the enlargements of the cord, a greater number of these axones is required. Their cells of origin, being in the gray substance of the cord, contribute to its bulk and thus both the cells and the axones of this system serve to make the enlargements more marked. In the lumbar and sacral regions the greater mass of the entire white substance consists of axones belonging to this system. It forms a dense felt-work about the gray column throughout the cord. Necessarily this system contains axones of various lengths. Some merely associate different levels within a single segment of the cord; others associate the different segments with each other. Many of these axones cross the midline both in the gray and in the white substance to associate the neurones of the two sides. For purposes of distinction, such as cross the midline are called **commissural fibers**, while those which arise and course upward and downward on the same side are **association fibers.** Coursing in longitudinal bundles about the gray substance, the latter compose the **fasciculi proprii** or 'ground bundles' of the spinal cord. Naturally, these are mixed with fibers which have crossed the midline.

METHODS BY WHICH THE CONDUCTION PATHS HAVE BEEN DETERMINED

A purely anatomical examination of a normal adult cord, prepared by whatever means gives no indication of the fact that the mass of longitudinally coursing fibers of the white substance is composed of more or less definite bundles or fasciculi, each having a definite origin, course and termination and forming links (conduction paths) in a definite system of neurone chains. Present information as to the size, position, and connections of the various fasciculi is based upon evidence obtained by three different lines of investigation:—

(1) **Physiological investigation.**—(*a*) Direct stimulation of definite bundles or areas in section and carefully noting the resulting reactions which indicate the function and course of the axones stimulated. (*b*) Experimental section of fasciculi and observation of any impaired function resulting. (*c*) 'Wallerian degeneration' and the application of such methods as that of Marchi. When an axone is severed, that portion of it which is separated from its parent cell-body degenerates. Likewise a bundle of axones severed from their cells of origin, whether by accident or design, will degenerate from the point of the lesion on to the locality of their termination in whichever direction this may be. This phenomenon was noted by Waller in 1852 and is known as **Wallerian degeneration.** By the application of a staining technique which is differential for these degenerating axones and a study of serial sections containing the axones in question, their course and distribution may be determined. The locality of their cells of origin, if unknown, may be determined by repeated experiment till a point of lesion is found not followed by degeneration of the axones under investigation. (*d*) The axonic reaction or 'reaction from a distance.' Cell-bodies whose axones have been severed undergo chemical change and stain differently from those whose axones are intact. Thus cell-bodies giving origin to a bundle of severed axones may be located in appropriately stained sections of the region containing them.

(2) **Embryological evidence.**—In the first stages of their development axones of the cerebrospinal nervous system are non-medullated. They acquire their sheaths of myelin later. Axone pathways forming different chains become medullated at different periods. Based upon this fact a method of investigation originated by Flechsig is employed, by which the posi-

tion and course of various pathways may be determined. A staining method differential for medullated axones alone is applied to the nervous systems of fetuses of different ages, and pathways medullated at given stages may be followed from the locality of their origin to their termination. In the later stages, when most of the pathways are medullated and therefore stain alike, the less precocious pathways may be followed by their absence of medullation.

(3) **Direct anatomical evidence.**—(*a*) Stains differential for axones alone are applied to a given locality to determine the fact that the axones of a given bundle actually arise from the cell-bodies there, or that axones traced to a given locality actually terminate about the cell-bodies of that locality. For example, it may be proved anatomically that the axones of a dorsal root arise from the cells of the corresponding spinal ganglion, and then these axones may be traced into the spinal cord and the terminations noted either of their collateral or terminal twigs, or the fasciculus they join in their cephalic course may be determined. (*b*) The staining properties and the size and distribution of the tigroid masses in the cell-bodies of sensory neurones differ from those in the motor neurones, and recently Malone has claimed that, in the central

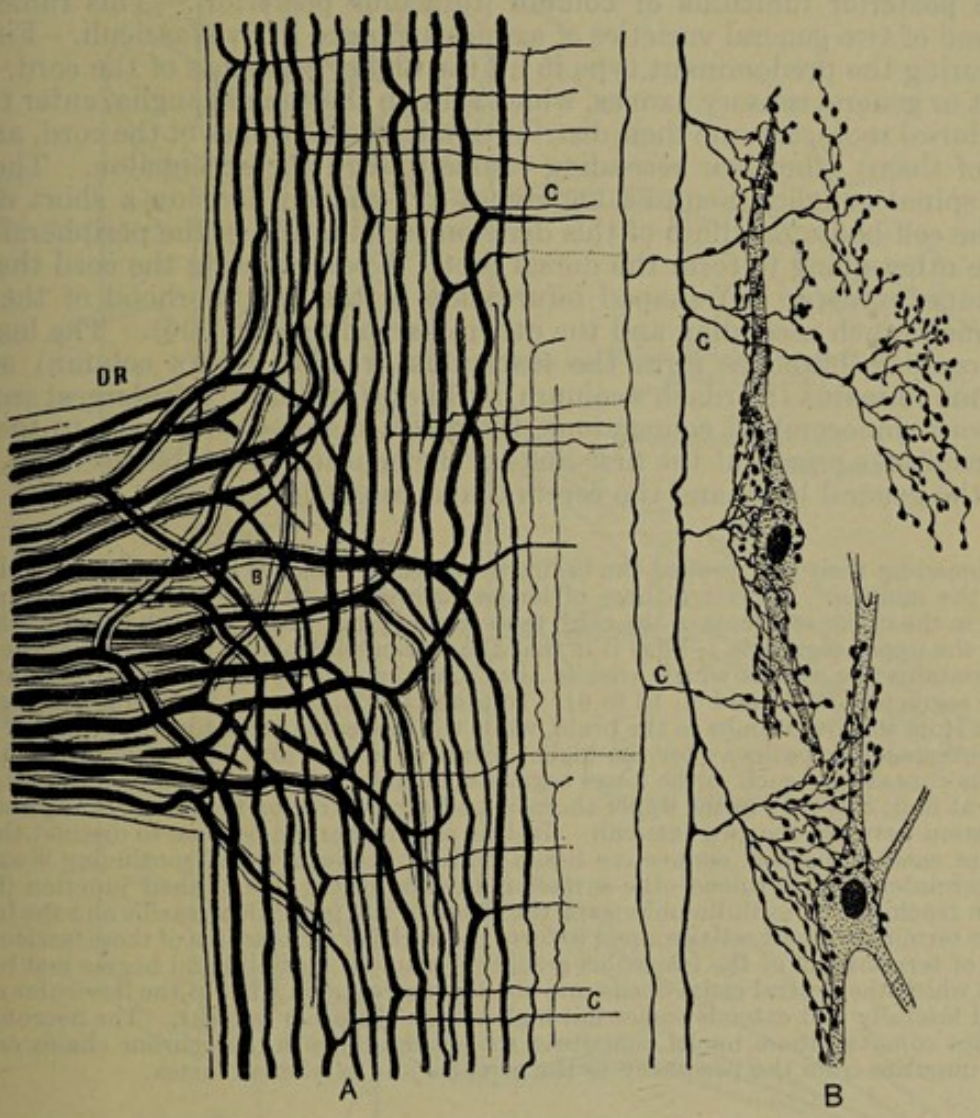

FIG. 696.—SHOWING DISPOSITION OF THE DORSAL ROOT FIBERS UPON ENTERING THE SPINAL CORD. (From Edinger after Cajal.)

A shows dorsal root axones DR, entering the spinal cord, bifurcating at B, and giving off collaterals C to the neurones of the cord. B shows the telodendria of these axones or of their collaterals forming synapses with cell-bodies of the gray substance of the cord.

system, the cell-bodies in the nuclei of sensory neurone-chains, those chains ascending toward the cerebral cortex, may be distinguished from the cell-bodies of the motor or descending chains by the arrangement and size of their tigroid masses. He claims further that in the same way, the cell-bodies of the somatic efferent neurones may be distinguished from those of the visceral efferent neurones. In this way the locality of origin of certain physiologically known paths may be determined. (*c*) Direct dissection in case of the larger bundles in the brain.

(4) The so-called **pathologic-anatomical method** is based upon the same general principles as is the physiological (or experimental) method. A pathological lesion, a local infection or a tumor for example, may destroy a nucleus of cell-bodies or sever a bundle of axones, and the resulting degeneration of the axones may be followed through serial sections suitably prepared. The locality of the lesion known, the path may be followed to determine the locality of its termination; its locality of termination known from the symptoms resulting, the path may be followed to its cells of origin, or to the locality of the lesion.

Funiculi.—In order that the various fasciculi may be referred to with greate ease, the white substance of the spinal cord in transverse section is divided int three areas known as funiculi or columns and which correspond to the funicul already mentioned as evident upon the surface of the cord when intact. Th funiculi are outlined wholly upon the basis of their position in the cord and wit reference to the median line and the contour of the column of gray substance their component fasciculi are defined upon the basis of function. (1) The *posterio funiculus* or column is bounded by the posterior median septum and the line o the dorsal horn; (2) the *lateral funiculus* or column is bounded by the latera concavity of the gray column and the lines of entrance and exit of the dorsa and ventral roots; (3) the *ventral funiculus* or column is bounded by the line o exit of the ventral roots, and by the anterior median fissure. (See figs. 695, 698.)

The posterior funiculus or column [funiculus posterior].—This funiculus is composed of two general varieties of axones arranged in five fasciculi. First, and constituting the predominant type in all the higher segments of the cord, are the afferent or general sensory axones, which arise in the spinal ganglia, enter the cord as the dorsal roots, assume their distribution to the neurones of the cord, and then (some of them) take their ascending course toward the encephalon. The axone of the spinal ganglion neurone undergoes a T-shaped division a short distance from the cell-body, one limb of this division terminating in the peripheral organs and the other going to form the dorsal root. Upon entering the cord the dorsal root-axones undergo a Y-shaped bifurcation in the neighborhood of the dorsal horn, one branch ascending and the other descending (fig. 696). The longest of the ascending branches form the **fasciculus gracilis** (Goll's column) and the **fasciculus cuneatus** (Burdach's column). These fasciculi are the largest ascending or sensory spinocerebral connections, the direct main sensory path to the brain. Their neurones represent the first links in the neurone chains between the periphery of the general body and the cerebral and cerebellar cortex.

In threading their way toward the brain, these sensory axones of long course tend to work toward the midline. Therefore those of longest course are to be found nearer the posterior septum, in the upper segments of the cord, than those axones which enter the cord by the dorsal roots of the upper segments. Thus it is that the fasciculus gracilis, the medial of the two fasciculi, contains the axones which arise in the spinal ganglia of the sacral, lumbar and lower thoracic segments (S., L. and T. 12 to 6). In other words, it is the fasciculus bearing sensory impulses from the lower limbs to the brain, while the fasciculus cuneatus, the lateral of the two, is the corresponding pathway for the higher levels (T. 6 to 1 and C.). Naturally, there is no fasciculus cuneatus as such in the lower segments of the spinal cord. The axones being much blended at first, it is only in the upper thoracic and cervical region that there is any anatomical demarcation between the two fasciculi. In this region the two become so distinct that there is in some cases a distinct connective tissue septum between them, continuing inward from the posterointermediate sulcus—the surface indication of the line of their junction (fig. 695).

Upon reaching the medulla oblongata the fibers of the fasciculus gracilis and the fasciculus cuneatus terminate about cells grouped to form the nuclei of termination of these fasciculi. The nucleus of termination of the fasciculus gracilis is situated medially and begins just below the point at which the central canal opens into the fourth ventricle; that of the fasciculus cuneatus is placed laterally and extends somewhat higher than the other nucleus. The neurones whose cell-bodies compose these nuclei constitute the second links in the neurone chains conveying sensory impulses from the periphery to the cerebral and cerebellar cortex.

The descending or *caudal branches* of the dorsal root-axones are concerned wholly with the neurones of the spinal cord. They descend varying distances, some of them as much as four segments of the cord, and give off numerous collaterals on their way to the cells of the gray column. Those terminating about cell-bodies of the ventral horn, which give rise to the ventral or motor root-fibers, are responsible for certain of the so-called *'reflex activities'* and thus contribute to the simplest of the **reflex arcs.** In descending they serve to associate different levels of the gray substance of the cord with impulses entering by way of a single dorsal root. Some of their collaterals cross the midline in the posterior white commissure, and thus transfer impulses to neurones of the opposite side. The caudal branches of longer course are scattered throughout the ventral portion of the fasciculus cuneatus (*middle root zone*), and the longest show a tendency to collect along the border-line between the fasciculus cuneatus and the fasciculus gracilis, and thus contribute largely to the **comma-shaped fasciculus** (*fasciculus interfascicularis.*) Also a few of the longest of them in the lower levels course in the *oval bundle of Flechsig* or septomarginal root zone.

The ascending branches of the dorsal-root axones also give off collaterals to the gray substance of the cord, thus extending the area of distribution of a given dorsal nerve-root to levels of the cord above the region at which the root enters.

The greater number of the terminations of dorsal root-axones within the spinal cord form synapses with neurones other than those directly contributing ventral root-fibers. The greater mass of the neurones concerned are those of the Golgi type II and those contributing the **fasciculi proprii** or **ground bundles** of the spinal

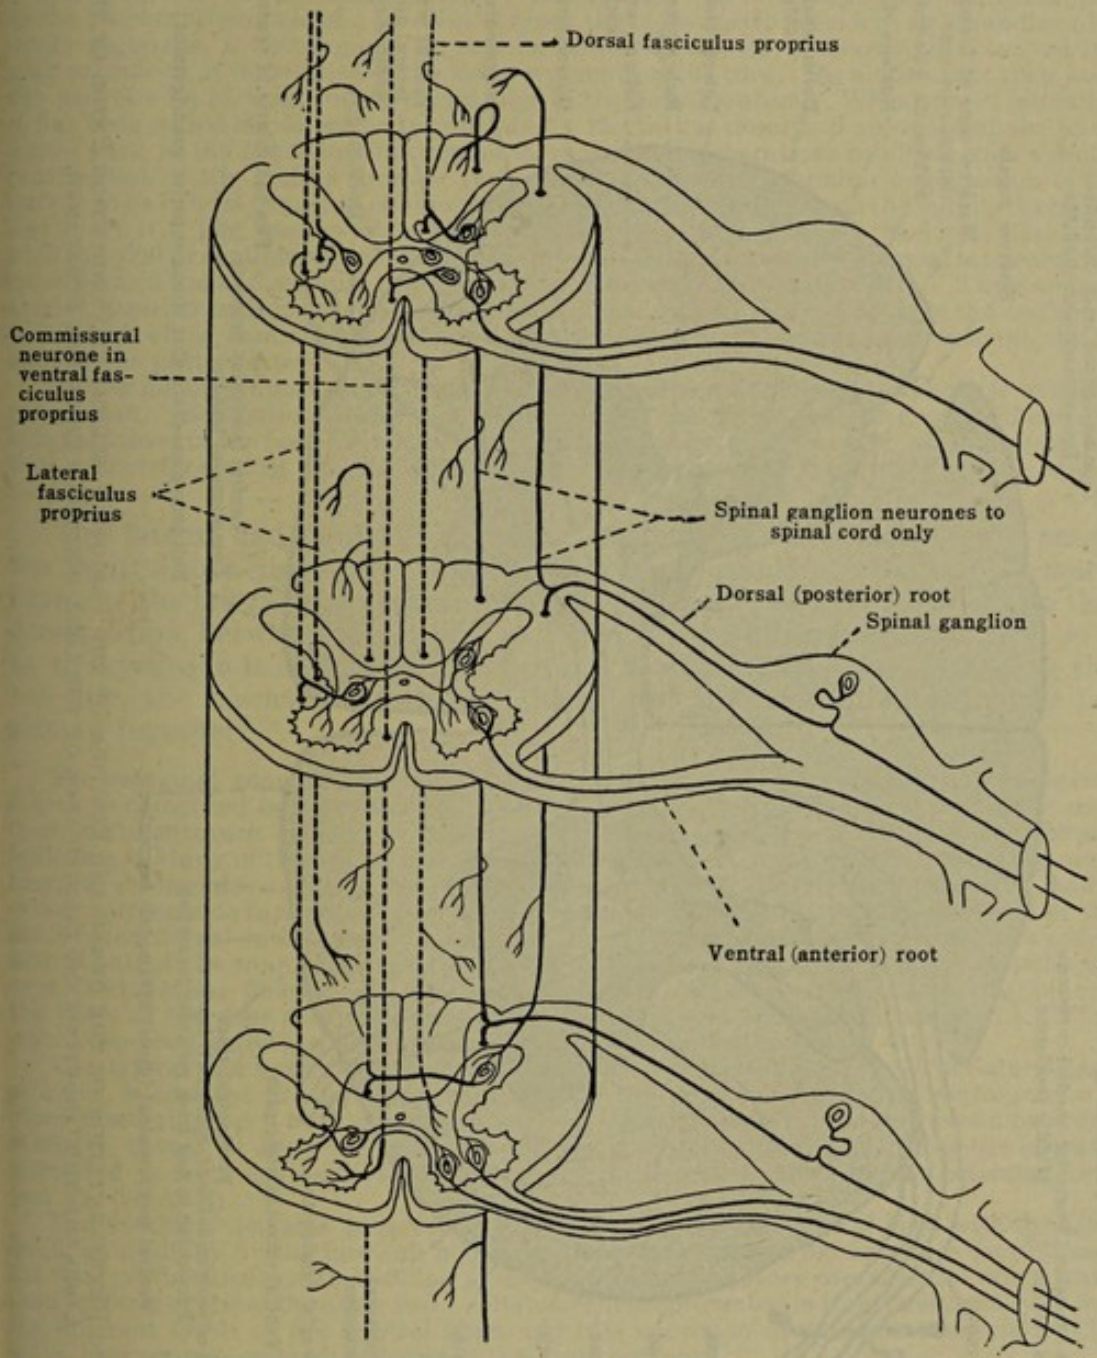

FIG. 697.—DIAGRAM ILLUSTRATING THE FORMATION OF THE FASCICULI PROPRII (ASSOCIATION FASCICULI) AND COMMISSURAL FIBERS OF THE SPINAL CORD, AND THE GENERAL ARCHITECTURE OF THE CORD AS A MECHANISM FOR REFLEX ACTIVITIES.

The ventral fasciculus proprius is omitted and the lateral is shown on one side only. The lower spinal ganglion neurone shown illustrates the type whose ascending branch is of much longer extent than that of the upper one. Reflex arcs involving the sympathetic are not included.

cord, or the second variety of axones composing the posterior funiculus. The latter fasciculi arise from the smaller cells of the gray column (figs. 697, 698).

These axones pass from the gray substance to enter the surrounding white substance, bifurcate into ascending and descending branches, which in their turn give off numerous collaterals to the cells of the gray substance of the levels through which they pass. The cell-bodies giving origin to such axones are so numerous that the entire column of gray substance is surrounded by a continuous felt-work of fasciculi proprii.

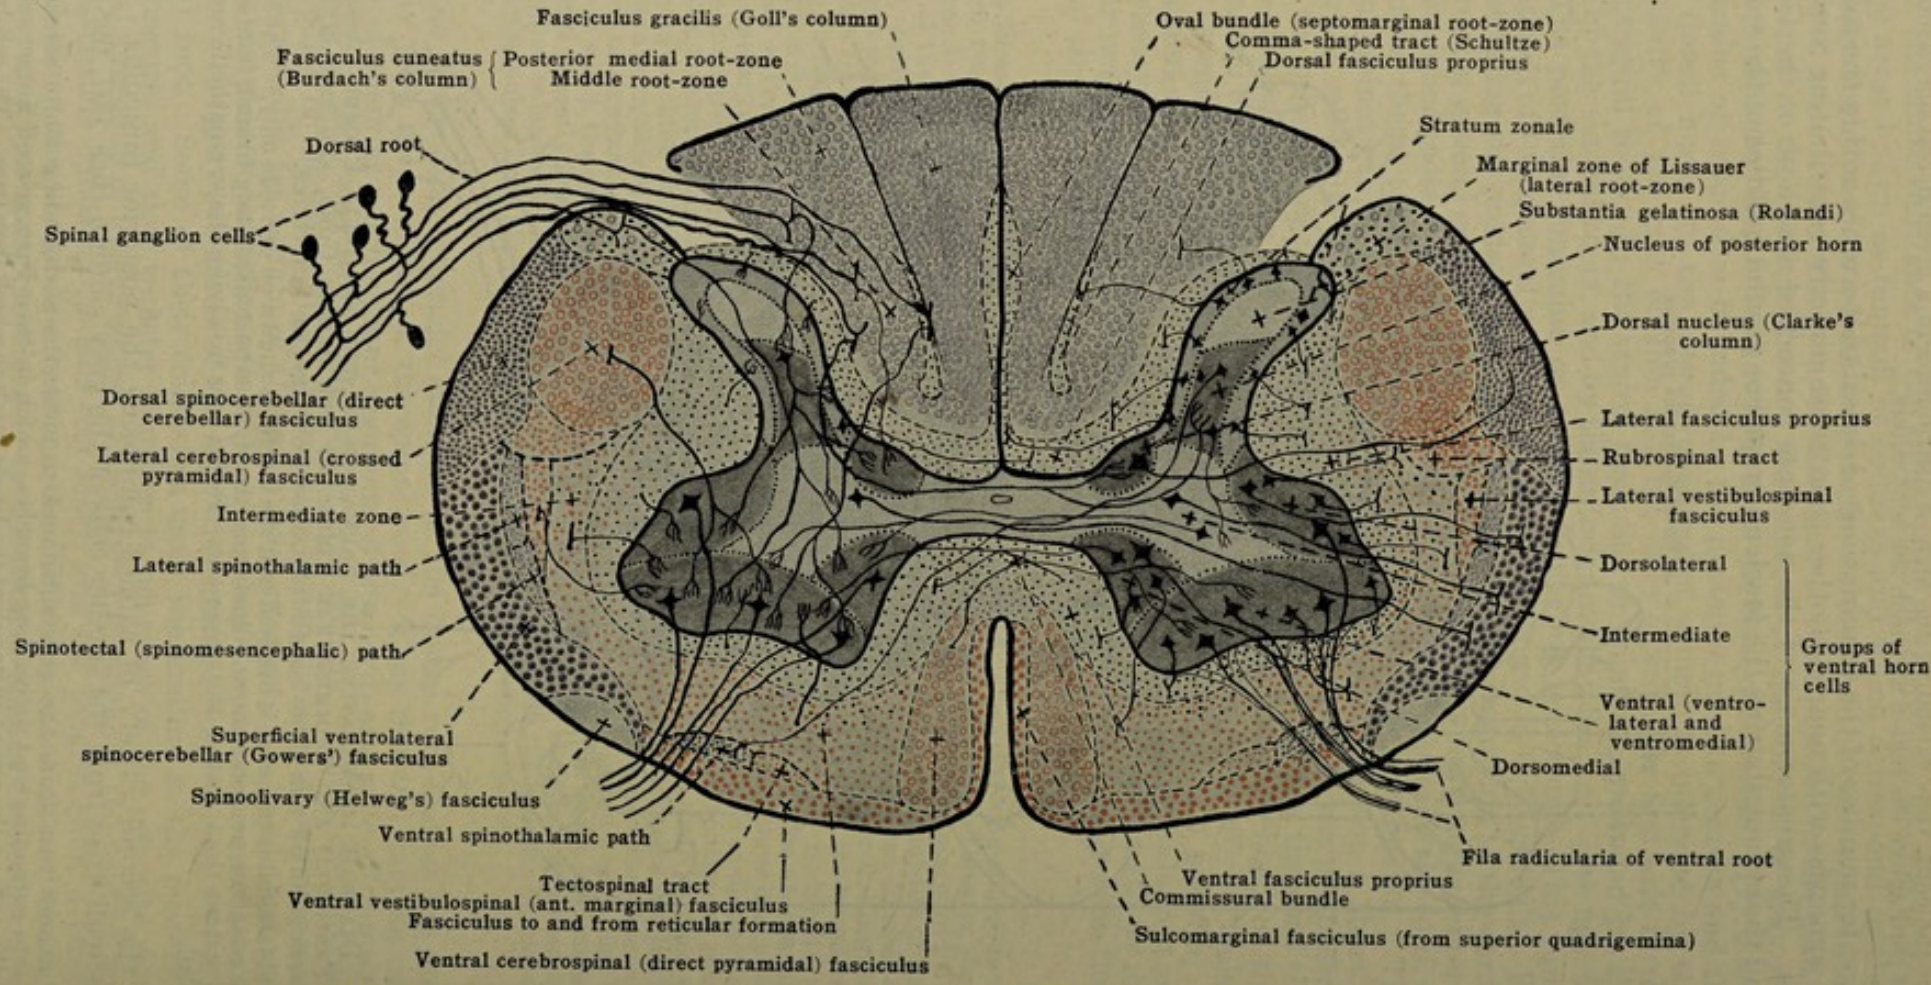

FIG. 698.—SCHEMATIC REPRESENTATION OF THE SHAPE AND POSITION OF THE VARIOUS FASCICULI OR CONDUCTION PATHS OF THE SPINAL CORD AND THE GROUPING AND SIGNIFICANCE OF THE CELL-BODIES OF THE GRAY SUBSTANCE.

The **dorsal fasciculus proprius** (anterior zone of posterior column) arises chiefly from cells situated in the dorsal horn (*stratum zonale*). Coincident with the ingrowth and arrangement of the fasciculi gracilis and cuneatus many of the longer fibers of the dorsal fasciculus proprius go to form both the oval bundle and the comma-shaped fasciculus. Thus these two bundles are mixed, being fasciculi proprii which also contain caudal branches of dorsal root-axones. The association fibers in the oval bundle are the longest of any belonging to the dorsal fasciculus proprius. The cephalic and caudal branches of some, combined, are said to extend more than half the length of the cord and it has been claimed that some even associate the conus medullaris with the cervical region. Based upon this claim, Obersteiner has called the oval bundle the 'dorsomedial sacral field' and Edinger has referred to the most dorsal part of it as the '*tractus cervicolumbalis dorsalis.*' Since this dorsal part is evident as a bundle only in the upper segments, a better name for it is *lumbosacral tract*, for, to become so removed from the gray substance, it must arise in the lower segments of the cord. As a tract it courses just under the pia, one on each side of the dorsal edge of the dorsal septum. When spread laterally there, it has been called *the dorsal peripheral band.* Hoche has described an oval bundle, minus this dorsal part, in the lower lumbar segments, shown in degenerations resulting from a destructive compression of the middle thoracic region. This indicates a lumbar composition of the oval bundle to be caudal branches of association neurones descending from the middle thoracic region and above it. The '*median triangle*', is formed by the continuation of the dorsal fasciculi proprii with the oval or septomarginal fasciculus. Some of the axones of the dorsal fasciculus proprius cross the midline to distribute impulses to the neurones of the opposite side. These commissural axones, together with certain collaterals of the dorsal root-axones, which cross the midline outside the dorsal white commissure, compose the so-called **cornucommissural tract** at the ventral edge of the posterior septum.

Only a minor proportion of the axones of the posterior or dorsal nerve-roots extend to the encephalon. Estimation shows that the sum of all the dorsal roots is greatly in exeess of the sum contained in the fasciculi cuneatus and gracilis just before these enter their nuclei of termination. Therefore most of the ascending branches are concerned wholly with spinal cord relations.

The lateral and ventral funiculi or columns.—The region of the passage of the ventral root-fibers from the ventral horn is considered the line of demarcation between the lateral and ventral funiculi. In that it is much less definite than the demarcation between the lateral and dorsal funiculi and because it is so broad as to involve in it certain of the tracts to be considered, some extending through the line, the fasciculi comprising the lateral and ventral funiculi will be considered together.

The **marginal zone of Lissauer,** situated along the lateral margin of the posterolateral sulcus, is composed largely of dorsal root-axones which bifurcate lateral instead of medial to their line of entrance. Many of these finally work across the line of entrance into the posterior funiculus. Many of the dorsal root-fibers which do not reach the brain occur in Lissauer's zone. Lissauer's zone also contains fibers arising from the small cells of the dorsal horn, and to this extent corresponds to a fasciculus proprius. Ranson has found that large numbers of the non-medullated dorsal root-axones which enter the cord are contributed to Lissauer's zone. The lateral half of the zone consists very largely of the fibers arising in the gray substance of the cord (endogenous fibers). It has been suggested (Ranson), that one of the functions of the fibers of the zone as a whole has to do with pain and temperature sensations. Thus they would comprise a division of the spinal lemniscus, discussed below.

The **lateral and ventral fasciculi proprii** (ground or basis-bundles).—The lateral fasciculus proprius is situated in the lateral concavity of the gray column and is continuous with the other fasciculi proprii both dorsal and ventral. Except that it probably contains fewer commissural axones, it is of the same general significance as the others. It is the largest of the three and is more or less divided throughout into small bundles by the reticular formation (see fig. 695A, B).

The ventral fasciculus proprius is continuous around the ventral horn with the lateral, is bounded medially by the fasciculi bounding the ventral median fissure and is continuous under the floor of this fissure with its fellow of the opposite side. More commissural fibers traverse it than traverse either of the other two. The neurones represented in it serve especially to associate the different levels of the ventral horn, and it is known to contain some association-fibers of extra long course—extending between the brain and cord.

The lateral cerebrospinal fasciculus (crossed pyramidal tract).—In contrast to the sensory fibers passing through the spinal cord and conveying impulses destined to reach the cerebral cortex, axones are given off from the pyramidal cells of the cortex, which descend to terminate about the cells of the gray substance of the spinal cord, chiefly about the cells which give origin to the ventral root-fibers.

Upon reaching the medulla oblongata in their descent, these axones are accumulated into two well-defined, ventrally placed bundles, the **pyramids,** one from each cerebral hemisphere. In passing through the brain stem the pyramids contribute many fibers which cross the midline to terminate in the motor nuclei of the cranial nerves of the opposite side (cortico-medullary fibers), and thus here they decrease appreciably in bulk. According to the estimate of Thompson only about 160,000 of the pyramidal fibers are destined to enter the spinal cord.

Upon reaching the lower part of the medulla, the greater mass of the fibers of each pyramid, which are destined to enter the cord, suddenly cross the midline in the 'decussation of the pyramids.' The remainder retain their ventral position in their descent, decussating gradually

in the cord itself. The pyramidal fibers which cross in the medulla course in the lateral colum ventral to Lissauer's zone, and lateral to the lateral fasciculus proprius, and form the *latera cerebrospinal fasciculus* (crossed pyramidal tract). It is a large fasciculus, oval-shaped i transection, and since its axones terminate in the gray column of the cord all along its length, i decreases in bulk as the cord is descended.

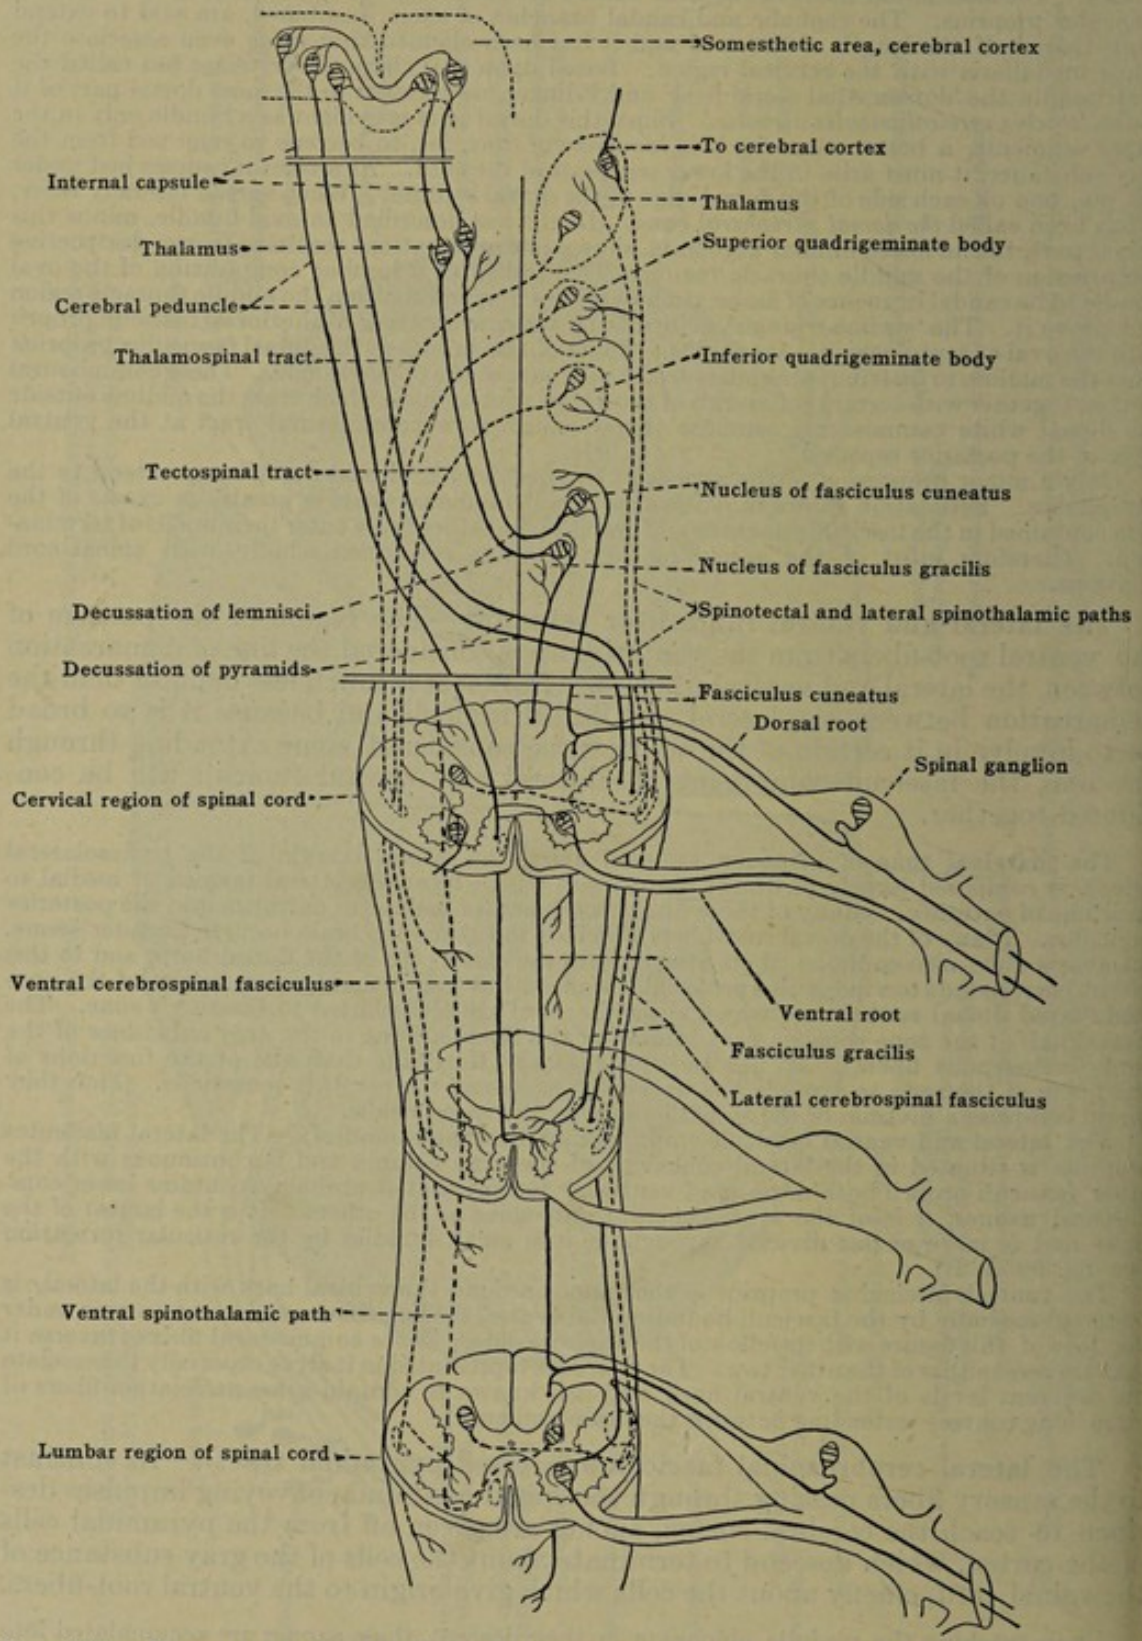

FIG. 699.—DIAGRAM OF SPINAL CORD ILLUSTRATING THE TWO CHIEF VARIETIES OF SPINOCEREBRAL AND CEREBROSPINAL NEURONE CHAINS. The ventral tectospinal (sulcomarginal) fasciculus, fibers descending from the superior quadrigeminate bodies, and the rubrospinal path are not filled in.

The **ventral cerebrospinal fasciculus** (anterior or direct pyramidal tract), as stated above, is the uncrossed portion of the descending cerebrospinal system of neurones. It is a small, oblong bundle, situated mesially in the anterior funiculus,

parallel with the anterior median fissure. Like the lateral cerebrospinal fasciculus (crossed pyramidal tract), its axones arise from the large pyramidal cells of the motor area of the cerebral cortex, and transmit their impulses to the neurones of the ventral horns of the gray substance of the spinal cord, and almost entirely to those neurones which give origin to the ventral or motor root-fibers

It represents merely a delayed decussation of the pyramidal fibers, for instead of crossing to the opposite side in the lower portion of the medulla oblongata, as do the fibers of the lateral fasciculus, its fibers decussate all along its course, crossing in the ventral white commissure and in the *commissural bundle* of the cord to terminate about the ventral horn cells of the opposite side. Hoche, employing Marchi's method, found that a few of its fibers terminate in the ventral horn of the same side. This conforms to the pathological and experimental evidence that there may be a few homolateral or uncrossed fibers in the crossed pyramidal tracts also. Like the crossed tract, the ventral pyramidal tract diminishes rapidly in volume as it descends the cord. Its loss is greatest in the cervical enlargement, and it is entirely exhausted in the upper half of the thoracic cord, its fibers for the most part having decussated. With the exception of the anthropoid apes and certain monkeys, none of the mammalia below man, which have been investigated, possess this ventral pyramidal tract, the decussation being completed in the medulla above.

There is also a group of cerebrospinal paths known collectively as the 'extrapyramidal system.' Instead of arising from the cerebral cortex as do the regular pyramidal fasciculi, these extrapyramidal fibers arise in the basal ganglia (corpus striatum) of the cerebrum, and some of them from the thalamus and red nucleus. There is evidence that they descend to transfer impulses to ventral horn cells of the cord and thereby mediate a control and coordination of the muscular activities induced by the regular pyramidal fibers. (See extrapyramidal system, p. 965.)

In addition to the dispositions of the dorsal root-axones given above, certain of them, either by collaterals or terminal twigs, form synapses with the cells of the dorsal nucleus (Clarke's column), which nucleus, tapering in its two ends, extends from about the seventh cervical to the third lumbar segment of the cord. The axones given off by these cells pass to the dorsolateral periphery of the lateral funiculus and there collect to form the **dorsal spinocerebellar fasciculus** (direct cerebellar tract of Flechsig). As such they ascend without interruption, and in the upper level of the medulla oblongata pass into the cerebellum by way of the inferior cerebellar peduncle or restiform body. Necessarily, this fasciculus is not evident in levels below the extent of the nucleus dorsalis.

Also situated superficially in the lateral funiculus is another ascending conduction path, and, like the dorsal spinocerebellar fasciculus, to which it is adjacent, it is also in great part at least a cerebellar connection. Its position suggests its name, **superficial ventrolateral spinocerebellar fasciculus (Gowers' tract).**

This tract at present does not include as great an area in transverse section as when originally described. The more internal portion of the original Gowers' tract is now given a separate significance, and will be considered separately. While the exact location in the gray column of all the cell-bodies giving origin to the superficial ventrolateral spinocerebellar fasciculus is uncertain, it is known that certain ventral horn cells contribute their axones to it. Many of its cells of origin are scattered in the area immediately ventral to the nucleus dorsalis, others in the intermediate group and mesial portion of the lateral group of ventral horn cells. In the lumbar region these cells increase in line with the position of the nucleus dorsalis above and are quite numerous; therefore, the fasciculus arises for the most part at a lower level in the spinal cord than does the direct cerebellar tract and from cells analogous to those of the nucleus dorsalis. In degenerations it becomes visible in the upper segments of the lumbar region, and has been proved to increase notably in volume as the cord is ascended. Its axones arise for the most part directly from cell-bodies of the same side of the cord, though it has been shown by several investigators that many of its axones come from the gray substance of the opposite side by way of the ventral white commissure. Terminal twigs and collaterals of the dorsal root-fibers, mostly of the same side, but occasionally from the opposite side, transfer sensory impulses to its cells of origin. At one time Gowers' tract was considered an entity, but now, even in the more limited area it occupies, it must be considered a mixture of axones of several terminal destinations or distinct neurone systems. The destination of some of its axones has not been determined with certainty. The spinocerebellar fibers proper go to the cerebellum, and there have been traced to the cortex of the superior vermis. Most of these reach the cerebellum not by way of the restiform body, as does the dorsal spinocerebellar tract, but pass on in the brain-stem to the level of the inferior corpora quadrigemina, and there turn back to join the brachium conjunctivum or superior cerebellar peduncle. Only a few of its axones leave the fasciculus lower down in the medulla, to enter the cerebellum by way of the restiform body, in company with the dorsal spinocerebellar tract. (Rossolimo, Tschermak.) Another portion of its axones are thought to reach the cerebrum, probably the nucleus lentiformis, though it has not been positively traced further than the superior corpora quadrigemina. Many axones in Gowers' tract of the cord correspond to those of the fasciculi proprii, and merely run varying distances in the cord, to turn again into its gray substance. Schaeffer followed some of these from the lumbar region up to the level of the second cervical nerve.

In the ventromesial border of Gowers' tract and immediately upon th periphery, near the anterolateral sulcus (exit of ventral nerve-roots), there i found in the higher segments of the cord a small oval bundle, the **spino-olivar** fasciculus or **Helweg's** (Bechterew's) **bundle.** The functional direction of it fibers has not been settled.

The bundle was at first thought to arise wholly within the olive in the medulla oblongat and to terminate in the cord. More recent claims assert that it arises from cell-bodies in th cord and thus is spino-olivary. By some observers it has been traced as far down as the mid thoracic region; by others, however, only as far as the third cervical segment. Goldstei suggests that spino-olivary fibers arise from the entire length of the cord. Others hold that th fasciculus contains both spino-olivary and olivospinal fibers, the latter having the shorte extent. The olives being nuclei largely concerned with cerebellar connections, Helweg' fasciculus is probably an indirect cerebellar association with the cervical spinal cord neurones It is composed of axones of relatively very small diameter, and it is one of the last fasciculi o the spinal cord to become medullated.

Considering Helweg's bundle as spinocerebellar, it may be noted that there are three spino-cerebellar fasciculi, one for the cervical region, one for the thoracic and one for the lumbosacral region of the cord, the origin of each considerably overlapping that of the succeeding.

Situated between the lateral and ventral fasciculi proprii and the superficially placed fasciculi is an area which, in transverse sections, may be, by position, referred to collectively as the **intermediate zone.** So intermingled are the axones comprising it that it has been called the **mixed zone.** It extends through both the lateral and ventral funiculi and it contains fibers of the following functional varieties:

1. Fibers ascending and descending, belonging to the lateral and ventral fasciculus proprius, which are of longer extent and gradually course farther away from the gray substance of the cord and as such mix into the intermediate zone. It is said to contain fibers descending from the cerebellum to synapse with the neurones of spinal cord, probably directly with the ventral root or motor neurones. However, it is doubtful that there are present in the cord any fibers arising directly from cell-bodies situated in the cerebellum. None are indicated by anatomical evidence through degenerations. Some may occur as a downward continuation of the *tractus cerebellotegmentalis bulbi* claimed by some authors. It is thought that the cortical cerebrospinal (pyramidal) and rubrospinal fasciculi serve for descending impulses in responses to the several paths conveying sensory impulses from the body into the cerebellum.

2. **The rubrospinal fasciculus.**—This arises from cell-bodies in the red nucleus of the tegmentum (in the mesencephalon) and is a crossed fasciculus. Axones arising from the red nucleus of one side cross the midline in the mesencephalon (ventral tegmental decussation) and descend the medulla, ventral to the nucleus of termination of the trigeminus, into the lateral funiculus of the cord to terminate gradually about cell-bodies of the ventral horn, both those which give rise of ventral root fibers and those which contribute to the fasciculi proprii. In passing it gives off fibers to the pons and medulla. Its fibers are more thickly bundled in a crescentic area fitting onto the ventral side of the lateral cerebrospinal fasciculus, and some are said to mix into the area of this latter.

3. **The lateral vestibulospinal fasciculus** is a much smaller tract than one of similar significance in the ventral funiculus of the cord. It arises from some of the cell-bodies comprising Deiters' nucleus, the lateral nucleus of termination of the vestibular nerve, and from some of those of the spinal nucleus (nucleus of the descending root) of this nerve, all of which are in the medulla. It descends the cord, uncrossed, to terminate gradually about ventral horn cells, thus comprising a part of the apparatus for the equilibration of the body. Its fibers are thought to be more closely collected in the area immediately ventral to the rubrospinal fasciculus, but of course commingle with the latter.

4. *The corpora-quadrigemina-thalamus paths.* In the lateral, ventrolateral and medial portions of the intermediate zone are small tracts, both ascending and descending, which connect the spinal cord with the thalamus (diencephalon) and the quadrigeminate bodies of the mesencephalon. These are crossed paths. The ascending fibers arise from cell-bodies situated in the dorsal horns and carry sensory impulses received by direct synapses made by collaterals and terminal twigs of the dorsal root-fibers invading the dorsal horns. Of the descending components, fibers arising in the quadrigeminate bodies are best established. For description, the components of the paths are named as follows:

(a). **The spinal lemniscus.**—The *ascending* components of the corpora-quadrigemina-thalamus paths are known collectively as the spinal lemniscus, not because of any 'band-like' shape assumed by the tracts but because, like the well-known lemniscus in the rhombencephalon, they carry sensory impulses from the general body, received from spinal ganglion neurones, to the cerebrum. As distinguished from the former, the spinal lemniscus is claimed to carry impulses which are interpreted by the brain as sensations of pain, temperature and the finer touch sensations. They are described as ascending in three paths:

The spinotectal (spinomesencephalic) path arises from cell-bodies in the dorsal horn of one side, crosses in the commissures of the cord (chiefly the ventral), turns cephalad and accumulates into a bundle in the lateral part of the intermediate zone, medial to Gowers' tract. It terminates in the gray substance of the quadrigeminate bodies or tectum of the mesencephalon. These bodies likewise receive visual and auditory impulses for transmission to the nuclei of origin of the oculomotor and trochlear nerves. Therefore, by this path, general body-sensations may induce eye movements.

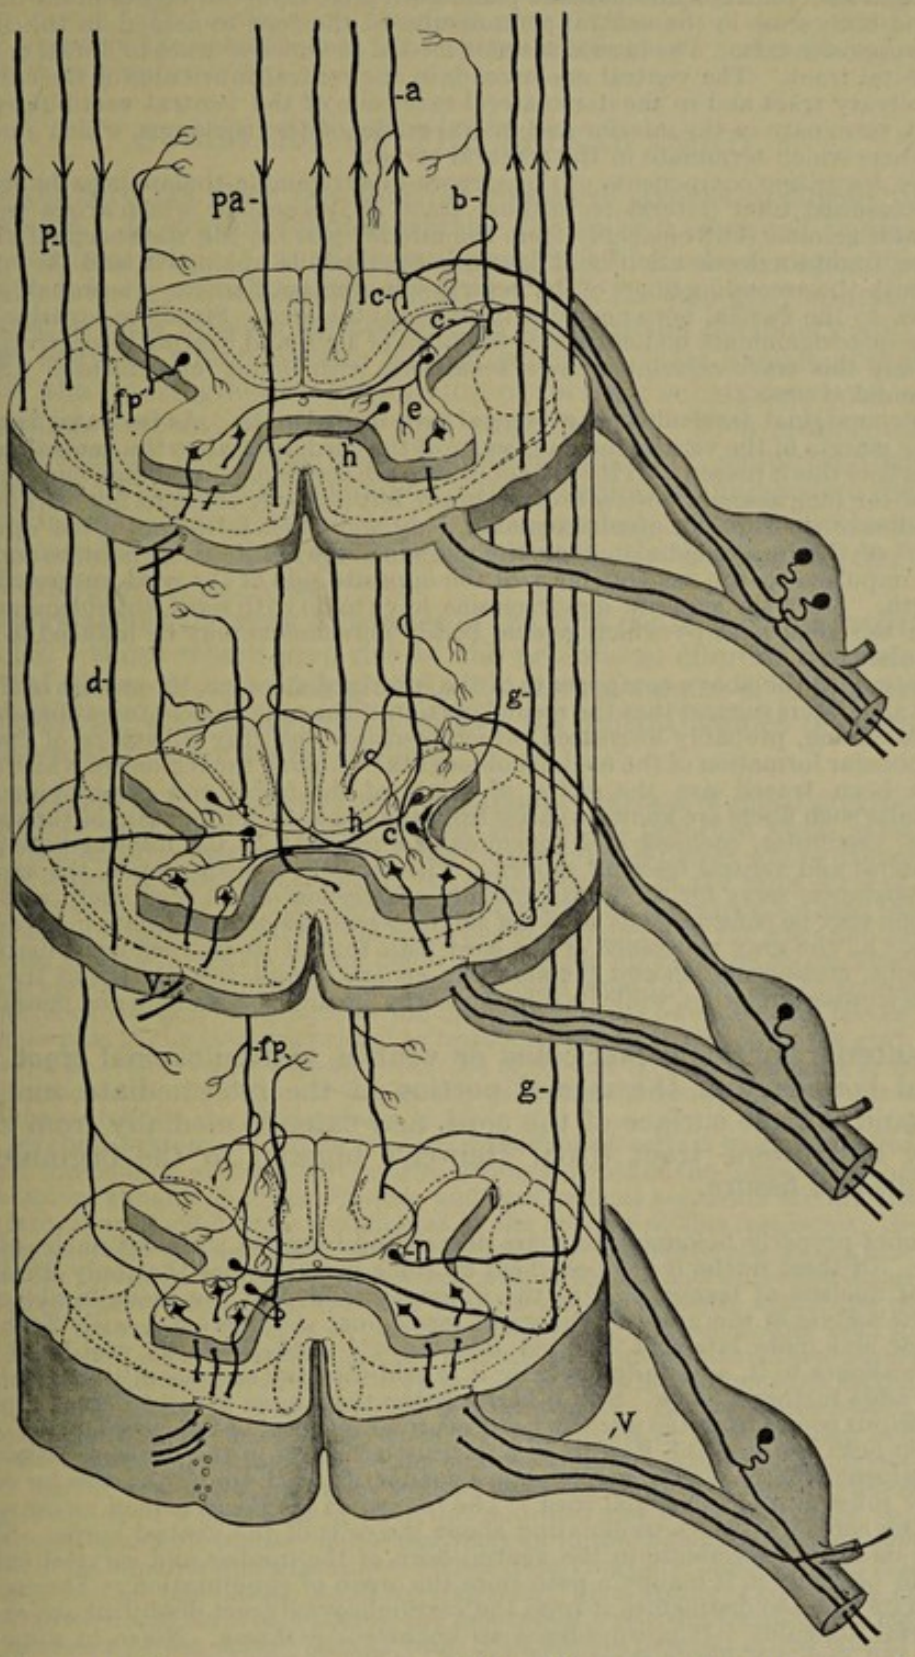

FIG. 700.—SCHEMATIC REPRESENTATION OF THE MORE IMPORTANT ARCHITECTURAL RELATIONS OF NEURONES IN THE SPINAL CORD, OMITTING THOSE INVOLVING THE MESENCEPHALON AND THALAMUS.

a, afferent (spinal ganglion) axone of spinocerebral chain with bifurcation and caudal branch; b, afferent axone coursing in Lissauer's zone, and distributed wholly within the cord; c, collaterals of a and b disposed in three ways; p, pyramidal axone in lateral (crossed) cerebrospinal fasciculus distributed to levels of grey substance; pa, axone in ventral cerebrospinal fasciculus decussating before termination; v, ventral root or motor neurones; n, nucleus dorsalis giving axone to dorsal spinocerebellar fasciculus; g, ascending neurones of Gowers' tract; d, descending axone from cerebellum (uncertain); fp, neurones of fasciculi proprii, association proper; h, commissural neurones; e, Golgi cell of type II.

The lateral and ventral spinothalamic paths both arise from cell-bodies in the dorsal horn o one side and both cross in the ventral commissures of the cord to ascend in the intermediat zone of the opposite side. The lateral ascends medial to Gowers' tract in dorsal company wit the spinotectal tract. The ventral one ascends in the ventral funiculus of the cord, medial t the spino-olivary tract and in the dorsolateral extension of the ventral vestibulospinal fasci ulus. Both terminate in the inferior and lateral nuclei of the thalamus, which nuclei in the turn give fibers which terminate in the cerebral cortex.

(b). The *descending* components of the corpora-quadrigemina-thalamus paths are as follow

The tectospinal tract (lateral tectospinal tract of Löwenthal) which arises from the fou corpora quadrigemina (but especially from the inferior pair) of the mesencephalon, decussate there in the 'fountain decussation' and descends the medulla oblongata and the spinal cord i company with the ascending fibers of the ventral spinothalamic tract. It probably distribute its impulses to the ventral horn neurones throughout the cord. Since the superior and inferio pairs of the quadrigeminate bodies receive impulses of sight and hearing respectively, it may b assumed that this tract correlates these sensations with bodily movements. (See also th extrapyramidal system.)

The sulcomarginal fasciculus, is a ventral tectospinal path. As its name implies, it des cends in the margin of the ventral median fissure of the cord, medial to the ventral cerebrospina fasciculus where this is present. It is continuous into the cord with the median longitudinal fascic ulus, one of the long association-tracts of the brain, but it chiefly contains fibers which arise fron the cell-bodies of the superior quadrigeminate body and which form part of the 'optic-acoustic reflex path' of the mesencephalon, cross the midline in the fountain decussation and descend t distribute impulses to the ventral horn of the opposite side of the cord, supposedly along it entire length. Since the superior quadrigemina have to do with sight, the sulcomarginalfascic ulus forms the chief path by which general bodily movements may be induced in response t visual impulses.

In addition to the above components of the intermediate zone, the studies of Flechsig, vor Bechterew and others suggest that the medial portion of the zone also contains fibers both ascend ing and descending, probably uncrossed, which associate the gray substance of the spinal cord with the reticular formation of the medulla oblongata. Among the regions to which it is claimed they have been traced are the nuclei of origin of the facial and eye-moving nerves and in the medulla such fibers are known to arise from the nuclei of termination of the vagus, glosso pharyngeal, vestibular, cochlear and trigeminal nerves. All of the intermediate zone grades into the lateral and ventral fasciculi proprii. The fasciculi proprii proper, the axones nearest the gray substance, serve for the intersegmental association of the cord itself, while the inter mediate zone may be considered as carrying axones which serve to associate more distant levels of the axis, i.e., the gray substance of the cord with that of its upward continuation into the medulla, pons, mesencephalon and thalami. In general terms, the relation of the cord to the cerebrum is a crossed relation, while its relation to the medulla, cerebellum and pons is uncrossed.

The **anterior marginal fasciculus or ventral vestibulospinal tract** forms the superficial boundary of the medial portion of the intermediate zone. It is a narrow band, on the surface of the cord, and extends medially from the medial extremity of Gowers' tract (from Helweg's bundle) to the beginning of the anterior median fissure.

The axones properly belonging to it are descending from the recipient nuclei of the vestib ular nerve. Of these nuclei it has been held by some investigators that only Deiters' nucleus (the lateral nucleus of termination in the upper extremity of the medulla oblongata) gives origin to the axones of the anterior marginal fasciculus. Others agree with Tschermak that the superior and more laterally situated Bechterew's nucleus of the vestibular nerve also contributes axones to it, and quite logically it is held that the nucleus of the spinal root of the vestibular adds further axones. Still other investigations have suggested that a part at least of the fasciculus comes from the nucleus fastigius (roof nucleus) of the cerebellum. Since many axones from both Deiters' and Bechterew's nucleus terminate in the nucleus fastigius, the ven tral vestibulospinal fasciculus is, in any case, a conduction path from the nerve for equilibration to the gray substance of the spinal cord. The fasciculus is said to extend as far as the sacral region of the cord, its axones terminating about the cells of the ventral horns. The greatest number of its axones terminate in the ventral horn of the lumbar and cervical enlargements. This should be since it is mainly a path from the organ of equilibration. The term 'ventral' is added to its name to distinguish it from the vestibulospinal tract described above as coursing in the lateral funiculus. It is considered an uncrossed pathway. Since to some extent the vestibular and cochlear nerves share each other's nuclei of termination, it may also distribute to the cord impulses aroused in the organ of hearing.

The **commissural bundle** is situated about the floor of the anterior median fissure, and is the most dorsal tract of the anterior funiculus. It contains decussating or commissural axones of four varieties.

(1) It contains the decussating axones of the ventral cerebrospinal fasciculus throughout the extent of that fasciculus; (2) it is chiefly composed of the axones of the ventral fasciculus proprius which arise in the gray substance (ventral horn) of one side, cross the midline as commissural fibers, and course both upward and downward to be distributed to the neurones of different levels of the gray substance of the opposite side; (3) it contains decussating axones which arise from cell-bodies in the gray substance of one side and cross the midline to terminate about cell-bodies in practically the same level of the opposite side. The latter are merely axones belonging to the ventral white commissure which course without the confines of the grey

figure. (4) It carries most of the decussating fibers of the spinothalamic and spinotectal tracts, the spinal lemniscus. The commissural bundle is present throughout the length of the spinal cord, and is largest in the enlargements, i. e., where the association and commissural neurones occur in greater number generally.

SUMMARY OF THE SPINAL CORD

The spinal cord contains two general classes of axones arranged into three general systems. It contains axones which—(a) enter it from cell-bodies situated outside its boundaries, i. e., in the spinal ganglia and in the encephalon, and (b) axones which arise from cell-bodies situated within its own gray substance, some of which axones pass outside its boundaries both to the periphery and into the encephalon; some of which remain wholly within it. Its axones comprise—(1) a system for the intersegmental association of its gray substance, both ascending and descending, association proper and commissural; (2) a spinocerebral and cerebrospinal system, ascending and descending; and (3) a spinorhombencephalic (spinocerebellar and spinobulbar) and a rhombencephalospinal system, descending (bulbospinal and including rubrospinal). In general terms the relation of the cord to the cerebrum is a crossed relation, while its relation to the medulla, cerebellum and pons is uncrossed.

For these relations the gray substance of the cord contains three general classes of nerve-cells: those which give rise to the peripheral efferent or motor axones of the ventral roots; those which give rise to central axones of long course, going to the encephalon; and those which supply its central axones of short course, the association and commissural systems.

The three systems: (1) Association and commissural.—Axones of spinal ganglion (afferent) neurones bifurcate within the cord into cephalic and caudal branches which extend varying distances upward and downward and terminate, (*a*) about cell-bodies whose axones are short and terminate within the gray substance of the same side and in the same level as their cell-bodies (*Golgi neurones of type II*); (*b*) about cell-bodies whose axones pass without the gray substance, bifurcate into cephalic and caudal branches to terminate in the gray substance of the same side but in various levels above and below (association fibers in the *dorsal*, *lateral* and *ventral fasciculi proprii*); (*c*) about cell-bodies whose axones cross the midline to terminate either in the same level of the gray substance of the opposite side, or bifurcate and the cephalic and caudal branches pass in the fasciculi proprii to terminate in various levels of the gray substance of the opposite side. The longer cephalic branches of (*b*) and (*c*) may terminate in the medulla oblongata. Synapses of any of the above axones with efferent ventral root neurones complete the neurone-chains for the so-called *reflex activities*.

(2) **The cerebral system.**—(*a*) The cephalic branches of certain spinal ganglion neurones *ascend* beyond the bounds of the spinal cord to terminate within the medulla. Those ascending from the spinal ganglia of lower thoracic and lumbosacral segments accumulate medially to form the *fasciculus gracilis* which terminates in the nucleus of this fasciculus; those arising from the upper thoracic and cervical segments accumulate more laterally in the posterior funiculus to form the *fasciculus cuneatus* which terminates in the nucleus of the fasciculus cuneatus. (*b*) The impulses transferred to the neurones of these nuclei are borne across the midline and finally reach the sensory-motor area of the cerebral cortex, and cell-bodies here give rise to axones which *descend*, some decussating in the medulla to form the *lateral cerebrospinal fasciculus*, others form the uncrossed *ventral cerebrospinal fasciculus* which crosses the midline as it descends the cord, practically all crossing in the cervical region. Both of these fasciculi transfer their impulses either directly to efferent ventral horn neurones, or to association neurones and these to the efferent neurones, thus completing chains for activities of cortical control. (*c*) The cephalic and caudal branches of spinal ganglion neurones terminate about cell-bodies in the dorsal horns of the cord whose axones cross the mid-line and *ascend* laterally to terminate either in the quadrigeminate bodies (*spinotectal tract*), or in the thalamus (*spinothalamic pnths*). (*d*) Cell-bodies in the superior quadrigeminate bodies (receiving optic impulses) and in the inferior quadrigeminate bodies (mediating auditory impulses), give axones which cross the midline in the mesencephalon and *descend*, forming the *tectospinal tracts*, to terminate in contact with the efferent neurones of the cord. Axones from both sources descend in the lateral funiculus, (lateral tectospinal fasciculus) while from the superior quadrigeminate body, a separate bundle descends in the ventral funiculus as the *sulcomarginal* (*ventral tectospinal*) *fasciculus*. (*e*) The *rubrospinal tract* arises from cell-bodies in the red nucleus (in the mesencephalon), crosses the midline in the ventral tegmental decussation and descends in the lateral funiculus to transfer (probably cerebellar) impulses to the efferent neurones of the spinal cord. (*f*) The extrapyramidal fibers arise in the striate body in addition to arising in the thalamus and red nucleus and terminate in the cord to mediate control and coordination of the muscular activities induced by the regular cerebrospinal (pyramidal) fasciculi.

(3) **The rhombencephalic system.**—(*a*) The cephalic and caudal branches of spinal ganglion neurones give telodendria about the cell-bodies forming the *dorsal nucleus* of the cord (Clarke's column) and about cell-bodies situated in grey substances ventral to the dorsal nucleus and in line with it in the lumbar and sacral regions. Axones arising from the cells of the dorsal nucleus pass laterally to form the *dorsal spinocerebellar fasciculus* which *ascends* into the cerebellum by way of its inferior peduncle of the same side and terminates about cell-bodies of its cortex and its nuclei. Axones arising from near and in line with the dorsal nucleus, of both the *same*

and *opposite sides* of the cord, accumulate to form the *superficial ventrolateral spinocerebellar fasciculus*, which *ascends* to enter the cerebellum by way of its superior peduncle and terminate about the cells of the cerebellum. (*b*) Possibly a few axones arising in the roof nucleus of the cerebellum *descend* in the *anterior marginal fasciculus* in company with the *ventral vestibulospinal tract* to terminate upon the efferent neurones of the cord. (*c*) The inferior olivary nucleus, in the medulla, is a cerebellar relay and its cell-bodies are associated with the neurones of the upper portion of the same side of the spinal cord. Whether the axones arise in the olivary nucleus or in the gray substance of the cord is uncertain, but the more usual supposition favors the cord and thus the name *spino-olivary fasciculus* is given them. (*d*) Among its other functions the cerebellum is concerned with muscular tone and equilibration. The vestibular nerve is the chief afferent pathway of equilibration and a large mass of the axones arising from its nuclei of termination terminate in the cerebellum, in the roof nuclei especially. Axones arising from cell-bodies in Deiters' nucleus (its lateral nucleus of termination) and in the nucleus of its descending root *descend* the cord in the lateral funiculus to form the *lateral vestibulospinal tract* and also in the *anterior marginal fasciculus* to form *ventral vestibulospinal tract.* Impulses borne by these axones reach the efferent or motor root neurones. The rubrospinal fasciculus, mentioned above, also is considered as belonging to the cerebellar system. (*e*) The fasciculi proprii contain ascending and descending association-fibers between the spinal cord and the medulla oblongata.

Sympathetic relations.—The cell-bodies of the efferent neurones in the ventral horns are of two general varieties: (*a*) those whose axones terminate upon skeletal muscle (somatic efferent), and (*b*) those whose axones terminate in contact with cell-bodies of sympathetic neurones, *preganglionic* or *visceral efferent neurones.* The axones of the sympathetic neurones in their turn, terminate upon cardiac and smooth muscle (motor) and in glands (secretory). Like the somatic, the visceral efferent neurones receive impulses within the ventral horn: (*a*) from the cephalic and caudal branches of spinal ganglion neurones, (*b*) the descending cerebrospinal fasciculi, including the extrapyramidal fibers, and (*c*) from either, by way of the fasciculi proprii and Golgi neurones of type II. Their cell-bodies are situated for the most part in the dorsal portion of the lateral horn (dorsolateral or intermediolateral group of cells), which is the only portion of the lateral horn present in the thoracic region of the cord. Many of the visceral efferent fibers leave the spinal nerves distal to the spinal ganglia, mostly in the white communicating rami, thus going to the nearest sympathetic ganglia; many pass over these ganglia and on in the sympathetic nerves, or on in the trunk of the spinal nerve and its branches, to terminate in more distant sympathetic ganglia. Some axones arising in symphatic ganglia enter the spinal cord by either the dorsal or ventral roots of the spinal nerves or by separate roots (meningeal rami) to supply the muscle of the blood vessels of the cord (fig. 818).

Functionally, the peripheral afferent (spinal ganglion) neurones have been referred to as *receptors* and the efferent or peripheral motor neurones as *effectors.* According to the tissues and organs innervated, they are grouped into (1) somatic receptors and effectors and (2) visceral receptors and effectors. The somatic tissues are the skin, including its appendages and the epithelium of the organs of special sense, the subcutaneous fascia, membranes of joints, tendons and skeletal muscle; the visceral tissues are all glands and glandular epithelium, cardiac muscle and all smooth muscle, including that of blood-vessels and hair-follicles. A somatic afferent neurone may give some of its branches in the cord for synapsis with visceral efferent neurones.

Sherrington, Head and others who hold specific or separate afferent neurones for the different sensations experienced suggest three groups of receptor neurones:

1. *An exteroceptive group,* comprising those spinal ganglion neurones whose peripheral processes collect impulses from the skin and its appendages especially (impulses aroused by stimuli outside the body), but doubtless from any or all the somatic tissues and even the visceral tissues also, and which, in the cord, transfer these impulses to those cell-bodies in the dorsal horn whose axones cross the midline to form the two spinothalamic tracts of the opposite side. The lateral of these tracts is claimed to carry sensations of pain and heat and cold, while to the ventral are given sensations of touch and pressure and both are included within the so called *spinal lemniscus.* These tracts terminate in the ventral and lateral nuclei of the thalamus. In passing, each may give collaterals which form synapses with the nuclei of origin of the motor cranial nerves. The inferior and lateral nuclei of the thalamus send axones to the cerebral cortex and the corticospinal impulses aroused in response may descend the cord by way of the cerebrospinal fasciculi. The functions of the neurone chains of this group are classed within 'conscious phenomena.' The neurones of the eye and cochlea are included among the exteroceptive neurones of the cranial nerves.

(2) *A proprioceptive group.* This group is subdivided into two classes: (*a*) spinal ganglion neurones which collect impulses from the somatic tissues (skin, tendons, joints, skeletal muscle, etc.) and whose cephalic branches within the cord form the fasciculus gracilis and fasciculus cuneatus. The nuclei of termination of these fasciculi in the medulla give rise to the medial lemniscus of the opposite side and this transfers the impulses to the ventral thalamic gray substance, whose cell-bodies in turn send axones to the cerebral cortex. Corticospinal impulses, which descend in response, are distributed to the cord by the cerebrospinal fasciculi. The neurone chains included are claimed to mediate tactile sensations of position and spatial relations and to make possible motor control, aiding also in regulating reactions mediated through the exteroceptive group. Most of the functions of this class are likewise within consciousness. (*b*) spinal ganglion neurones which collect impulses from the somatic tissues, especially from tendons, joints, skeletal muscle and muscle-fasciæ, and which in the spinal cord give collaterals and terminal twigs to the cell-bodies giving origin to the dorsolateral and superficial ventrolateral spinocerebellar fasciculi. The chief functions of the cerebellum are coördination of muscular contractions and maintenance of muscular tone. Impulses from it are distributed to the cord by way of the rubrospinal and cerebrospinal fasciculi. The functions of the neurones of this class are considered unconscious. The neurones of the vestibular nerve (supplying the membranous laybrinth, exclusive of cochlea) are considered proprioceptive.

3. *An interoceptive group* (visceral receptors), comprising those spinal ganglion neurones which collect impulses from the visceral tissues (the epithelium of the digestive canal, including the infoldings of the skin continuous with it, from all glands, from the mesothelium lining the cavities of the body, from blood-vessels and probably from both smooth and cardiac muscle), and which in the cord give collaterals and terminal twigs for synapses with the dorsolateral (visceral efferent) cell-group of the ventral horn. These cell-bodies give rise to ventral root preganglionic axones which form synapses in the sympathetic ganglia, the cells of which in turn give off sympathetic or postganglionic axones for the secretory and motor innervation of glands and smooth muscle (visceral effectors). These afferent or visceral receptors also give branches which form synapses with the neurones of the fasciculi proprii of the cord, the longer of which may transfer impulses to visceral efferent or preganglionic neurones in the cranial nerves. Certain of the cranial nerves, the vagus especially, are very rich in both visceral receptors and visceral effectors. The central control, largely inhibitory, of the muscle of the heart and of many of the blood-vessels of the body, of the lungs, esophagus, stomach and intestine is mediated chiefly by the vagus. (See figs. 815 and 818.)

It must be remembered that the above three general groups of neurones functionally and anatomically overlap each other. An afferent neurone of either the exteroceptive or proprioceptive group may, in the cord, give some of its many terminals to form synapses with visceral efferent neurones, and a visceral receptor may give a branch in the cord whose synapsis will make it a chain from the peripheral structures to the cerebral cortex, bringing sensations aroused in the visceral organs into the domain of consciousness, as sensations of pain, pressure, temperature, etc. Also, the contention for a specific afferent neurone for conveying each of the many varieties of sensation, verbally indicated by man, is not satisfactorily supported. There are peculiar anatomical differentiations of peripheral tissue-elements (sense organs) of such character and arrangement as to be especially acted upon, specifically irritated, each by a cer-

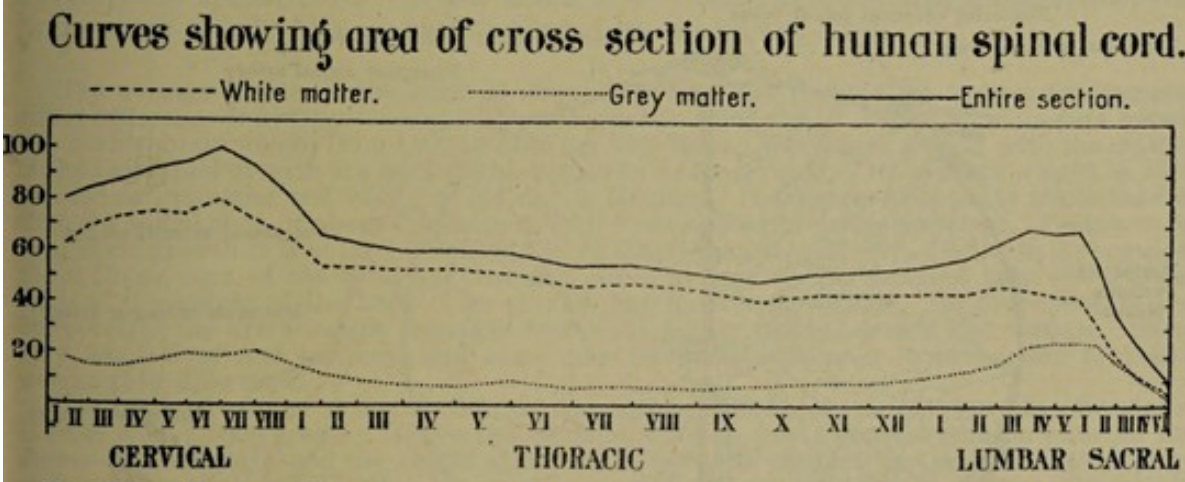

FIG. 701.—GRAPHIC REPRESENTATION OF THE VARYING AMOUNTS OF GRAY AND WHITE SUBSTANCE AND OF THE VARIATIONS IN AREA OF ENTIRE SECTIONS OF THE DIFFERENT SEGMENTS OF THE SPINAL CORD. (From Donaldson and Davis.)

(Based upon measurements from several adult human spinal cords.)

tain form of stimuli. It is probable that impulses may be aroused in any spinal ganglion neurone by any form of stimulus. These impulses, reaching the cerebral cortex or entering 'consciousness', are analyzed and interpreted there according to the character, quality and intensity of the stimulus applied and according to the locality of its application. Certain tracts in the cord carry impulses destined for certain areas of the cerebral cortex especially devoted to the analysis of certain forms of stimuli.

In transverse sections of the spinal cord (figs. 695, 701), the relative area of white substance as compared with that of gray increases as the cord is ascended. The gray substance predominates in the conus medullaris and lower lumbar segments. The white substance begins to predominate in the upper lumbar segments, not because of the increased presence of ascending and descending cerebral and cerebellar axones, but because of the increased volume of the fasciculi proprii coincident with the greater mass of gray substance to be intersegmentally associated in this region. In the thoracic region the greatly predominating white substance is composed mostly of the axones of long course. The absolute area of each substance varies locally, both being greatest in the enlargements. The greatly increased absolute amount of white substance in the cervical region is due both to the greater accumulation of cerebral and cerebellar axones in this region and to the increased volume of the fasciculi proprii necessary for the increased amount of gray substance of the cervical enlargement.

ORDER OF MEDULLATION OF THE FASCICULI OF THE CORD

The axones of the spinal cord begin to acquire their myelin sheaths during the fifth month of intrauterine life and myelinization is not fully completed till between the fifteenth and twentieth

years. In general, axones which have the same origin and the same locality of termination—the same function—acquire their sheaths at the same time. While it has been proved that th medullary sheath does not necessarily precede the functioning of an axone, it may be said ths those fasciculi which first attain complete and definite functional ability are the first to becom medullated. At birth all the fasciculi of the spinal cord are largely medullated except the spinc olivary fasciculus, and occasionally the lateral and ventral cerebrospinal tracts. The latte tracts vary considerably and in general may be said to become distinguishably medullate between the ninth month (just before birth) and the second year. As indicated by thei medullation, those axones by which the cord is enabled to function as an organ *per se*, that i the axones making possible the simpler reflex activities, complete their development befor those axones which involve the brain with the activities of the cord.

According to Flechsig and van Gehuchten, and investigators succeeding them, the followin is the order in which the axones of the cord become medullated:

(1) The afferent and efferent nerve-roots and commissural fibers of the gray substanc

(2) The fasciculi proprii, first the ventral, then the lateral, and last the dorsal fasciculu proprius.

(3) The fasciculus cuneatus (Burdach's column) and Lissauer's zone—the area of thos ascending spinocerebral fibers which run the shorter course and which convey impulses fro the upper limbs, neck and thorax (including chains for the earlier respiratory reflexes).

(4) Fasciculus gracilis (Goll's column).

(5) The dorsal spinocerebellar fasciculus (direct cerebellar tract).

(6) The superficial ventrolateral spinocerebellar fasciculus (Gowers' tract).

(7) The lateral cerebrospinal fasciculus (crossed pyramidal) and the ventral cerebrospin fasciculus (direct pyramidal tract).

(8) The spino-olivary fasciculus.

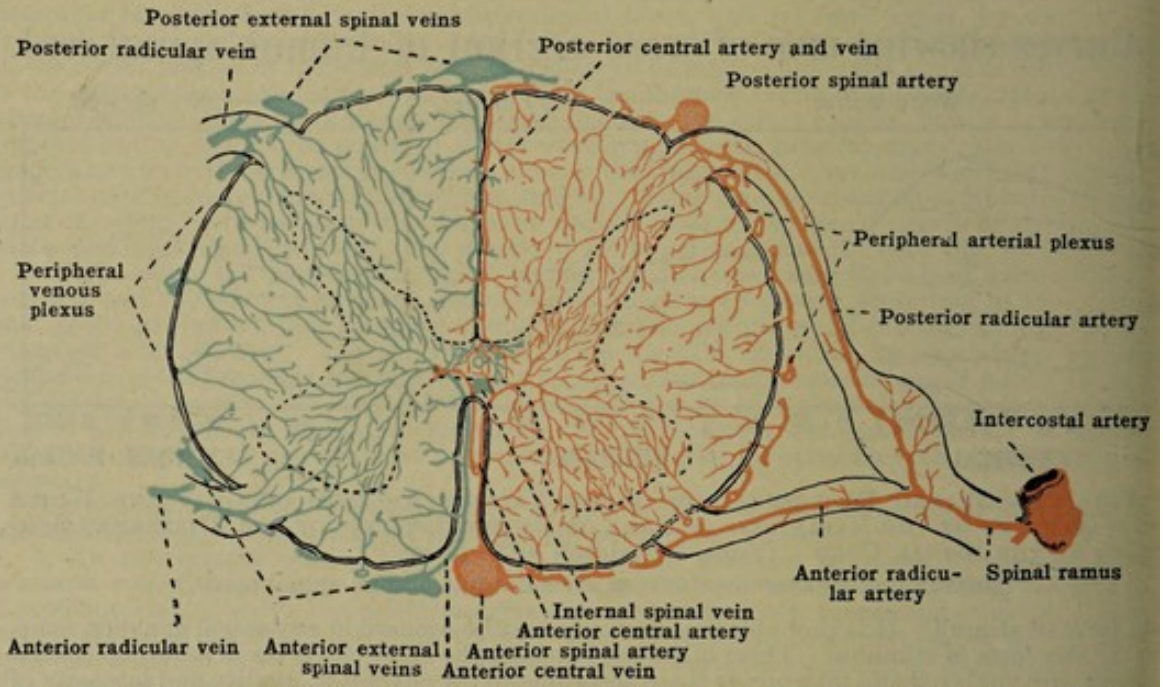

FIG. 702.—SEMI-DIAGRAMMATIC REPRESENTATION OF THE BLOOD-SUPPLY OF THE SPINAL CORD.

The remaining fasciculi are so mixed with other axones that it is difficult to determine th sequence of their medullation. The fasciculi containing them also contain axones of the variety in the fasciculi proprii and so show medullation early.

BLOOD-SUPPLY OF THE SPINAL CORD

The **spinal rami** of the sacral, lumbar, intercostal, or vertebral arteries, as the case may be, accompany the spinal nerves through the intervertebral foramina, traverse the dura mate and arachnoid, and each divides into a **dorsal** and a **ventral radicular artery.** These accompany the nerve-roots to the surface of the cord, and there break up into an anastomosing plexus in the pia mater. From this superficial plexus are derived three tortuously coursing longitudinal arteries and numerous independent central branches, which latter penetrate the cord directly. Of the longitudinal arteries, the **anterior spinal artery** zigzags along the anterior median fissure and gives off the anterior central branches, which pass into the fissure and penetrate the cord. These branches give off a few twigs to the white substance in passing, but their most partial distribution is to the ventral portion of the gray substance. The two **posterior spinal arteries,** one on each side, course near the lines of entrance of the dorsal root-fibers. They each branch and anastomose, so that often two or more posterior arteries may appear in section upon either side of the dorsal root. These give off transverse or central twigs to the white substance, but especially to the gray substance of the dorsal horns. Of the remaining central branches many enter the cord along the efferent fibers of the ventral roots, and are distributed chiefly to the grey substance; others from the superficial plexus throughout penetrate the cord and break up into capillaries within the white substance. Some of the terminal twigs of these also enter the gray substance. The blood-supply of the gray substance is so much more abundant than that

of the white substance that in injected preparations the outline of the gray figure may be easily distinguished by its greater abundance of capillaries alone. The central branches are of the terminal variety. In the white substance the capillaries run for the most part longitudinally, or parallel with the axones. The radicular arteries in passing give twigs supplying the spinal ganglia and the nerve-roots. The anterior spinal artery anastomoses with the vertebral arteries on the ventral surface of the medulla oblongata, making continuous the sources of blood for cord and brain (fig. 536).

The *venous system* is quite similar to the arterial. The blood of the central arteries is collected into corresponding central venous branches which converge into a superficial venous plexus in which there are six main longitudinal channels, one along the posterior median sulcus, one along the anterior median fissure, and one along each of the four lines of the nerve-roots. These comprise the **posterior** and **anterior external spinal veins** (fig. 702).

The **internal spinal veins** course along the ventral surface of the gray commissure, and arise from the convergence of certain of the twigs flowing into the *anterior central veins*. The *posterior central vein* courses along the posterior median septum in company with the posterior central artery, and empties into the *median dorsal vein*. The venous system communicates with the coarser extradural or internal vertebral plexus chiefly by way of the **radicular veins**.

II. THE BRAIN OR ENCEPHALON

The brain is that greatly modified and enlarged portion of the central nervous system which is enclosed within the cranial cavity. It is surrounded and supported by continuation over it of the same three membranes (meninges) that envelop the spinal cord. While there is a considerable subarachnoid space, the brain more nearly fills its cavity than does the spinal cord.

The average length of the brain is about 165 mm. and its greatest transverse diameter about 140 mm. It averages longer in the male than in the female. Exclusive of its dura mater, the normal brain weighs from 1100 to 1700 gm. (40–60 oz.), varying in weight with the stature of the individual or with the bulk of the tissues to be innervated. Its average weight is 1360 gm. (48 oz.) in males and 1250 gm. (44 oz.) in females. It averages about fifty times heavier than the spinal cord, or about 98 per cent. of the entire central nervous system. Owing to its precocious growth it is at birth relatively much larger than at maturity. At birth it comprises about 13 per cent. of the total body-weight, while at maturity it averages only about 2 per cent. of the weight of the body. Its specific gravity averages 1.036. In proportion to the body-weight the brain-weight averages somewhat higher in smaller men and women. Some very small dogs and monkeys and some mice have brains heavier in proportion to body-weight than does man.

The minimal weight of the adult brain compatible with human intelligence may be placed at from 950 to 1000 grams. Above the minimal, there is only a general relation between the degree of intelligence and the weight of the brain, owing to the fact that several factors (large statue, congenital defects, disease) may be coincident with large brains. It may be said in general, however, that the average brain-weight of eminent men is above the general average. Some men judged eminent have had brains weighing less than the general average. Of the records generally accepted, the greatest brain-weight for eminent men is 2012 grams, recorded for the poet and novelist, IvanTourgenieff. The trustworthiness of this weighing is doubted by some authorities. From the undisputed records the following may be taken: Cuvier, 1830 grams; John Abercrombie, 1786 grams; Thackeray, 1658 grams; Kant, 1600 grams; Spurzheim, 1559 grams; Daniel Webster, 1518 grams; Louis Agassiz, 1495 grams: Dante, 1420 grams; Helmholtz, 1440 gram; Goltz, 1395 grain; Liebig, 1352 grams; Walt Whitman, 1282 grams; Gall, 1198 grams. In the average brain-weights for the races that for the Caucasian stands highest, the Chinese next, then the Malay, followed by the Negro, with the Australian lowest. Size or volume of the cranium is but a general index for the size of the brain. The shape and thickness of the skull and of the subarachnoid space vary. Todd found that of two heads of the same size, one may carry a brain with a volume as much as 200 cc. greater than the other.

The differences between the meninges of the brain and those of the spinal cord occur chiefly in the dura mater. The cranial *dura mater* is about double the thickness of the spinal dura, and consists of two closely adhering layers, the outermost of which is the internal periosteum of the cranial bones, while that of the cord is entirely separate from the periosteum lining the vertebral canal. The semilunar ganglion and the hypophysis cerebri are pocketed between the two layers of the cranial dura. The inner layer is duplicated in places into strong partitions which extend between the great natural divisions of the encephalon. Of these, the sickle-shaped *falx cerebri* extends between the hemispheres of the cerebrum, the crescentic *tentorium cerebelli* extends between the cerebellum and the overlapping posterior portion of the cerebrum, and the smaller *falx cerebelli* occupies the notch between the hemispheres of the cerebellum. Contained within these partitions of the dura mater are the great collecting venous sinuses of the brain. These will be considered in the more detailed description of the cranial meninges.

General topography.—In its superior aspect or **convex surface** the encephalon is oval in contour, with its **frontal pole** usually narrower than its **occipital pole.** Viewed from above, the **cerebrum** comprises almost the entire dorsal aspect, the occipital lobes overlapping the **cerebellum** to such an extent that only the lateral and lower margins of the cerebellar hemispheres are visible. The **great longitudinal fissure** of the cerebrum separates the cerebral hemispheres.

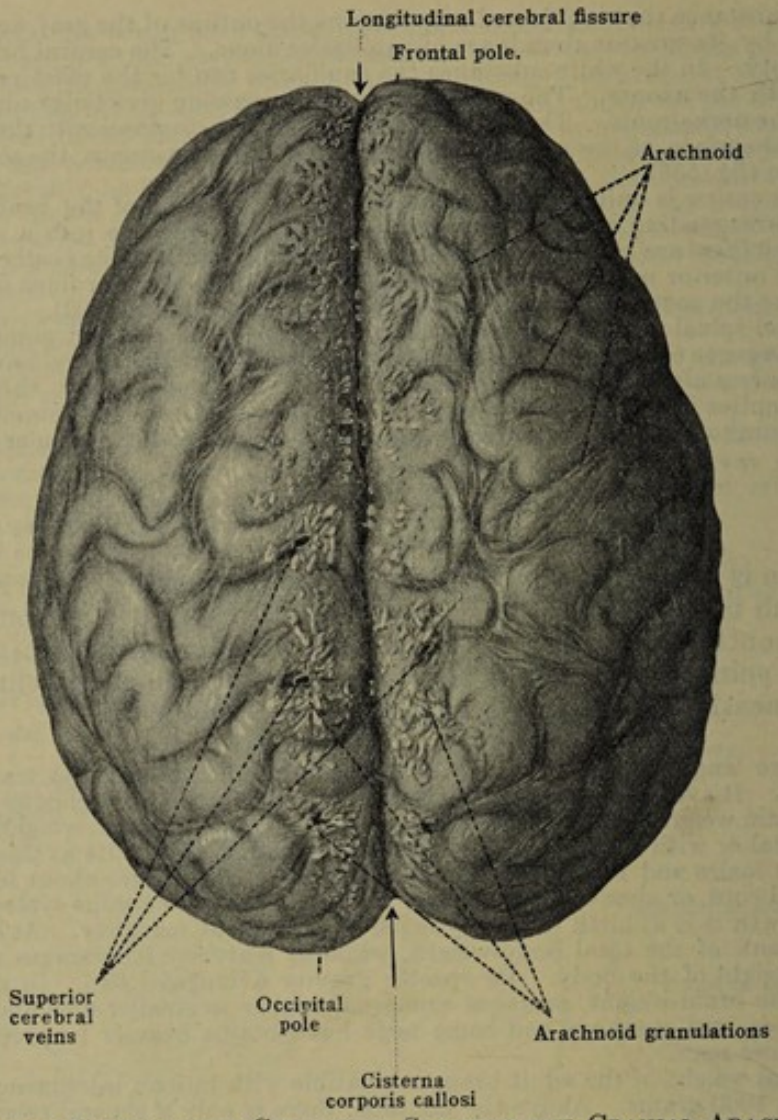

FIG. 703.—SUPERIOR VIEW OF THE CEREBRUM, SHOWING THE CRANIAL ARACHNOID. (From Sobotta-McMurrich, Atlas of Human Anatomy.)

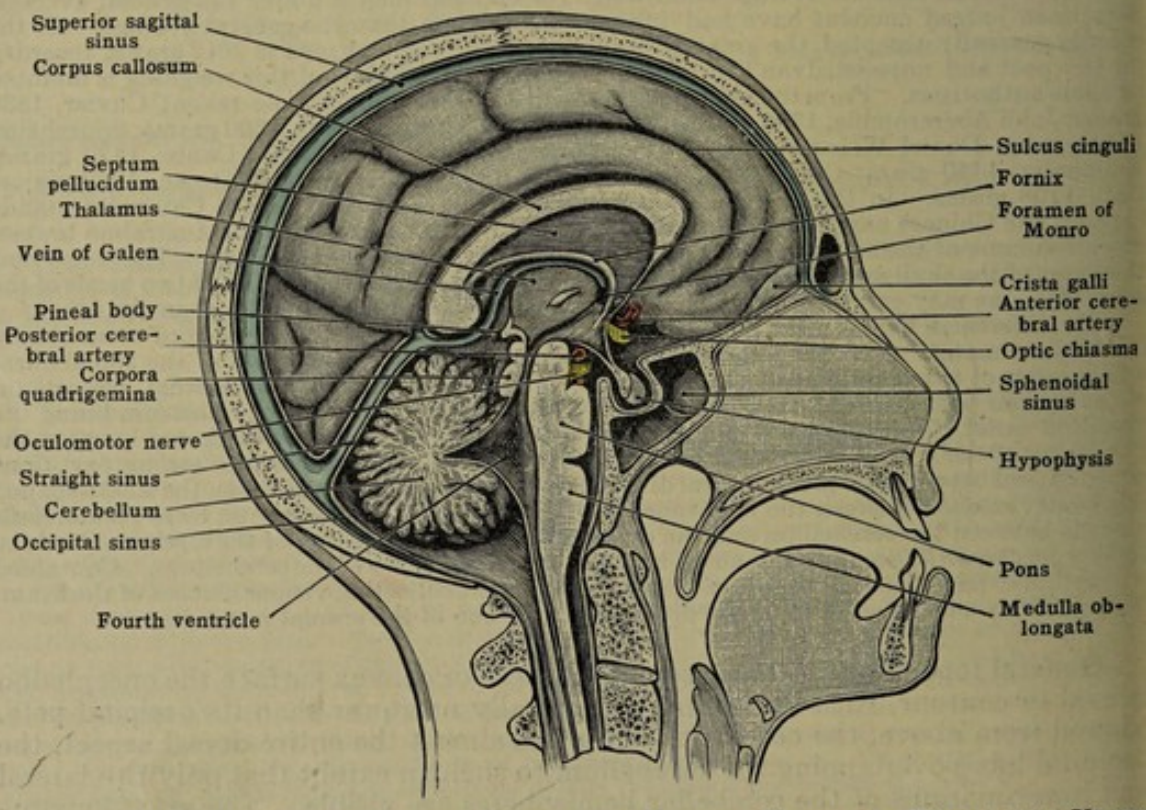

FIG. 704.—DIAGRAM OF MEDIAN SECTION OF HEAD OF FEMALE OF THIRTY-FIVE YEARS

Laterally the **temporal lobes,** with their rounded anterior extremities, the **temporal poles,** are each separated from the frontal and **parietal lobes** above by the **lateral cerebral fissure** (fissure of Sylvius). In the depths of this fissure and overlapped by the temporal lobe is situated the **insula,** or **island of Reil** (central lobe).

The surface of each cerebral hemisphere is thrown into numerous folds or curved elevations, the **gyri cerebri** or convolutions, which are separated from each other by slit-like fissures, the **sulci cerebri.** The gyri (and sulci) vary greatly in length, in depth, and in their degrees of curvature. The larger and deeper of them are similar in the two hemispheres; most of them are individually variable, but each gyrus of one hemisphere is homologous with that of the like region of the other hemisphere. By gently pressing open the great longitudinal fissure, the **corpus callosum,** the chief commissural pathway between the cerebral hemispheres, may be seen. The occipital margin of this large transverse band of white substance is rounded and thickened into the **splenium** of the corpus callosum, while its frontal margin arches downward to form its **genu** and continues downward and backward to form its **rostrum.**

The **base of the encephalon** (fig. 705) is more irregular than the convex surface, and consists of a greater variety of structures. In the midline between the frontal lobes appears the anterior and inferior extension of the great longitudinal fissure. When the margins of this are separated, the outer aspect of the **rostrum** of the *corpus callosum,* the downward continuation of the curve of the genu, is exposed.

The inferior surface of each frontal lobe is concave, due to its compression upon the superior wall of the orbit. The *orbital gyri* with their respective *orbital sulci* occupy this concave area.

The cranial nerves [nervi cerebrales].—Along the mesial border of each orbital area, and parallel with the great longitudinal fissure, lie the **olfactory bulbs,** continued into the **olfactory tracts.** Each olfactory bulb is the first central connection or the 'nucleus of termination' of the **olfactory nerve,** the first of the cranial nerves. A few fine filaments of this nerve may often be discerned penetrating the ventral surface of the bulb. The olfactory bulb and tract lie in the *olfactory sulcus,* which forms the lateral boundary of the *gyrus rectus,* the most medial gyrus of the inferior surface of the frontal lobe. Upon reaching the parolfactory area of Broca, or the region about the posterior extremity of the gyrus rectus, each olfactory tract undergoes a slight expansion, the **olfactory tubercle,** and then divides into three roots or **olfactory striæ**—a medial, an intermediate, and a lateral, which comprise the **olfactory trigone.** The striæ begin their respective courses upon the **anterior perforated substance,** an area which contains numerous small foramina through which the anterolateral group of central cerebral arteries enters the brain. This region forms the anterior boundary of that area of the base of the encephalon in which the substance of the brain becomes continuous across the midline.

At the posterior boundary of the anterior perforated substance the **optic nerves** come together and fuse to form the **optic chiasma.** Thence the **optic tracts** disappear under the poles of the temporal lobes in their backward course to the *thalami,* the geniculate bodies and superior quadrigeminate bodies.

Immediately behind the optic chiasma occurs that diverticulum from the floor of the third ventricle known as the **tuber cinereum.** It is continuous by its tubular stalk, the **infundibulum,** with the **hypophysis** or pituitary body, which occupies its special depression (sella turcica) in the floor of the cranium and is usually torn from the encephalon in the process of its removal. Behind the tuber cinereum are the two **mammillary bodies** (corpora albicantia), each of which is connected with the fornix, one of the larger association fasciculi of the cerebrum. The **peduncles of the cerebrum** (crura cerebri) are the two great funiculi which associate the cerebral hemispheres with all the structures below them. They diverge from the anterior border of the **pons** (Varoli) and, one for each hemisphere, disappear under the poles of the temporal lobes. The pons (with the brachia pontis or middle cerebellar peduncles) is chiefly a bridge of white substance or a commissure between the cerebellar hemispheres.

The **oculomotor** or third pair of cranial nerves make their exit from the **posterior perforated substance** in the **interpeduncular fossa** just behind the corpora mammillaria.

The **trochlear nerves** come to view on the basal surface around the lateral aspects of the cerebral peduncles along the anterior border of the pons. They

actually emerge from the dorsal surface just inferior to the posterior quadrigeminate bodies and decussate while approaching this surface. The trochlear is the smallest of the cranial nerves, and the only pair arising from the dorsal aspect of the brain and the only pair thus decussating.

The **trigeminus,** or fifth cranial nerve, is the largest. It penetrates the pons to find its terminal nuclei in the depths of the brain-stem. It is a purely sensory nerve, but it is accompanied by the much smaller **masticator nerve** which is motor and is usually referred to as the motor root of the trigeminus.

Five pairs of cranial nerves are attached to the brain-stem along the inferior border of the pons: the **abducens** nerve, which is motor, emerges near the midline; the **facial,** motor, emerges from the more lateral aspect of the brain-stem; the **glossopalatine** or the intermediate nerve of Wrisberg, largely sensory, is attached in company with the facial; and entering the extreme lateral aspect of the stem are the **cochlear** and **vestibular** nerves. These latter two, when taken together as one, are known as the **acoustic** (auditory) or eighth cranial nerve.

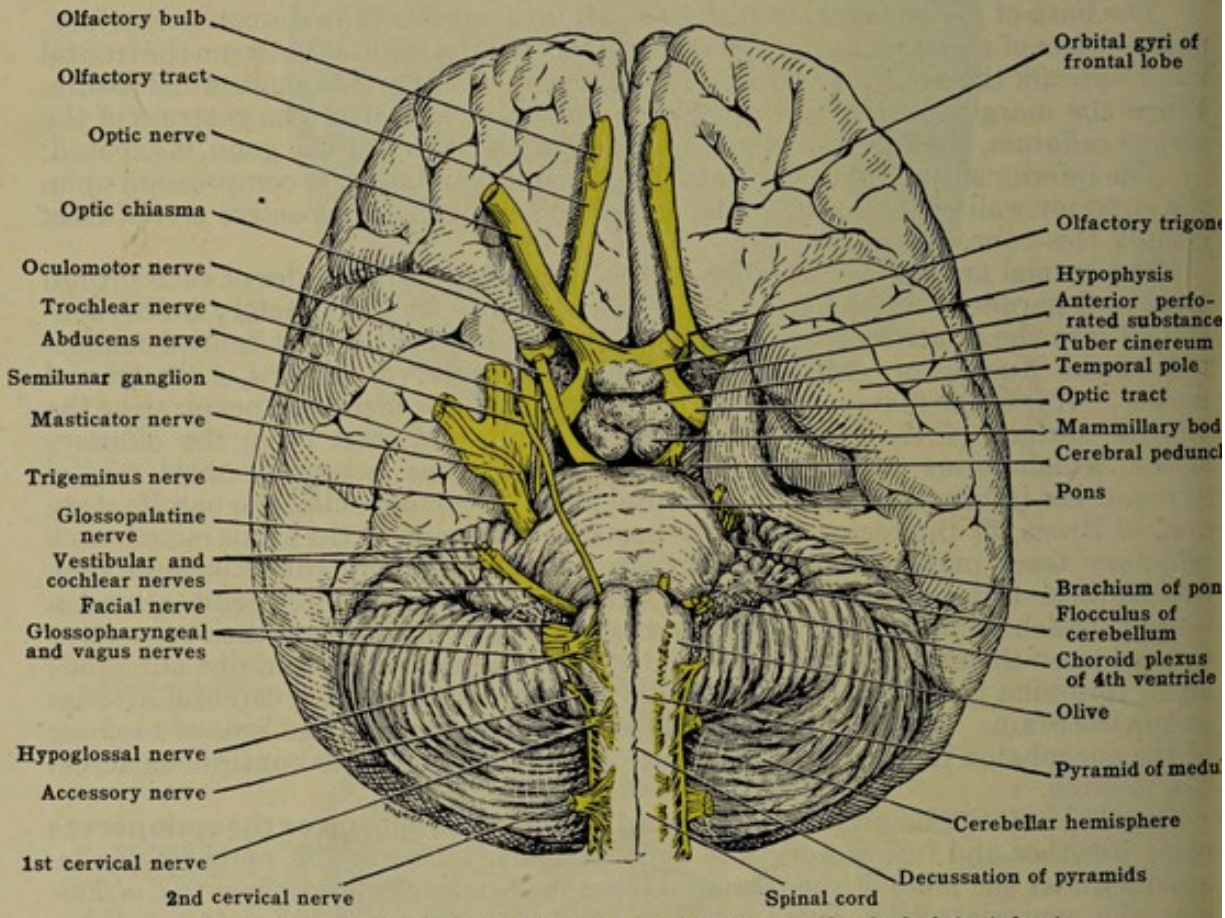

FIG. 705.—VIEW OF THE BASE OF THE BRAIN. (Spalteholz's Atlas.)

They are both purely sensory. The cochlear nerve courses for the most part laterally and dorsally around the *inferior cerebellar peduncle,* giving to the latter the ropelike appearance from which it derives its name, **'restiform body.'**

The remaining four pairs of the cranial nerves are attached directly to the **medulla oblongata.** This comprises that portion of the brain-stem beginning at the inferior border of the pons above, and continuous into the first segment of the spinal cord below. On its ventral surface the **pyramids** and the **olives** (olivary nuclei) are the two most prominent structures. The pyramids, which are continuous below into the pyramidal (cerebrospinal) tracts of the spinal cord, form the two tapering prominences along either side of the anterior median fissure; the olives are the oblong oval elevations situated between the pyramids and the restiform bodies, and each is the superficial indication of the inferior olivary nucleus.

The **glossopharyngeal,** the **vagus** (pneumogastric), and the **spinal accessory** nerves are attached along the lateral aspect of the medulla oblongata in line with the facial nerve and between the olive and the restiform body. The spinal accessory, purely motor, is assembled from a series of rootlets which emerge from the lateral aspect of the first three or four cervical segments of the spinal

cord, as well as from the medulla. It becomes fully formed before reaching the level of the olive, and passes lateralward in company with the vagus and further on joins the latter in part. The root-filaments of the vagus and glossopharyngeal are arranged in a continuous series, and, if severed near the surface of the medulla, those belonging to the one nerve are difficult to distinguish from those belonging to the other. Both of these are mixed motor and sensory.

The **hypoglossal,** purely motor, emerges as a series of rootlets between the pyramid and the olive. Thus it arises nearer the midline, and in line with the abducens, trochlear, and oculomotor.

If the occipital lobes be lifted from the superior surface of the cerebellum, the tentorium cerebelli removed, the **quadrigeminate bodies** of the mesencephalon may be observed. These are situated above the cerebral peduncles, at the level of the ventral appearance of the oculomotor and trochlear nerves. Resting upon the superior pair of the quadrigeminate bodies [colliculi superiores] is the **pineal body** (epiphysis), and just anterior to this is the cavity of the third ventricle, bounded laterally by the thalami and roofed over by the **tela chorioidea of the third ventricle** (velum interpositum).

By separating the inferior margin of the cerebellum from the dorsal surface of the medulla oblongata the lower portion of the **fourth ventricle** (rhomboid fossa) may be seen. The **cisterna cerebellomedullaris,** the locally enlarged subarachnoid space in this region, is occupied in part by a thickening of the arachnoid. This is continuous with the tela chorioidea and the choroid plexus of the fourth ventricle. The former roofs over the lower portion of the fourth ventricle, and passing through it in the medial line is the passage, the **foramen of Magendie,** by which the cavity of the fourth ventricle communicates with the subarachnoid space. Also there are two lateral apertures into the ventricle, one on either side. The fourth ventricle, as it becomes continuous with the central canal of the spinal cord terminates in a point, the **calamus scriptorius.** From the inferior surface, the cerebellar hemispheres are more definitely demarcated, and between them is the **vermis** or central lobe of the cerebellum.

Divisions of the Encephalon

The encephalon as a whole is developed from a series of expansions, flexures, and thickenings of the wall of the cephalic portion of the primitive neural tube, the three primary brain vesicles. Being continuous with the spinal cord, it is arbitrarily considered as beginning just below the level of the decussation of the pyramids, or at a line drawn transversely between the decussation of the pyramids and the level of the first pair of cervical nerves.

In its general conformation four natural divisions of the brain are apparent; the two most enlarged portions—(1) the cerebral hemispheres and (2) the cerebellum; (3) the midbrain (mesencephalon) between the cerebral hemispheres and the cerebellum, and (4) the medulla oblongata, the portion below the pons and above the spinal cord (fig. 681). However, the most logical and advantageous arrangement of the divisions and subdivisions of the encephalon is on the basis of their development from the embryonic brain vesicles. (See figs. 677, 706, 707.) On this basis, for example, both the medulla oblongata and the cerebellum with its pons are derived from the posterior of the primary vesicles, and are, therefore, included in a single gross division of the encephalon, viz., the *rhombencephalon.* In the outline on p. 874 the anatomical components of the encephalon are arranged with reference to the three primary vesicles from the walls of which they are derived, and the primary flexures and thickenings of the walls of which they are elaborations.

During the early growth of the neural tube its basal or ventral portion and the lateral portions acquire a greater thickness than the roof of the tube, and thus the tube is longitudinally divided into a basal or **ventral zone** and an alar or **dorsal zone.** This is especially marked in the brain-vesicles. Structures arising from the dorsal zone begin as localized thickenings of the roof. For example, in the rhombencephalon the greater part of the medulla oblongata and of the pons region is derived from the ventral zone, while the cerebellum is derived from the superior part of the dorsal zone of the posterior vesicle. The first of the flexures occurs in the region of the future mesencephalon, and is known as the **cephalic flexure;** next occurs the **cervical flexure,** at the junction with the spinal cord; third, the **pontine flexure,** in the region of the future fourth ventricle. Both the cervical and pontine flexures, while having a significance in the growth processes, are almost entirely obliterated in the later growth of the encephalon.

OUTLINE OF THE DIVISIONS OF THE ENCEPHALON

(The numerals refer to like numerals in figs. 706, 707 and 708.)

- Encephalon (Brain)
  - Cerebrum.
    - Prosencephalon (Forebrain)
      - Telencephalon (Endbrain)
        - Optic portion of hypothalamus, VI_1
        - (Hypophysis),
        - Optic nerves and retinæ. VI,
        - *Anterior portion of third ventricle.*
        - Corpus striatum, VI_2,
        - Olfactory bulb and tract, VI_2,
        - Cerebral cortex (pallium), VI_4,
        - *Lateral ventricles.*
      - Diencephalon (Interbrain)
        - Thalamencephalon
          - Thalamus, V_2,
          - Metathalamus, V_3
          - (Geniculate bodies),
          - Epithalamus, V_4
          - (Epiphysis or pineal body).
        - Mammillary portion of hypothalamus, V_1,
        - *Posterior portion of third ventricle.*

    Anterior primary vesicle.

    - Mesencephalon (Midbrain)
      - Quadrigeminate bodies (colliculi), IV_2,
      - Cerebral peduncles (crura), IV_1,
      - Posterior perforated substance, IV,
      - *Aquæductus cerebri (Sylvii).*

    Middle primary vesicle.

  - Rhombencephalon

      - Superior cerebellar peduncles,
      - Anterior medullary velum,
      - Cerebral peduncles,
      - *Superior part of fourth ventricle.*

    III.

    - Metencephalon (Hindbrain)
      - Cerebellum, II_2,
      - Pons (Varoli), II_1,
      - *Middle part of fourth ventricle.*
    - Medulla oblongata—myelencephalon, I.
      (Afterbrain) *Inferior part of fourth ventricle.*

    Posterior primary vesicle.

The location of the development of the various parts of the encephalon may be determined, and their elaboration and changes in shape and position may be traced by comparing the accompanying figs. 706, 707, 708. The reference numbers in the last three figures correspond with the like numerals after the names of the parts on p. 874 in the outline of the divisions of the encephalon. The more detailed subdivisions of the parts will be met with in their individual descriptions.

FIG. 706.—MEDIAN SAGITTAL SECTION THROUGH EMBRYONIC HUMAN BRAIN AT END OF FIRST MONTH. (After His.)

(Showing the localities of origin of the derivatives of the vesicles named in outline on p. 874.)

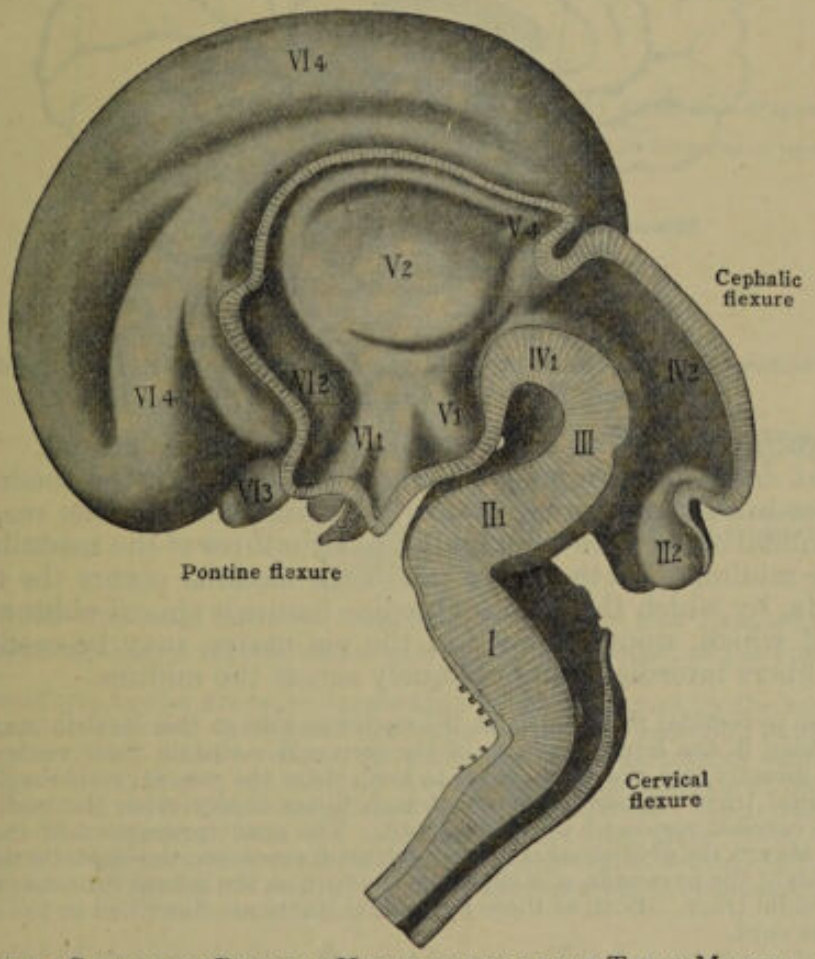

FIG. 707.—SAGITTAL SECTION OF BRAIN OF HUMAN FETUS OF THE THIRD MONTH. (After His.)

(Reference numerals correspond with those of fig. 706 and those after names of parts in outline on p. 874.)

THE RHOMBENCEPHALON

1. THE MEDULLA OBLONGATA

The **medulla oblongata** [myelencephalon] is the upward continuation of the spinal cord. It is only about 25 mm. long, extending from just above the first cervical nerve (beginning of the first cervical segment of the spinal cord) to the inferior border of the pons. It lies almost wholly within the cranial cavity, resting upon the superior surface of the basal portion of the occipital bone, with its lower extremity in the foramen magnum. Its weight is from 6 to 7 gm. or about one-half of 1 per cent. of the central nervous system. It is a continuation of the spinal cord, and more. It contains structures continuous with and homologous to the structures of the spinal cord, and in addition it contains structures which have no homologues in the spinal cord. Due in part to these additional structures, the medulla, as it approaches the pons, rapidly expands in its dorsoventral and especially in its lateral diameter. With it are associated nine of the pairs of cranial nerves.

On its **ventral aspect** (figs. 705, 747) the continuation of the anterior median fissure of the spinal cord becomes broader and deeper because of the great height attained by the **pyramids.** At the level at which the pyramids emerge from the pons, the region in which they are largest, the fissure terminates in a

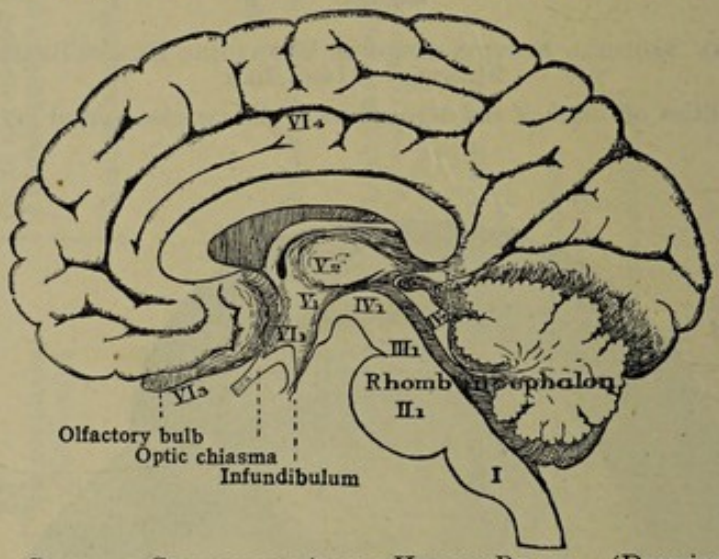

FIG. 708.—MEDIAN SAGITTAL SECTION OF ADULT HUMAN BRAIN. (Drawing of model by His.) (Reference numerals same as in figs. 706 and 707.)

triangular recess so deep as to merit the name **foramen cecum.** The pyramids are the great descending cerebral or motor funiculi. In the medulla oblongata they decrease in bulk in passing toward the spinal cord, for the reason that many of the pyramidal axones are contributed to structures of the medulla, chiefly after crossing the midline. At the lower end of the medulla occurs the **decussation of the pyramids,** by which the anterior median fissure is almost obliterated for about 6 mm., and which, upon removal of the pia mater, may be easily observed as bundles of fibers interdigitating obliquely across the midline.

Not all the pyramidal fibers cross to the opposite side at this level in man, but a portion of those coursing in the lateral portion of the pyramid maintain their ventromedial position and continue directly into the spinal cord, to form there the ventral cerebrospinal fasciculus or direct pyramidal tract. However, most of such fibers finally cross the midline during their course in the cervical region of the spinal cord. The exact proportion of the direct fibers is variable, but always the greater mass of each pyramid crosses to the opposite side at the level of the decussation of the pyramids, and descends the cord as the lateral cerebrospinal fasciculus or crossed pyramidal tract. Both of these pyramidal tracts are described in the discussion of the fasciculi of the cord.

Each pyramid is bounded laterally by the **anterolateral sulcus,** also continuous with that of the same name in the spinal cord. Toward the pons this sulcus separates the pyramid from the **olive** [oliva] (inferior olivary nucleus), and in the region of the olive there emerge along this sulcus the root-filaments of the hypoglossal nerve. The olives, as their name implies, are oblong oval eminences about 1.2 cm. in length. They extend to the border of the pons, and are somewhat

thicker at their upper ends. Their surfaces are usually smooth, except at their lower ends, where they frequently appear ribbed, owing to bundles of the **external arcuate fibers** passing across them to and from the *restiform* body, which occupies the extreme lateral portion of the medulla. Along the line between the restiform body and the olive are attached the root-filaments of the *vagus*, *glossopharyngeal*, and *spinal accessory nerves*. Both the *abducens* and the *facial* nerves emerge along the inferior border of the pons, the facial in line with the glossopharyngeal, but the abducens in line with the hypoglossal.

Dorsal aspect.—The increased lateral diameter of the medulla oblongata is contributed to a great extent by the **restiform bodies.** These are the inferior cerebellar peduncles and contain the majority of the ascending fibers, which associate the cerebellum with the structures below it.

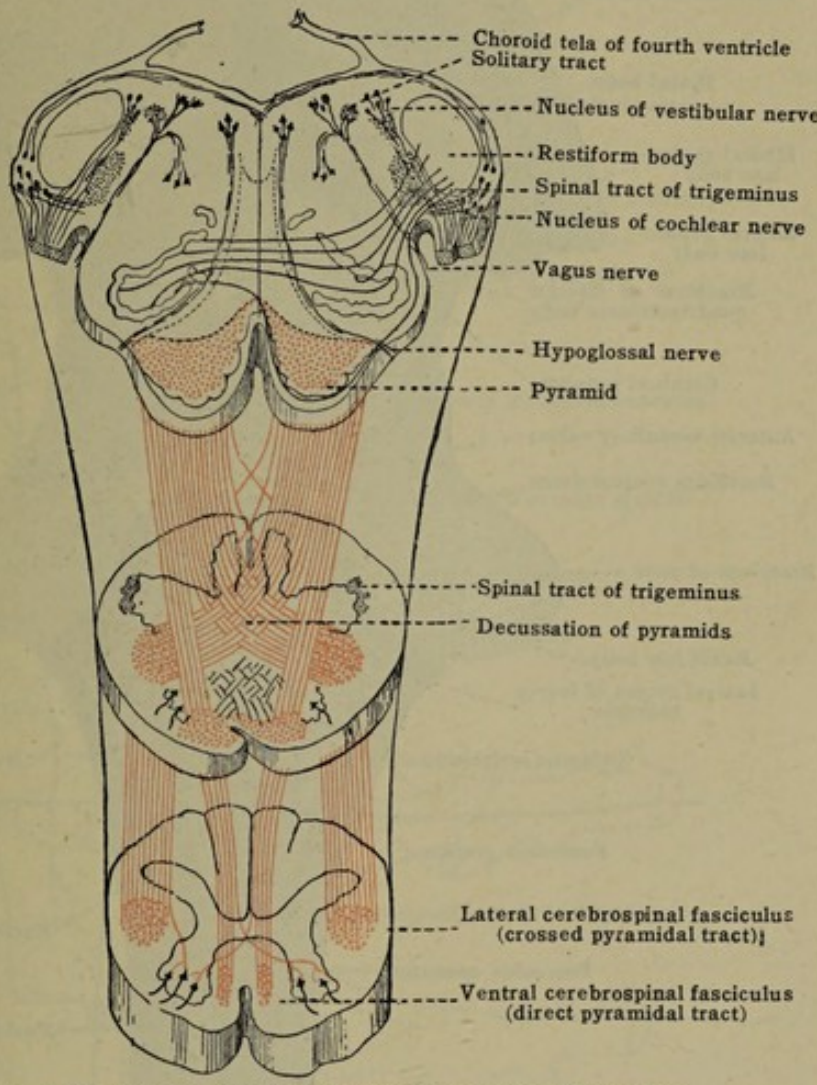

FIG. 709.—DIAGRAM SHOWING THE DECUSSATION OF THE PYRAMIDS.
The uppermost level represented is near the inferior border of the pons.

In toto, the restiform bodies are much larger than could be formed by the combined cerebellar fasciculi of the spinal cord, their great size being due to their receiving numerous axones coursing in both directions, which connect the cerebellum with structures contained in the medulla oblongata alone, so that in the medulla they increase as they approach the cerebellum. Their mesial borders form the lateral boundaries of the fourth ventricle. Their name (*restiform*, meaning rope-like) was suggested from the appearance frequently given them by the fibers of the cochlear nerve, which course around their lateral periphery to become in part the *striæ medullares* in the floor of the fourth ventricle. (Corpus restiforme or crus medullocerebellare NK.)

Upon removal of the cerebellum it may be seen that below the *calamus scriptorius* (inferior terminus of the fourth ventricle) the structures manifest in the dorsal surface of the medulla are directly continuous with those of the spinal cord. The fasciculus gracilis (Goll's column) of the spinal cord acquires a greater height and volume and becomes the **funiculus gracilis** of the medulla, and because of this increased height the posterior median sulcus of the cord becomes deepened into the **posterior median fissure.** The posterior intermediate sulcus is also accentuated

by the fasciculus cuneatus (Burdach's column) likewise now enlarged into the **funiculus cuneatus** of the medulla. The lateral funiculus of the medulla, of course, does not contain the lateral or crossed pyramidal tract present in the spinal cord.

At the border of the calamus scriptorius the funiculus gracilis terminates in a slight elevation, the **clava**, which is the superficial indication of the (terminal) **nucleus of the fasciculus gracilis.** Beginning somewhat more superiorly, and

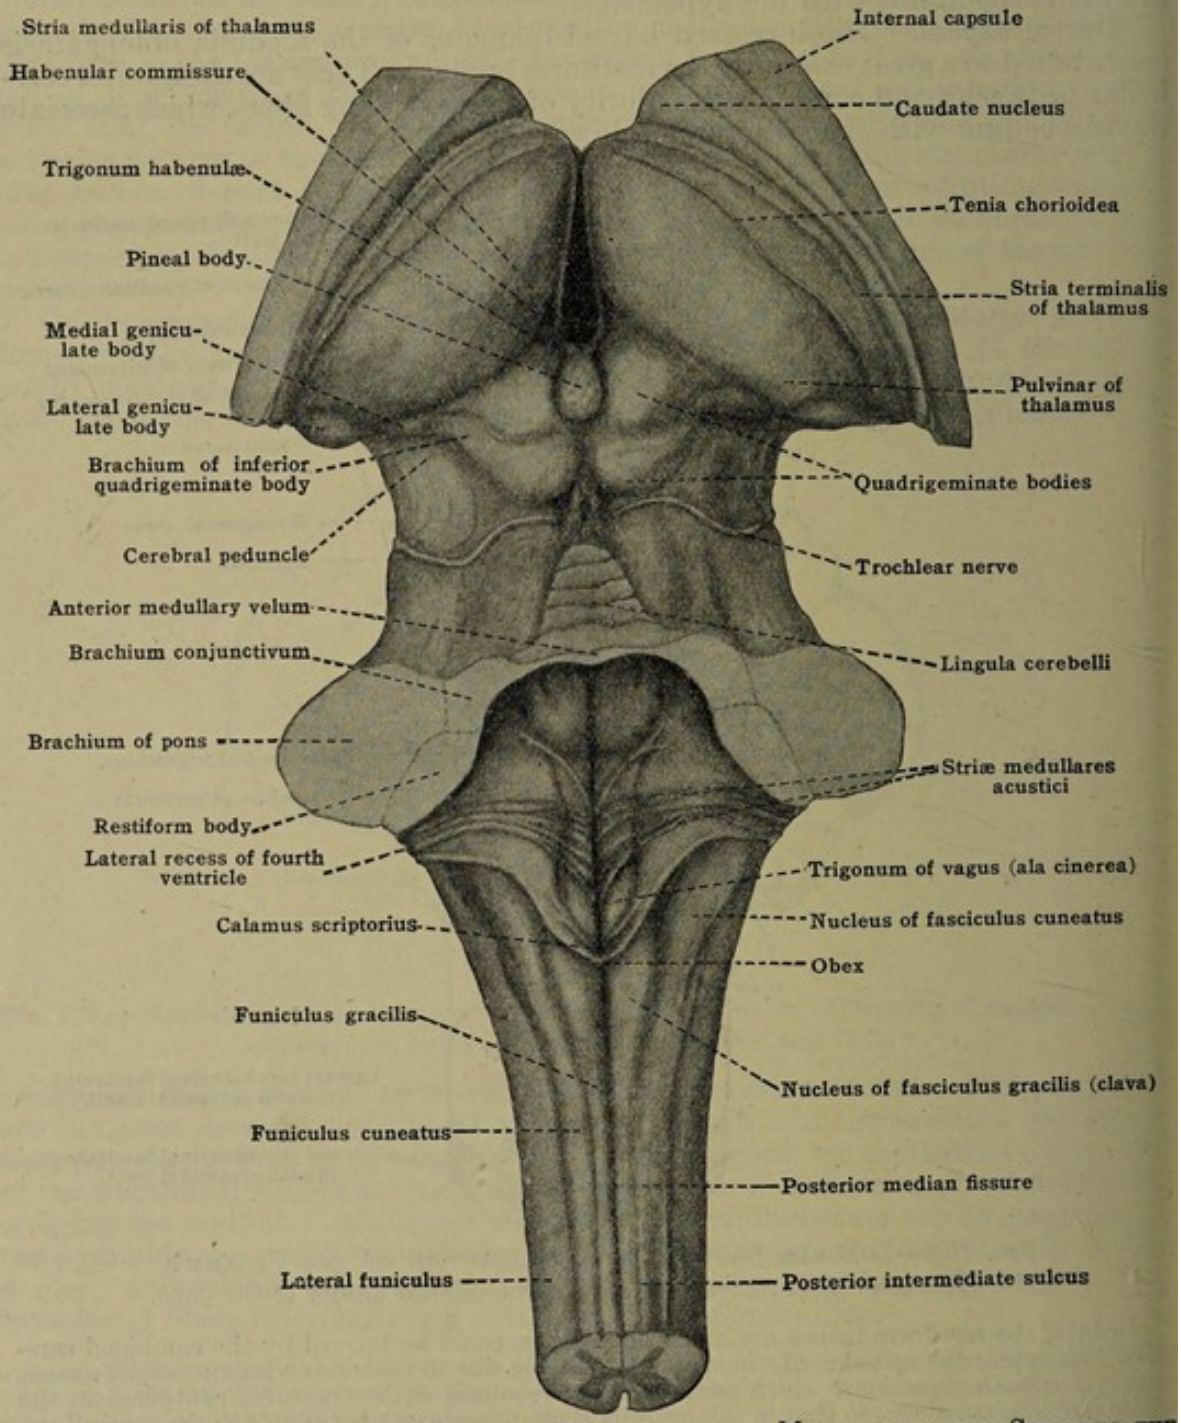

FIG. 710.—DORSAL ASPECT OF MEDULLA OBLONGATA AND MESENCEPHALON, SHOWING THE FLOOR OF THE FOURTH VENTRICLE (RHOMBOID FOSSA). (Modified from Spalteholz.)

having a somewhat greater length, is a similar enlargement of the funiculus cuneatus, the **tuberculum cuneatum** or **nucleus of the fasciculus cuneatus.**

These nuclei are the groups of nerve cell-bodies about which the ascending or sensory axones of the respective fasciculi terminate or where the sensory impulses are transferred to a second neurone in their course to the structures of the encephalon. These cell-bodies in their turn give off axones which immediately cross the midline and assume a more ventral position, contributing largely to the *lemniscus* or fillet of the opposite side. Thus such axones are the encephalic continuation of the central sensory ('proprioceptive')pathway conveying impulses from the periphery of one side of the body to the opposite side of the cerebrum. These axones comprise one of the components of the *internal arcuate fibers* and their crossing is known as the *decussation of the lemnisci.*

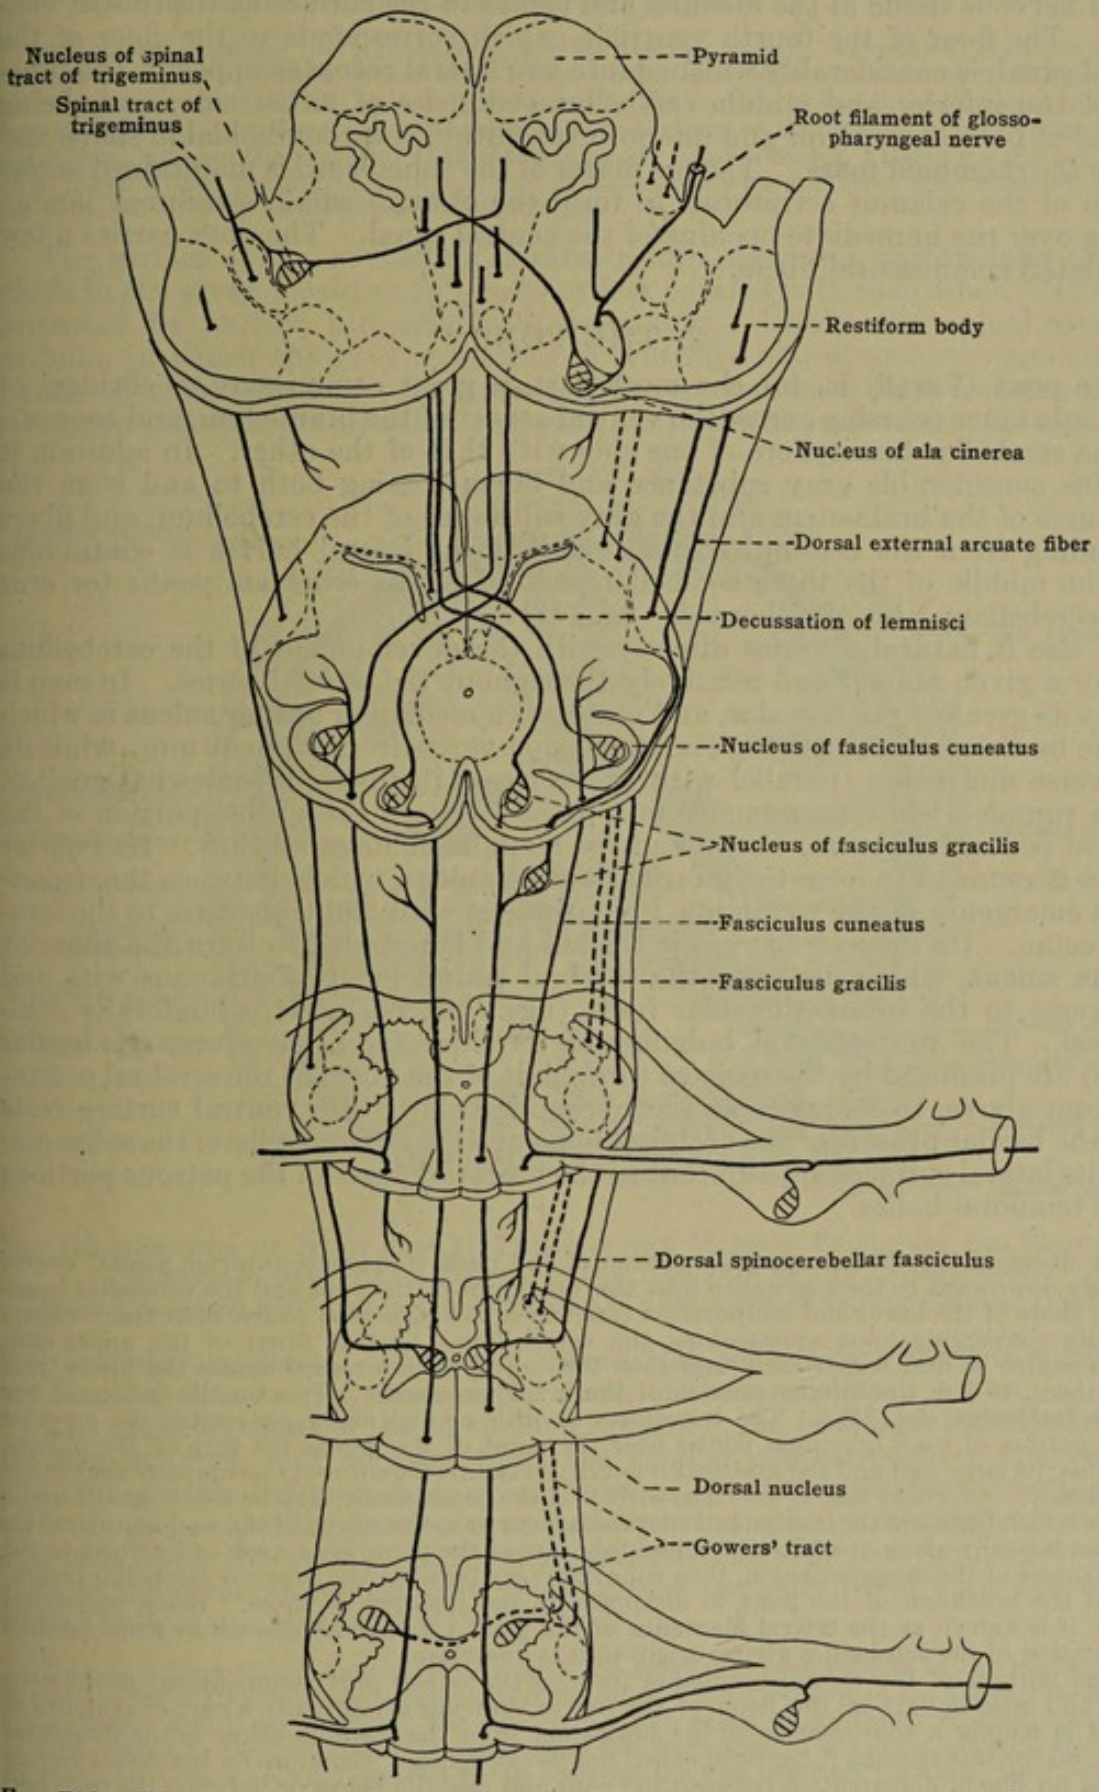

FIG. 711.—DIAGRAM OF THE SPINOCEREBELLAR FASCICULI AND THE ORIGIN AND DECUSSATION OF THE MEDIAL LEMNISCI.

With the termination of the dorsal funiculi and the ventral course of the fibers of the lemnisci in their decussation, the central canal of the spinal cord loses its roof of nervous tissue in the medulla and comes to the surface as the fourth ventricle. The floor of the fourth ventricle, which corresponds to the floor of the central canal, is considerably widened into two **lateral recesses** opposite the junction of the inferior and middle cerebellar peduncles of either side, and, being pointed at both its superior and inferior extremities, it is rhomboidal in shape and thus is the **rhomboid fossa.** The pia mater of the spinal cord is maintained across the tip of the calamus scriptorius to form the **obex,** a small, semilunar lamina roofing over the immediate opening of the central canal. The obex carries a few medullated commissural fibers.

2. THE PONS

The **pons (Varoli)** is, for the most part, a great commissure or 'bridge' of white substance coursing across the ventral aspect of the brain-stem, and connecting the cerebellar hemisphere of one side with that of the other. In addition it contains considerable gray substance and fibers passing both to and from the structures of the brain-stem and the gray substance of the cerebellum, and fibers descending from the cerebral cortex. Each of its lateral halves is continuous into the middle of the three cerebellar peduncles, the *brachium pontis* (or crus pontocerebellare NK) of either side (fig. 747).

In size it naturally varies directly with the development of the cerebellum both in a given animal and relatively throughout the animal series. In man it attains its greatest relative size, and possesses a median or **basilar sulcus** in which lies the basilar artery. Its sagittal dimension varies from 25 to 30 mm., while its transverse dimension (parallel with the course of its fibers) is somewhat greater. It is a rounded white prominence interposed between the visible portion of the cerebral peduncles (crura) above and the medulla oblongata below. Its *inferior margin* is rounded to form the **inferior pontine sulcus,** which, between the region of the emergence of the pyramids, is continuous with and transverse to the foramen cecum. Its *superior margin* is thicker and is rounded to form the **superior pontine sulcus,** which, between the cerebral peduncles, is continuous with and transverse to the interpeduncular fossa (figs. 705, 747). It is bilaterally symmetrical. The ventrolateral bulgings of its sides (and, therefore, the basilar sulcus) are produced by the passage through it of the fibers of the cerebral peduncles from above, to reappear as the pyramids below. Its ventral surface rests upon the basilar process of the occipital bone and the dorsum sellæ of the sphenoid, while its lateral surfaces are adjacent to the posterior parts of the petrous portions of the temporal bones.

The fibers of the thicker superior portion of the pons (*fasciculus superior pontis*) course obliquely downward to their entrance into the brachium of the pons and the cerebellar hemisphere; those of the lower and midportions (*fasciculus medius pontis*) course more transversely, naturally converging upon approaching the cerebellum. Certain fibers of the upper midportion course at first transversely and then turn abruptly downward across the fibers from above them, to join the inferior portion of the brachium pontis. This bundle is termed the **oblique fasciculus** (fig. 747). The *trigeminus* or fifth cranial nerve penetrates the superior lateral portion of each brachium pontis near the point of the downward turn of the oblique fasciculus; its large root and the masticator nerve (its small efferent root) accompany each other quite closely. On either side of the basal surface of the pons usually may be seen a small bundle of fibers which begins in the interpeduncular fossa, near or in the sulcus of the oculomotor nerve. It passes laterally along or under the superior border of the pons, loses some of its fibers in the lateral sulcus of the mesencephalon, then runs inferiorly between the superior cerebellar peduncle and the brachium of the pons to disappear in the junction of these. Being sometimes double, it is known as the **lateral filaments of the pons** (*fila lateralia pontis* or *tenia pontis*). The location of the cell-bodies giving origin to it is uncertain.

That portion of the rhombencephalon forming the dorsal part (tegmentum) of the pons region and making part of the floor of the fourth ventricle is not really a part of the pons at all. It is merely a continuation of the brainstem from the medulla below to the structures above and for this reasons it has been called the *preoblongata.* Therefore on the *dorsal surface* there is no line of demarcation between the pons and medulla below or between the pons and isthmus above. The fibers of the trigeminus and masticator nerve pass through the pontine fibers to and from their nuclei in the brain-stem.

3. THE CEREBELLUM

The **cerebellum** or *hindbrain* is the largest portion of the rhombencephalon. It lies in the posterior or cerebellar fossa of the cranium, and dorsal to the pons and

medulla oblongata, overhanging the latter. It fits under the occipital lobes of the cerebral hemispheres, from which it is separated by a strong duplication of the inner layer of the dura mater, the *tentorium cerebelli*.

Its greatest diameter lies transversely, and its average weight, exclusive of the dura mater, is about 140 gm., or about 10 per cent. of the entire encephalon. It varies in development with the cerebrum, and, like it, averages larger in the male. It is relatively larger in adults than in children. Its development begins as a thickening of the anterolateral portion of the roof (dorsal zone) of the posterior of the three primary brain-vesicles. Resting upon the brain-stem, it roofs over the fourth ventricle and is connected with the structures anterior, below, and posterior to it by its three pairs of peduncles.

The surface of the cerebellum is thrown into numerous narrow **folia** or **gyri**, which in the given localities run more or less parallel with each other. They are separated by narrow but relatively deep **sulci**. Unlike the spinal cord and medulla, in which the gray substance is centrally placed and surrounded by a mantle of white substance, the surface of the cerebellum is itself a cortex of gray substance [substantia corticalis], enclosing a core of white substance, the *medullary*

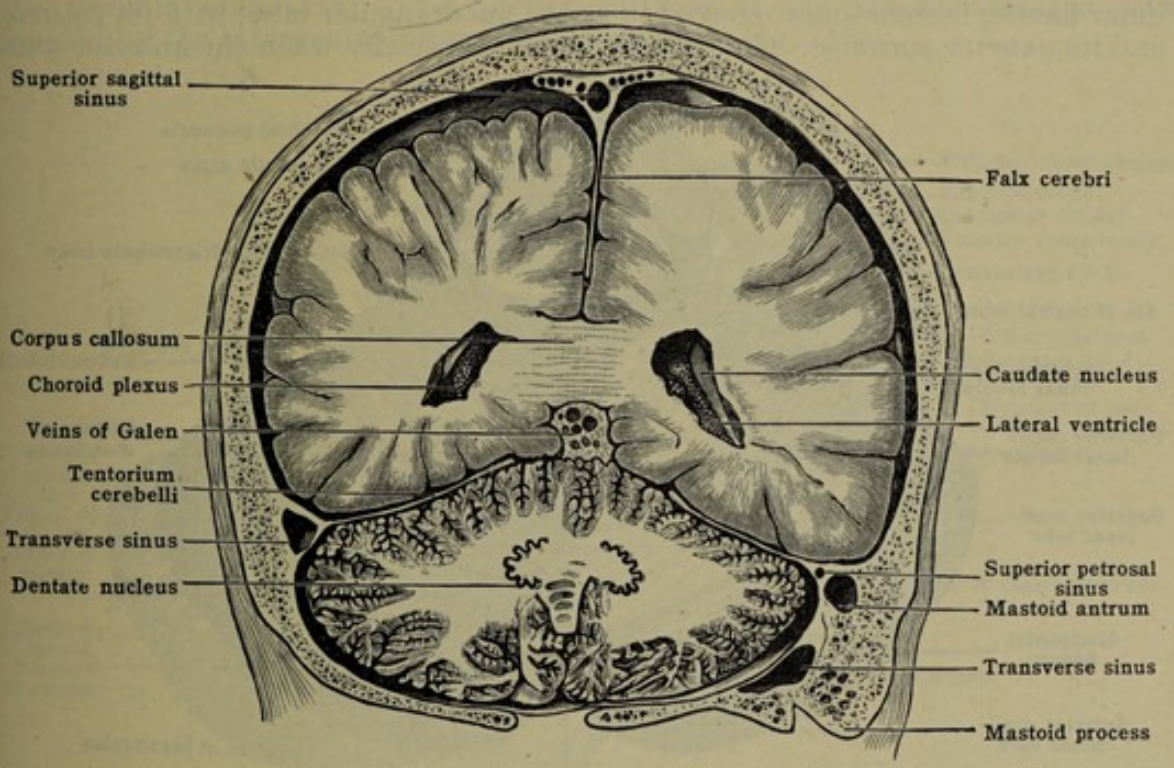

FIG. 712.—SECTION OF HEAD PASSING THROUGH THE MASTOID PROCESSES AND BEHIND THE MEDULLA OBLONGATA, SHOWING THE POSITION OF THE CEREBELLUM.
(From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)

body [corpus medullare]. However, within this central core of white substance are situated definite gray masses, the *nuclei* of the cerebellum.

The **gross divisions** of the cerebellum are three: the two larger lateral portions, the **hemispheres,** and between these the smaller central portion, the **vermis.** The demarcation between these gross divisions is not very evident from the dorsal surface, because the hemispheres in their extraordinary development in man encroach upon the vermis, and, being pressed under the overlapping occipital ends of the cerebral hemispheres, they become partially fused upon the vermis along the dorsal midline (fig. 713).

Though differentiated simultaneously with the cerebellar hemispheres in the human fetus, in most of the mammalia, the vermis is the largest and most evident of the parts during early development, and it is practically the only part which exists in the fishes, reptiles, and birds. In man, owing to the fact that the vermis does not keep pace in development with the hemispheres, there results a very decided notch between the two hemispheres along the line of the entire ventral and inferior aspect of the cerebellum, the floor of this notch being the surface of the vermis (fig. 715).

The inferior portion of the notch between the hemispheres is the **posterior cerebellar notch** (incisura marsupialis); its prolongation above is wider than below, and is termed the **superior cerebellar notch.** It is occupied by a fold of the dura mater, the falx cerebelli. With the variations in contour of the cere-

bellum, certain of its sulci are broader and deeper, and merit the name **fissures.** These are more or less definitely placed, and subdivide the hemispheres into **lobes** and the vermis (the median lobe) into **lobules.**

Superior surface.—The superior surface (facies tentoralis NK) is bounded from the inferior surface by the **horizontal fissure** (fig. 713) which extends anterolaterally, to the entrance of the brachium of the pons. Between this and the extreme anterior border of the dorsal surface are two other fissures, the **posterior** and **anterior semilunar fissures.** These, like the horizontal fissure, may be traced, with slight interruptions, across the midline, and consequently mark off not only the two hemispheres but also the vermis into corresponding divisions.

The **superior semilunar lobe** [lobulus semilunaris superior] (posterosuperior lobe) of each hemisphere lies between the horizontal and the posterior semilunar fissures. It largely composes the outer border of the cerebellum, and, therefore, is the longest of the lobes.

The adjacent surface of the hemispheres anterior to the superior semilunar lobe, because of the frequently less complete development of the anterior semilunar fissure, is sometimes referred to as the **quadrangular lobe,** with its *posterior* and its *anterior portions.* On the other hand, especially when the anterior semi-

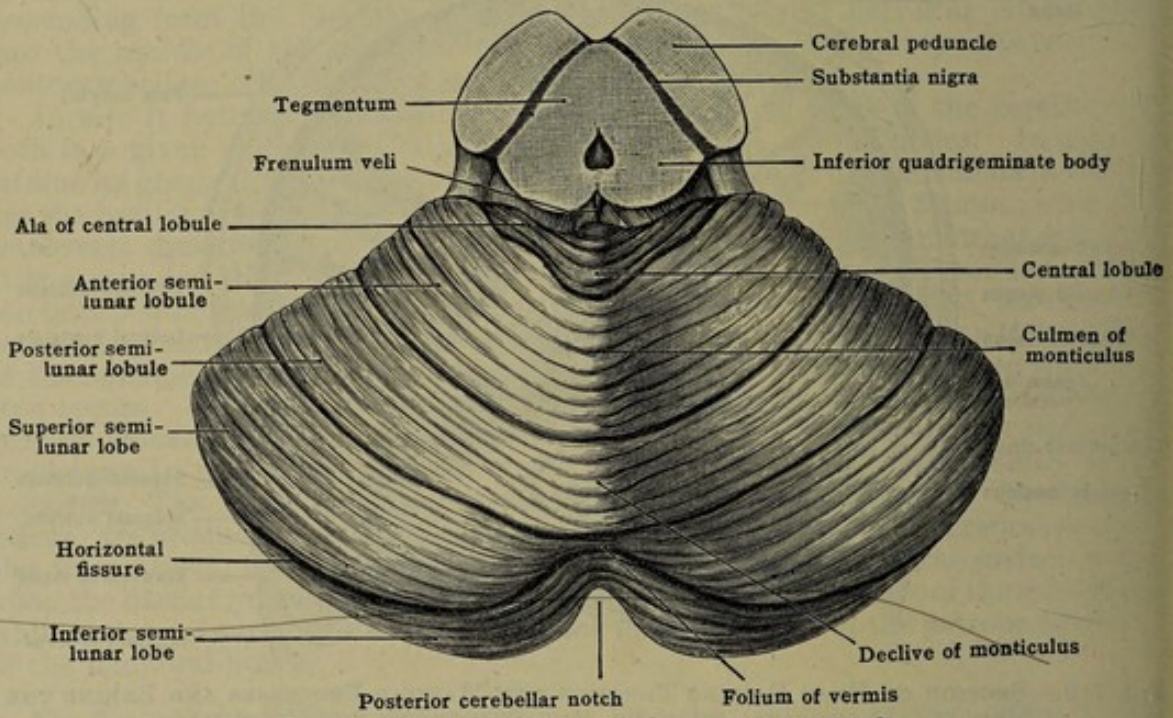

FIG. 713.—DIAGRAM OF THE SUPERIOR SURFACE OF THE CEREBELLUM.
(The anterior and posterior semilunar lobes form the quadrangular lobe.)

lunar fissure is well marked, this area may be divided into—(1) the *posterior semilunar lobule,* between the posterior and anterior semilunar fissures, and (2) the *anterior semilunar lobule,* anterior to the anterior semilunar fissure (fig. 713).

Anterior to the quadrangular lobe on each hemisphere is the **ala of the central lobule** bounded by the postcentral and the precentral sulci. Anterior to this, on the anterior margin of the hemisphere, is the **vinculum lingulæ,** a slender process continuous with the lingula of the cerebellum (fig. 738).

The superior aspect of the vermis, the **superior vermis,** because of the fusion of the hemispheres, is, for the most part, a slight ridge, the **monticulus** (fig. 713), instead of a depression. However, in the posterior portion of the superior surface the depression of the posterior notch begins, and here the horizontal and the posterior semilunar fissure approach each other so closely that the corresponding subdivision of the vermis is seldom more than a single folium, the **folium vermis** (*cacuminis*).

The monticulus proper is divided into an inferior lobule, the **declive,** and a superior lobule, the **culmen.** These appear as continuations across the midline of the posterior and anterior semilunar lobes of the hemispheres, and are separated by the corresponding fissures (fig. 713).

At the extreme anterior part of the superior surface and in the bottom of the anterior cerebellar notch lies a more definitely defined portion of the vermis.

This is the **central lobule** (fig. 713). It is broadened laterally into two pointed wings, the *alæ* of the central lobule, the folia of which, if present, are parallel with those of the anterior semilunar lobes and separated from them by the **post-central sulcus.**

If the anterior margin of the central lobule be lifted, the **lingula cerebelli** (*lingula vermis*) will appear separated from the central lobule by the **precentral sulcus.** It is a thin, tongue-like anterior projection of the cortical substance comprising four to eight folia adhering upon the *anterior medullary velum*, the roof of the superior portion of the fourth ventricle (figs. 714, 738).

Inferior surface.—The three cerebellar peduncles of each side join to form a single mass of white substance, and enter the ventral aspect of each hemisphere medially and ventrally in the extremity of the horizontal fissure. The inferior surface of the cerebellum is less convex than the superior surface. The hemispheres are decidedly separated by a continuation of the posterior cerebellar notch, which becomes broader, the **vallecula of the cerebellum,** which contains the inferior portion of the vermis, **vermis inferior,** and whose margins embrace the medulla oblongata. The inferior surfaces of the hemispheres are each divided by the intervening fissures into four lobes (fig. 715).

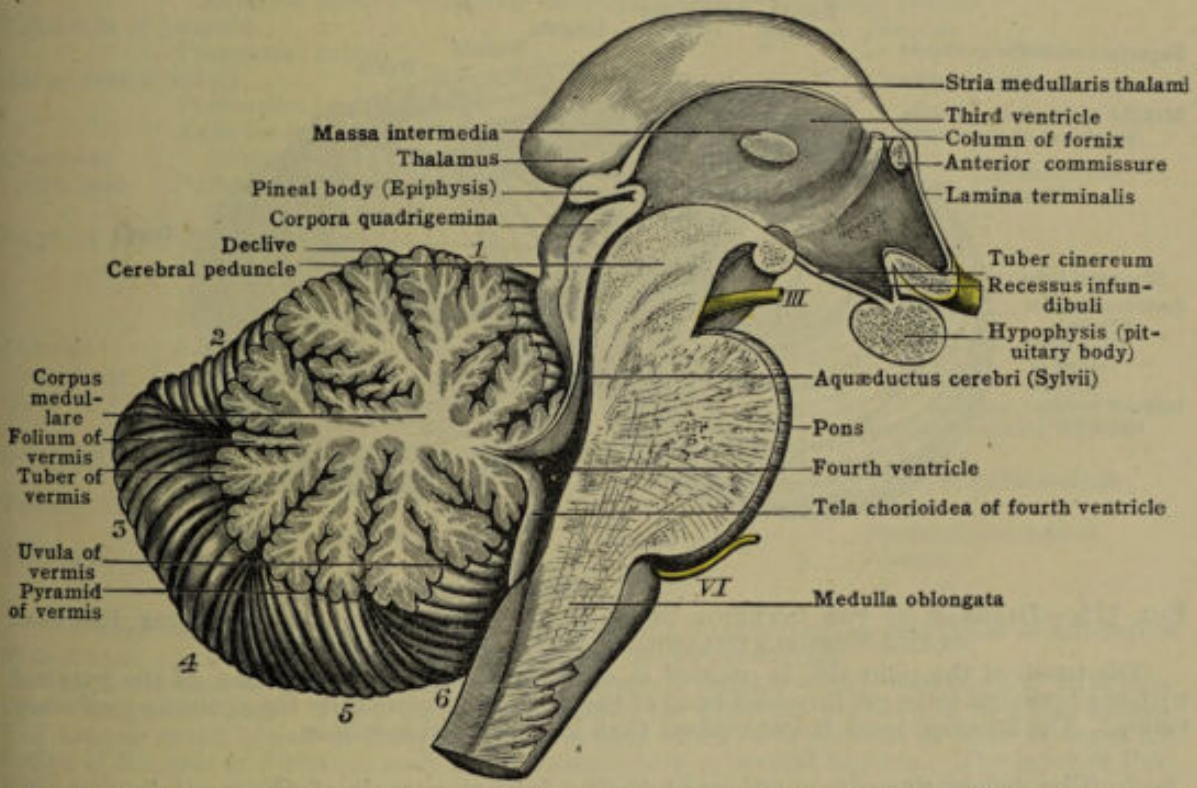

FIG. 714.—MEDIAN SECTION THROUGH CEREBELLUM AND BRAIN-STEM. (Allen Thomson after Reichert.)

1. Culmen monticuli; 2, superior semilunar lobe; 3, inferior semilunar lobe; 4, slender lobe; 5, biventral lobe; 6, tonsil.

Below, the **inferior semilunar lobe** (posteroinferior lobe) is separated from the superior semilunar lobe of the superior surface by the horizontal fissure. It is the largest of the inferior lobes, and is broader at its medial extremity. Frequently two and sometimes three of its curved sulci appear deeper than others, and separate it into two or three **slender lobules** [lobuli graciles]. More commonly there are two of these, the *lobulus gracilis posterior* and *lobulus gracilis anterior*, separated by the *posteroinferior sulcus.*

The **biventral lobe** is smaller and more curved than the inferior semilunar lobe, from the anterior margin of which it is separated by the curved **anteroinferior sulcus.** Its medial extremity is pointed and does not extend to the vermis; its lateral extremity is broader and curves anteriorly to the extremity of the horizontal fissure—the line of outer termination of the inferior semilunar lobe.

The **tonsil** [tonsilla cerebelli] (*amygdala*) is a rounded, triangular mass, placed medially within the inner curvature of the biventral lobe, and separated from it by the **retrotonsillar fissure.** Its inferior medial border slightly overlaps the vermis.

The smallest of the lobes is the **flocculus.** It lies adjacent to the inferior and lateral surface of the mass of white substance produced by the confluence of the three cerebellar peduncles, and extends into the medial extremity of the horizontal fissure. It is so flattened that its short folia give it the appearance suggesting its name. Occasionally there is added a second, less perfectly formed portion, the *secondary flocculus.* From each floccular lobe there passes toward the midline a thin band of white substance, the **peduncle of the flocculus.** From the flocculi of the two sides the peduncles extend to meet each other at the most anterior portion of the inferior vermis, and thus form the narrow **posterior medullary velum.**

The **inferior vermis** (figs. 714, 715) is more definitely demarcated than the superior. Lying in the floor of the vallecula cerebelli, it is separated on each side from the adjacent lobes of the hemispheres by a well-marked sulcus about it, the *nidus avis.* By contour and by deeper transverse fissures (sulci) occurring at intervals across it, four divisions or lobules of the inferior vermis are recognized. These lobules, like those of the superior vermis, are each in intimate relation with the pair of lobes of the hemispheres adjacent to it on either side.

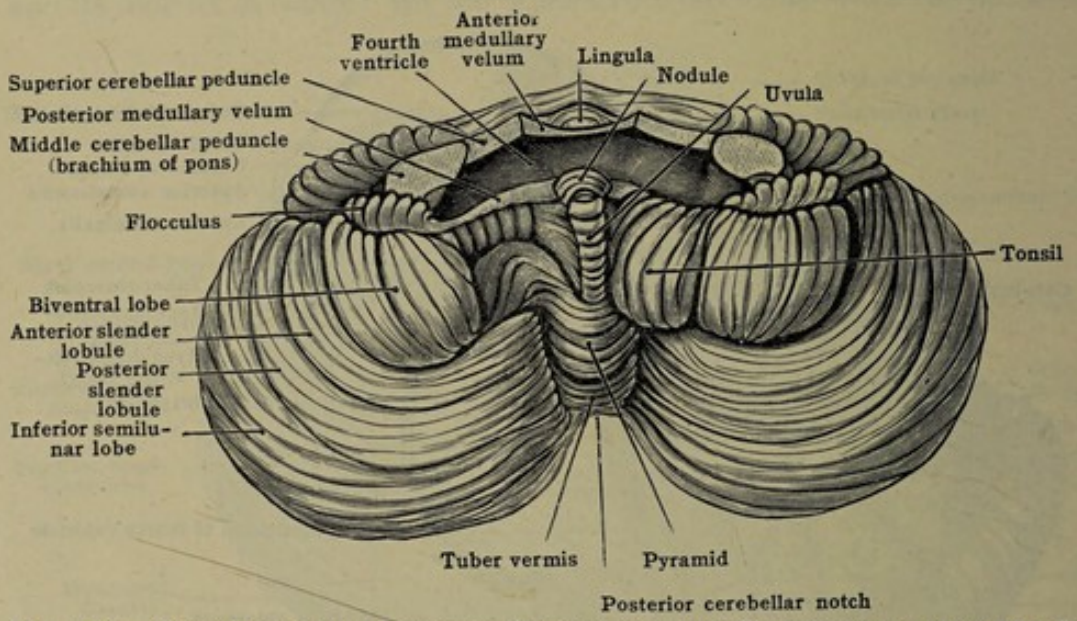

FIG. 715.—DIAGRAM OF THE INFERIOR SURFACE OF THE CEREBELLUM AFTER THE REMOVAL OF THE MEDULLA OBLONGATA, PONS, AND MESENCEPHALON.

The tonsil of the right side is omitted in order to display the connection of the pyramid with the biventral lobe, the furrowed band of the uvula, and more fully the posterior medullary velum. The anterior notch is less evident than in the actual specimen.

1. The **tuber vermis** is adjacent to the folium vermis of the superior aspect. It is a short, somewhat pyramidal-shaped division, whose four or five transversely arranged folia are continuous with the folia of the inferior semilunar lobes on either side.

2. The **pyramid** is separated from the tuber vermis by the *postpyramidal sulcus.* Its several folia cross the vallecula cerebelli and curve to connect with the biventral lobes on either side.

3. The **uvula** is separated from the pyramid by the *prepyramidal sulcus.* It is triangular in shape. Its base or broader superior portion appears as two laterally projecting ridges of gray substance, the **furrowed bands** or *alæ uvulæ,* which extend across the floor of the nidus avis and under the medial margins of the tonsils on either side. In these bands its folia curve and become continuous with the tonsils. The uvula and the two tonsils are sometimes referred to collectively as the *uvular lobe.*

4. The **nodule** is the smallest and most anterior division of the inferior vermis. It is separated from the uvula by the **postnodular sulcus,** and is closely associated anteriorly with the posterior medullary velum, the transverse continuation of the peduncles of the floccular lobes.

Internal structure of the cerebellum (figs. 714, 716).—The white substance of the cerebellum is continuous with its peduncles and forms a compact central mass [corpus medullare]. Over the surface of this the gray substance or cortex

is spread in a thin but uniform and much folded layer. Upon section of the cerebellum certain of the sulci as well as the fissures are shown to be much deeper than is apparent from the surface. The deeper sulci separate the lobes into divisions, the **medullary laminæ,** each of which is composed of a number of folia and each of which has its own core of white substance. The folia of the laminæ line the sulci (and fissures), and also comprise their surface aspect, and are separated by the shallow, *secondary sulci.* The larger laminæ are subdivided into from two to four secondary laminæ of varying size. Such subdivision is especially marked in the vermis. Here each lamina comprises a lobule and is, therefore, separated by a fissure, and each lobule is usually subdivided, with the exception of the nodule, the folium, and the lingula. In sagittal sections, or sections transverse to the general direction of the sulci, this arrangement of the laminæ gives a foliate appearance, which, especially in sagittal sections of the vermis, is termed the **arbor vitæ** (fig. 714).

SUMMARY OF EXTERNAL FEATURES OF CEREBELLUM

Superior Surface

HEMISPHERE		VERMIS	
Anterior border—Anterior medullary velum—Anterior border			
Vinculum of Lingula		*Lingula*	
Precentral sulcus			
Ala of central lobule		*Central lobule*	
Postcentral sulcus			
Quadrangular lobe	*Anterior semilunar lobule*	*Culmen*	*Monticulus*
	Anterior semilunar fissure		
	Posterior semilunar lobule	*Declive*	
	Posterior semilunar fissure		
Superior semilunar lobe		*Folium*	
Horizontal Fissure			

Inferior Surface

Horizontal Fissure			
Inferior semilunar lobe	*Posterior slender lobule*		*Tuber*
	Posteroinferior sulcus		
	Anterior slender lobule		
Anteroinferior sulcus		Postpyramidal sulcus	
Biventral lobe		*Pyramid*	
Retrotonsillar fissure		Prepyramidal sulcus	
Tonsil		*Uvula*	
Horizontal Fissure		Postnodular sulcus	
Flocculus		*Nodule*	
Posterior medullary velum			

The **cerebellar cortex** consists of three layers and contains four general types of cell-bodies of neurones, all of which possess features peculiar to the cerebellum.

The outermost or **molecular layer** contains small **stellate cells,** 'basket cells,' with relatively long dendrites. These serve to associate the different portions of a given folium. The axones of the largest of them give off branches which form pericellular baskets about the bodies of the *cells of Purkinje,* each axone contributing to several baskets. The **layer of Purkinje cells,** or the middle layer, is quite thin. The bodies of the cells of Purkinje are arranged in a single layer, and their elaborate systems of dendrites extend throughout and largely compose the molecular layer. The dendrites of these, the most essential cells of the cortex, are displayed in the form of arborescent fans (see fig. 684), arranged parallel with each other and transverse to the long axis of the folium containing them. Their axones are given off from the base of the cell-body and acquire their medullary sheaths quite close to the cell-body, and, after giving off several collaterals in the inner layer, pass into the general white substance and thence to other laminæ or lobes. Many of them go to structures outside the cerebellum. The inner layer is the **granular layer.** It contains numerous small nerve-cells or 'granule-cells' which possess from two to five radiating dendrites, unbranched except at their termination, which occurs suddenly in the form of three to six claw-like twigs. Their axones are given off either from the cell-body direct or more often from the base of one of the dendrites, and pass outward into the molecular layer, where they bifurcate and course in both directions parallel to the long axis of the folium, to become associated with the dendrites of the cells of Purkinje. In the layer of the cells of Purkinje there is situated at intervals a neurone of the Golgi type II (see fig. 684). The short, elaborately branched axone of this neurone is distributed among the cells of the granular layer. Axones conveying impulses to the cerebellar cortex terminate upon the granule cells in the granular layer as '*moss fibers,*' or directly upon the cells of Purkinje as '*climbing fibers,*' and probably upon the 'basket' cells and the cells of the Golgi type II.

Thus the neurones which receive impulses coming to the cortex are the cells of Purkinje, probably the Golgi cells of type II, the basket-cells and the granule-cells; those which distribute these impulses to other neurones of the folia are the Golgi cells of type II, the granule-cells, and the basket-cells (association neurones), and the collaterals of the cells of Purkinje. Impulses are conveyed from the cortex of a folium to that of other folia, lamina, lobules or lobes, or to the nuclei of the cerebellum, or to structures outside the cerebellum by the axones of the cells of Purkinje.

The **nuclei of the cerebellum** (figs. 716, 730) are in its central core [corpus medullare] of white substance. They are four in number, and all are paired, those of each pair being situated opposite each other on either side of the midline. They include (1) the dentate nucleus, (2) nucleus emboliformis, (3) nucleus globosus, and (4) roof-nucleus.

1. The largest of the cerebellar nuclei is the **dentate nucleus.** This is an isolated mass of gray substance situated in the core of white substance of each hemisphere. It is in the form of a folded or corrugated cup-shaped lamina, with the opening of the cup (*hilus*) directed anteriorly and obliquely toward the midline. It contains a mass of white substance and possesses a capsule. Its cell-bodies give rise to most of the fibers forming the superior cerebellar peduncles. It receives its impulses from axones of Purkinje cells and some direct from the axones of the spinocerebellar fasciculi.

2. The **nucleus emboliformis** is an oblong and much smaller mass of gray substance, which lies immediately medial to the hilus of the dentate nucleus. It is probably of the same significance as the dentate nucleus, being merely a portion separated from it.

3. The **nucleus globosus**, the smallest of the cerebellar nuclei, is an irregular horizontal mass of gray substance with its larger end placed in front. It lies close to the medial side of the nucleus emboliformis (fig. 730), and often appears separated into two or more rounded or globular masses.

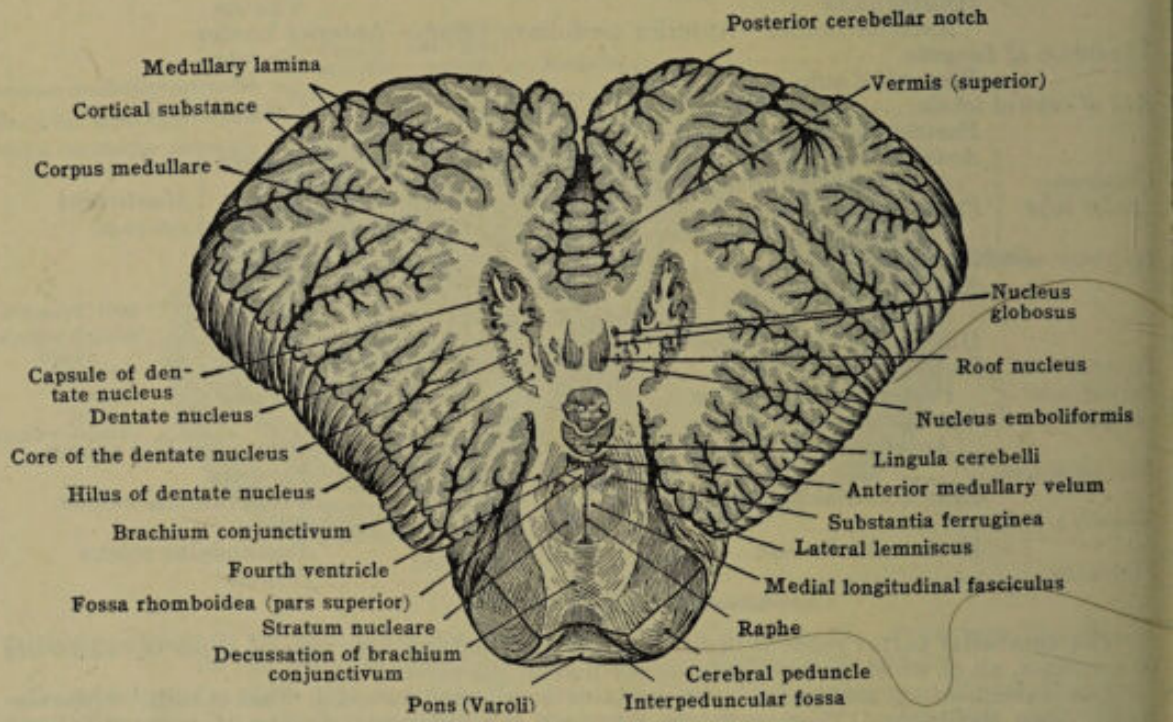

FIG. 716.—SECTION OF CEREBELLUM AND BRAIN-STEM PASSING OBLIQUELY THROUGH INFERIOR PORTION OF CEREBELLUM TO SUPEROIR MARGIN OF PONS. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

4. The **roof-nucleus** [nucleus fastigii] is the second largest of the cerebellar nuclei, and is the most mesially placed. The pair is situated in the roof of the fourth ventricle, and so near the midline that both nuclei are in the white substance of the vermis. They are ovoid in shape, and the nucleus of one side receives axones from the nucleus of the vestibular nerve chiefly of the opposite side, the decussation of these axones taking place in the vermis. Its cells are larger than those of the two first-mentioned nuclei.

The peduncles of the cerebellum.—The peduncles consist of three pairs—the inferior, middle, and superior. The three peduncles of each side come together at the level of the lower border of the pons, and the entering and emerging fibers of which they are composed become continuous with the central core of white substance of the cerebellar hemispheres (figs. 710, 716, 717, 718).

The **restiform body** (fig. 718) of the medulla oblongata is the inferior peduncle. (crus medullocerebellare NK). It forms the lateral boundary of the inferior portion of the fourth ventricle, and upon reaching the level of the pons turns sharply backward into the cerebellum. In the region of the turn it is encircled externally by fibers of the cochlear nerve. It contains fibers, both ascending and descending, between the cortex and nuclei of the cerebellum and the structures below the cerebellum.

Its fibers include: (1) fibers from the spinal cord including the dorsal spinocerebellar fasciculus (direct cerebellar tract) and probably a small proportion of the ascending fibers of

the superficial ventrolateral spinocerebellar fasciculus (Gowers' tract); (2) fibers from the olive of the same but chiefly from that of the opposite side of the medulla oblongata; (3) fibers from the nuclei of the funiculus gracilis and cuneatus of the same and opposite sides (dorsal and ventral external arcuate fibers); (4) fibers to the olive of the opposite side; (5) fibers from the nuclei of termination of the sensory cranial nerves, especially those of the vestibular nerve; (6) fibers to the nuclei of the motor cranial nerves; (7) fibers descending to the ventral horn cells of the spinal cord. The ascending or afferent fibers of the spinocerebellar and cerebello-olivary fasciculi are the principal components of the inferior peduncle; the existence of fibers (5) and (6) is not well established. The fibers of the direct cerebellar tract terminate in the cortex of the superior vermis of both sides of the midline, but, for the most part, in that of the same side. The olivary fibers end in the cortex of both the superior vermis and the adjacent cortex of the hemispheres, and some of them terminate in the nucleus dentatus.

The **brachium pontis** or the middle peduncle (crus pontocerebellare NK) (figs. 718, 736) is the largest of the three cerebellar peduncles. In it the pons

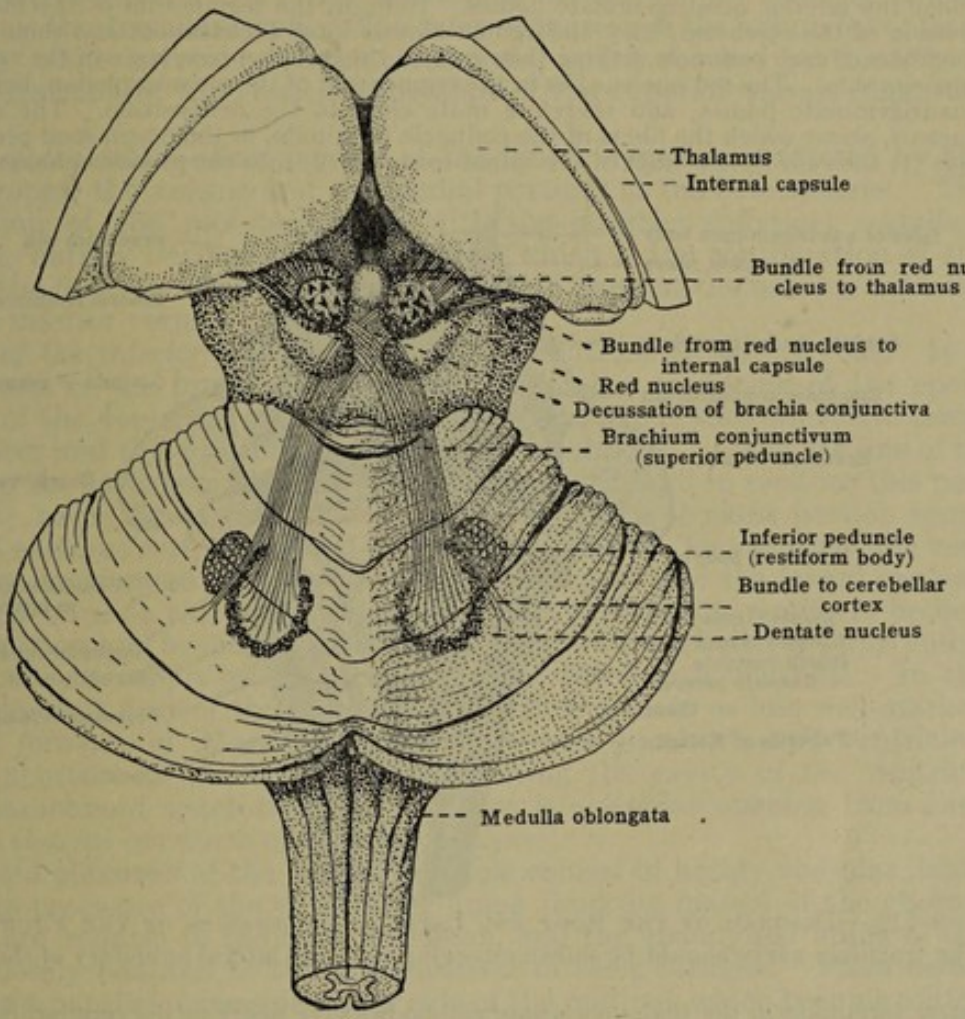

FIG. 717.—TRANSPARENCY DRAWING SHOWING THE ORIGIN, COURSE, AND CONNECTIONS OF THE SUPERIOR CEREBELLAR PEDUNCLES (BRACHIA CONJUNCTIVA) IN THE RESEMBLANCE KNOWN AS 'STILLING'S SCISSORS.'

fibers pass into the cerebellar hemisphere, between the lips of the anterior part of the horizontal fissure, entering lateral to the inferior peduncle.

It consists of the transverse fibers of the pons, and within the cerebellum its fibers are distributed in two main groups—the upper transverse fibers of the pons apparently pass downward to radiate in the lower portion of the hemisphere, while the lower transverse fibers pass upward and medialward to radiate in the superior part of the hemisphere and vermis. For the most part the fibers of the middle peduncle may be considered as commissural fibers, passing from one side of the cerebellum to the other. Each peduncle contains fibers coursing in opposite directions. Many of these fibers are interrupted in their course to the opposite side by cells scattered throughout the pons, *nuclei pontis*, and, therefore, in each brachium pontis some of the fibers are processes of the cells of the cerebellum and course toward the opposite side, while others are processes of the cells of the pontine nuclei, which receive impulses from cerebellar axones, and course to the cerebellar hemisphere chiefly of the same side. Many cell-bodies of the nuclei of the pons whose axones terminate in the cerebellum receive impulses from fibers descending from the *cerebral* cortex of the opposite side—*corticopontine fibers*. Furthermore, there are evidences after degeneration that the brachium pontis also contains a few fibers to and from the cerebellum and the structures of the brain-stem and spinal cord.

The **brachium conjunctivum** or superior peduncle (crus cerebrocerebellare NK) (figs. 717, 718) emerges from the cerebellum on the medial side of the brachium pontis and also on the superior and medial side of the course of the restiform body. It forms the lateral boundary of the superior portion of the fourth ventricle and is the cerebello-cerebral peduncle. Its transverse section appears semilunar in shape, with the concave side next to the cavity of the ventricle. The medial border, which inclines toward the midline, is connected with that of the corresponding peduncle of the opposite side by the *anterior medullary velum*, which thus roofs over the superior part of the fourth ventricle. The lateral border is bounded from the pons by an open furrow or lateral sulcus.

The superior cerebellar peduncles are almost entirely efferent pathways as to the cerebellum and form the chief connections between the cerebellum and the cerebrum. They arise almost wholly from the dentate nuclei. As they course forward they converge slightly and disappear under the inferior quadrigeminate bodies. Here, in the tegmentum of the mesencephalon, a division of the cerebrum, they undergo an almost total **decussation,** and then the majority of the fibers of each peduncle, having thus crossed the midline, terminate in the *red nucleus* of the opposite side. The red nucleus lies in the tegmentum of the mesencephalon, below the superior quadrigeminate bodies, and therefore quite close to the decussation. The cells of the red nucleus, about which the fibers of the peduncle terminate, in their turn send processes (axones) into (1) the rubrospinal tract of the spinal cord and (2) into the prosencephalon, most of which

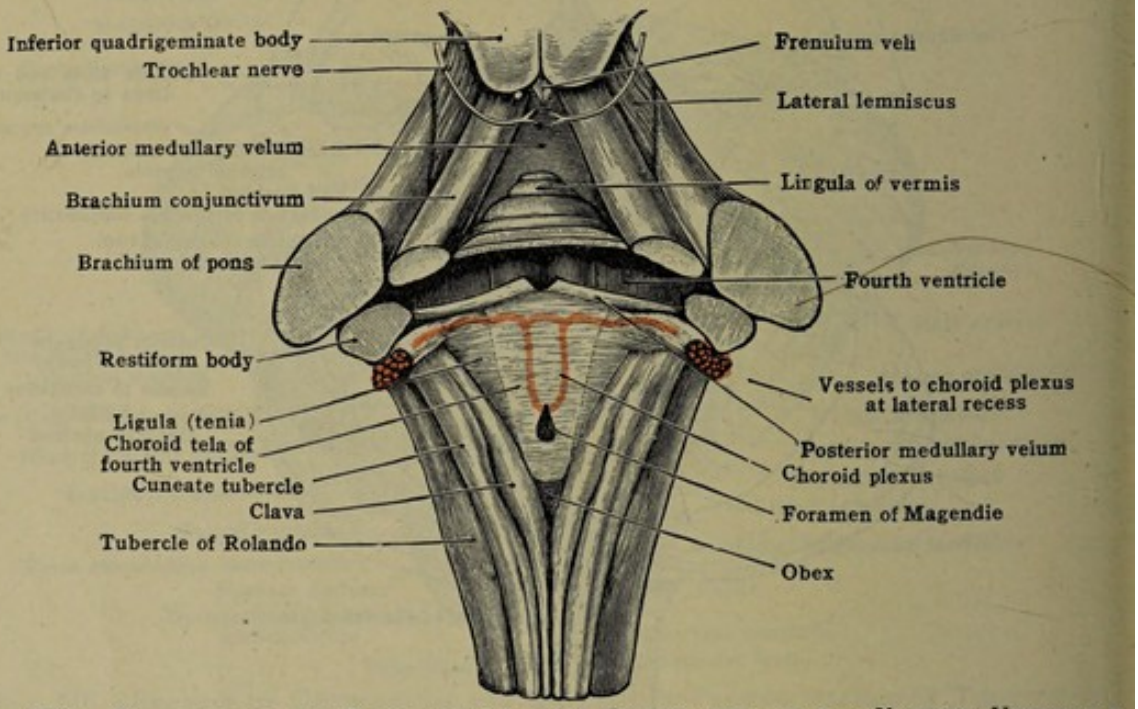

FIG. 718.—DIAGRAM OF THE ROOF AND LATERAL BOUNDARIES OF THE FOURTH VENTRICLE. The trochlear nerve should be shown emerging from the lateral boundary of the frenulum veli.

latter terminate in the thalamus whose cell-bodies give fibers to the cerebral cortex by way of the internal capsule, though some pass from the red nucleus under the thalamus to join the internal capsule.

In addition to the fibers having the origin and course described above, and which constitute the greater mass of the superior cerebellar peduncle, each peduncle is said to contain fibers which—(1) arise in the cerebellar cortex of the same and opposite sides, instead of from the dentate nucleus of one side only, and which join the peduncle at the side of the dentate nucleus, between it and the restiform body; (2) fibers which do not cross the midline in the decussation, but terminate in the red nucleus of the same side; (3) some fibers are not interrupted in the red nucleus, but pass directly into the thalamus; (4) a small proportion of fibers to the cerebellum, which arise in the structures of the cerebrum and pass into the cerebellum; and (5) the greater part, if not all, of the ascending fibers of the superficial ventrolateral spinocerebellar fasciculus (Gowers' tract) of the spinal cord. The latter, instead of entering the cerebellum by way of the restiform body, are deflected in the upper medulla and pass in the lateral tegmentum of the pons to the anterior medullary velum, where they turn backward to enter the cerebellum in its superior peduncle and pass to its cortex, probably by way of the lateral side of the dentate nucleus (see fig. 735). (See also the Extrapyramidal System.)

The anatomy of the fourth ventricle.—The fourth ventricle (figs. 710, 714, 718, 719) is rhomboidal in shape, being considerably widened at the level of the brachia pontis and pointed at each end. Its floor consists of a slight depression in the brain-stem, the *fossa rhomboidea*, and corresponds to the floor of the central canal. Its pointed inferior end, the **calamus scriptorius,** is directly continuous

with the central canal, and its narrowed superior end is continued into the aqueductus cerebri (Sylvii) of the mesencephalon, which is nothing more than a resumption of the tubular form of the canal.

The entire cavity of the ventricle is lined with an epithelium which is continuous with the epithelioid ependyma of the central canal below and the aqueduct above. The entire ventricle involves the *isthmus of the rhombencephalon*, the *metencephalon* and a portion of the *medulla oblongata*. It is divided for study into an inferior, an intermediate and a superior part.

The *roof of the superior portion* of the fourth ventricle is nervous, consisting of a thin lamina of white substance, the *anterior* (superior) *medullary velum*, thickened at the sides by the brachia conjunctiva. At its extreme mesencephalic end (in the isthmus of the rhombencephalon) the anterior medullary velum is slightly thickened by a continuation of the white substance of the inferior quadrigeminate bodies, forming the **frenulum veli.** The inferior portion of the velum is continuous with the white substance of the cerebellum, and is covered by the *lingula cerebelli*, an extension of the cortical substance of the superior vermis (figs. 710, 718).

The *roof of the intermediate portion* of the fourth ventricle is formed by the cerebellum proper, the vermis and the medial portions of the hemispheres. The nervous portion of the roof terminates with the *posterior* (inferior) *medullary velum*, a thin, narrow band of white substance which is the continuation of the peduncles of the floccular lobes, and which connects them at the midline with the nodule of the inferior vermis.

The *roof of the inferior portion* of the fourth ventricle is non-nervous. It is the **choroid tela** of the fourth ventricle, a thin lamina consisting of the ependymal lining of the ventricle, reinforced by a continuation of the connective tissue of the pia mater and the adjacent portion of the arachnoid. Along the line of its attachment to the surface of the medulla it is thickened, and in sections this portion bears the name **ligula** [*tenia ventriculi quarti*]. The thickest portion spans the tip of the calamus scriptorius and is termed the **obex.** The width of the ventricular cavity is extended laterally from its widest part into the *lateral recesses*, narrow pockets on each side and around the upper parts of the restiform bodies, inferior to the choroidal branches of the posterior inferior cerebellar arteries entering on each side to supply the choroid plexus of the fourth ventricle. In the midline of the lower part of the choroid tela there is a more or less well-marked opening, the *foramen of Magendie* (medial aperture of the fourth ventricle), which is an aperture in the ependyma connecting the cavity of the ventricle with the subarachnoid space (fig. 718). There is a similar opening from each lateral recess (*lateral apertures of Key and Retzius*).

The **choroid plexuses** of the fourth ventricle consist of highly vascular, lobular, villus-like processes of the ventricular lining (and pia mater) of the choroid tela. They are reddish in the fresh specimen, and the ependymal lining of the ventricle is closely adapted to the unevennesses of their surfaces. From below they run as two parallel masses on either side of the midline, which become united above, and then are separated again into two lateral processes which bend at right angles and project into the lateral recesses. Portions frequently protrude through the three openings of the ventricle into the subarachnoid space.

The ependyma, an epithelioid lining, is considered physiologically as a semipermeable membrane controlling the amount of cerebrospinal fluid in the ventricles. The foramina are the only openings by which the ventricles may be supposed to communicate with the subarachnoid space. These apertures are webbed over by the arachnoid.

The floor of the fourth ventricle [fossa rhomboidea] (fig. 719).—This is marked by eminences and depressions indicative of the internal structures of the brainstem subjacent to it. Its *inferior portion* is the dorsal surface of the upper portion of the medulla oblongata; its *intermediate portion* is the dorsal surface of the pons region, while its *superior portion* belongs to the isthmus of the rhombencephalon. Its triangular lower extremity terminates as the opening of the central canal of the spinal cord. This portion is deepened at the obex and shows furrows which point downward and converge medialward, giving the appearance known as the **calamus scriptorius.** The midline of the floor is sharply distinguished by the well-marked **median sulcus,** which becomes shallower above than below. In the tip of the calamus scriptorius, immediately ventral to the

obex, the median sulcus deepens as it becomes continuous into the central canal. This terminal depression is known as the **ventricle of Arantius.** Throughout the length of the floor on either side of the median sulcus is a continuous ridge, the **medial eminence,** which is bounded laterally by the **limiting sulcus.** Underlying the floor of the ventricle is a layer of gray substance of varying thickness, which is continuous with the gelatinous substance around the central canal of the cord. The medial eminence is subdivided into portions of unequal width and elevation, and the limiting sulcus accordingly shows foveæ of different depths.

Beginning at the calamus scriptorius, the following areas of the floor of the fourth ventricle are usually distinguished (fig. 719):

The **area postrema** of Retzius is a superficial vascular structure bounded inferiorly by the tenia and overlying the terminal portion of the nucleus of the fasciculus gracilis (clava) and a portion of the nucleus of termination of the vagus nerve. The **funiculus separans,** a short oblique fold of the floor, composed chiefly of neuroglia, separates the area postrema from the **ala cinerea** (*trigonum vagi*), which is an oblique, gray-colored, wing-shaped eminence indicating

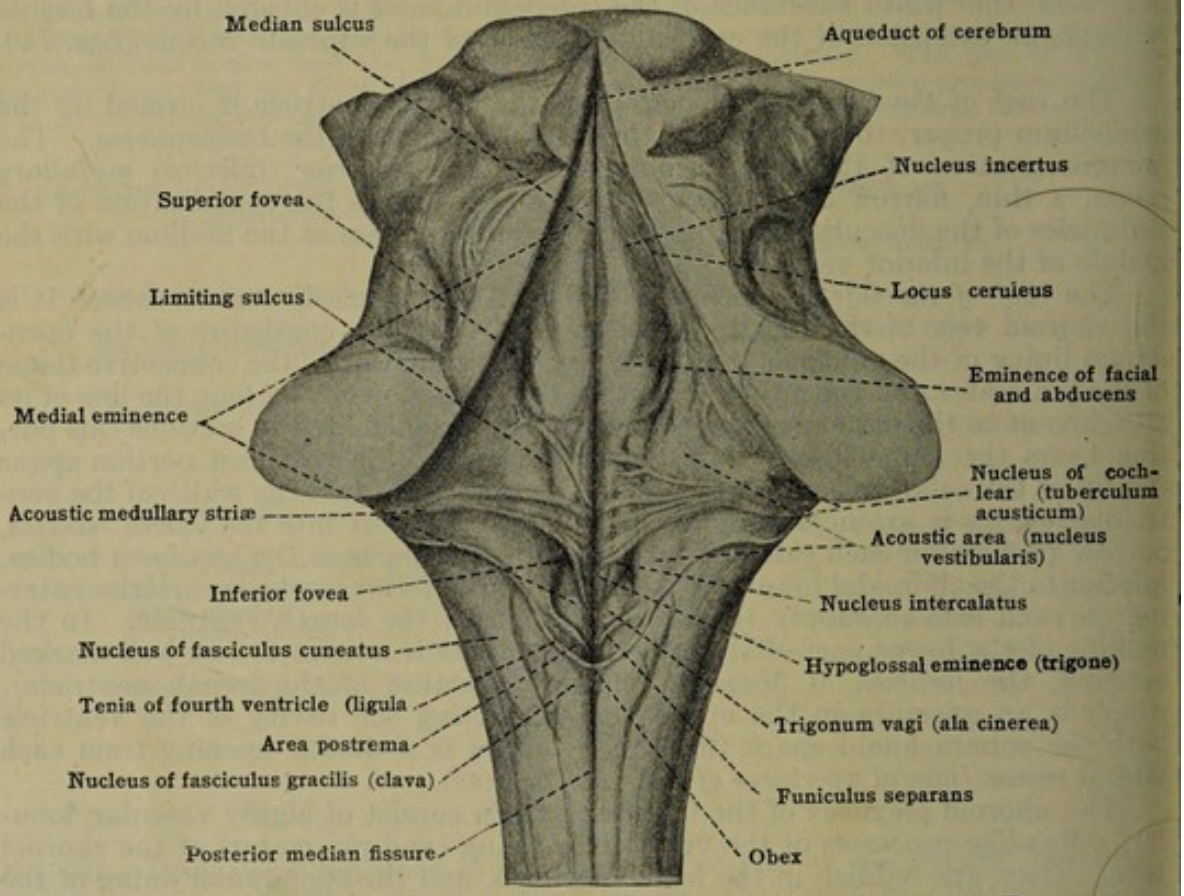

FIG. 719.—DORSAL SURFACE OF THE BRAIN-STEM SHOWING THE ANATOMY OF THE FLOOR OF THE FOURTH VENTRICLE. (Modified from Spalteholz.)

the middle third of the nucleus of termination (recipient nucleus) of the vagus and glossopharyngeal nerves. At the superior extremity of the ala cinerea is a well-marked triangular depression of the limiting sulcus known as the **inferior fovea.** Medial to and extending above the ala cinerea is a narrow triangular eminence lying close to the median sulcus, which represents the nucleus of origin of the hypoglossal nerve, the **hypoglossal eminence** [trigonum n. hypoglossi]. The lateral field of this eminence shows small oblique rugæ, giving it a 'feathery' appearance, the **area plumiformis** of Retzius. The **nucleus intercalatus** of Van Gehuchten is a wedge shaped portion very slightly demarcated from the hypoglossal eminence, and intercalated between it and the inferior fovea. This nucleus is considered by some observers as an inferior medial extension of the nucleus of termination of the vestibular nerve (area acustica), but Streeter, who has made a detailed study of the floor of the fourth ventricle by means of serial sections, doubts that it is a part of this nucleus. It is much more probable that it supplies visceral efferent fibers to the vagus and thus represents the dorsal efferent nucleus of the vagus.

Superior to the inferior fovea, and crossing each half of the floor of the fourth ventricle, are the **acoustic striæ.** These are bundles of axones arising in part from the dorsal nuclei of termination of the cochlear or auditory nerve, which nuclei are situated in the lateral periphery of each restiform body. The bundles course around the dorsal periphery of the upper portion of the restiform body, then across each half of the floor of the ventricle to the median sulcus, in which they suddenly turn ventrally into the substance of the medulla oblongata, and in doing so they cross the midline to enter the substance of the opposite side. The striæ vary greatly in different individuals, both in the degree of their prominence and their direction. Sometimes no striæ are visible from the surface. Frequently a bundle may be discerned which courses obliquely upward and lateralward from the median sulcus to disappear in the floor further away

from the midline and, again, a bundle may depart from the transverse course before reaching the median sulcus. Such a bundle ascending is sometimes called *conductor sonorus*. The acoustic striæ cross the **acoustic area**. This is the flattened elevation which occupies the whole lateral portion of the intermediate portion of the floor of the ventricle, lateral to the limiting sulcus, and extends into the inferior portion lateral to the inferior fovea. It represents the subjacent nuclei of termination of the vestibular nerve. The dorsal and ventral nuclei of the cochlear nerve are indicated by the ventrolateral fullness (*tuberculum acusticum*) in the contour of the restiform body. In many of the mammals the cochlear nuclei produce a well-marked protuberance.

In its superior portion the medial eminence occupies the greater part of the floor of the fourth ventricle, and in the upper part of the intermediate portion of the floor it presents a broader, well-marked, elongated elevation, the eminence of the facial and abducens or the **colliculus facialis**. This represents the medially placed nucleus of origin of the abducens and the genu of the root (internal genu) of the facial nerve, which root courses around and above the nucleus of the abducens. The nucleus of the facial is too deeply situated to produce an eminence. Lateral to the facial eminence is a depression of the limiting sulcus, which overlies the medial part of the region of the larger portion of the nucleus of termination of the trigeminus. This is the *fovea trigemini* or **superior fovea**. The strip of the floor above the superior fovea and lateral to the medial eminence often appears grayish blue or dark brown, owing to pigmented cells subjacent to it, and is known as the **locus ceruleus**. It also represents a portion of the nucleus of the trigeminus. The most superior portion of the medial eminence becomes narrow and lies close to the midline. The function of the underlying gray substance producing it is uncertain, and for this reason Streeter has named the elevation **nucleus incertus**, noting that by position it is closely related to the upper portion of the nucleus of the trigeminus.

Internal Structure of the Medulla Oblongata and Pons

The finer detail of the internal structure lies within the scope of microscopic rather than of gross anatomy. However, the significance and relations of certain of the more important and larger of the internal structures of the medulla and pons as observed in sections (figs. 720–736) must be considered.

The entire brain-stem may be regarded as an upward continuation of the spinal cord, to which structures are added and in which the structures characteristic of the spinal cord are modified in varying degrees, giving each part its peculiar character and conformation.

The **pyramids**, the great descending or motor cerebrospinal fasciculi, are directly continuous into the pyramidal fasciculi of the spinal cord. They form the extreme ventromedial portion of the medulla, and from the fact that they contribute numerous fibers to the efferent nuclei (nuclei of origin) of the cranial nerves and to other portions of the gray substance of the brain-stem, they decrease appreciably in bulk in descending toward the spinal cord. Most of the fibers contributed to the medulla, as well as to other divisions of the brain-stem, decussate as they leave the pyramids, and terminate in the gray substance of the opposite side. However, the chief **decussation of the pyramids** occurs in the lower end of the medulla. Here usually about three-fourths of the fibers then comprising the pyramids cross the midline to form the lateral cerebrospinal fasciculus (crossed pyramidal tract) of the spinal cord immediately below (fig. 709). The remaining fourth, comprising the more lateral fibers, furthest away from the midline, continues uncrossed into the spinal cord as the ventral cerebrospinal fasciculus or direct pyramidal tract. The majority of the latter fibers decussate gradually in the commissural bundle and in the ventral white commissure of the cord as they approach the levels of their termination. In practically all vertebrates except man and the anthropoid apes there are no ventral pyramidal fasciculi, the decussation in the medulla being a total one. In man, the proportion of fibers crossing in the chief decussation varies. Cases have been noted in which apparently the entire pyramids decussate at this level. In other cases the direct or ventral pyramidal tract may be much larger than usual, at the expense of the lateral. The chief decussation usually appears to be symmetrical and it occurs so suddenly that the fibers, in coursing from the ventral to the lateral positions, 'sew up' the ventral median fissure and detach the tips of the ventral horns of the spinal cord from the remainder of the gray figure, making these appear in transverse sections as isolated, irregularly shaped masses of gray substance (fig. 720). From this level upward the outline of the gray figure of the cord is lost, and the cell-columns of the ventral horns occur in more or less detached groups as the motor nuclei of the cranial nerves. Naturally there are some "aberrant pyramidal fibers" to the nuclei of the motor cranial nerves, cortico-medullary fibers which never enter the pyramids but descend and decussate in the reticular formation of the brain stem (Dejerine).

The **origin and decussation of the lemnisci** (medial lemnisci, fillet). The medial lemniscus of either side begins immediately above the decussation of the pyramids, and here the arrangements characteristic of the spinal cord are further modified. The dorsal portion of the gray figure of the cord is manifest up to this level, but here, after a considerable increase in its thickness, the gray commissure gives rise to two thick dorsal outgrowths on each side of the midline. These dorsal projections of gray substance comprise the nuclei of termination (relays) of the chief ascending or sensory spinocerebral fasciculi of the spinal cord. The **nucleus of the fasciculus gracilis** (nucleus of Goll's column) arises a little before the **nucleus of the fasciculus cuneatus** (nucleus of Burdach's column). The former extends slightly downward from its point of origin, so that its inferior extremity is included in sections through the decussation of the pyramids (fig. 720). It produces a slight bulbous enlargement (the *clava*) of the end of the funiculus gracilis, while the nucleus of the fasciculus cuneatus corresponds to the *cuneate tubercle* of the dorsolateral contour of the medulla (figs. 711, 719). From the cells of these nuclei arise axones which contribute largely to the lemniscus—the cephalic continuation of the spinocerebral pathway which conveys general bodily sensations (proprioceptive) to the cerebrum. In passing out of the nuclei the fibers of the lemniscus course in a ventromedial direction. Curving around the region of the central canal, they contribute largely to the **internal arcuate fibers**,

then, sweeping across the midline, they, together with those from the opposite side, convert it into the **raphe**, and immediately after crossing (decussating) they turn cephalad and collect to form the bundle known as the **lemniscus.** While these two ascending fasciculi, because of their prior discovery, larger size and more general significance, are referred to as the lemnisci they should be called the **medial lemnisci** to distinguish them throughout from the **lateral lemnisci** described below, which have quite different nulcei of origin and are concerned with the apparatus for hearing.

In the medulla, the lemnisci are two thin bands of fibers spread vertically on each side of the raphe, with their lower or ventral edges thicker than their dorsal edges. In their course toward the cerebrum they increase in bulk, owing chiefly to fibers being added to them from

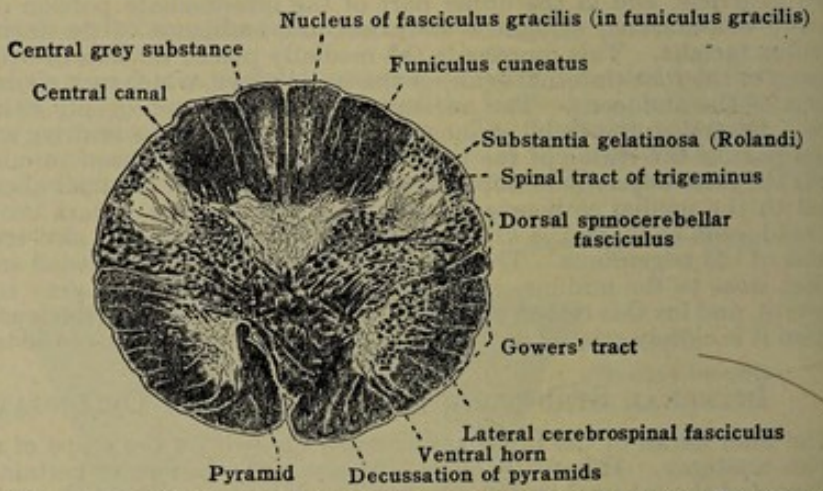

FIG. 720.—TRANSVERSE SECTION OF MEDULLA OBLONGATA AT THE LEVEL OF THE DECUSSATION OF THE PYRAMIDS.

the nuclei of termination of the afferent roots of the cranial nerves, which fibers likewise cross the midline as internal arcuate fibers to join the lemniscus of the opposite side. In passing through the pons, the lemnisci gradually become spread laterally (horizontally) and beyond the pons their then more lateral portions are further displaced and come to course in the lateral borders of the isthmus rhombencephali and mesencephalon, while the medial portions remain nearer the midline. This lateral spreading of each lemniscus produces the **lateral lemniscus** and the **medial lemniscus,** distinguished in sections of the superior pons and lower mesencephalic regions of the brain-stem (fig. 740). During the spreading, the lateral lemniscus is contributed very largely by the cell-bodies of the nuclei of termination of the cochlear nerve of he opposite side and is thus the '*auditory lemniscus.*' The **spinal lemniscus** (spinothalamic

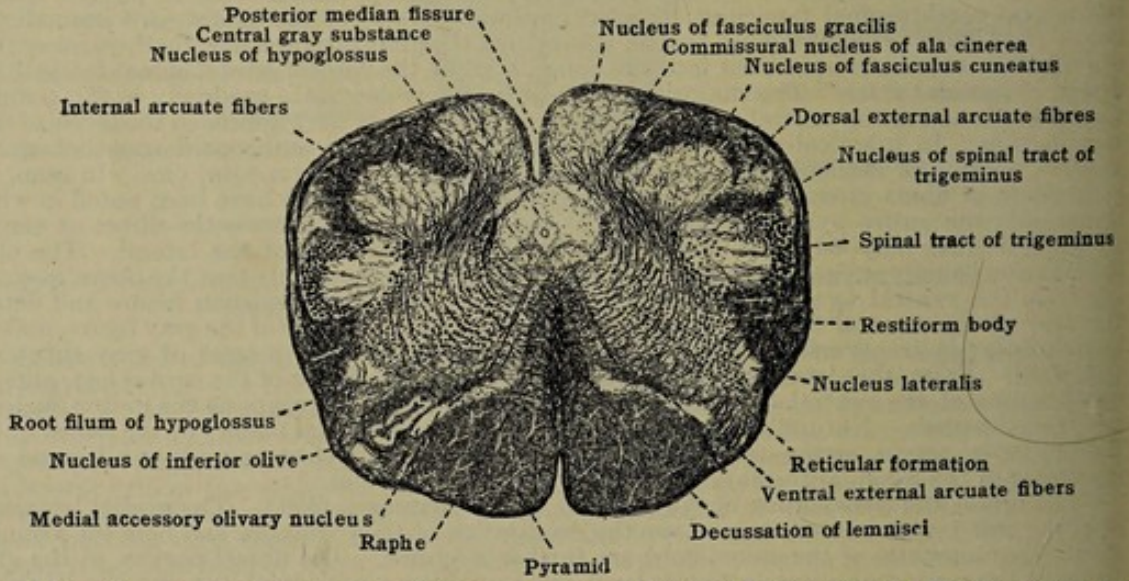

FIG. 721.—TRANSVERSE SECTION OF MEDULLA OBLONGATA AT LEVEL OF THE DECUSSATION OF THE LEMNISCI.

and spinotectal paths) courses as the dorsal part of the medial lemniscus during its vertical position throughout the medulla and in the lateral part of it, medial to the lateral lemniscus proper, throughout the pons and midbrain.

The **reticular formation** of the medulla and pons region is considerably more abundant than in the spinal cord. As in the spinal cord, it consists of gray substance through which nerve-fibers, singly and in small bundles, course in all directions, but more sparsely than in other regions. In the medulla it is traversed by the internal arcuate fibers. It may be considered an enlarged continuation of the middle portion of the gray column of the cord, dispersed by numerous fibers, giving it the reticulated appearance which suggests its name. Its numerous nerve-cells belong, for the most part, to the association and commissural systems of the brain

stem, and, therefore, the fibers arising in it correspond largely to the fasciculi proprii of the spinal cord. As in the cord, most of the fibers are of short course, serving to associate different portions of the same level and adjacent levels with each other. Those of long course show a tendency to collect into a small, well-marked bundle which courses one on each side close to the midline, ventral to the central canal in the closed part of the medulla, and near the median sulcus of the floor of the fourth ventricle, in the open part. In the mesencephalon this bundle is continued closely ventral to the aqueductus cerebri. This bundle is known as the **medial longitudinal fasciculus** (posterior longitudinal bundle). It corresponds more nearly to the ventral fasciculus proprius of the spinal cord than to others of the fasciculi proprii. In the medulla it appears as the dorsal edge of the lemniscus, but in the shifting of the position of the lemniscus in the pons region it retains its medial position and thus becomes isolated. By position it is especially adapted for the association of the nuclei of the cranial nerves. Evidence has been found that those fibers which arise in the superior corpora quadrigemina and descend the spinal cord in its sulcomarginal or ventral mesencephalospinal fasciculus, pass through the medulla in the medial longitudinal fasciculus. (See extrapyramidal system.) The nuclei of termination of the vestibular nerve, and probably those of the cochlear nerve, are said also to contribute many fibers to the medial longitudinal fasciculus.

The **inferior olivary nucleus** is an added structure in the medulla oblongata, i. e., it has no homologue in the spinal cord. The two of them occupy the olivary prominences, *the olives* of the exterior, and constitute the most conspicuous and striking isolated masses of gray substance in sections of the medulla. They appear as crenated laminæ of gray substance folded so as to encup a dense mass of white substance, and in actual shape the entire nucleus has the form of an irregular corrugated cup with the opening or **hilus** on the side toward the midline (fig. 723). The mass is so crumpled that the diameter of the hilus is appreciably less than

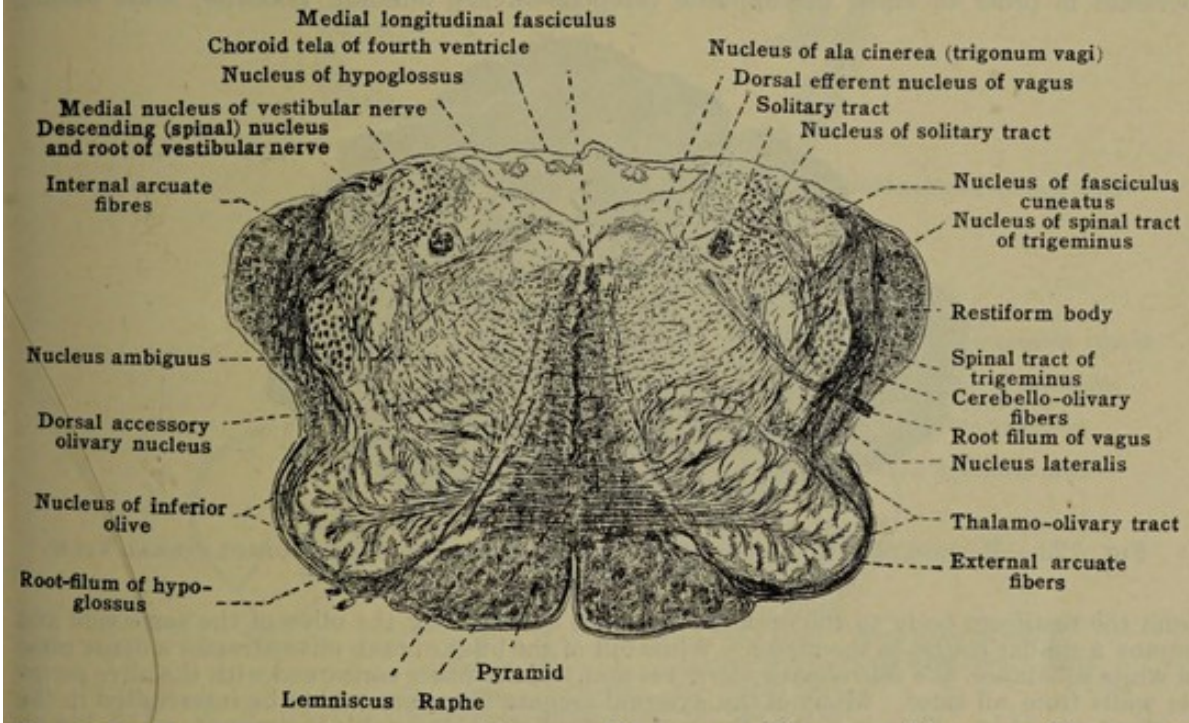

FIG. 722.—TRANSVERSE SECTION OF MEDULLA OBLONGATA THROUGH NUCLEI OF VAGUS AND HYPOGLOSSUS AND THROUGH THE MIDDLE OF THE OLIVES.

the length of the nucleus, and thus transverse sections of either extremity of it appear as closed capsules.

There are several small detached portions of the olivary nucleus known as the **accessory olivary nuclei.** These are named according to their position with reference to the chief portion or olive proper. They are plates less corrugated than the chief nucleus, and appear rod-like in transverse sections. The largest is the *dorsal accessory olivary nucleus.* The *medial accessory olivary nucleus* is widest at its inferior end, which extends a little below the inferior extremity of the olive proper. The *lateral accessory olivary nucleus* is the smallest. In serial sections the accessory nuclei are found to be plates of gray substance usually continuous with one another.

The olivary nuclei are mainly cerebellar connections. By both ascending and descending fibers each cerebellar hemisphere is connected with the olivary nucleus of the same and opposite sides. Serial sections of a human brain with congenital absence of one cerebellar hemisphere, described by Strong, show that the chief connection of a hemisphere is with the olive of the opposite side. These fibers necessarily pass from the olives to the cerebellum by way of the restiform body, and, in so doing, form an obliquely coursing bundle in the lateral border of the medulla known as the **cerebello-olivary fibers** (fig. 722). The olivary nuclei also comprise a secondary relay between the spinal cord and the cerebellum by way of the spino-olivary fasciculus of the cervical cord, and it will be noted that they receive fibers from the thalami. The latter fibers, the **thalamo-olivary tract,** approach the olive at its lateral periphery, while above through the brain-stem the tract courses in a more medial position. This tract comprises one of the cerebrocerebellar paths. Arising in the thalamus and terminating in the olive, its impulses reach the opposite cerebellar hemisphere by way of the cerebello-olivary fibers.

The **arcuate fibers** are referred to as internal and external, in accordance with their course dorsal or ventral to the inferior olivary nucleus. The **internal arcuate fibers** comprise fibers destined

for both the cerebellum and cerebrum, and also for the association of the tegmental gray substance of the two sides in which they course. Certain of the fibers pass between one restiform body (cerebellar hemisphere) and the olive of the opposite side course internal to the olive of the same side, and thus form the ventral portion of the internal arcuate fibers. As noted above, the internal arcuate fibers consist in greatest part of fibers being contributed to the lemnisci, arising from the cells of the nuclei of termination of the fasciculus gracilis and fasciculus cuneatus and sweeping downward and decussating to form the lemniscus of the opposite side. However, all the fibers arising in these nuclei do not enter the lemniscus. A few of them cross the midline with the internal arcuates, but pass on to enter the restiform body (cerebellar hemisphere) of the opposite side. Some of these course ventrally and, upon approaching the olive of the opposite side, are deflected around the ventral side of both the olive and the pyramid, and thus pass to the restiform body as external arcuate fibers also. Certain of the internal arcuate fibers arise from the cells of the nuclei of termination of the cranial nerves and from small cells situated in the gray substance of the reticular formation. These, in crossing the midline, correspond to the white commissures of the spinal cord. Some of them terminate in the medulla; others, especially those from the nuclei of termination of the sensory cranial nerves, join the lemniscus and pass toward the cerebrum; others reach the cerebellar hemisphere of the opposite side (see figs. 724, 725).

The **external arcuate fibers,** in addition to those mentioned above, comprise certain fibers which arise in the nuclei of the fasciculus gracilis and cuneatus and pursue a dorsolateral course to enter the restiform body (cerebellar hemisphere) of the same side. These form largely the dorsal external arcuate fibers. The greater mass of the external arcuates are cerebello-olivary fibers. Certain of those passing from one olive to the restiform body of the opposite side are deflected at the raphe, and course on the ventral side of both the other olive and the pyramid in order to reach the opposite cerebello-olivary bundle. Likewise, some passing

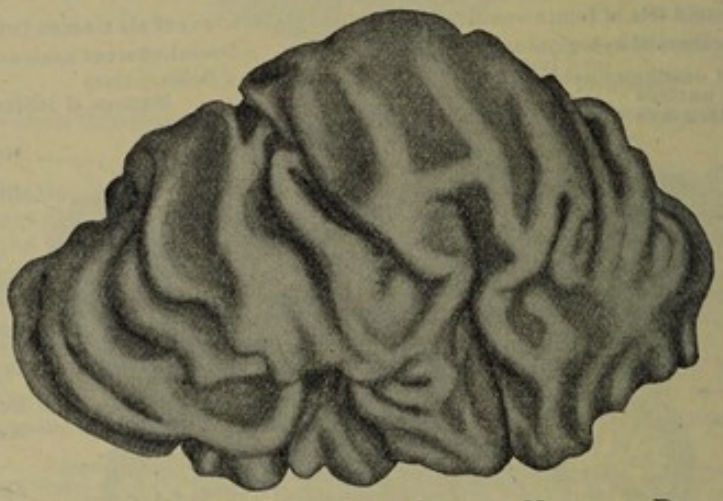

FIG. 723.—RECONSTRUCTION OF THE INFERIOR OLIVARY NUCLEUS, DORSOLATERAL VIEW. (After Sabin.)

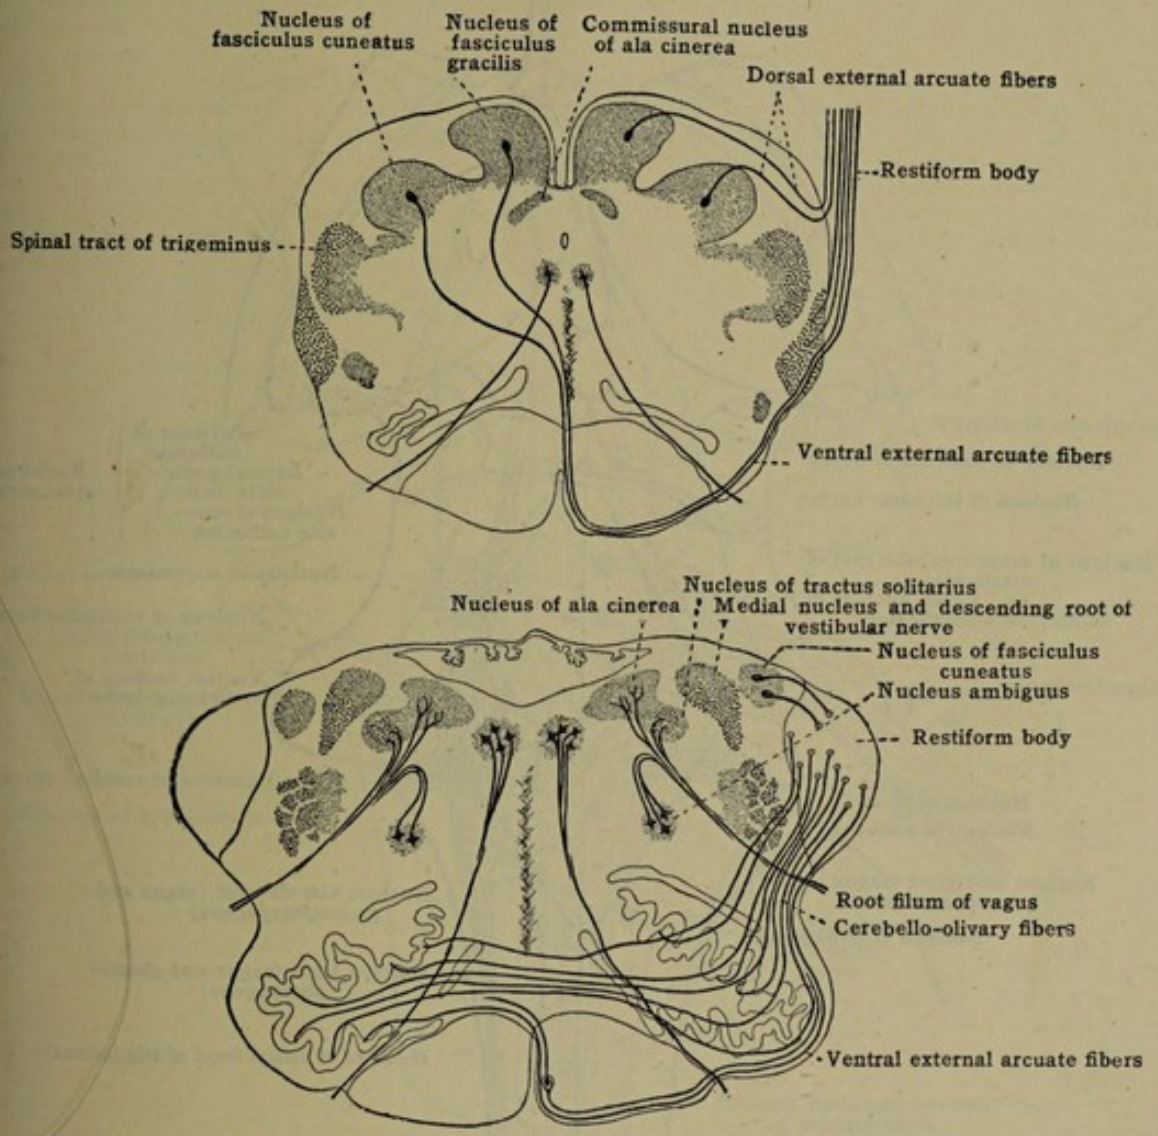

from the restiform body to the opposite olive are deflected by the olive of the same side and pursue a similar course to the raphe. While out of the hilus of each olive streams a dense mass of white substance, the *interolivary fibers*, yet many of the fibers concerned with the olive pierce its walls from all sides. Many of the external arcuate fibers are said to be interrupted in the **nucleus arcuatus.** This is a thin sheet of gray substance, variable in amount, which lies on the ventral aspect of each pyramid, and, though it decreases inferiorly, it may be evident down to the decussation of the pyramids. The nucleus receives its name from the fact that its larger portion is interpolated in the ventral external arcuate fibers. It is continuous anteriorly with the gray substance or nuclei of the pons. The external arcuate fibers of longer course, like the olives with which they are largely concerned, have no homologues in the spinal cord.

The *central canal* of the closed portion of the medulla is surrounded by a greater amount of **central gray substance** [substantia grisea centralis] than is the canal in the spinal cord. This is largely *the central gelatinous substance*, and the nerve-fibers in coursing through the gray substance are partially deflected by it, leaving it as a cylindrical, more evident area of gray substance than in other regions. In the open portion of the medulla the central gray substance haturally forms a more transparent lamina just under the floor of the fourth ventricle. In the mesencephalon, occurring in still greater amount, it again surrounds the resumed canal or aqueduct of the cerebrum.

The **central connections of the cranial nerves** are easily homologized with spinal cord structures. Functionally the cranial nerves are of three varieties:—(1) the motor or efferent nerves, comprising the oculomotor, the trochlear, masticator, the abducens, the facial, the spinal accessory, and the hypoglossus; (2) the sensory or afferent, comprising the olfactory, the optic, the trigeminus, the vestibular, and the cochlear and (3) the mixed, motor and sensory nerves, comprising the glossopalatine, the glossopharyngeal, and the vagus. The **nuclei of origin** of the motor or efferent cranial nerves and the efferent portions of the mixed nerves are directly continuous with the cell-columns of the ventral horns of the spinal cord, while the emerging root-filaments and roots of these nerves

correspond to the ventral roots of the spinal nerves. The **nuclei of termination** of the afferent or sensory cranial nerves and of the sensory portions of the mixed nerves correspond directly to the nuclei of the fasciculus gracilis and fasciculus cuneatus, and to the cell-bodies of association and commissural neurones of the medulla and cord and, functionally, are merely superior continuations of these.

The nuclei of the efferent or motor cranial nerves lie in two parallel lines, one near the midline and the other more laterally placed. The nuclei giving origin to the oculomotor, the trochlear, the abducens, and the hypoglossus are near the midline, and correspond to the ventromedial and dorsomedial cell-groups of the ventral horns of the spinal cord; the nuclei of origin of the masticator (motor root of the trigeminus), of the facial, and the nucleus ambiguus contributing to

FIGS. 724 AND 725.—DIAGRAMS SHOWING THE COMPOSITION OF THE CEREBELLAR PORTIONS OF THE INTERNAL AND EXTERNAL ARCUATE FIBERS.

the motor portions of the glossopharyngeal and vagus nerves, together with the nucleus of the spinal accessory, correspond to the ventrolateral and dorsolateral (intermediolateral) cell-groups of the ventral horns of the spinal cord. The nerve-roots having medial nuclei of origin are those which make their exit from the brain-stem along the more medial superficial line, while those having the more lateral nuclei comprise the more lateral line of roots apparent on the surface of the stem. Some of the efferent fibers of the vagus, supposedly visceral efferent, arise from a small nucleus dorsomedial to the nucleus ambiguus, the *dorsal efferent of the vagus*. Visceral efferent fibers in the glossopharyngeal and glossopalatine nerves arise chiefly in nuclei corresponding to the dorsal efferent nucleus of the vagus, that for the glossopalatine being called the *salivatory nucleus*. The first two pairs of cranial nerves, the olfactory and optic, are attached to the prosencephalon. These are purely sensory, and make their entrance near the midline of the brain, both having superficially placed nuclei of termination.

The two are peculiar in that their ganglia of origin are situated in the neuro-epithelium of their end-organs. Of the other nerves, all having sensory or afferent functions enter the brain along the lateral or more dorsal line, and the ganglia giving origin to their afferent axones correspond directly to the spinal ganglia of the dorsal or afferent roots of the spinal nerves.

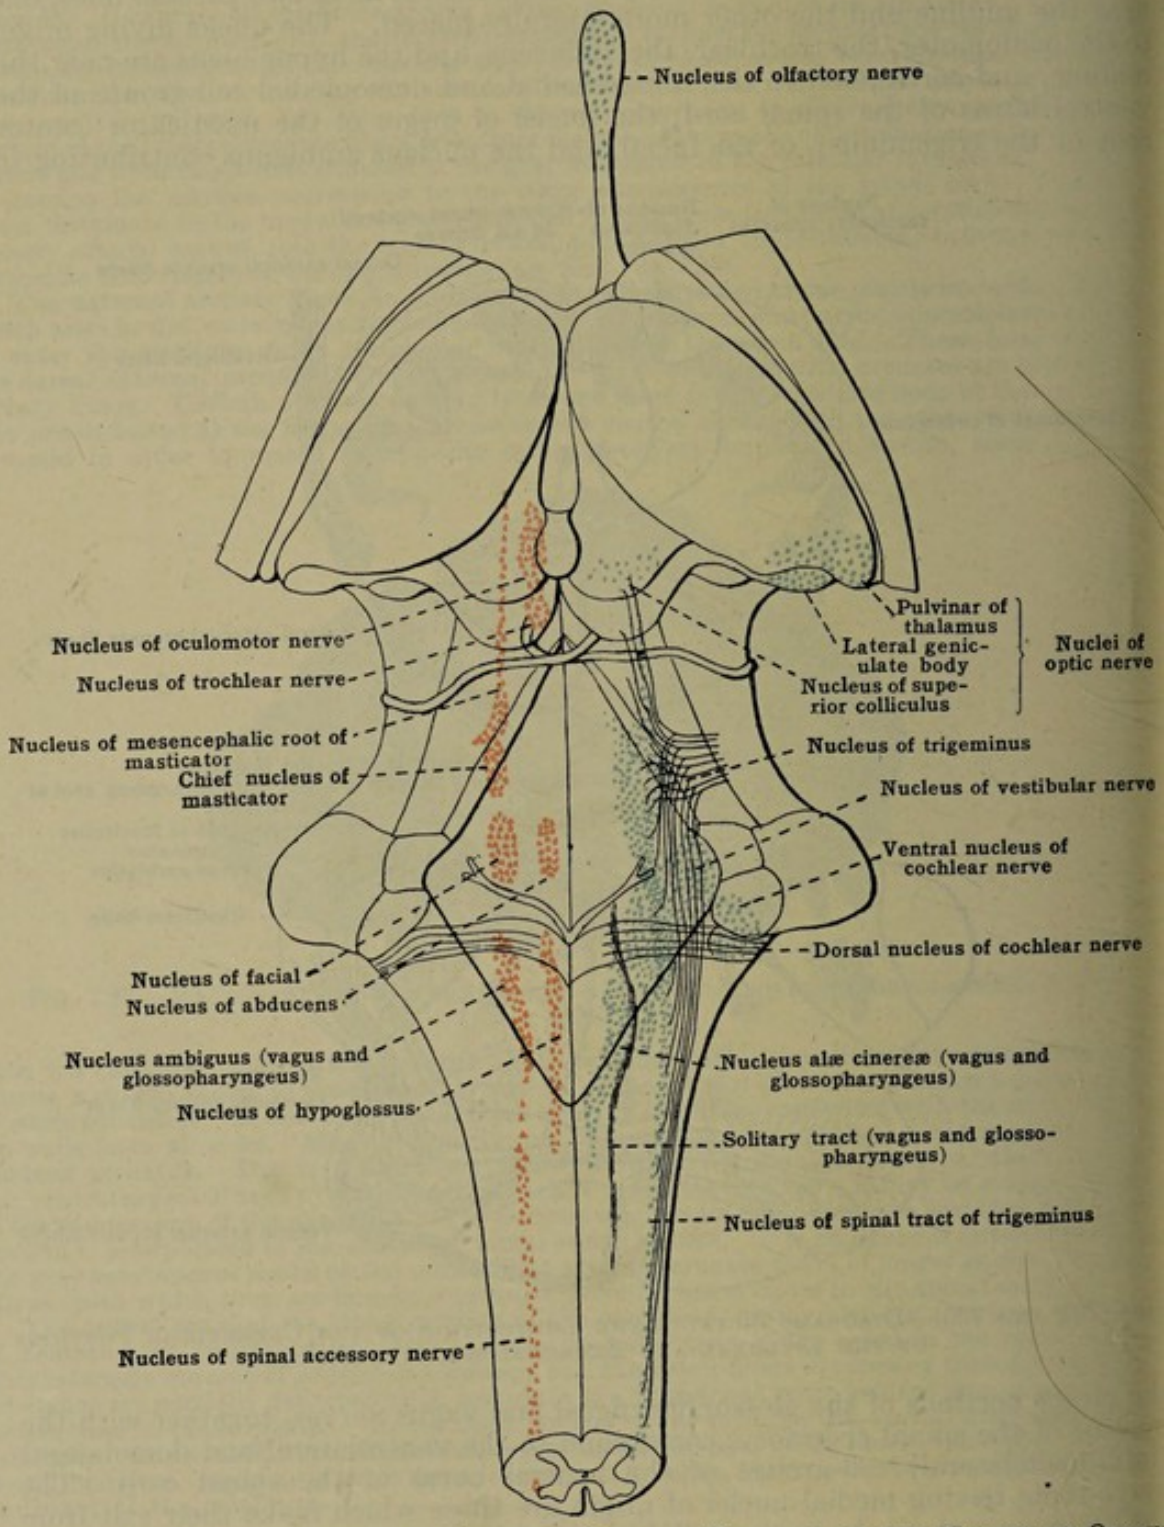

FIG. 726.—SCHEME SHOWING THE RELATIVE SIZE AND POSITION OF THE NUCLEI OF ORIGIN (RED) OF THE MOTOR AND THE NUCLEI OF TERMINATION (BLUE) OF THE SENSORY CRANIAL NERVES.

Commissural and associational neurones are much more numerous in the brain-stem than in the spinal cord. Their axones serve to correlate the structures on the two sides of the midline and to associate the different levels of the same side. Just as in the spinal cord, those of longer course form fasciculi proprii. Many of their axones descend into the spinal cord.

Of the fifteen pairs of cranial nerves, eleven pairs are attached to the medulla oblongata and pons, viz., the trigeminus, the masticator, abducens, facial,

glossopalatine, vestibular, cochlear, glossopharyngeal, vagus, spinal accessory, and hypoglossus.

The **hypoglossus**, the motor nerve of the tongue, has its nucleus of origin beginning in the lower portion of the floor of the fourth ventricle caudal to and at the level of the acoustic striæ. It is a long nucleus, lying close to the midline and just under the floor of the ventricle (hypoglossal eminence) and extending down to the region of the funiculus separans. Here it curves ventrally to a slight degree, and below the obex assumes a position ventrolateral to the central canal, and thus extends a short distance below the level of the inferior tip of the olive. The nerve arises as a series of rootlets which traverse the entire thickness of the medulla (fig. 722), to emerge in line in the furrow between the olive and the pyramid and fuse to form the trunk of the nerve. The lowermost of the rootlets usually emerge below the olive. The nucleus

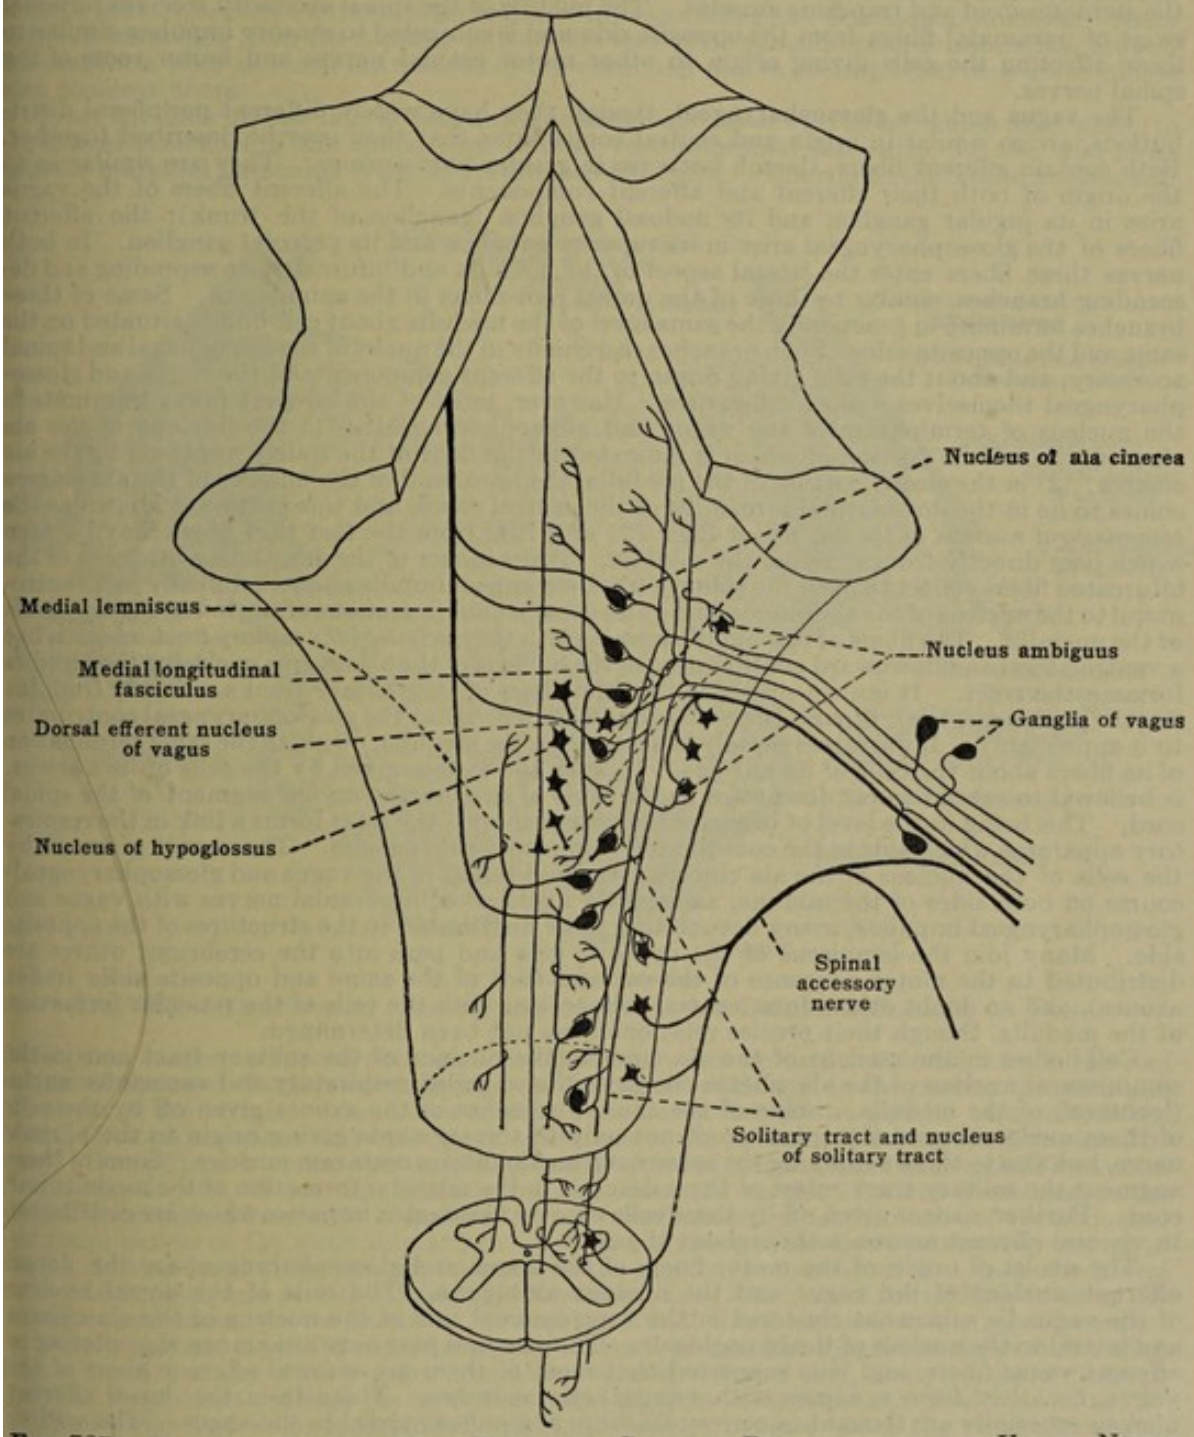

FIG. 727.—DIAGRAM ILLUSTRATING PRINCIPAL CENTRAL RELATIONS OF THE VAGUS NERVE EXCLUSIVE OF RELATIONS TO DESCENDING CEREBRAL OR PYRAMIDAL FIBERS.

receives impulses—(1) from the cerebrum by way of divergent fibers from the pyramid of the opposite side (voluntary); (2) impulses brought in by the sensory fibers of the cranial nerves (reflex); and (3) by axones from other levels of the medulla (associational). None of its axones are supposed to decussate, though numerous commissural fibers are known to pass between the nuclei of the two sides.

The **spinal accessory** is likewise a purely motor nerve, and has a laterally placed, long, and much attenuated nucleus of origin. Above, its nucleus is in line with and practically continuous with the nucleus giving motor fibers to the vagus and glossopharyngeus (nucleus ambiguus).

Below, it is the nucleus lateralis of the medulla in large part and it consists of the lateral an dorsolateral groups of cells of the ventral horn of the first five or six segments of the spin cord. The nerve arises as a series of rootlets which emerge laterally and join a commo trunk, which passes upward between the dorsal and ventral roots of the upper cervical nerve and parallel with the medulla to turn lateralward in company with the vagus. (See figs. 72 and 747.) The upper rootlets arise from that part of the nucleus contiguous to the inferior en of the nucleus ambiguus, and are described as comprising the medullary (bulbar) or *accessor part* of the nerve; those which arise from the ventral horn cells below are described as the *spina part*. The trunk of the spinal accessory fuses with the vagus in the region between its tw ganglia, and, before separation, contributes fibers (the accessory part) to the trunk of the vagus Some of the accessory fibers are distributed as motor fibers to the muscles of the larynx an some of them are visceral efferent fibers (visceral effectors). The latter probably terminat chiefly in sympathetic ganglia which send axones to the heart. The spinal part is distributed t the sternomastoid and trapezius muscles. The nucleus of the spinal accessory receives termina twigs of pyramidal fibers from the opposite side and is subjected to sensory impulses similar t those affecting the cells giving origin to other motor cranial nerves and motor roots of th spinal nerves.

The **vagus** and the **glossopharyngeal**, though they have widely different peripheral distributions, are so similar in origin and central connections that they may be described together Both contain efferent fibers, though both are in greater part sensory. They are similar as t the origin of both their efferent and afferent components. The afferent fibers of the vagu arise in its jugular ganglion and its nodosal ganglion (ganglion of the trunk); the afferen fibers of the glossopharyngeal arise in its superior ganglion and its petrosal ganglion. In both nerves these fibers enter the lateral aspect of the medulla and bifurcate into ascending and descending branches, similar to those of the dorsal root-fibers in the spinal cord. Some of these branches terminate in practically the same level of the medulla about cell-bodies situated on the same and the opposite sides. Such branches end chiefly in the nuclei of the hypoglossal and spinal accessory, and about the cells giving origin to the efferent components of the vagus and glossopharyngeal themselves—short reflex arcs. However, most of the afferent fibers terminate in the nucleus of termination of the vagus and glossopharyngeal:—(1) the **nucleus of the ala cinerea**, the middle portion of which is indicated in the floor of the fourth ventricle by the ala cinerea: (2) in the closed portion of the medulla, the lower end of the nucleus of the ala cinerea comes to lie in the dorsolateral proximity of the central canal, and this portion is known as the *commissural nucleus of the ala cinera* (figs. 721 and 724) from the fact that fibers may be seen which pass directly from it across the midline; (3) the longer of the descending branches of the bifurcated fibers collect to form the **solitary tract**, a compact bundle situated dorsally just ventrolateral to the nucleus of the ala cinerea and quite conspicuous in sections of the lower olivary levels of the medulla. The fibers of this bundle terminate in the *nucleus of the solitary tract*, which is but a ventrolateral and downward continuation of the nucleus of the ala cinerea enclosing the bundles forming the tract. It is most probable that the fibers of the solitary tract are chiefly from the vagus (pneumogastric), though Bruce has found evidence that the glossopharyngeal contributes to it appreciably. It decreases rapidly in descending the medulla, owing to the rapid termination of its fibers about the cells of its nucleus. It, with the axones given by the cells of its nucleus, is believed to extend as far downward as the level of the fourth cervical segment of the spinal cord. This being in the level of origin of the phrenic nerve, the tract forms a link in the respiratory apparatus which aids in the coordinated respiratory movements. The axones given off by the cells of the nucleus of the ala cinerea (terminal nuclei of the vagus and glossopharyngeal) course on both sides of the midline, associating nuclei of other cranial nerves with vagus and glossopharyngeal impulses, many decussating to be distributed to the structures of the opposite side. Many join the lemniscus of the opposite side and pass into the cerebrum; others are distributed to the motor neurones of the cervical cord of the same and opposite sides (reflex axones), and no doubt others form central connections with the cells of the reticular formation of the medulla, though their precise relations have not been determined.

Cell-bodies in the nucleus of the ala cinerea, the nucleus of the solitary tract and in the commissural nucleus of the ala cinerea comprise the so-called **respiratory** and **vasomotor nuclei** (**'centers'**) of the medulla. Some of the caudal branches of the axones given off by the cells of these nuclei descend the spinal cord, not only to the segments giving origin to the phrenic nerve, but also to those supplying the intercostal and levatores costarum muscles. Some of these augment the solitary tract; most of them descend in the reticular formation of the medulla and cord. Further, axones given off by these cells convey vasomotor impulses which are distributed to visceral efferent neurones throughout the cord.

The nuclei of origin of the motor fibers of the vagus and glossopharyngeal are the **dorsal efferent nucleus of the vagus** and the **nucleus ambiguus**. The cells of the dorsal nucleus of the vagus lie somewhat clustered in the ventromedial side of the nucleus of the ala cinerea and lateral to the nucleus of the hypoglossus. Their axones pass outward among the entering or afferent vagus fibers, and it is suggested that most of them are visceral efferent fibers of the vagus, i.e., they form synapses with sympathetic neurones. Those from the dorsal efferent nucleus especially are thought to convey inhibitory impulses carried in the vagus. The *nucleus ambiguus* or ventral efferent nucleus of both nerves lies in the lateral half of the reticular formation, about midway between the olive and the line traversed by the rootlets of the two nerves. Its upper end is larger. Its cells are considerably dispersed by the fibers of the reticular formation. The axones arising from its cells course at first dorsalward and then turn abruptly outward to join the rootlets of the vagus or glossopharyngeal, as the case may be. The vagus is thought to receive more efferent fibers from the nucleus ambiguus than does the glossopharyngeal, and Cunningham notes that it may be questioned whether the latter nerve contains any motor fibers at all, there being paths by which the fibers of its motor branch (to the stylopharyngeus muscle) might enter it other than directly from motor nuclei.

The *vestibular* and *cochlear* nerves have been considered as one nerve and together designated as the **acoustic** or eighth cranial nerve. While both are purely sensory, are similar in develop-

ment and their roots course together, they are distinct as to function and origin and their nuclei of termination differ. They are here described as separate cranial nerves. The two nerves approach the brain stem together and enter it at the lateral aspect of the junction of medulla oblongata and pons.

The **vestibular nerve** (nerve of equilibration) arises as the central processes of the bipolar cells of both the superior and inferior parts of the *vestibular ganglion*, and passes into the brain-stem on the ventromedial side of the restiform body to find its nucleus of termination (nucleus vestibularis) in the floor of the fourth ventricle. This nucleus occupies a triangular area of considerable extent (area acustica, fig. 719), and is usually subdivided into a *lateral nucleus* (Deiters'), a *medial nucleus* (Schwalbe's), a *superior nucleus* (Bechterew's), and an *inferior nucleus* (nucleus spinalis). The latter is a downward prolongation of the general nucleus vestibularis which accompanies the *descending or spinal root* of the nerve and may be traced to near the superior extremity of the nucleus of the fasciculus gracilis. The fibers of the vestibular nerve, like those of other sensory nerves, bifurcate after entrance into ascending and descending branches. Some of the fibers arising from the superior part of the vestibular ganglion pass dorsolaterally around the vestiform body to reach the nucleus of the vestibular and in passing thus, they must mingle with cochlear fibers.

From the cells of the lateral and inferior nuclei axones are given off which form paths to the lateral funiculus of the spinal cord (lateral vestibulospinal fasciculus, fig. 698) and to its anterior marginal fasciculus (ventral vestibulospinal tract). From both the lateral nucleus and

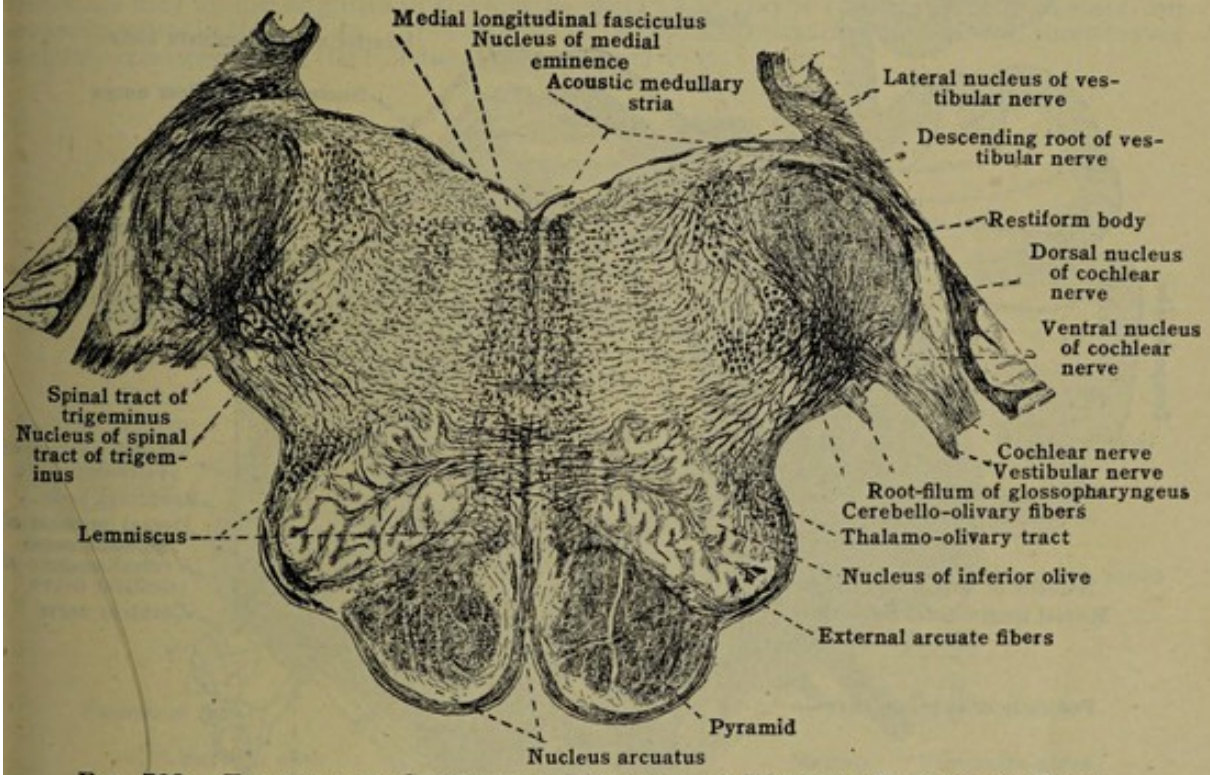

FIG. 728.—TRANSVERSE SECTION OF MEDULLA AT INFERIOR BORDER OF PONS.

the superior nucleus a special path is given off which passes upward and terminates in the roof nucleus of the cerebellum (nucleus fastigii) of the opposite side and in the nucleus dentatus and the cortex of the vermis. Also, fibers arising in the nuclei fastigii are said to terminate in the lateral (Deiters') nucleus and other gray substance of the medulla (forming the *fastigiobulbar tract*). Some fibers from the roof nucleus possibly descend into the anterior marginal fasciculus of the spinal cord. From the medial and also from the superior nucleus fibers pass to the medial longitudinal fasciculus of both sides, and are distributed to the nuclei of the abducens and facial nerves of the same side and to the nuclei of the trochlear and oculomotor nerves of the opposite side and of the masticator nerve of the same and opposite sides. From the lateral and medial nuclei, and probably from all, a few fibers arise which cross the midline to enter the lemniscus and ascend to the cerebrum (lateral portion of the thalamus) on the opposite side.

Deiters' nucleus is said to contribute more fibers to the medial longitudinal fasciculus than does a nucleus of any other sensory cranial nerve and fewer, if any, fibers to the lemniscus. If any of these fibers descend the cord, they must do so in its anterior marginal fasciculus.

The *inferior nucleus* is accompanied by the *descending* or *spinal root* of the vestibular nerve, which begins to assemble in the nuclei above. This root is composed of both caudal branches of the entering fibers of the nerve and chiefly of fibers arising from the cells of its nuclei. Thus for the vestibular nerve it corresponds in every way to the solitary tract for the vagus, and to the spinal tract of the trigeminus. Such of its fibers as descend into the spinal cord most probably do so in the lateral vestibulospinal fasciculus.

Many of the anatomical details of the central connections of the vestibular nerve have not yet been determined with exactness. In addition to whatever other functions it may have, it is considered to be the nerve of equilibration, and the connections noted above may be considered the pathways by which it exercises this function. The fibers of the apparatus which are represented in the spinal cord are supposed to convey impulses to the ventral horn (motor) cells of the cord as far down as the sacral region.

The **cochlear nerve**, the auditory nerve proper, arises as the central processes of the bipolar cells of the *spiral ganglion* of the cochlea. Its fibers enter the medulla laterally at the inferior border of the pons and divide into ascending and descending branches. In the lateral periphery of the restiform body, just before the latter enters the cerebellum, the nerve finds its two nuclei of termination, the *ventral nucleus* and the *dorsal nucleus* (tuberculum acusticum, figs. 719, 728).

From the **dorsal nucleus** arise many of the fibers forming the *acoustic medullary striæ*. These bundles pass around the dorsal aspect of the restiform body and course just under the ependyma of the floor of the fourth ventricle to the midline, where they suddenly turn downward into the substance of the medulla and in doing so, cross to the opposite side and join the lemniscus (fig. 729). As the lemniscus becomes separated higher up into a medial and lateral portion, these auditory fibers course in the lateral lemniscus and are distributed chiefly to the grey substance of the inferior quadrigeminate body and medial geniculate body of that side. At the midline some of their fibers join the medial longitudinal fasciculus and by way of it are distributed to the nuclei of origin of the efferent fibers of other cranial nerves. In frequent cases, the acoustic striæ course so deeply beneath the ependyma as not to be superficially visible in the floor of the fourth ventricle. It has been asserted recently that there are many fibers in these striæ which are passing between the olivary nuclei and the cerebellum as 'superficial internal arcuate fibers' and may not be cochlear connections at all.

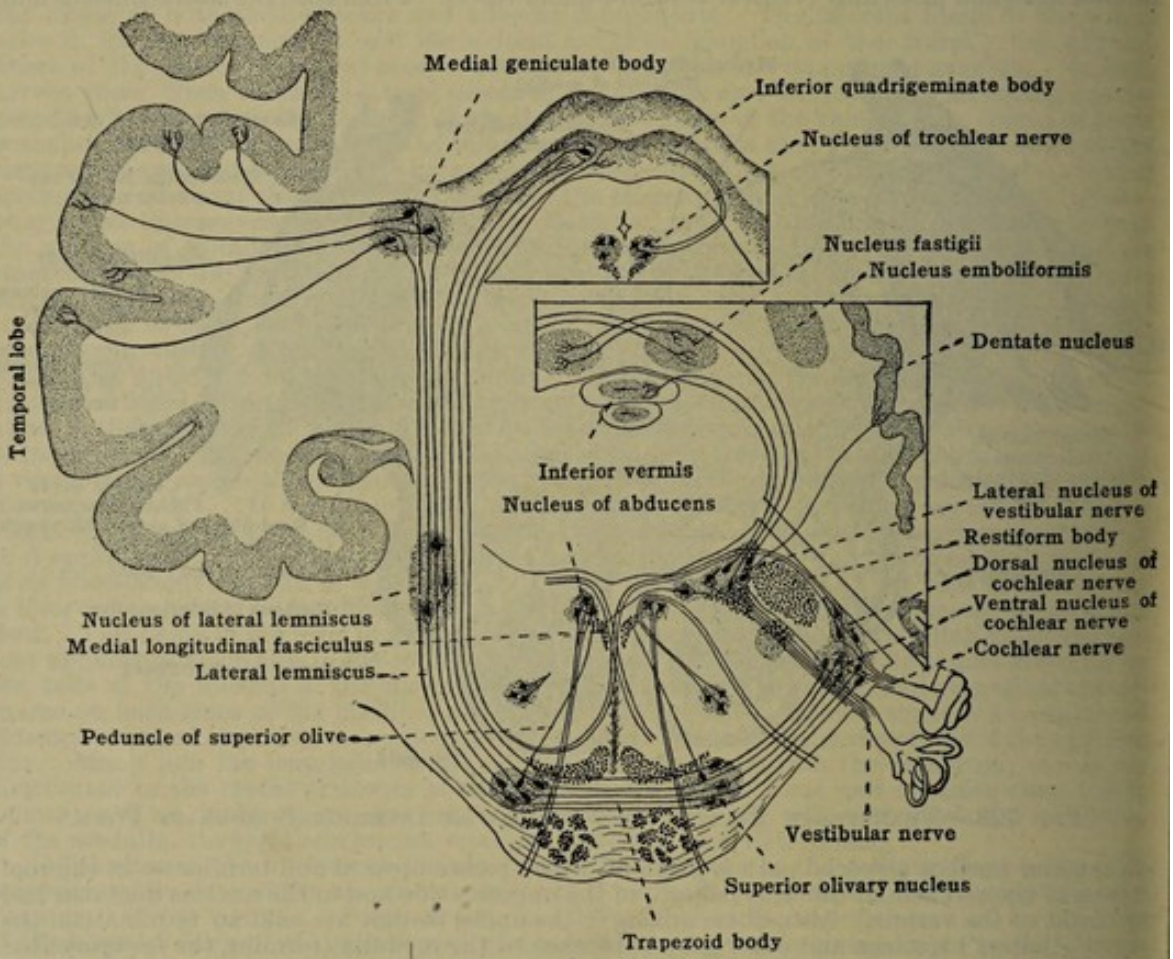

FIG. 729.—SCHEME SHOWING SOME OF THE CENTRAL CONNECTIONS OF THE ACOUSTIC NERVE. (In part after Edinger.)

From the **ventral nucleus**, fibers arise which terminate about (or give collaterals to) the cells of the **superior olivary nucleus** of the same and opposite sides. The superior olive is a small accumulation of gray substance which lies in the level of the inferior portion of the pons, and in line with the much larger inferior olivary nucleus of the medulla. However, it is not analogous to the latter in any sense. The two superior olives form links in the central acoustic chain. From cells of the superior olivary nucleus of the same and opposite sides, fibers arise which join the lateral lemniscus and terminate in the gray substance of the inferior quadrigeminate body and in the medial geniculate body, thus associating these bodies with the ventral nucleus of cochlear termination of the opposite side. From the medial geniculate body fibers arise which pass to the cortex of the superior temporal gyrus. Only a few of the fibers arising in the inferior quadrigeminate body terminate in the cortical area of hearing. In the lateral lemniscus some of the acoustic fibers are interrupted by cells of the *nucleus of the lateral lemniscus*. In crossing the midline, between the superior olives, the ventral fibers from the two sources form a more or less compact bundle, the **corpus trapezoideum** (trapezium). To this are added fibers crossing between the **nuclei trapezoidei**, smaller masses of gray substance just ventral to the superior olive and probably of the same significance. Experimental evidence has suggested that the more ventrally coursing fibers in the trapezoid body are not concerned with auditory impulses proper, but instead are concerned with cochlear motor reflexes only. And further it is asserted that some vestibular fibers cross in the trapezium.

Also, some fibers arising in the nuclei of termination of the cochlear nerve pass to the inferior quadrigeminate body of the same side. On the other hand, the relation with the medial geniculate body is thought to be wholly a crossed one. Further, some fibers are described as terminating in the *superior quadrigeminate body* of both the same and the opposite side. These, forming the *stratum lemnisci* of this body, are especially suggestive of associating auditory impulses with eye-movements.

All the fibers arising in the superior olivary nucleus do not enter the corpus trapezoideum. A small bundle, the **peduncle of the superior olive**, arises in each nucleus and courses dorsally to the region of the nucleus of the abducens. Here certain of its fibers terminate about the cells of the nucleus of the abducens, while others enter the medial longitudinal fasciculus and pass to the nuclei of the trochlear and oculomotor nerves, thus further establishing connections between auditory impulses and eye-movements. Also fibers from the nuclei of termination of the cochlear nerve are known to enter the medial longitudinal fasciculus and doubtless by way of this they distribute impulses to the motor nuclei of other cranial nerves and to the ventral hours of the spinal cord.

The vestibular and cochlear nerves enjoy a certain amount of community of origin in their ganglia and a certain community of distribution as to the origin and general character of the ectodermal neuroepithelium in their respective divisions of the labyrinth. Winkler's work has suggested that to some extent they may use their nuclei of termination in common and to some extent share each other's central paths in the medulla and midbrain, making paths usually considered purely vestibular and purely cochlear doubtfully so. It is not impossible that sound vibrations may arouse impulses in the macula sacculi and maybe changes in body posture can arouse impulses in the cochlea. However, it can be said with certainty that each of these nerves is chiefly concerned with the functions long ascribed to it.

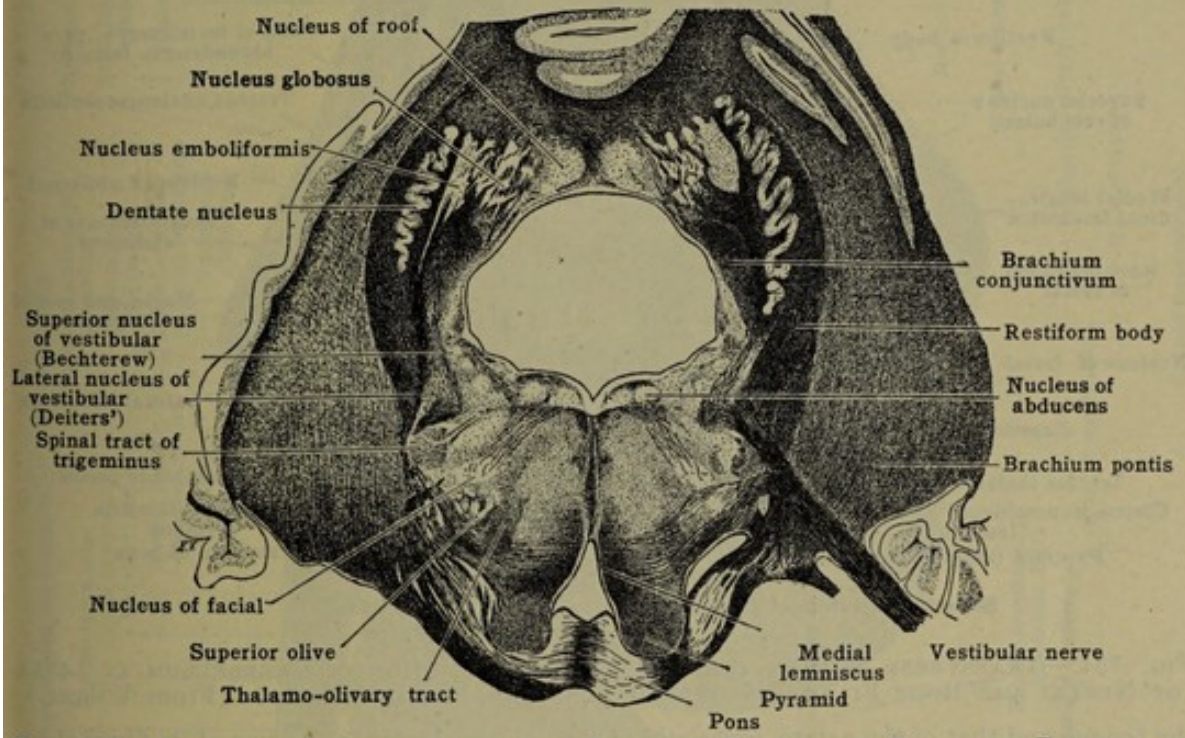

FIG. 730.—TRANSVERSE SECTION THROUGH INFERIOR BORDER OF PONS AND PORTION OF OVERLYING CEREBELLUM. (From Villiger.)

The **facial nerve** is commonly described as consisting of the 'facial proper' and its so-called sensory root or *pars intermedia*, the two together being designated as the seventh cranial nerve. However, the pars intermedia neither serves as a sensory root for the facial nor is it purely sensory. Many years ago Sapolini considered it a separate nerve and later it was called the *intermediate nerve of Wrisberg*. More recent investigations of its development and distribution, especially those of Streeter and Sheldon, further indicate that it merits a separate description and a separate name, and, indicative of its distribution, it is here described as the *glossopalatine nerve*. The facial, the glossopalatine and the abducens all have their nuclei within the level of the pons, though the roots of all appear from under its inferior border and are considered as attached to the medulla.

The **facial** [nervus facialis] has its nucleus (of origin) in the ventrolateral region of the reticular formation, superior to and in line with the nucleus ambiguus (figs. 726, 730). The axones given off by the cell-bodies of the nucleus collect into a bundle which, instead of passing ventrally and directly to the exterior of the pons, courses at first dorsomedially to the mesial side of the nucleus of the abducens (ascending root of the facial); then it turns and courses superiorly for a few millimeters, parallel with the nucleus of the abducens immediately beneath the floor of the fourth ventricle (*genu internum*, figs. 731 and 732); then it turns abruptly in a ventrolateral and inferior direction to its point of exit at the inferior border of the pons, just lateral to the olive and medial to the entrance of the vestibular nerve. Its exit usually involves a few pons fibers. In transverse sections through the middle of the nucleus of the abducens the genu of the facial appears as a compact transversely cut bundle at the dorsomedial side of this nucleus.

The nucleus of the facial is described as consisting of two chief groups of cells, an anterior and a posterior group which give rise respectively to the axones of the superior and inferior branches of the facial nerve. It receives cortical impulses from the lower portion of the anterior central gyrus of the cerebral cortex, from the root fibers of the trigeminus of the same side, which serves as its sensory root, and (chiefly) fibers arising from the nuclei of termination of the trigeminus. The nuclei of termination of the optic and the cochlear nerves of the same and opposite sides give rise to fibers which terminate about its cells. The fibers from the cerebral cortex descend in the pyramidal fasciculi and cross by way of the raphe and arcuate fibers to terminate in the nucleus of the opposite side. The anterior group of the cells of the facial nucleus must receive cortical fibers not only from the cerebral hemisphere of the opposite but also from that of the same side, evidenced by the fact that the superior branch of the nerve is but little affected in facial paralysis resulting from a lesion in the cerebral cortex of one side. A lesion destroying the root of the nerve or its nucleus of origin will of course give total facial paralysis of the side of the lesion.

The **glossopalatine nerve** (*nervus intermedius*, sensory root of facial, etc.) is a mixed nerve but largely sensory. It accompanies the facial nerve trunk from a short distance beyond the geniculum (genu externum) of the facial to its attachment to the brain stem. Its *sensory fibers* arise as T-fibers of the cells of the *geniculate ganglion* (at the geniculum of the facial). The peripheral processes go as the *chorda tympani* to supply the epithelium of the anterior part of

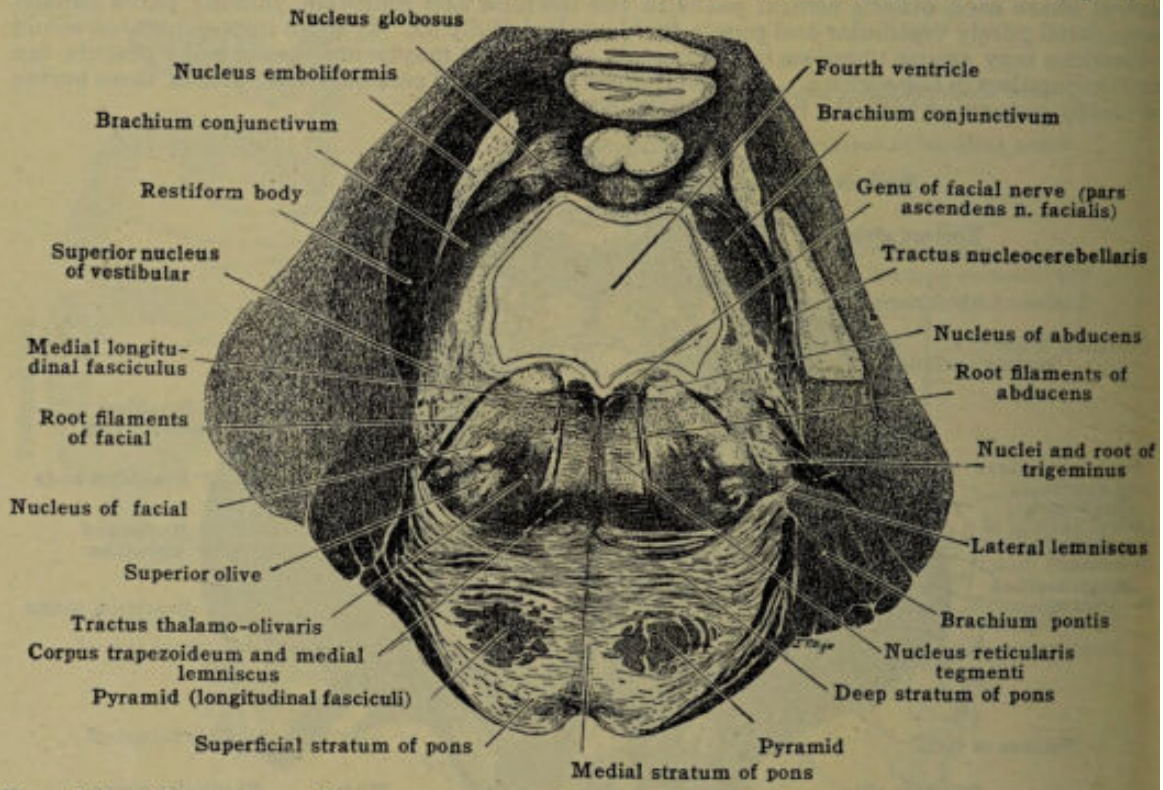

FIG. 731.—TRANSVERSE SECTION THROUGH PONS AND PORTION OF CEREBELLUM AT LEVEL OF NUCLEI AND ROOT FILAMENTS OF ABDUCENS AND FACIAL NERVES. (From Villiger.)

the tongue and that of the palate, especially of the palatine arches, and some of its fibers share with the glossopharyngeal nerve the innervation of the taste-buds. The central processes enter the brain stem, bifurcate into caudal and cephalic branches, and find their nucleus of termination in a superior extension of the nucleus of the solitary tract (the ventral portion of the nucleus of the ala cinerea). The geniculate ganglion contains some cell-bodies of sympathetic neurones, left over in it during the period of migration of the sympathetic neuroblasts.

The *efferent fibers* of the glossopalatine arise from cell-bodies lying dorsomedial to the nucleus of the facial and in the level between this and the nucleus of the masticator nerve superior to it. Its cells are usually scattered in the reticular formation in line with the dorsal efferent nucleus of the vagus. Since most of its fibers, at least, are visceral efferent and are concerned with sympathetic neurones (terminate in sympathetic ganglia) and convey secretory impulses destined for the salivary glands, chiefly the submaxillary and sublingual, this nucleus has been called the **nucleus salivatorius.**

The **abducens** is a small, purely motor nerve, which supplies the lateral rectus muscle of the eye. Its *nucleus of origin* lies close to the midline in the medial eminence of the floor of the fourth ventricle, superior to and in line with that of the hypoglossus. Its root-fibers, uncrossed, pursue a ventral course, inclining a little laterally and curving inferiorly to emerge from under the inferior border of the pons. They pass lateral to the pyramid, and often between some of its fasciculi. The nucleus receives cortical or voluntary impulses by way of the pyramidal fasciculi chiefly of the opposite side. Its connection with the auditory apparatus and the medial longitudinal fasciculus has already been noted. It probably receives afferent impulses through the fibers of the trigeminus as well as by fibers descending from the nuclei of termination of the optic nerve. It is also associated, by way of the medial longitudinal fasciculus, with the nucleus of the oculomotor nerve of the same and opposite side.

The **trigeminus** is considerably larger than any of the nerves inferior to it, and has the most extensive central connections of any of the cranial nerves. It is a purely sensory nerve which

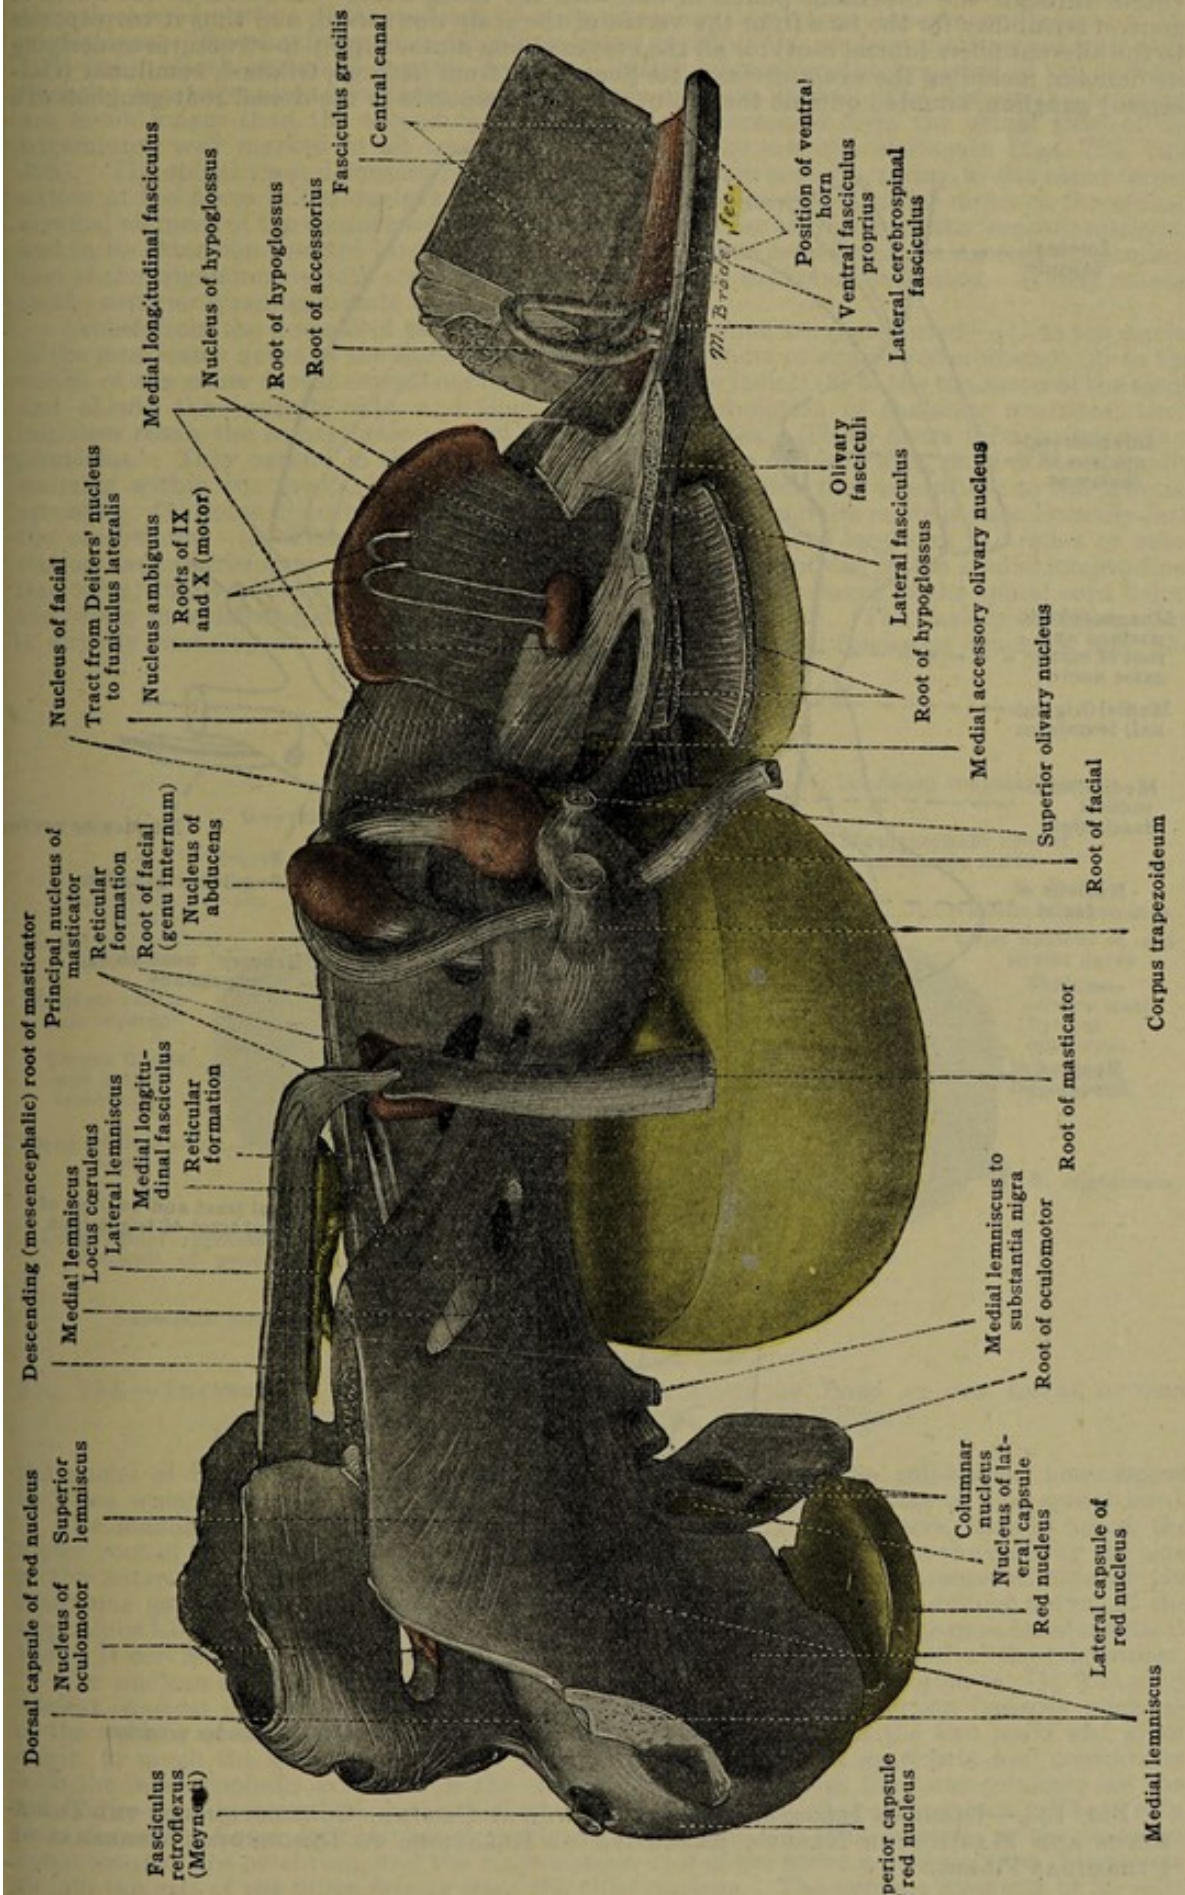

FIG. 732.—DRAWING OF MODEL OF BRAIN-STEM OF AN INFANT, SHOWING THE NUCLEI OF ORIGIN OF THE MOTOR CRANIAL NERVES. (After Sabin.)

enters through the brachium pontis in line with the facial nerve. It serves as the nerve o general sensibility for the face from the vertex of the scalp downward, and thus it correspond to the afferent fibers (dorsal root) for all the nerves giving motor supply to structures underlyin its domain, including the eye-muscles. Its fibers arise from its large, trilobed, **semilunar** (Gas serian) **ganglion,** situated outside the brain. This corresponds to the dorsal root-ganglion of

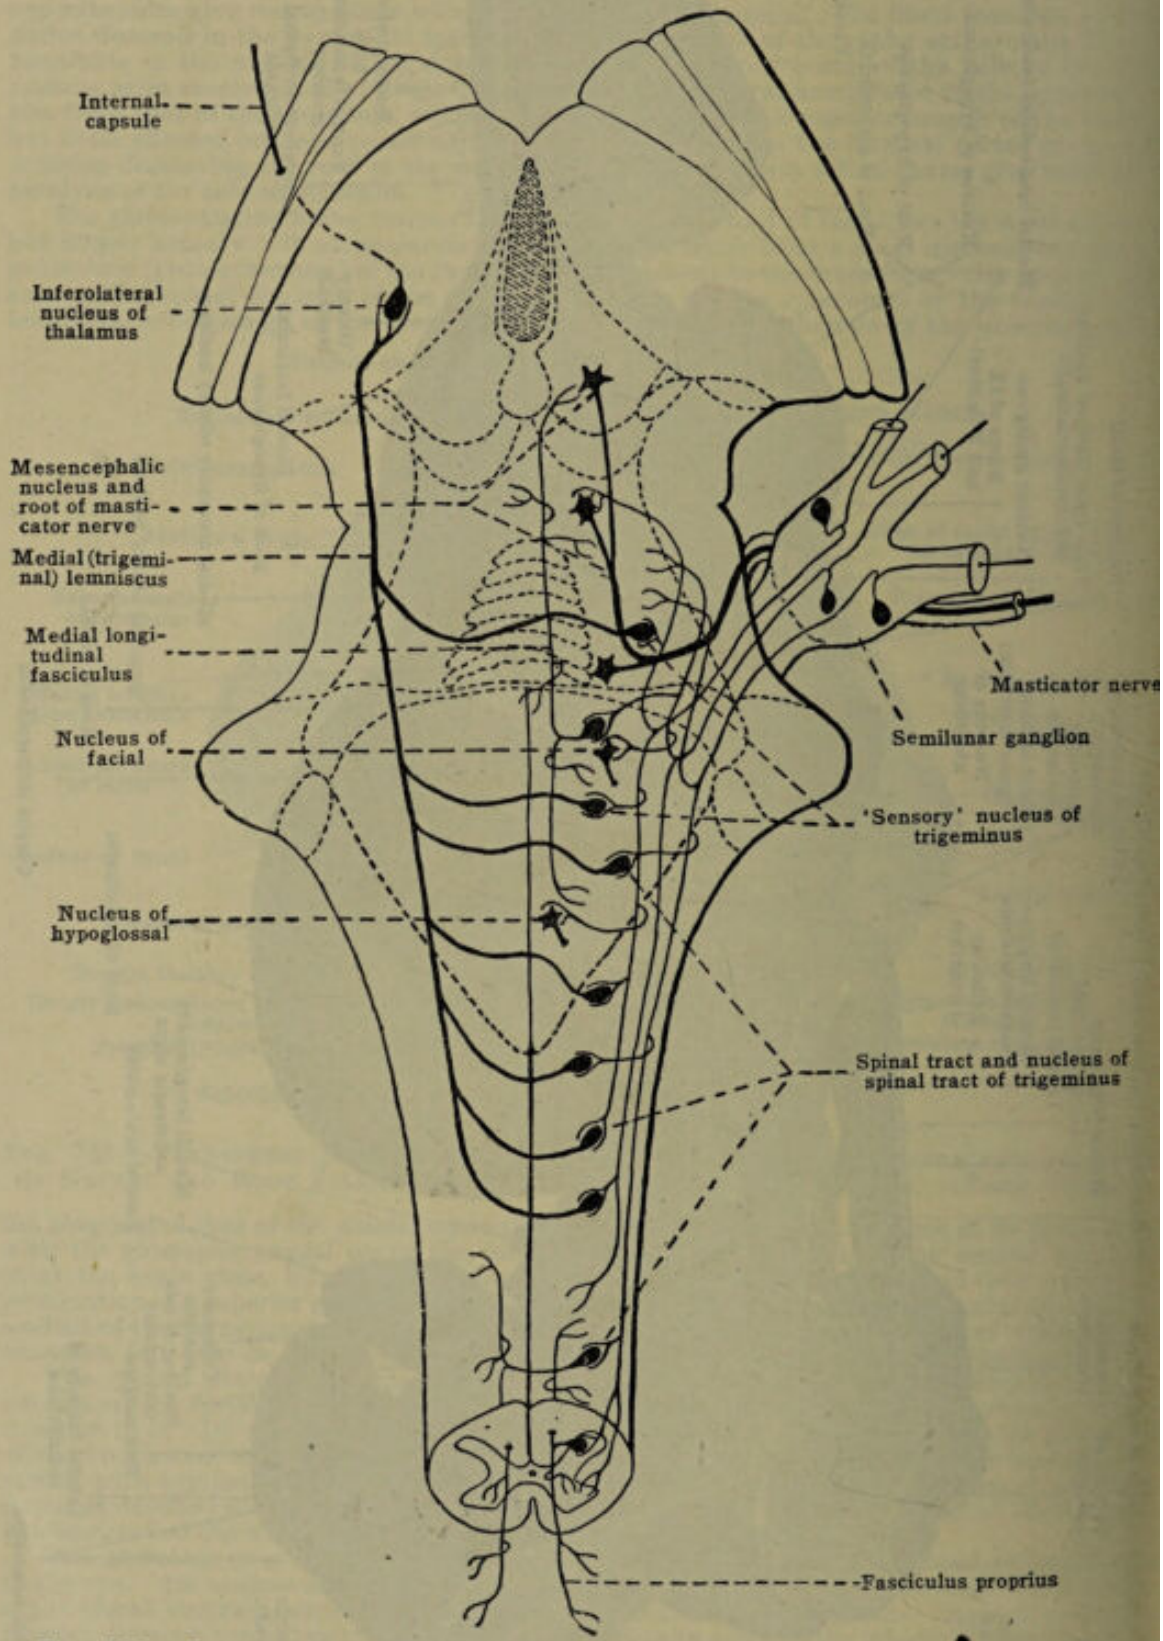

FIG. 733.—DIAGRAM ILLUSTRATING THE PRINCIPAL CENTRAL CONNECTIONS OF THE TRIGEMINUS AND MASTICATOR NERVES, EXCLUSIVE OF RELATIONS TO DESCENDING CEREBRAL OR PYRAMIDAL FIBERS.

spinal nerve, and its cells give off the characteristic T-fibers with peripheral and central branches. The central or afferent branches upon entering the brain-steam bifurcate into ascending and descending divisions, just as the entering dorsal root-fibers of the spinal nerves, and find their *nucleus of termination* in a dorsolateral column of gray substance, lying deeply and extending longitudinally through the brain stem, and consisting of the upward continuation of the gelatin-

ous substance of Rolando of the spinal cord. Opposite the entrance of the nerve is a considerably thickened portion of this column of gray substance, known as the *sensory nucleus* of the trigeminus. The remainder of it extending below is called the *nucleus of the spinal tract* (figs. 726, 733). Both parts are equally 'sensory.' After bifurcation the branches of the entering fibers of the trigeminus terminate about the cells of these nuclei. The descending branches are much longer than the ascending, and in passing downward form the **spinal tract of the trigeminus,** well marked in all transverse sections of the medulla oblongata (figs. 720, 722, 728). The spinal tract decreases rapidly in descending the medulla, owing to the rapid termination of the fibers in the nucleus of the tract. It has been traced as far down as the second cervical segment of the spinal cord. The ascending branches terminate in the 'sensory nucleus,' and in its extension upward into the mesencephalon. This mesencephalic nucleus of termination of the trigeminus is both shorter and more scant than the spinal extension. It may extend to the superior quadrigeminate body.

Axones from the nucleus of termination of the trigeminus are distributed—(1) to the nuclei of the masticator nerve of the same and opposite sides (short or simple reflex fibers); (2) to the nuclei of the other motor cranial nerves, especially of the facial; (3) to the thalamus of the same and chiefly the opposite side, and thus, through interpolation of thalamic neurones, their impulses reach the somesthetic area of the cerebral cortex. These fibers form a *'trigeminal lemniscus.'* They ascend in the recticular formation of the opposite side, most of them finally coursing within the medial lemniscus. In crossing the midline they contribute to the internal arcuates. (4) Some fibers of both the trigeminus direct and from its nucleus pass laterally into the cerebellum. (5) Fibers to the quadrigeminate bodies. The longer of the reflex or association axones arising in the nucleus of termination may contribute to the medial longitudinal fasciculus; many of them descend to terminate in the gray substance of the spinal cord below the levels in which the fibers of the spinal tract proper terminate. The nucleus of termination is directly homologous to the nuclei of the fasciculus gracilis and fasciculus cuneatus, and, like

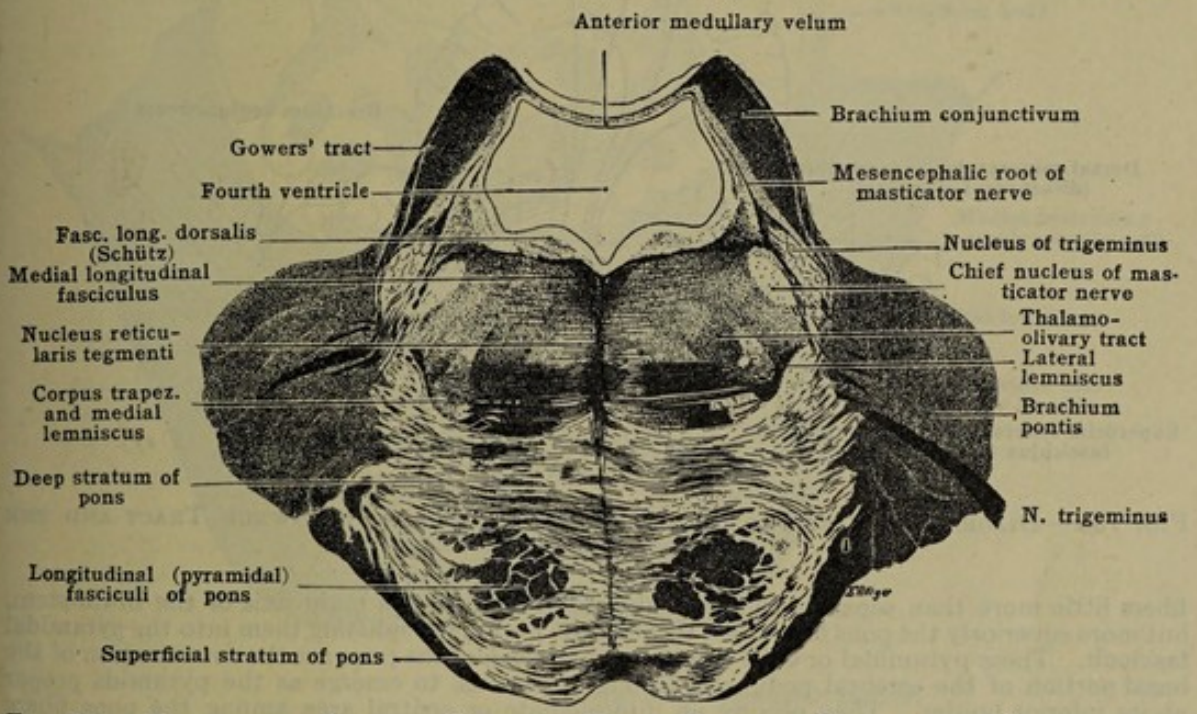

FIG. 734.—TRANSVERSE SECTION THROUGH UPPER PART OF PONS AT THE LEVEL OF THE ENTRANCE OF THE TRIGEMINUS. (From Villiger.)

the nuclei of termination of all sensory cranial nerves, it contains cell-bodies homologous to those which give rise to the fasciculi proprii and commissural fibers of the spinal cord.

The **masticator nerve** [*portio minor n. trigemini*] is a purely motor nerve, usually called the motor root of the trigeminus from the fact only that it makes its exit from the pons by the side of the entering fibers of the trigeminus, passes outward over the ventromedial side of the semilunar ganglion and accompanies the inferior maxillary division (mandibular nerve) of the trigeminus till it divides totally into its branches for the motor supply of the muscles of mastication. It serves, therefore, as but a relatively small part of the 'motor root' of the trigeminus.

The nucleus of origin of the masticator nerve is attenuated into two parts: (1) The *chief nucleus (nucleus princeps)* lies on the dorsomedial side of the larger portion (sensory nucleus) of the nucleus of termination of the trigeminus. It is the larger of the two parts and gives origin to much the greater part of the masticator. (2) Scattered anteriorly and continuous with the mesencephalic extension of the chief nucleus, in line with the *locus ceruleus*, are the cell-bodies usually described as the *nucleus of the mesencephalic* (descending) *root.* These cells lie in decreasing linear distribution, through the mesencephalon, as far anterior as the posterior commissure of the cerebrum, and the *mesencephalic root* of the nerve accumulates as it descends to join the exit of the fibers arising from the chief nucleus. The average diameter of its cells is somewhat less than for the chief nucleus.

It is not clearly settled that the fibers arising from the mesencephalic nucleus of the masticator nerve go to the muscles of mastication. As suggested by Kölliker, some of these may supply the tensor veli palatini and tensor tympani muscles. Investigations of lower animals by Johnston and Willems indicate that the mesencephalic root may contain but few motor

fibers, representing instead a portion of the sensory trigeminus fibers, whose cell-bodies of origin are retained during development within the central system, their peripheral processes passing out in the root of the trigeminus. It is claimed that some fibers, probably sensory, in descending give off collaterals which terminate about cells in the chief nucleus, to form simple reflex arcs.

It is claimed also that each masticator nerve receives a few fibers arising from the cells of the nucleus of that of the opposite side.

Both parts of the nucleus of the masticator receive afferent impulses brought in by the trigeminus of the same (chiefly) and of the opposite side, and both receive cortical impulses by fibers from the inferior portion of the precentral gyrus which descend in the cerebral peduncles and cross to terminate in the nucleus of the opposite side.

The internal structure of the pons.—The nuclei and roots of the trigeminus, masticator, abducens, facial, glossopalatine, cochlear and vestibular nerves are extended within the level of the pons, and their position and course have been described above. The pons proper (the bridge) consists of a mass of transversely running fibers continuous on either side into the brachia pontis or middle cerebellar peduncles. In the animal series the relative amount of these fibers varies with the size of the cerebellum upon which they are dependent. They are relatively more abundant in man than in other animals.

In transverse sections the pons fibers are seen to course ventrally about the main axis of the brain-stem, making it possible to divide the section into a *basilar* or *ventral part* (pons proper) and a *dorsal part* (*tegmentum* or *preoblongata*). The fibers in their transverse and ventral course around the medulla oblongata involve the pyramids. At the inferior border of the pons the

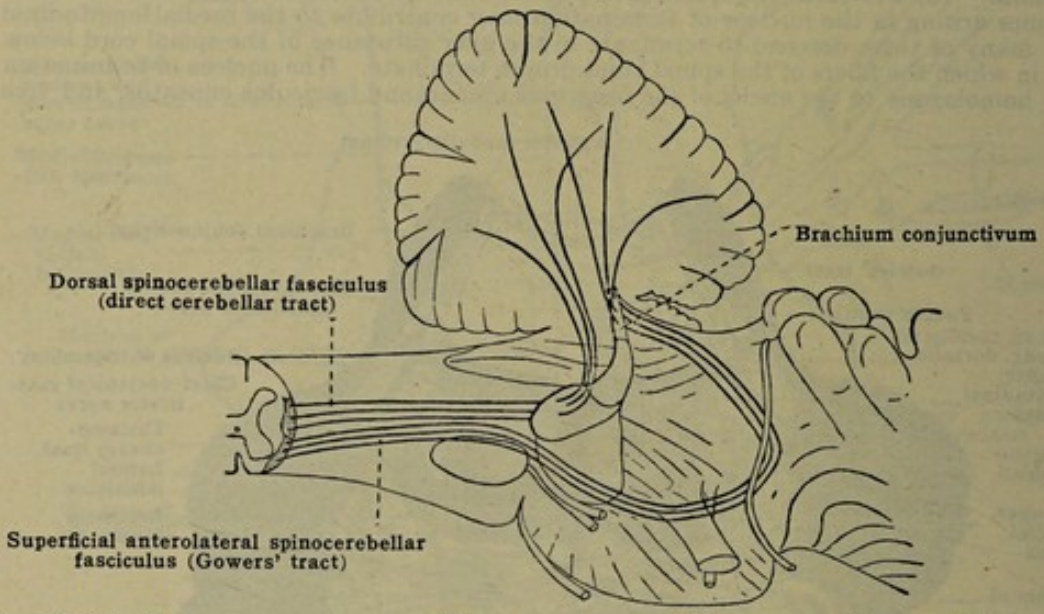

FIG. 735.—DIAGRAM SHOWING THE RHOMBENCEPHALIC COURSE OF GOWERS' TRACT AND THE DIRECT CEREBELLAR TRACT.

fibers little more than separate the pyramids as such from the main axis of the brain-stem, but more superiorly the pons fibers pass through the pyramids, splitting them into the **pyramidal fasciculi**. These pyramidal or chief *longitudinal fasciculi* of the pons are the continuation of the basal portion of the cerebral peduncles through the pons, to emerge as the pyramids proper at its inferior border. They occupy an intermediate or central area among the pons fibers of either side, leaving the periphery of the pons uninvaded. The *superficial pons-fibers* form the solid bundle of its ventral and lateral periphery and the *deep pons-fibers* form similar bundles dorsally enclosing the area of pyramidal fasciculi, which latter are involved in a *medial stratum of the pons* (figs. 731, 734, 736).

In the transverse sections through the *inferior portion* of the pons, the *dorsal or tegmental part* consists of structures continuous with and analogous to the structures of the medulla oblongata immediately below, exclusive of the pyramids. In addition, this region contains the superior olivary nucleus and the corpus trapezoideum. The significance of these structures and their relation to the nucleus of termination of the cochlear nerve are shown in figs. 729–731. In this region the *lemniscus* (fillet) changes from the sagittal to the coronal plane, and its lateral edges are becoming drawn outward and carry the lateral lemniscus of the regions superior to this. The medial longitudinal fasciculus, left alone by the change in the arrangement of the lemniscus, maintains its dorsal and medial position throughout the pons and into the mesencephalon above. The **thalamo-olivary tract** appears loosely collected in the dorsal part of the pons, dorsomedial to the nucleus of the superior olive.

The **restiform body** acquires in this inferior region a more dorsolateral position than in the medulla below. Its fibers are beginning to turn upward in their course to the cerebellum mesial to the brachium pontis. Here the restiform body is nearing completion, and the fibers now contained in it may be summarized as follows:—

(1) The fibers of the dorsal spinocerebellar fasciculus (direct cerebellar tract) of the same side.

(2) Fibers from the nuclei of the fasciculus gracilis and fasciculus cuneatus of the same and opposite side (external and internal arcuate fibers).

(3) Fibers to and from the inferior olives of the same and (chiefly) the opposite side (cerebello-olivary fibers).

(4) Sensory cerebellar fibers from the nuclei of termination of the vagus, glossopharyngeal, vestibular and trigeminus, vestibular especially, and from the cells of the reticular formation.

(5) Descending fibers to the motor nuclei of the vagus and glossopharyngeal, and possibly some fibers descending into the anterior marginal fasciculus of the spinal cord, the latter, however, being in large part interrupted by cells in the nuclei of the vestibular nerve.

(6) A few fibers arising from the arcuate nuclei. These nuclei are continuous superiorly with the nuclei of the pons and some of their fibers are described as entering the cerebellum by way of the restiform body instead of by way of the brachium of the pons as in the levels above.

The ascending fibers of the restiform body are distributed to the cortex of the vermis, the nucleus of the roof (*fastigii*), the nucleus dentatus, nucleus emboliformis, and nucleus globosus.

Very few if any of the fibers ascending the cord in *Gowers' tract* enter the cerebellum by way of the restiform body. This tract (the superficial anterolateral spinocerebellar fasciculus) ascends the medulla, dispersed in the reticular formation, and therefore in a more ventral position than that of the direct cerebellar tract. In this position it becomes enclosed by the fibers of the pons, and so it passes upward, beyond the pons, around the lateral lemniscus to the brachium conjunctivum, and there turns back to enter the cerebellum by way of this brachium. Certain clinical phenomena, probably purely psychological, have been alleged to indicate that some of the fibers of Gowers' tract pass on to the cerebrum instead of turning in the medullary velum to enter the cerebellum.

The dorsal part of a transverse section through the *upper part* of the pons contains the **superior cerebellar peduncles** [brachia conjunctiva] instead of the restiform bodies (inferior

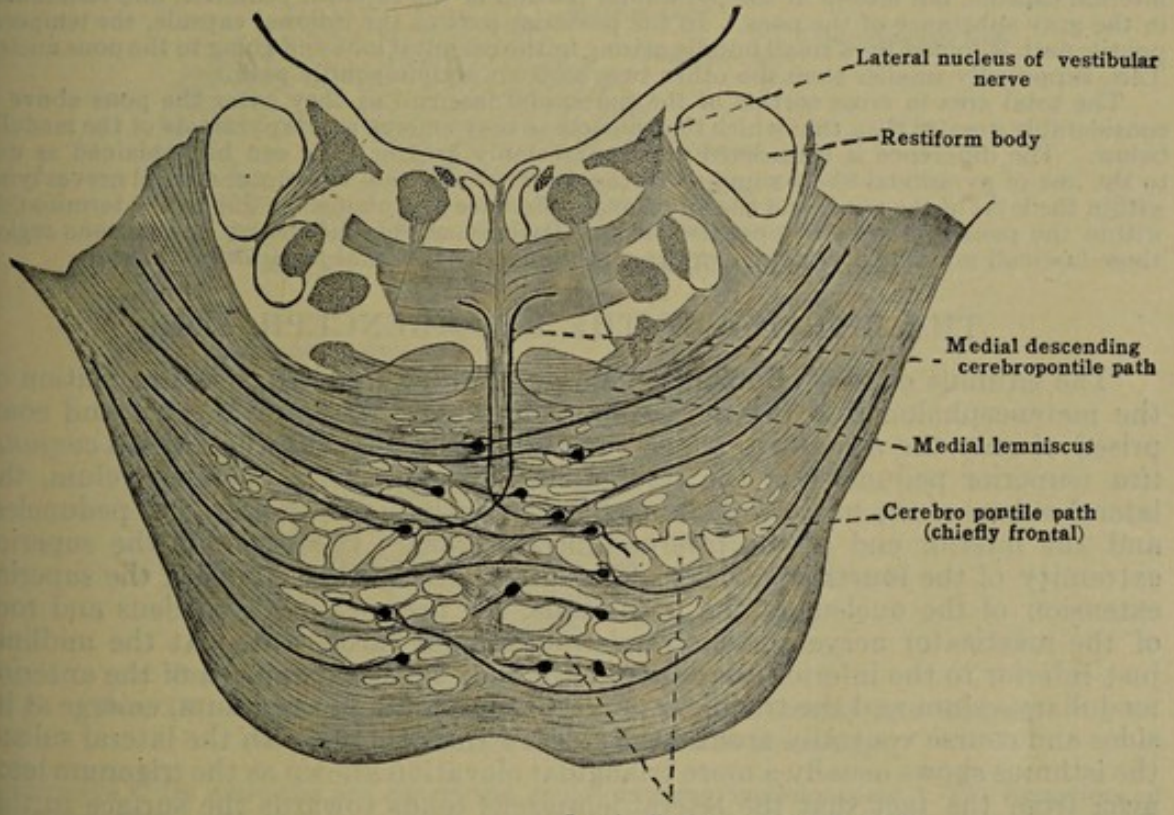

FIG. 736.—DIAGRAM SHOWING CONNECTIONS OF THE NUCLEI OF THE PONS.
The plane of the section is obliquely transverse or parallel with the direction of the brachia pontis.

peduncles). Instead of the cerebellum forming the roof of the fourth ventricle, in this region the roof is formed by the anterior medullary velum bridging the space between the two brachia conjunctiva (fig. 734). Adhering upon the medullary velum is the **lingula cerebelli**—the superior and ventral extremity of the superior vermis. This is the only portion of the cerebellum attached to this region.

The lemniscus (fillet) is found more lateral than at the inferior border of the pons, and is divided into the *medial lemniscus* and *lateral lemniscus* proper. The lateral lemniscus has shifted dorsally until in this region it courses in the dorsolateral margin of the section external to the brachium conjunctivum. The mesencephalic root of the masticator nerve occurs in the dorsolateral margin of transverse sections through this region, and this and the trigeminus are the only cranial nerves represented here.

The transverse fibers of the ventral part of the section (pons proper), and therefore the brachia pontis, consist of fibers coursing in opposite directions. Many are fibers which are outgrowths of the Purkinje cells of the cortex of the cerebellar hemispheres, and pass either directly to the cerebellar hemisphere of the opposite side or turn dorsalward in the raphe to course longitudinally in the brain-stem both toward the spinal cord and toward the mesencephalon. Others terminate in the gray substance (nuclei) of the pons. Others are fibers which arise in the gray substance of the pons and pass to the cerebellar hemispheres, and still others are the cerebropontile fibers, from the temporal, occipital and frontal lobes.

The **gray substance of the pons** [**nuclei pontis**] occurs quite abundantly. At the inferior border of the pons it is found concentrated about the then more accumulated bundles of the emerging pyramids, and serial sections show it to be a direct upward continuation of the arcuate

nuclei of the medulla oblongata below. Higher up it is dispersed throughout the central ar in the interspaces between the transverse pontile and longitudinal pyramidal fasciculi. large portion of the nerve-fibers passing through it are thought to be interrupted by its cel which thus serve as links in some of the neurone-chains represented by the fibers of the por Of the more important of such relations, the following are said to exist:—

(1) Fibers which arise in the cortex of one cerebellar hemisphere and terminate about ce of the nucleus pontis of the same and opposite sides of the midline. These cells give off axon which pass to the other cerebellar hemisphere. In this relation the nuclei of the pons a analogous to the arcuate nuclei, save that the cerebellar fibers interrupted in the former a connected with the cerebellum by way of the brachia pontis instead of the restiform bodies.

(2) Certain of the descending cerebropontile fibers terminate about cells of the nuclei the pons. Such cells give off fibers which probably, for the most part, pass to the cerebell hemispheres, the impulses from the cerebral hemisphere of one side being conveyed to th opposite cerebellar hemisphere. Most of the descending cerebropontile fibers are thought cross the midline to terminate about cells of the nuclei of the pons of the opposite side, a relatio not sufficiently emphasized in the accompanying diagram (fig. 736).

Of the cerebropontile paths, (see fig. 775) the **frontal pontile path** (Arnold's bundle) described as arising in the cortex of the frontal lobe (frontal operculum), passing in the anteri portion of the internal capsule down into the medial part of the base of the cerebral peduncl and terminating in the gray substance of the pons. The descending **temporal pontile pat** (Türk's bundle), arises in the cortex of the temporal lobe, traverses the posterior portion of th internal capsule, lies lateral in the pyramidal portion of the cerebral peduncle, and terminat in the gray substance of the pons. In the posterior part of the internal capsule, the tempor pontile path is joined by a small bundle arising in the occipital lobe and going to the pons nucle This, supposedly smaller than the other two, adds an **occipitopontile path.**

The total area in cross section of the pyramidal fasciculi as they enter the pons above considerably greater than that which they possess as they emerge as the pyramids of the medul below. The difference is considered very appreciably greater than can be explained as du to the loss of pyramidal fibers supplied to the nuclei of origin of the motor cranial nerves lyin within the level of the pons, and the additional difference is explained as due to the terminatio within the pons of the cerebropontile paths. Because of this difference, in the pons regio these fasciculi must be given the more general name, *longitudinal fasciculi of the pons.*

THE ISTHMUS OF THE RHOMBENCEPHALON

The isthmus of the rhombencephalon is nothing more than the transition o the metencephalon into the mesencephalon above. It is quite short and com prised of only the structures which run through it, namely, the *brachia conjunc tiva* (superior peduncles of the cerebellum), the anterior medullary velum, th lateral sulcus of the mesencephalon, the substantia nigra, the cerebral peduncles and the inferior end of the interpeduncular fossa. It surrounds the superio extremity of the fourth ventricle. The lateral and medial lemnisci, the superio extension of the nucleus of the trigeminus, the mesencephalic nucleus and roo of the masticator nerve and Gowers' tract extend through it. At the midline just inferior to the inferior quadrigeminate bodies is the **frenulum** of the anterio medullary velum and the trochlear nerves, decussating in the velum, emerge at it sides and course ventrally around the sides of the isthmus. In the lateral sulcus the isthmus shows usually a more triangular elevation known as the **trigonum lem nisci** from the fact that the lateral lemniscus tends towards the surface in this region and the nucleus of the lateral lemniscus begins there.

Functions of the cerebellum.—From the above descriptions involving the structures of th metencephalon, it may be noted: (1) that a given side of the cerebellum is associated chiefly with the same side of the general body and with the opposite side of the cerebrum. (2) That it receives afferent impulses from the spinal cord (brought into the cord by the dorsal roots o the spinal nerves) by way of the direct cerebellar fasciculus of the same side, and by Gowers tract, arising in the same and opposite sides of the cord, and from the nuclei of the fasciculus graci lis and cuneatus of the same and opposite sides. It further receives afferent impulses from the nuclei of termination of the trigeminus, glossopharyngeal and vagus of the same side chiefly, and especially does it receive afferent impulses from the nuclei of the vestibular nerve of the opposite and same side. (3) That the cerebellum sends impulses to the red nucleus, the thala mus and the cerebral cortex of the opposite side, and some of its fibers terminate in the nuclei of termination of the vestibular nerve and possibly some fibers arising in its roof nuclei descend into the spinal cord direct. (4) That the cerebellum receives impulses from the thalamus of the opposite side by way of the thalamo-olivary tract and the inferior olive, and especially from the cerebral cortex of the opposite side by way of the frontal, temporal and occipital pontile paths and the nuclei of the pons. Further, fibers from the longitudinal pyramidal fasciculi are described as terminating about cells of the nuclei of the pons and bearing impulses which are distributed to the opposite side of the cerebellum.

Taking into consideration these known associations of the cerebellum, the anatomically possible paths which in part may distribute cerebellar impulses to the gray substance which sends efferent fibers to the peripheral tissues are (1) the pyramidal fasciculi whose cortex of origin may receive impulses by *fibræ propriæ* from the cortical areas receiving impulses from the cerebellum. The pyramidal fasciculi, decussating, distribute impulses to the gray substance of the medulla and cord of the same side as that from which the cerebellocerebral impulses

passed to the cortex. (2) The lateral vestibulospinal and the anterior marginal fasciculi to the ventral horn of the spinal cord of the same side, probably carrying impulses descending from the cerebellum as well as impulses brought in by the vestibular nerve and descending direct from its nuclei of termination into the spinal cord. (3) The rubrospinal tract of the cord and probably some of the thalamospinal fibers (corpora-quadrigemina-thalamus path), since the red nuclei and thalami are associated abundantly with the cerebellum. These tracts likewise decussate in descending, but also do the cerebellar impulses ascending to the red nuclei and thalami.

Whatever other functions it may possess, developmental defects and pathologic lesions show that the cerebellum has to do with muscular tone, with the equilibration of the body and the finer coördinations, the adjustive control of contractions of functionally correlated groups of muscles. Making this possible, in part at least, it is seen above that it is associated (1) directly with the special nerve of equilibration, the vestibular; (2) with the optic apparatus by way of the thalamus, and (3) with the afferent impulses from the general body, by way of the direct cerebellar and Gowers' tracts, by way of the nuclei of the fasciculus gracilis and cuneatus, and the nuclei of termination of the trigeminus, glossopharyngeal and vagus. It has been suggested that by way of these latter paths the cerebellum deals especially with those general afferent impulses which arise within the muscles of the body (sensory fiber-terminations on tendons, muscle-sheaths, neuromuscular spindles, etc.), and which are grouped under the name 'Pro-

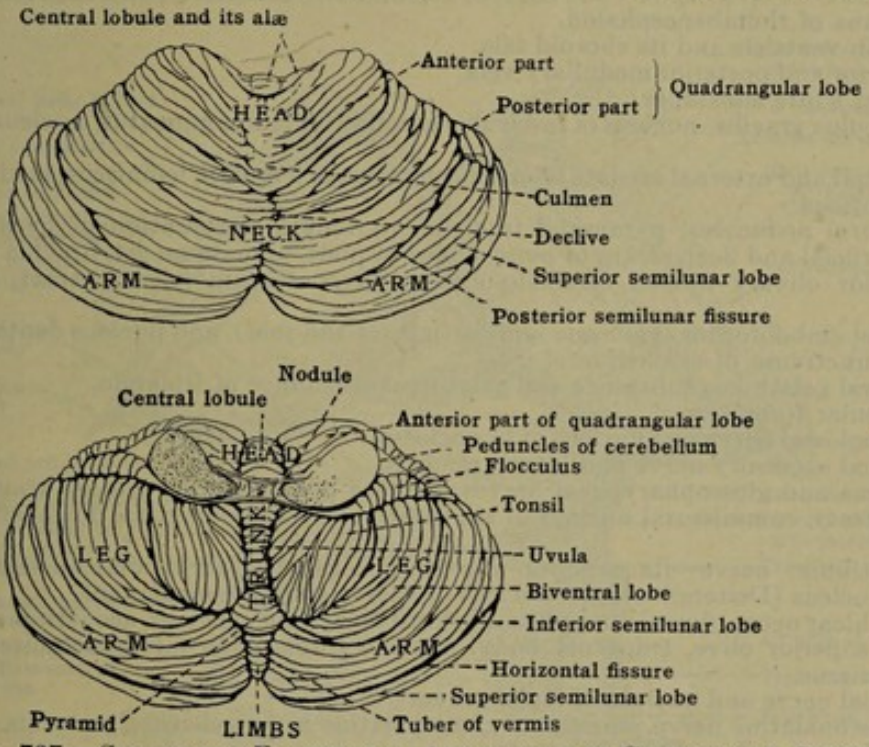

FIG. 737.—SUGGESTED FUNCTIONAL AREAS OF THE CEREBELLAR CORTEX.
(In part from Herrick's Introduction to Neurology.)

prioceptive.' Its activities are considered as not entering 'consciousness.' The sensations of muscular sense,' and pain from joints, muscles and tendons must reach the *cerebral* cortex to be recognized as such. (See also extrapyramidal system.)

Studies of the comparative anatomy of the cerebellum by Elliot Smith, Bolk and van Rynberk, experimental studies by André-Thomas, Luciani and Durupt, and clinical studies of symptoms resulting from localized lesions in the human cerebellum by Bárány and others have led to the conclusion that there is a certain amount of localization of function in the cerebellar gray substance. In fig. 737 are indicated some of the functional areas of the cerebellar cortex suggested. It will be seen that the anatomical distinction made between the cerebellar hemispheres and the vermis is not functionally important, especially on the superior surface. Beginning on the superior surface, the following areas may be noted:—The anterior part of the quadrangular lobe, the culmen and the central lobule with its ala comprise an unpaired area for the coördinations of muscular contraction resulting in subconscious movements of the head. The posterior portion of the quadrangular lobe, anterior part of it especially, together with the declive comprise an unpaired area for the similar control of movements of the neck. The tuber of the vermis is given as an unpaired area for similar control of bilateral movements of the upper and lower limbs. The superior and inferior semilunar lobes are considered paired areas for the control of unilateral movements of the arms, and, on the inferior surface, the biventral lobes are paired areas likewise controlling unilateral movements of the lower extremities. The pyramid, uvula and nodule of the inferior vermis are given as unpaired areas for coördinating contractions of the muscles of the trunk. The tonsil and flocculus are concerned with tail movements in the tailed mammals. Their significance in man is unknown. The chief function of cerebellar control of muscular contraction is for equilibration of the body, it being especially large in the primates. Of the nuclei of the cerebellum, the roof nuclei, associated as they are with the (vestibular) nerve of equilibration, are especially concerned with this function, probably bilaterally.

The cerebellum and medulla oblongata can be considered as an enlarged and modified portion of the spinal cord, receiving a greater number and variety of sensory impulses, and with

these mediating more comprehensive and complicated reflex (unconscious) activities than a possible in the less abundant gray substance of a given portion of the cord proper. Th cerebellum itself may be considered as an elaboration of the primary vestibular (equilibratic and orientation) region as found in the lower forms of vertebrates, in which the cerebellum often rudimentary. Unlike the different areas of the cerebral cortex, the cell structure of th cerebellar cortex is quite similar throughout. This must indicate greater similarity function throughout and greater simplicity of neurone chains than occur in the cerebr hemispheres.

SUMMARY OF PRINCIPAL STRUCTURES IN THE RHOMBENCEPHALON

A. Gross Exterior.

1. Medulla oblongata (Myelencephalon).
2. Metencephalon
   - Cerebellum
     - Hemispheres—lobes and lobules.
     - Vermis—lobules and lingula.
   - Pons
     - Dorsal part (tegmentum or preoblongata).
     - Ventral part (pons proper).
   - Cerebellar peduncles
     - superior—brachium conjunctivum.
     - middle—brachium of pons.
     - inferior—restiform body.
3. Isthmus of rhombencephalon.
4. Fourth ventricle and its choroid tela.
5. Anterior and posterior medullary vela.

B. Grey and white substance.

1. Funiculus gracilis, nucleus of fasciculus gracilis, funiculus cuneatus, nucleus of fasciculu cuneatus.
2. Internal and external arcuate fibers, decussation of lemnisci, lemniscus, medial lemniscu lateral lemniscus.
3. Cerebral peduncles, pyramidal fasciculi, pyramids, decussation of pyramids.
4. Superficial and deep strata of pons, nuclei of pons, arcuate nuclei, brachia of pons.
5. Inferior olivary nuclei, cerebello-olivary fibers, thalamo-olivary tract, spino-olivar tract.
6. Nuclei emboliformis, globosus and fastigii (of the roof), and nucleus dentatus with br chium conjunctivum of cerebellum.
7. Central gelatinous substance and gelatinous substance of Rolando.
8. Reticular formation.
9. Hypoglossal nerve and nucleus of hypoglossal.
10. Spinal accessory nerve and lateral nucleus.
11. Vagus and glossopharyngeal nerves, nucleus of ala cinerea, solitary tract and nucleu of solitary tract, commissural nucleus of ala cinerea, nucleus ambiguus, dorsal efferent nucleu of vagus.
12. Vestibular nerve—its superior nucleus (Bechterew), its medial nucleus (Schwalbe its lateral nucleus (Deiters), and the nucleus of its descending (spinal) root.
13. Cochlear nerve, dorsal nucleus and ventral nucleus of cochlear, acoustic medullary stria nucleus of superior olive, trapezoid body, nucleus trapezoidei, lateral lemniscus, nucleus o lateral lemniscus.
14. Facial nerve and nucleus of facial nerve.
15. Glossopalatine nerve, nucleus of glossopalatine and nucleus salivatorius.
16. Abducens and nucleus of abducens.
17. Trigeminus, 'sensory nucleus' of trigeminus, spinal tract and nucleus of spinal trac of trigeminus.
18. Masticator nerve, chief nucleus and (so-called) mesencephalic nucleus and root o masticator.
19. Medial longitudinal fasciculus.
20. Nucleus intercalatus, nucleus of medial eminence, nucleus incertus.

THE CEREBRUM

1. THE MESENCEPHALON

The mesencephalon or midbrain (figs. 681, 704, 714, 738, 747) is that smal portion of the encephalon which is situated between and connects the rhombencephalon below with the prosencephalon above. It is continuous with the isthmus rhombencephali, and occupies the tentorial notch, the aperture of the dura mater which connects the meningeal cavity containing the cerebellum with that occupied by the prosencephalon. Its greatest length is about 18 mm., and it is broader ventrally than dorsally. Its dorsal surface is hidden by the overlapping occipital lobes of the cerebral hemispheres. It consists of—(1) the **lamina quadrigemina,** a plate of mixed gray and white substance which goes over lateralward and below into (2), the **cerebral peduncles** (crura) and their tegmental structures and it contains (3), the *nuclei of origin* of the *trochlear* and *oculomotor* nerves. It arises from thickenings of the walls of the middle cerebral vesicle of the embryo, the lamina quadrigemina arising from the dorsal or alar lamina of this portion of the neural tube, while the basal lamina thickens to form the nuclei of the nerves the substantia nigra, etc., and is thickened by the ingrowing of the cerebra

peduncles. By means of the lamina quadrigemina roofing it over, the central canal throughout the mesencephalon retains its tubular form and is known as the **aqueductus cerebri** (Sylvii), connecting the cavity of the fourth ventricle below with that of the third ventricle above.

External features.—*Dorsal surface* (figs. 710, 738).—The lamina quadrigemina shows four well-rounded elevations, the quadrigeminate bodies [**corpora quadrigemina**], separated from each other by the *cruciate sulci*, that is, by a flat median groove crossed at right angles by a transverse groove. The anterior pair of these, the *superior quadrigeminate bodies* [colliculi], are larger though less prominent than the inferior pair or *inferior colliculi*. Each colliculus is continued laterally and upward into its arm or brachium. The **inferior brachium** proceeds from the inferior colliculus, disappears beneath and is continuous into the **medial geniculate body,** and disappears beneath the thalamus. The **superior brachium** proceeds from the superior colliculus, passes between the medial geniculate body and the overlapping pulvinar of the thalamus, and becomes continuous with the **lateral geniculate body** and thus with the lateral root of the optic tract.

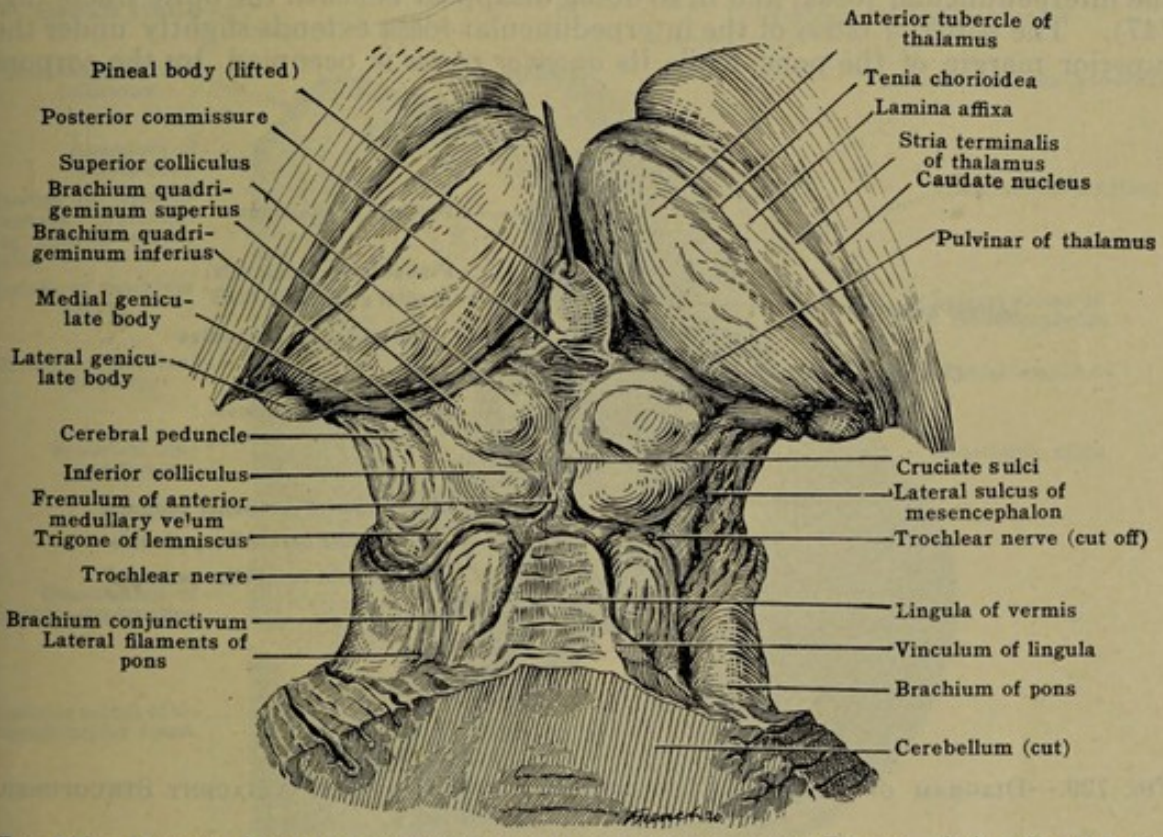

FIG. 738.—DORSAL SURFACE OF MESENCEPHALON AND ADJACENT PARTS. (After Spalteholz.)

The geniculate bodies are rounded elevations of gray substance which arise as detached portions of the thalami, and therefore belong to the thalamencephalon rather than to the mesencephalon. The superior quadrigeminate body or superior colliculus and the lateral geniculate body are parts of the *optic apparatus*, while the inferior colliculus and the medial geniculate body belong chiefly to the *auditory apparatus* (see CENTRAL CONNECTIONS OF COCHLEAR NERVE). Just as the cochlear nuclei of termination are connected by a few fibers with the superior colliculus, so do some fibers from the optic tract pass into the inferior colliculus. Also some fibers from the optic tract (medial root) are said to terminate in the medial geniculate body. Resting in the broadened medial groove between the superior quadrigeminate bodies lies the non-nervous **pineal body** (epiphysis). This also belongs to the thalamencephalon. Within the stem of the pineal body is a strong transverse band of white substance crossing the midline as a bridge over the opening of the cerebral aqueduct into the third ventricle. This is the **posterior commissure** of the cerebrum, and contains commissural fibers arising in both the thalamencephalon and mesencephalon. The triangular area bounded by the stem of the epiphysis, the thalamus, and the superior colliculus with its brachium, is known as the **habenular trigone.**

Inferiorly, the lamina quadrigemina is continuous with the isthmus of the rhombencephalon by way of the brachia conjunctiva or superior cerebellar peduncles, and the anterior medullary velum which bridges between the medial margins of these peduncles. The narrowed superior end of the velum, the part directly below the inferior quadrigeminate bodies, is thickened into a well-defined white band known as the **frenulum veli.** From the lateral margins of this band on each

side and just below the inferior quadrigeminate bodies emerge the **trochlear nerves** (the fourth pair of cranial nerves), and the increased thickness of the band is largely due to the decussation of this pair of nerves taking place within it.

The brachium conjunctivum, together with the inferior and superior colliculi of each side, form a marked ridge which results in the *lateral sulcus* of the mesencephalon, a lateral depression between the base of this ridge and the cerebral peduncle below and continuous into the transverse sulcus at the superior border of the pons. The ridge is thickened laterally by the lateral lemniscus, which is disposed as a band of white substance passing obliquely upward from under the brachium pontis, applied to the lateral surface of the brachium conunctivum and which enters the lateral margin of the mesencephalon. The region at which the lateral lemniscus approaches nearest the surface and in which the largest portion of its nucleus lies is the slightly elevated **trigone of the lemniscus.**

The **ventral surface** of the mesencephalon is formed by the **cerebral peduncles** (crura), two large bundles of white substance which are close to one another at the superior margin of the pons, but immediately diverge somewhat, producing the **interpeduncular fossa,** and in so doing disappear beneath the optic tracts (fig. 747). The *posterior recess* of the interpeduncular fossa extends slightly under the superior margin of the pons, while its *anterior recess* is occupied by the corpora

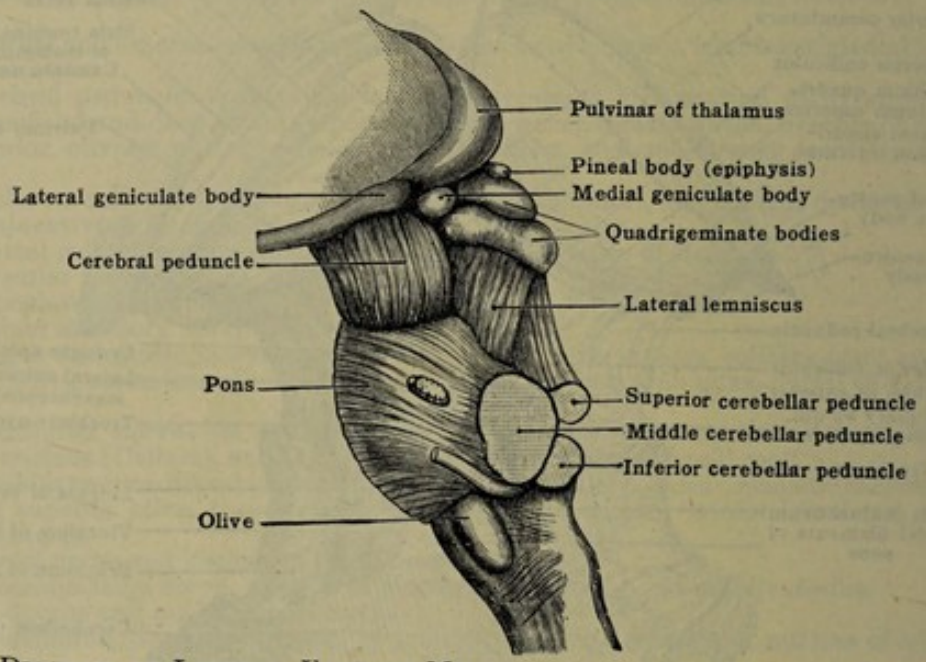

FIG. 739.—DIAGRAM OF LATERAL VIEW OF MESENCEPHALON AND ADJACENT STRUCTURES. (After Gegenbaur, modified.)

mammillaria of the prosencephalon (fig. 747). The triangular floor of the fossa is the **posterior perforated substance,** a grayish area presenting numerous openings for the passage of blood-vessels. It is divided by a shallow median (oculomotor) groove and is marked off from the medial surface of each peduncle by the lateral furrows, out of which emerge the root filaments of the **oculomotor nerve.** Each oculomotor nerve, formed by assembly of its root filaments makes an impression in the medial surface of the peduncle, the *oculomotor sulcus.* The ventral surface of each peduncle is rounded and has a somewhat twisted appearance, indicating that its fibers curve from above medialward and downward.

Sometimes two small, more or less transverse bands of fibers may be noted crossing the peduncle—an inferior, the *tenia pontis,* and a superior, the *transverse peduncular tract.* The inferior represents detached fibers of the pons; the superior, running from the brachium of the inferior quadrigeminate body and disappearing in the oculomotor sulcus, appears to be derived from the quadrigeminate bodies. Since it is well developed in the cat, dog, sheep, and rabbit, but is absent or little marked in the mole, it is supposed to be concerned with the optic apparatus.

Internal structure.—Transverse sections of the mesencephalon (figs. 740, 741) throughout are composed of—(1) a *dorsal part,* consisting of the lamina quadrigemina or the gray substance of the corpora quadrigemina, with the strata and bundles of nerve-fibers connected with them, and the abundant central gray substance surrounding the aqueduct; (2) a *tegmental part,* consisting of the upward

continuation of the reticular formation of the medulla oblongata and that of the dorsal (tegmental) portion of the pons region, to which are added the superior cerebellar peduncles and the red nuclei of the tegmentum in which these peduncles terminate; (3) a paired *ventral part*, the cerebral peduncles, each of which consists of a thick, pigmented stratum of gray substance, the *substantia nigra*, spread upon the large, superficial, and somewhat crescentic tract of white substance known as the *basis* of the peduncle. The bases of the peduncles correspond to the longitudinal or pyramidal fasciculi of the pons and medulla. Likewise the lemniscus and the medial longitudinal fasciculus of the medulla and pons continue through all sections of the mesencephalon, dorsal to the substantia nigra.

The **central gray substance** is a continuation of the central gelatinous substance of the spinal cord and the similar stratum of the medulla and pons which immediately underlies the ependymal floor of the fourth ventricle. As in the spinal cord and medulla, it is largely composed of gelatinous substance. It is much

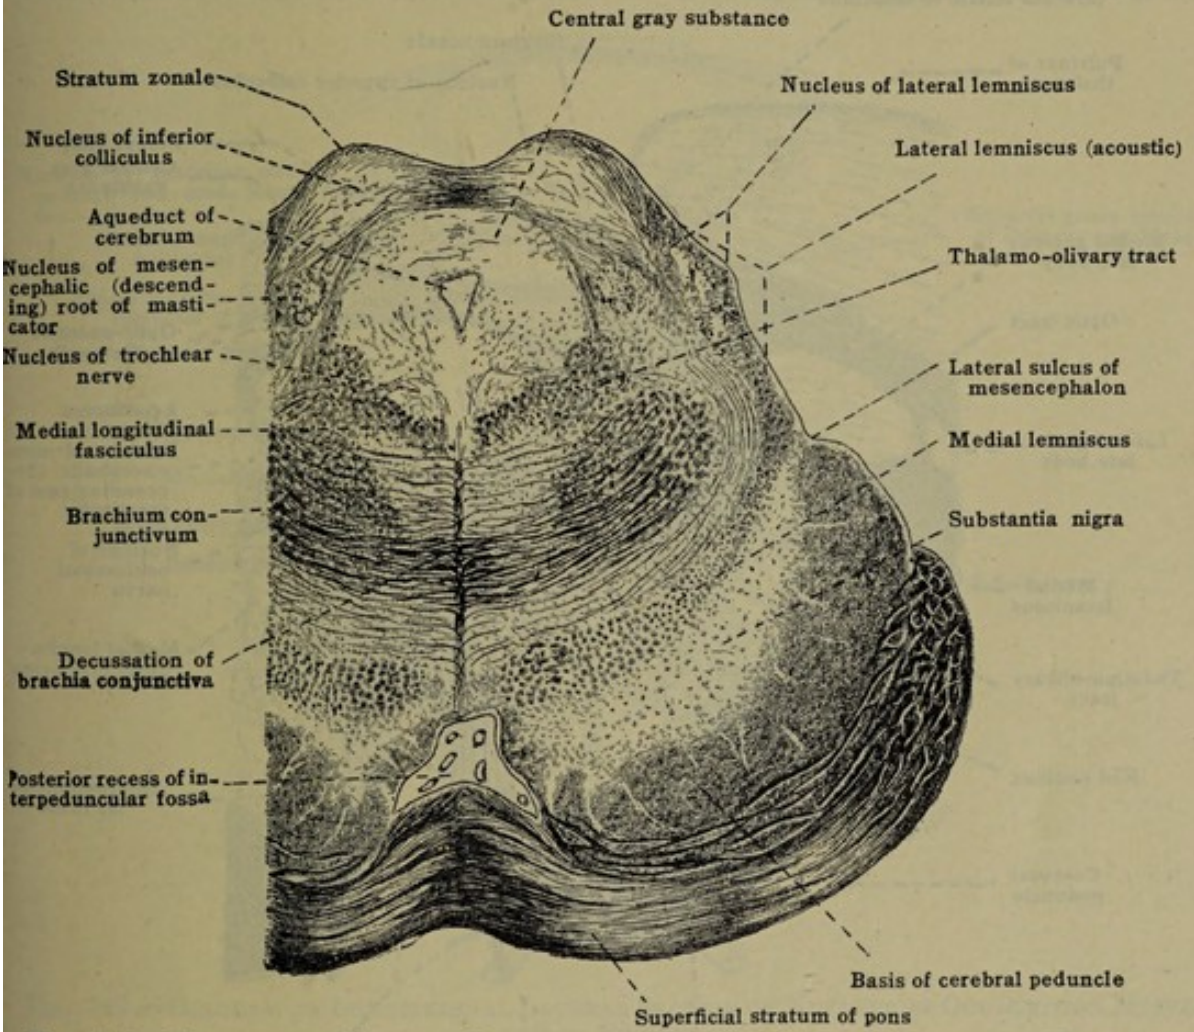

FIG. 740.—TRANSVERSE SECTION THROUGH THE INFERIOR QUADRIGEMINATE BODIES.

more abundant in the mesencephalon, and in sections appears as a circumscribed area comparatively void of nerve fibers.

The nucleus of the *mesencephalic root of the masticator nerve* and that of the mesencephalic tract of the trigeminus may likewise be traced throughout the mesencephalon. The former consists of a few small bundles of fibers surrounding a thin strand of nerve cells which give origin to its fibers. It courses caudalward close to the lateral margin of the central gray substance, and is quite small at its begining in the extreme superior part of the mesencephalon, but as it descends toward the exit of its fibers from the pons, it increases slightly in size, due to the progressive addition of fibers. Its nucleus also increases slightly in bulk in approaching its continuation with the chief motor nucleus of the nerve. As mentioned above, the investigations of Johnston and Willems in lower animals suggest that many cells of the mesencephalic nucleus of the masticator may be sensory instead of motor in character. The sensory nucleus (nucleus of termination) of the mesencephalic tract of the trigeminus tapers rapidly but probably extends throughout the mesencephalon.

The nuclei of the *trochlear* and *oculomotor* nerves form a practically continuous column of nerve-cells extending close to the midline and ventral to the aqueduct of the cerebrum. They are in line with the nuclei of origin of the abducens and hypoglossus, and, like them, may be regarded as an upward continuation of the ventral group of the cells of the ventral horn of the

spinal cord. The upper portion of the column, giving origin to the oculomotor nerve, is considerably larger than that for the trochlear.

A transverse section through the inferior quadrigeminate bodies involves the nuclei of origin of the trochlear nerves and a portion of the decussation of the brachia conjunctiva, while a transverse section through the superior quadrigeminate bodies passes through the red nuclei of the tegmentum and the nuclei of origin of the oculomotor nerves. The latter section will also involve the brachia of the inferior quadrigeminate bodies and the medial geniculate bodies connected with them, and, if slanting slightly forward it will involve the pulvinars of the thalami and the lateral geniculate bodies.

The **trochlear** (or fourth) is the smallest of the cranial nerves, and is the only one which makes its exit from the dorsal surface of the brain, as well as the only one whose fibers undergo a total decussation.

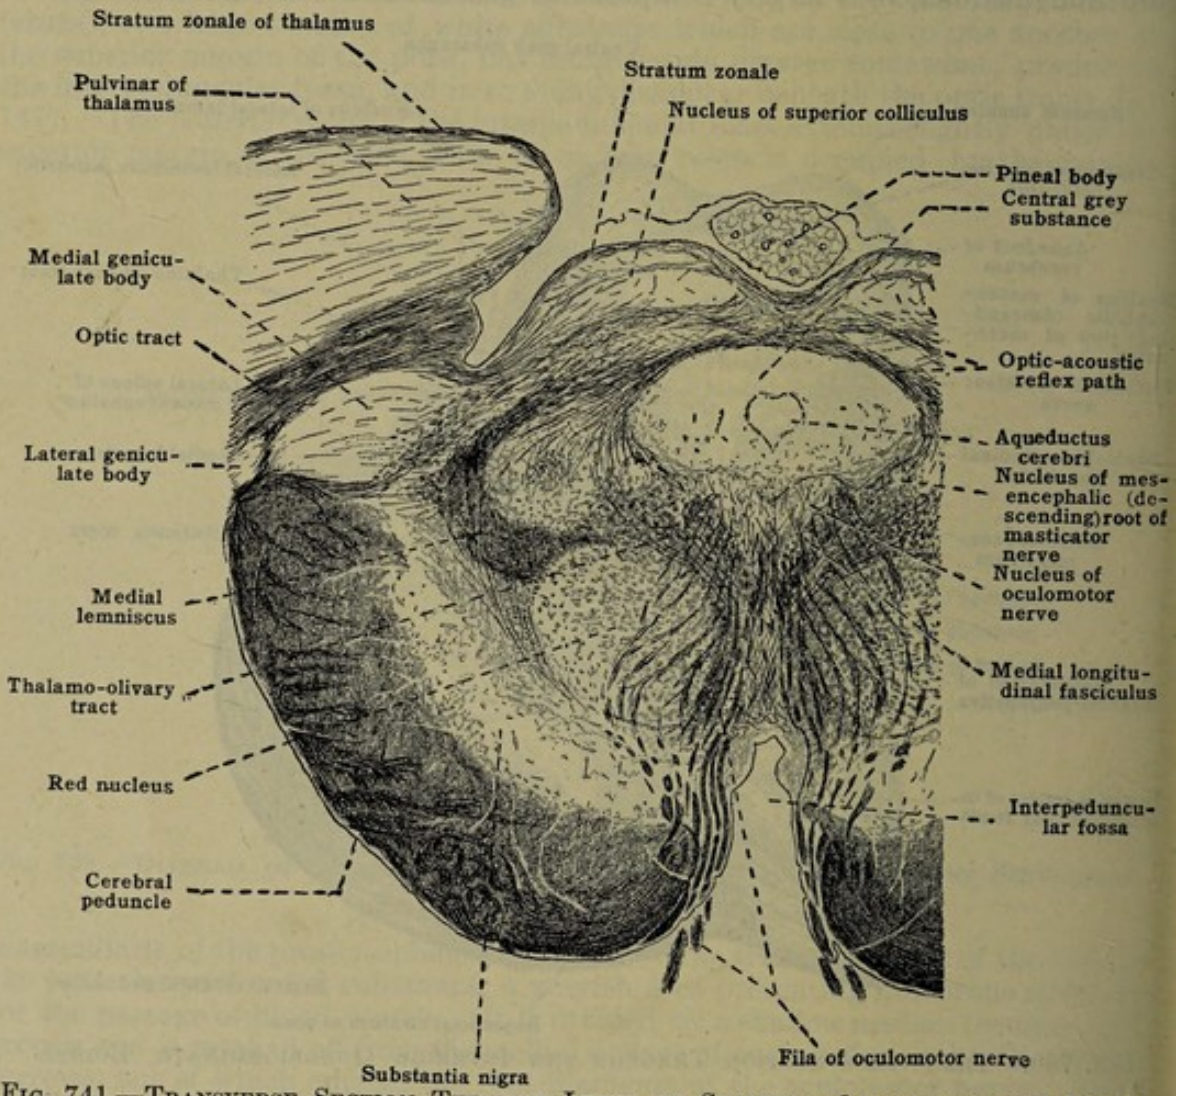

FIG. 741.—TRANSVERSE SECTION THROUGH LEVEL OF SUPERIOR QUADRIGEMINATE BODIES.

Its nucleus of origin is situated beneath the inferior quadrigeminate bodies in the ventral margin of the central gray substance, quite close to the midline and to its fellow nucleus of the opposite side, and it is closely associated with the dorsomedial margin of the medial longitudinal fasciculus. Its root-fibers pass lateralward and dorsalward, curving around the margin of the central gray substance, medial to the mesencephalic root of the masticator nerve. As the root curves toward the midline in the dorsal region just beneath the inferior quadrigeminate bodies, it turns sharply and courses inferiorly to approach the surface in the superior portion of the anterior medullary velum, the frenulum veli. In this it meets and undergoes a total decussation with the root of its fellow nerve, and then emerges at the medial margin of the superior cerebellar peduncle of the opposite side. Having emerged, it passes ventrally around the cerebral peduncle, and thence pursues its course to the superior oblique muscle of the eye. It receives optic impulses from the superior quadrigeminate bodies and impulses from the cerebral cortex of chiefly the same side, and it is associated with the nuclei of other cranial nerves by way of the medial longitudinal fasciculus.

The **oculomotor** (or third) nerve, like the trochlear, is purely motor. It is the largest of the eye-muscle nerves. It supplies in all seven muscles of the optic

apparatus:—two intrinsic, the sphincter iridis and the ciliary muscle (indirectly by its visceral efferent fibers), and five extrinsic (by somatic efferent fibers). Of the latter, the levator palpebræ superioris is of the upper eyelid, while the remaining four, the superior, medial, and inferior recti and the obliquus inferior, are attached to the eyeball. As is to be expected, its nucleus of origin is larger and much more complicated than that of the trochlear nerve.

Practically continuous with that of the trochlear below, the nucleus is 5 or 6 mm. in length and extends anteriorly a short distance beyond the bounds of the mesencephalon into the gray substance by the side of the third ventricle. It lies in the ventral part of the central gray substance, and is very intimately associated with the medial longitudinal fasciculus. Its thickest portion is beneath the summit of the superior quadrigeminate body. The root-fibers leave the nucleus from its ventral side and collect into bundles which pass transversely through the medial longitudinal fasciculus and course ventrally to the medial portion of the substantia nigra, where they emerge in from six to fifteen filaments which blend to form the trunk of the nerve in the oculomotor sulcus of the cerebral peduncles. Those bundles which arise from the more lateral portion of the nucleus course in a series of curves through and around the substance of the

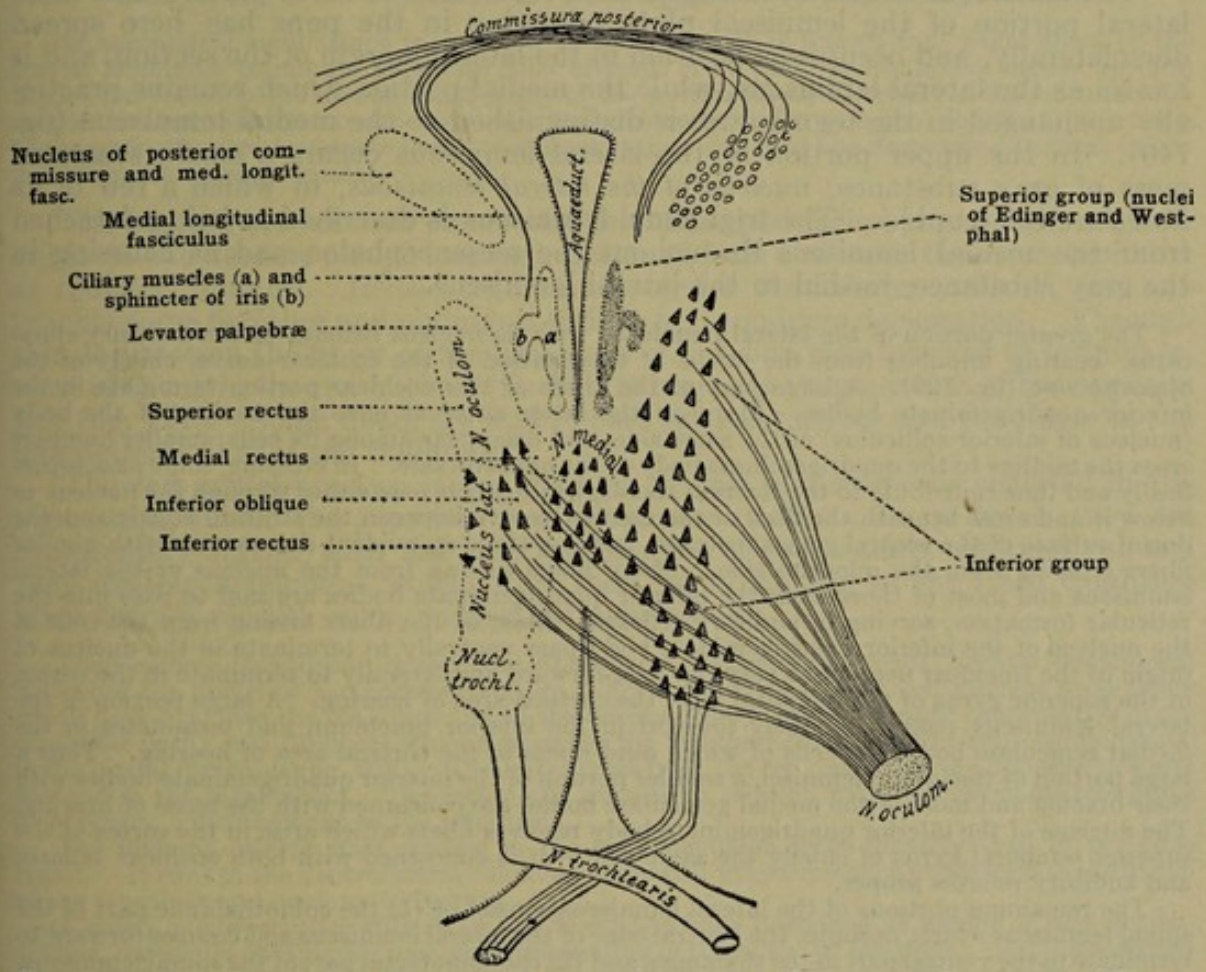

FIG. 742.—DIAGRAM OF LONGITUDINAL LATERAL SECTION OF NUCLEUS OF OCULOMOTOR NERVE. (After Edinger.)

red nucleus below and, in the substantia nigra, join those which pursue the more direct course. The trunk thus assembled passes lateralward around the medial border of the cerebral peduncle.

A portion of the fibers of the oculomotor nerve upon leaving the nucleus decussate in the tegmentum immediately below and pass into the nerve of the opposite side, in which they are believed to be distributed to the opposite medial rectus muscle. The cells of the nucleus have been variously grouped (fig. 742) and subdivided with reference to the different muscles supplied by the nerve. Perlia has divided them into eight cell-groups. The nucleus may be more easily considered as composed of an inferior group and a superior-medial group. The inferior group consists of a long lateral portion continuous with the nucleus of the trochlear nerve below, and a smaller medial portion, situated in the medial plane and continuous across the midline with its fellow of the opposite side. The superior medial group consists of cells of smaller size than the inferior, and is known as the *nucleus of Edinger and Westphal.* It is believed to give origin to the fibers (visceral efferent fibers) which terminate in the ciliary ganglion, axones from which supply the two intrinsic muscles concerned, viz., the ciliary muscle and the sphincter iridis.

The nucleus of the oculomotor is associated with the remainder of the optic apparatus—(1) by way of the neurones of the superior quadrigeminate body with the optic tract (retina) and it receives impulses from the occipital part of the cerebral cortex of the same and the opposite sides, and probably from the motor cortex of the frontal lobe; (2) by way of the medial longitudinal fasciculus with the nuclei of the trochlear and abducens (the latter making possible the co-

ordinate action of the lateral and medial recti for the conjugate eye-movements produced by these muscles), and with the nucleus of the facial (associating the innervation of the levator palpebræ with that of the orbicularis oculi); (3) with the nuclei of termination of the sensory nerves, especially the auditory, by way of the lateral lemniscus and medial longitudinal fasciculus. It is probably associated with the cerebellum by way of the brachia conjunctiva and red nuclei.

The eminence representing the **inferior quadrigeminate body** proper (colliculus caudalis NK) consists of an oval mass of gray substance, the *nucleus of the inferior colliculus*, containing numerous nerve-cells, most of which are of small size. A thin superficial lamina of white substance, the **stratum zonale**, forms its outermost boundary, and fibers from the lateral lemniscus enter it laterally and from below (*stratum lemnisci*). Near the lateral margin of the central gray substance occurs the beginning of the *inferior brachium*, a bundle containing fibers chiefly from the lateral lemniscus to the medial geniculate body and from the cerebral cortex to the inferior quadrigeminate body.

The **lemniscus** in the mesencephalon is considered in three parts. The more lateral portion of the lemniscal plate occurring in the pons has here spread dorsolaterally, and occupies a position in the lateral margin of the section, and is known as the **lateral lemniscus**, while the medial portion which remains practically unchanged in the tegmentum is distinguished as the **medial lemniscus** (fig. 740). In the upper portion of the lateral lemniscus occurs a small, scattered mass of gray substance, *nucleus of the lateral lemniscus*, in which a few of its fibers are interrupted. The **trigeminal lemniscus** is described as being detached from the medial lemniscus throughout the mesencephalon and as coursing in the gray substance, medial to the lateral lemniscus.

The greater portion of the **lateral lemniscus** with its nucleus belongs to the auditory apparatus, bearing impulses from the nuclei of termination of the cochlear nerve, chiefly of the opposite side (fig. 729). A large part of the fibers of this cochlear portion terminate in the inferior quadrigeminate bodies. Many of the latter enter at once the nucleus of the body (nucleus of inferior colliculus) of the same side, and disappear among its cells; smaller numbers cross the midline to the quadrigeminate body of the opposite side. In crossing, some pass superficially and thus contribute to the stratum zonale, while others pass either through the nucleus or below it and cross beneath the floor of the median groove between the stratum zonale and the dorsal surface of the central gray substance, forming there an evident decussation with similar fibers crossing from the opposite side. Many fibers arising from the nucleus of the lateral lemniscus and most of those from the inferior quadrigeminate bodies are said to pass into the reticular formation, serving in auditory reflexes. Most of the fibers arising from the cells of the nucleus of the inferior quadrigeminate body pass ventrally to terminate in the nucleus of origin of the trochlear nerve, but very few pass forward and laterally to terminate in the cortex of the superior gyrus of the temporal lobe, the cortical area of hearing. A large portion of the lateral lemniscus passes obliquely forward in the inferior brachium, and terminates in the medial geniculate body, the cells of which send fibers to the cortical area of hearing. Thus a large portion of the lateral lemnisci, a smaller portion of the inferior quadrigeminate bodies with their brachia and most of the medial geniculate bodies are concerned with the sense of hearing. The nucleus of the inferior quadrigeminate body receives fibers which arise in the cortex of the superior temporal gyrus of chiefly the same side. It is concerned with both cochlear reflexes and auditory reflexes proper.

The remaining portions of the lateral lemniscus consist of (1) the spinothalamic part of the spinal lemniscus which, occupies the ventral edge of the lateral lemniscus and courses forward to terminate in the ventral part of the thalamus, and (2) the spinotectal part of the spinal lemniscus, which courses in the extreme dorsal edge of the lateral lemniscus and is dispersed to terminate in the nuclei of the quadrigeminate bodies. In terminating in the nucleus of the superior quadrigeminate body, these spinotectal fibers are joined by some fibers of the auditory portion of the lateral lemniscus of the same and opposite side. Together, the spinal and auditory fibers approach the nucleus from below, and contribute to the well-marked band of fibers coursing on the dorsolateral margin of the central gray substance, and known as the '*optic-acoustic reflex path*' or *stratum lemnisci* (fig. 741).

The **medial lemniscus** arises in the medulla oblongata from the nuclei (of termination) of the funiculus gracilis and funiculus cuneatus of the opposite side, and likewise from the nuclei of termination of the sensory roots of the cranial nerves of the opposite side. It is, therefore, a continuation of the central sensory pathway conveying the general bodily (including the head) sensations into the prosencephalon. Coursing still more laterally than in the pons below, it passes into the inferolateral gray substance of the thalamus, in which most of its fibers terminate. By axones given off from the cells of the inferolateral thalamic gray substance the impulses borne thither by the lemniscus are conveyed by way of the internal capsule and corona radiata to the gyri of the somesthetic area of the cerebral cortex. The trigeminal lemniscus, here detached from the medial as noted above, arises from the nucleus of termination of the trigeminus of the opposite side and terminates as does the remainder of the medial lemniscus.

The **basis pedunculi** (crus cerebri NK) comprises the great descending pathway from the cerebral cortex, and thus is continuous with the internal capsule of the telencephalon.

The principal components of each basis pedunculi are as follows:—(1) The *pyramidal fibers.* which occupy the middle portion of the peduncle and comprise three-fifths of its bulk, and which are outgrowths of the giant pyramidal cells of the motor areas of the cerebral cortex, chiefly anterior central gyrus. These supply 'voluntary' impulses to the motor nuclei of the cranial nerves on the opposite side, form the pyramids of the medulla, and are distributed to the ventral horn cells of the spinal cord of the opposite side. (2) The *frontal pontile fibers*, which course in the mesial part of the peduncle from the cortex of the frontal lobe to their termination in the gray substance of the pons. (3) The *occipital and temporal pontile fibers* which run in the lateral portion of the peduncle from their origin in the occipital and temporal lobes to their termination in the gray substance of the pons.

The **substantia nigra** (nucleus niger NK) is continuous below with the gray substance of the pons, the arcuate nuclei, and that of the reticular formation; and above with that of the hypothalamic region. Its remarkable abundance begins at the superior border of the pons, and it conforms to the crescentic inner contour of the base of the peduncle, sending numerous processes which occupy the interfascicular spaces of the latter. It contains numerous deeply pigmented nerve-cells, which in the fresh specimen give the appearance suggesting its name.

Its anatomical significance is not well understood. It is known that some fibers of the medial lemniscus terminate about its cells instead of in the hypothalamus higher up, and Mellus has found in the monkey that many of the pyramidal fibers arising in the motor thumb area of the cerebral cortex are interrupted in the substantia nigra. It is probable that other fibers of the peduncle also terminate here, its cells serving as relays in the descending cortical chains including the extrapyramidal.

The **brachia conjunctiva** or superior cerebellar peduncles, in passing from their origin in the dentate nuclei, lose their flattened form and enter the mesencephalon as rounded bundles. In the tegmentum, under the inferior colliculi, the two brachia come together and undergo a sudden and complete decussation. Through this decussation the fibers of the brachium of one side pass forward to terminate, most of them, in the red nucleus [nucleus ruber] of the tegmentum of the opposite side (fig. 741). Some fibers are said to pass the red nucleus and terminate in the inferolateral part of the thalamus.

The **red nuclei** are two large, globular masses of nerve-cells situated in the tegmentum under the superior quadrigeminate bodies. At all levels they are considerably mixed with the entering bundles of the brachia conjunctiva, and they contain a pigment which, with their blood supply, in the fresh condition gives them a reddish color, suggesting their name.

They receive in addition descending fibers from the cerebral cortex (frontal operculum) and from the nuclei of the corpus striatum. From the cells of each red nucleus arise fibers which pass—(1) into the thalamus and to the telencephalon (prosencephalic continuation of the cerebellar path), and (2) fibers which descend as the 'rubroreticular' and the 'rubrospinal tracts' in the lateral funiculus (fig. 698). The latter cross from the red nucleus of the opposite side and descend in the tegmentum. The red nuclei are also in relation with the *fasciculus retroflexus* of Meynert, which belongs to the interbrain.

The **thalamo-olivary tract** courses in the mesencephalon more dorsally than in the pons region. It runs in the ventrolateral boundary of central gray substance just lateral to the nuclei of the trochlear and oculomotor nerves.

A small *quadrigeminopontile* strand of fibers has been described as arising in the quadrigemina, especially the inferior pair, and terminating in the nuclei of the pons. Impulses carried by these fibers are probably destined for the cerebellar hemisphere of the opposite side.

The **superior quadrigeminate bodies (superior colliculi)** are phylogenetically more important than the inferior. In certain of the lower vertebrates they are enormously developed and in most of the mammals they are relatively larger and appear more complicated in structure than in man. They are concerned almost wholly with the visual apparatus, mediating most of the reflexes with which it is concerned.

Though they receive some retinal fibers, in man they have little or nothing to do with actual visual sensation or perception. For such sensations the lateral geniculate body is the nucleus of termination especially concerned.

The *nucleus* of the superior colliculus is of somewhat greater bulk than that of the inferior. It is capped by a strong *stratum zonale* (fig. 741), which has been described as composed chiefly of retinal fibers, passing to it from the optic tract by way of the superior brachium; but, since Cajal found in the rabbit that extirpation of the eye is followed by very slight degeneration of the stratum zonale, it is probable that it is composed of other than retinal fibers—possibly fibers from the occipital cortex and fibers arising within the nucleus itself. The nucleus is separated from the central gray substance by a well marked band of fibers, the *stratum album profundum.* This contains fibers from two sources:—(1) fibers from the lateral lemniscus which approach the nucleus from the under side, some to terminate within it, others to cross to the nucleus of the opposite side; (2) fibers which arise within the nucleus and course ventrally

around the central gray substance, both to terminate in the nucleus of the oculomotor nerve and to join the medial longitudinal fasciculus and pass probably to the nuclei of the trochlear and abducens. The lemniscus fibers often course less deeply than (2) and give the *stratum lemnisci*. The optic fibers proper approach the nucleus by way of the *superior brachium*, and are dispersed directly among its cells; only a small proportion of them cross over to terminate in the nucleus of the opposite side. They consist of two varieties:—(1) retinal fibers which arise in the ganglion-cell layer of the retina and enter the superior brachium at its junction with the lateral root of the optic tract, and (2) fibers from the visual area of the occipital lobe of the cerebral hemisphere. Sometimes the optic fibers in their course within the nucleus of the superior colliculus form a more or less evident stratum near the stratum zonale This is known as the *stratum opticum* (stratum album medium). The portion of the nucleus between this stratum and the stratum zonale is then called the *stratum cinereum*. Experimental evidence indicates that, of the retinal fibers entering the nucleus, those from the lower half of the retina are distributed to the anterior portion of the nucleus and those from the superior half to the caudal portion.

The fibers entering the nucleus from the lateral lemniscus probably all represent auditory connections. The stratum album profundum, composed of the lemniscus fibers and fibers from cells of the nucleus, and the stratum opticum together, form the so-called **'optic-acoustic reflex path'** (fig. 741).

The **tectospinal** and the **spinotectal** (spinomesencephalic) paths course together ventrolateral to the nuclei of the colliculi. In the superior quadrigeminate bodies they course in the dorsal edge of the medial lemniscus, between the stratum opticum and stratum album profundum.

From the various studies that have been made it appears that the superior colliculus of the corpora quadrigemina is merely the central reflex organ concerned in the control of the eye muscles—eye muscle reflexes which result from retinal and cochlear stimulation, and from some general body sensations by way of the spinal cord and trigeminus. Fibers from its nucleus to the visual area of the occipital cortex have been claimed for certain mammals, but in man the superior colliculus may be entirely destroyed without disturbance of the perception of light or color and fibers arising from its nucleus to terminate in the cerebral cortex are denied.

In the level of the anterior part of the superior colliculus the fibers which arise from the cells of its nucleus and course ventrally in the stratum album profundum collect into a strong bundle. This bundle passes ventral to the medial longitudinal fasciculus and, in the space between the two red nuclei, it forms a dense decussation with the similar bundle from the opposite side. In decussating the fibers turn in spray-like curves downward and soon join the medial longitudinal fasciculus. This is the **'fountain decussation'** of Forel. Decussating fibers which arise in the nucleus of the oculomotor nerve also cross in this decussation and it is said to be augmented by decussating fibers from the two red nuclei.

There is abundant evidence that fibers arising in the corpora quadrigemina descend into the spinal cord. Various studies make it appear that at least part of these are fibers from the fountain decussation, and that these course through the medulla oblongata in the ventral part of the medial longitudinal fasciculus, and thence descend into the cord as the sulcomarginal fasciculus and in the tectospinal path of the opposite side. The termination of some of these fibers about those ventral horn cells of the cervical and upper thoracic cord which send fibers through the rami communicantes probably establishes the pathway by which the superior quadrigeminate bodies are connected with the cervical sympathetic ganglia, and by which may be explained the disturbances in pupillary reflexes induced by lesions of the cervical and upper thoracic spinal cord.

The medial geniculate body and the medial root of the optic tract, which runs into the former, probably have nothing to do with the functions of the optic apparatus. Both remain intact after extirpation of the eyes. The medial root of the optic tract is apparently nothing more than the beginning of the *inferior cerebral* (*Gudden's*) *commissure*, a bundle passing by way of the optic tract and chiasma, connecting the medial geniculate body of one side with that of the other side, and probably with the inferior colliculus.

The **medial longitudinal fasciculus** (posterior longitudinal fasciculus), continuous into the ventral fasciculus proprius and the sulcomarginal fasciculus of the spinal cord, extends throughout the rhombencephalon and mesencephalon, and is represented in the hypothalamic region of the prosencephalon. Deserted by the lemniscus at the inferior border of the pons, it maintains its closely medial position and courses throughout in the immediate ventral margin of the central gray substance of the medulla and floor of the fourth ventricle, and likewise in the ventral margin of the central gray substance of the mesencephalon.

The two fasciculi constitute the principal of the longer association pathways of the brain stem, and, true to their nature as such, they are among the first of its pathways to acquire medullation. In the mesencephalon they become two of its most conspicuous tracts, and their course in most intimate association with the nuclei of origin of the nerves supplying the eye-muscles suggests what is probably one of their most important functions, viz., that of associating these nuclei with each other and of bearing to them fibers from the nuclei of the other cranial nerves necessary for the co-ordinate action of the muscles of the optic apparatus associated with the functions of these other nerves.

Fibers from each medial longitudinal fasciculus terminate either by collaterals or terminal arborizations about the cells of the motor nuclei of all the cranial nerves, and each nucleus probably contributes fibers to it. It also receives fibers from the nuclei of termination of the sensory nerves especially those of the optic, the vestibular and cochlear. Thus it contains fibers coursing in both directions, and, while it is continually losing fibers by termination, it is being continually recruited and so maintains a practically uniform bulk. Thus, a given lesion never

results in its total degeneration. Many of the fibers coursing in it arise from the opposite side of the midline. A special contribution of fibers of this kind is received by way of the fountain decussation from the nucleus of the superior colliculus of the opposite side. As noted above, it is in part continuous into the spinal cord as the ventral fasciculus proprius. It receives some fibers by way of the posterior commissure of the prosencephalon from a small nucleus, common to it and the posterior commissure, situated in the superior extension of the central gray substance of the mesencephalon. Van Gehuchten and Edinger describe for it a special *nucleus of the medial longitudinal fasciculus* situated beyond this commissure in the hypotha-

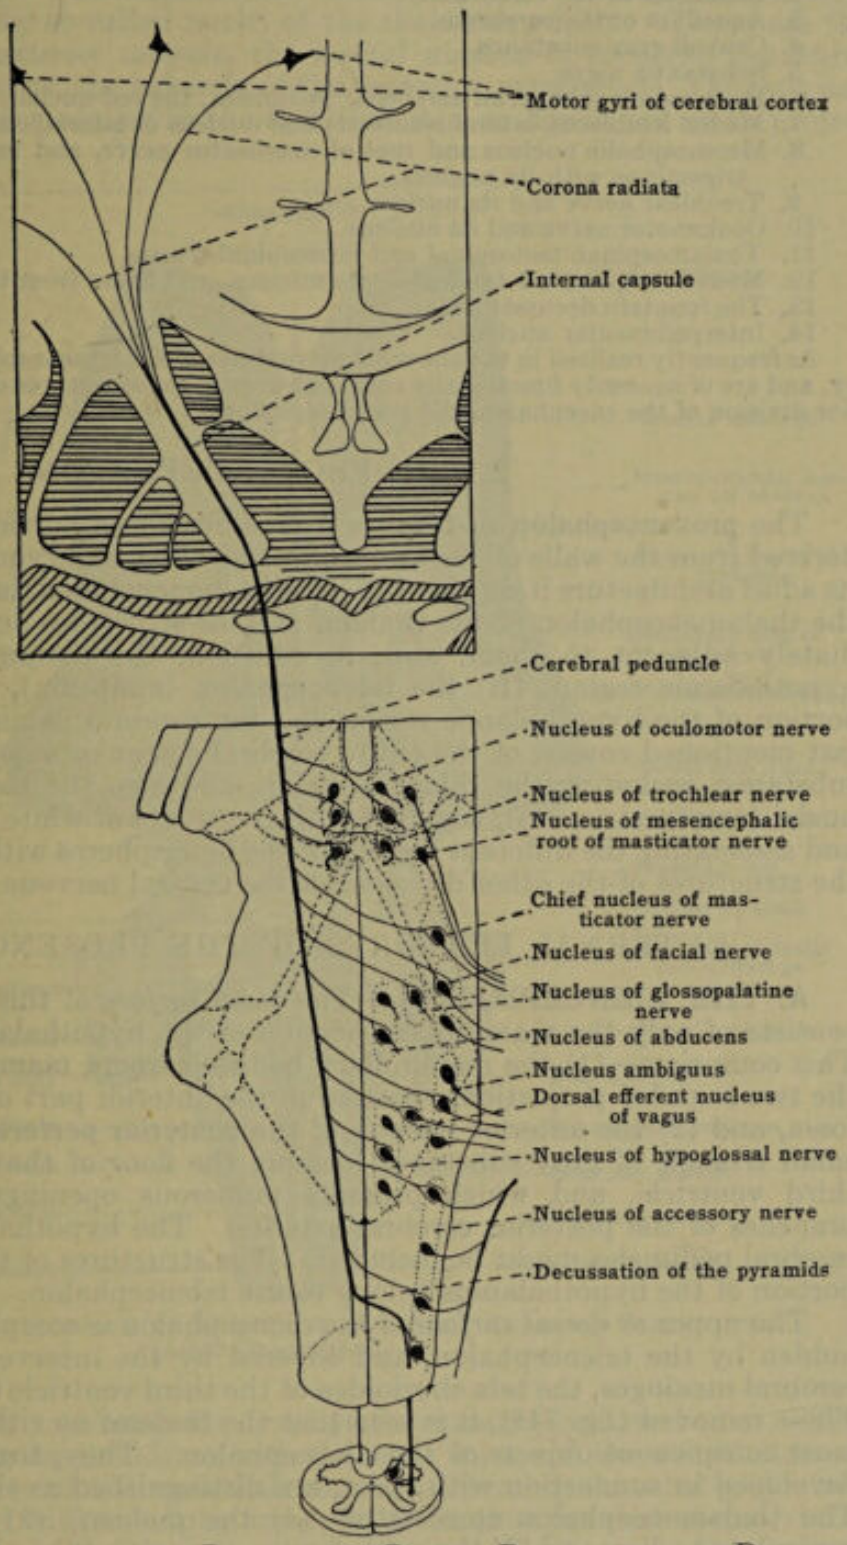

FIG. 743.—SCHEME TO ILLUSTRATE THE PRINCIPAL OR CROSSED RELATIONS OF THE DESCENDING CORTICAL (PYRAMIDAL) FIBERS TO THE NUCLEI OF ORIGIN OF THE CRANIAL NERVES.

lamic region. This nucleus may be explained as an accumulation of the gray substance of the reticular formation below and as receiving impulses from the structures of the prosencephalon which are distributed by its axones to the structures below by way of the medial longitudinal fasciculus.

Scattered in the posterior part of the posterior perforated substance, near the superior border of the pons, is a small group of cell-bodies forming the **interpeduncular nucleus** (interpeduncular ganglion of von Gudden). Fibers arising in the habenular nucleus of the diencephalon curve posteriorly, forming the *fasciculus retroflexus of Meynert*, and terminate about its

cells. Fibers arising from its cells course dorsalward and terminate about association neurones in the ventral periphery of the central gray substance. It is concerned with olfactory impulses.

SUMMARY OF THE MESENCEPHALON

1. Quadrigeminate bodies:
   (*a*) Inferior colliculi, their nuclei and brachia.
   (*b*) Superior colliculi, their nuclei and brachia.
2. Peduncles of the cerebrum.
3. Aqueduct of the cerebrum.
4. Central gray substance.
5. Substantia nigra.
6. Decussation of superior cerebellar peduncles; the red nuclei.
7. Medial lemniscus, lateral lemniscus and nucleus of lateral lemniscus.
8. Mesencephalic nucleus and root of masticator nerve, and mesencephalic tract of the trigeminus with its nucleus.
9. Trochlear nerve and its nucleus.
10. Oculomotor nerve and its nucleus.
11. Thalamospinal, tectospinal and rubrospinal tracts.
12. Medial longitudinal fasciculus, its nucleus, and fibers from the posterior commissure.
13. The fountain decussation.
14. Interpeduncular nucleus.

As frequently realized in the above, the structures of the mesencephalon are both overlapped by, and are of necessity functionally continuous with, the structures of the next and most anterior division of the encephalon, the prosencephalon.

2. THE PROSENCEPHALON

The **prosencephalon** or **forebrain** includes those portions of the encephalon derived from the walls of the anterior of the three embryonic brain-vesicles. In its adult architecture it consists of—(A) the **diencephalon (interbrain)**, comprising the thalamencephalon or the thalami and the structures derived from and immediately adjacent to them, and, in addition, the mammillary portion of the hypothalamic region; (B) the **telencephalon (endbrain)**, comprising the optic portion of the hypothalamic region and the cerebral hemispheres proper. The last mentioned consist of the entire cerebral cortex or superficial mantle of gray substance, including the rhinencephalon, and also the basal ganglia or buried nuclei (corpus striatum), together with the tracts of white substance connecting and associating the different regions of the hemispheres with each other and with the structures of the other divisions of the central nervous system.

EXTERNAL FEATURES OF THE PROSENCEPHALON

A. THE DIENCEPHALON.—The *basal surface* of this division of the brain consists of only the mammillary portion of the hypothalamic region (fig. 747). This comprises—(1) the mammillary bodies [**corpora mammillaria**] (albicantia), the two rounded projections situated in the anterior part of the interpeduncular fossa, and (2) the anterior portion of the **posterior perforated substance** or the small triangle of gray substance forming the floor of the posterior part of the third ventricle, and which presents numerous openings for the passage of branches of the posterior cerebral arteries. The hypothalamic portions of the cerebral peduncles might be included. The structures of the optic or remaining portion of the hypothalamus belong to the telencephalon.

The upper or *dorsal surface* of the diencephalon is completely overlapped and hidden by the telencephalon, and covered by the intervening ingrowth of the cerebral meninges, the tela chorioidea of the third ventricle (velum interpositum). These removed (fig. 744), it is seen that the thalami on either side are by far the most conspicuous objects of the diencephalon. They, together with the parts developed in connection with them, are distinguished as the **thalamencephalon**. The thalamencephalon consists of—(1) the *thalami;* (2) the *metathalamus* or geniculate bodies; and (3) the *epithalamus*, comprising the pineal body (epiphysis) with the posterior commissure below it and the habenular trigone on either side.

The **thalami** are two ovoid, couch-like masses of gray substance which form the lateral walls of the third ventricle. The cavity of the ventricle is narrow, and quite frequently the thalami are continuous through it across the midline by a small but variable neck of gray substance, the **massa intermedia** ('middle commissure'). The upper surfaces of the thalami are free. The edges of the tela chorioidea of the third ventricle are attached to the lateral part of the surface of each thalamus, and, when removed, leave the *tenia chorioidea* lying in the chor-

oidal sulcus. Each thalamus is separated laterally from the caudate nucleus of the telencephalon by a linear continuation of the white substance below, known as the **stria terminalis thalami** (tenia semicircularis) in which runs the terminal vein. Like the quadrigemina, each thalamus is covered by a thin capsule of white substance, the **stratum zonale.** The average length of the thalamus is about 38 mm., and its width about 14 mm.; its posterior extremity (pulvinar) is obliquely lateralward. The dorsal surface usually shows four eminences, indicating the position of the so-called nuclei of the thalamus within. These are the anterior nucleus or *anterior tubercle*, the *medial nucleus* or tubercle, the *lateral nucleus*, and the *pulvinar*, the tubercle of the posterior extremity. The pulvinar of the human brain is peculiar in the fact that it is so developed as to project

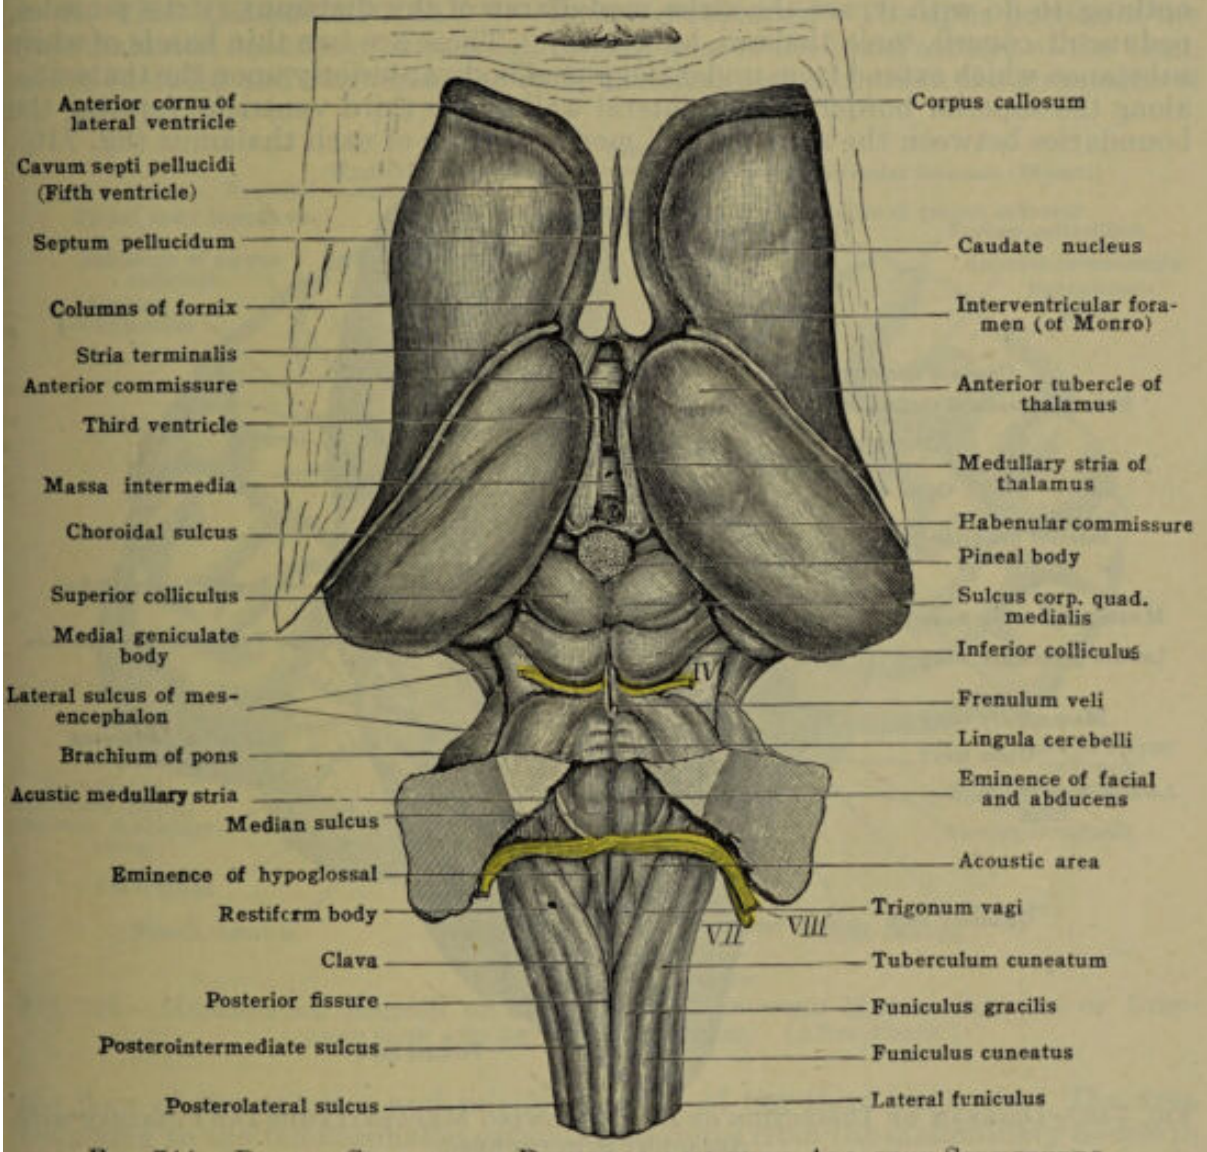

FIG. 744.—DORSAL SURFACE OF DIENCEPHALON WITH ADJACENT STRUCTURES. (After Obersteiner.)

inferiorly and slightly overhang the level of the quadrigeminate bodies. The projecting portion assumes relations with the optic tract and the metathalamus.

Both the structures of the **metathalamus,** the lateral and medial geniculate bodies, are connected with the optic tract, but it is thought that actual visual axones terminate only in the lateral geniculate body. As the optic tract curves around the cerebral peduncle it divides into two main roots. The *lateral geniculate body* receives a portion of the fibers of the lateral root of the optic tract; the remainder pass under this body and enter the pulvinar of the thalamus. The *medial geniculate body* is in relation with the medial root of the optic tract, which root consists partly, not of retinal fibers, as does the lateral root, but of the fibers forming Gudden's commissure (the inferior cerebral commissure). The retinal fibers contained in the medial root pass to terminate in the superior quadrigeminate bodies.

Of the **epithalamus,** the *pineal body* (epiphysis) is the most conspicuous external feature. This is an unpaired, cone-shaped structure, about 7 mm. long and 4 mm. broad, which also projects upon the mesencephalon so that its body rests in the groove between the superior quadrigeminate bodies. Its stem is attached in the midline at the posterior extremity of the third ventricle, and therefore just above the posterior commissure of the cerebrum (fig. 738). It is covered by pia mater, and is involved in a continuation of the tela chorioidea of the third ventricle. Though it develops as a diverticulum of that portion of the anterior primary vesicle which gives origin to the thalamencephalon, it is wholly a non-nervous structure, aside from the sympathetic fibers which enter it for the supply of its blood-vessels. (For further details, see p. 1433.)

Apparently arising from the base of the pineal dody, but having practically nothing to do with it, are the **striæ medullares of the thalamus** (striæ pineales, pedunculi conarii, tenia thalami, habenulæ). These are two thin bands of white substance which extend from under the pineal body anteriorly upon the thalamus, along the superior border of each lateral wall of the third ventricle, forming the boundaries between the superior and medial surface of each thalamus (fig. 710).

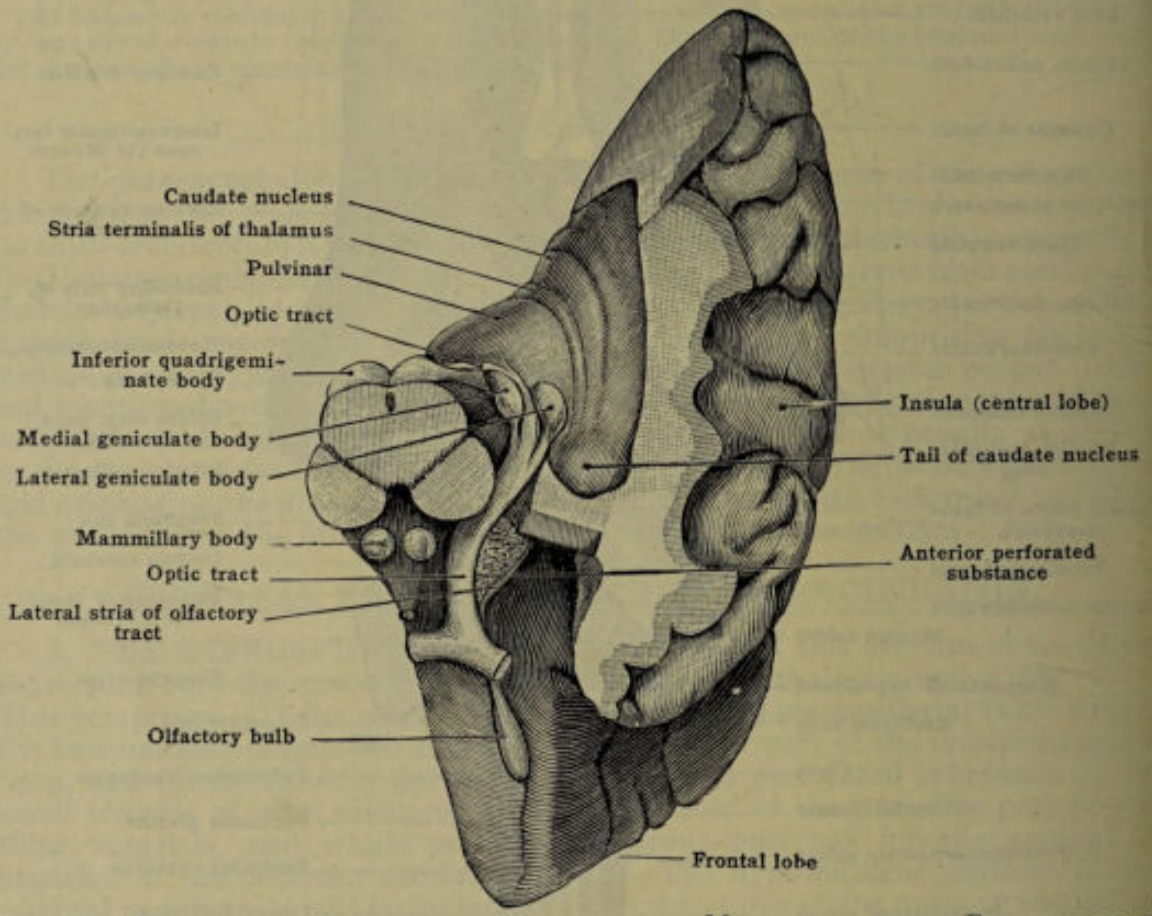

FIG. 745.—DIAGRAM OF DISSECTION OF BRAIN SHOWING METATHALAMUS AND PULVINAR WITH ADJACENT STRUCTURES.

They have been called the *habenulæ*, and the habenular nuclei, situated in the habenular trigone, are so called because related to them. They are continuous across the midline in the *habenular commissure*, the dorsal part of the posterior cerebral commissure, just below the neck of the pineal body (figs. 744, 773). It will be seen below that each habenula contains olfactory fibers from the fornix, the anterior perforated substance and the septum pellucidum, as well as fibers out of the thalamus, and that some of its fibers terminate in the habenular nucleus. Most of the thalamic fibers contained cross in the posterior commissure to the thalamus of the opposite side.

The inferolateral surface of the thalamencephalon is continuous into the hypothalamic tegmental region, the upward continuation of the tegmental gray substance of the mesencephalon. It is also adjacent to a portion of the internal capsule. Both these relationships, as well as the fiber connections of the diencephalon with the structures above and below it, are deferred until the discussion of the internal structure of the prosencephalon.

The **medial surface** of the diencephalon (fig. 746), allows a better view of the shape and relations of the **third ventricle.** Below the line of the massa inter-

media the ventricle is usually somewhat wider than it is along the upper margins of the thalami. This greater width is occasioned by a groove in the inferomedial surface of each thalamus, known as the **hypothalamic sulcus** (sulcus of Monro). It is along the line of this sulcus that the third ventricle is continuous with the aqueduct of the cerebrum, and thus with the fourth ventricle below, and, likewise, with the two lateral ventricles of the cerebral hemispheres at its anterior end. The latter junction occurs through a small oblique aperture, the **interventricular foramen** (foramen of Monro), one into each lateral ventricle. The upper portion of the third ventricle extends posteriorly beneath its choroid tela (velum interpositum) to form a small posterior recess about the pineal body. This is known as the **suprapineal recess.** The anteroinferior extremity of the third ventricle involves the pars optica hypothalami, which belongs to the telencephalon.

B. THE TELENCEPHALON.—External features.—The **optic portion of the hypothalamus** consists of that small central area of the basal surface of the brain which includes and surrounds the **optic chiasma,** and comprises the structures of

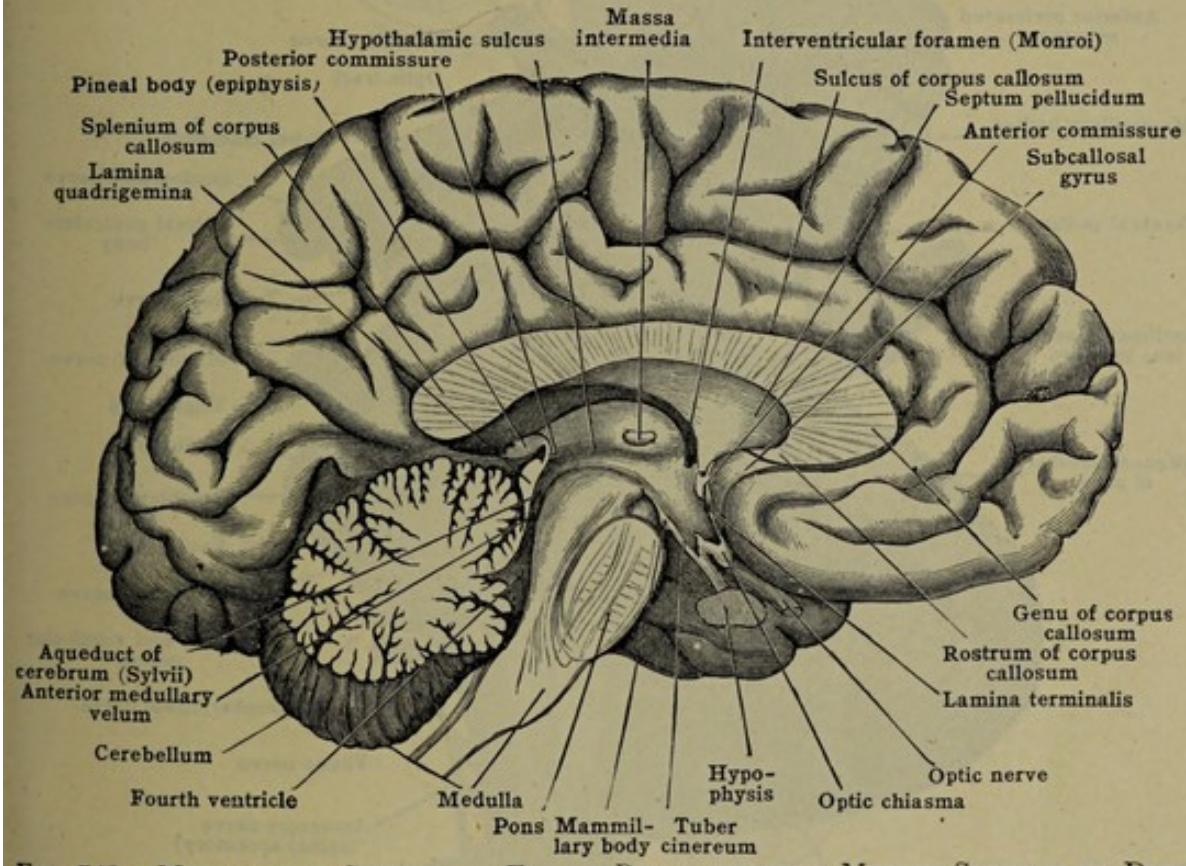

FIG. 746.—MIDSAGITTAL SECTION OF ENTIRE BRAIN, SHOWING MEDIAL SURFACE OF DIENCEPHALON AND OF TELENCEPHALON. (After Henle.)

the floor of the anterior and inferior portion of the third ventricle. The area belonging to the telencephalon extends anteriorly from the mammillary bodies in the interpeduncular fossa, and includes the **tuber cinereum** and **hypophysis** behind the optic chiasma, and some of the **anterior perforated substance** in front of it.

The most anterior portion of the third ventricle is in the form of an inferior extension. The wall of this extension is almost wholly non-nervous and quite thin, and thus the cavity of the ventricle is but thinly separated from the exterior of the brain. The front portion of this wall is the **lamina terminalis** and in the ventricular side of the upper part of this lamina the **anterior commissure** of the cerebrum is apparent.

The **optic chiasma** lies across and presses into the lower portion of the lamina terminalis, and in so doing produces an anterior recess in the cavity of the ventricle known as the **optic recess** (fig. 746). Behind the optic chiasma the floor of the third ventricle bulges slightly, giving the outward appearance known as the **tuber cinereum,** and the cavity bounded by this terminates in the **infundibular recess.**

The **tuber cinereum** then is a hollow, conical projection of the floor of the third ventricle, between the corpora mammillaria and the optic chiasma. Its wall

is continuous anteriorly with the lamina terminalis and laterally with the anterior perforated substance.

The **infundibulum** is but the attenuated apex of the conical tuber cinereum, and forms the neck connecting it with the hypophysis. It is so drawn out that it is referred to as the stalk of the hypophysis. The cavity of the tuber cinereum (infundibular recess) is sometimes maintained throughout the greater part of the length of the infundibulum, giving it the form of a long-necked funnel. Near the hypophysis the cavity is always occluded in man.

The **hypophysis cerebri** (pituitary gland) (figs. 746, 747) is an ovoid endocrine gland terminating the infundibulum. It lies in the sella turcica of the sphenoid bone, and consists of two lobes, a large *anterior lobe*, the glandular or buccal lobe,

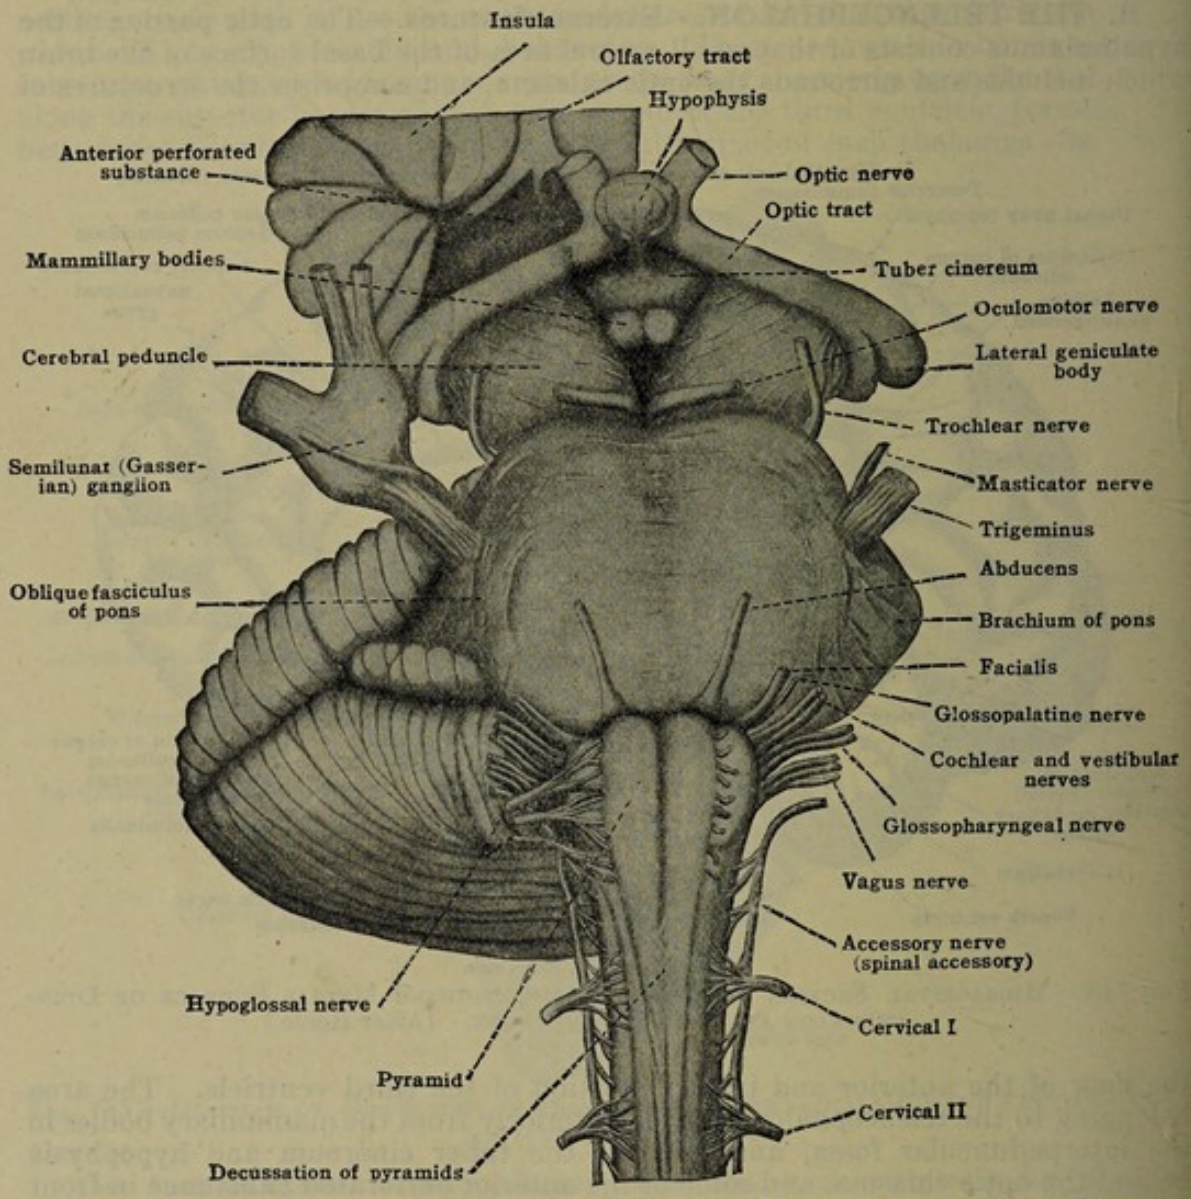

FIG. 747.—INFERIOR ASPECT OF BRAIN-STEM INCLUDING MAMMILLARY AND OPTIC PORTIONS OF THE HYPOTHALAMUS.

and a smaller *posterior* or *neural lobe*. For further details, see GLANDS OF INTERNAL SECRETION, p. 1430.

The fundaments of the **optic nerve** are derived from this portion of the telencephalon, though the nuclei of termination of its fibers are located in the thalamencephalon and mesencephalon. The optic apparatus consists of the retinæ and optic nerves, the optic chiasma, the optic tracts, the superior quadrigeminate bodies with their relations with the nuclei of the eye-moving nerves, the metathalamus, the pulvinar of the thalamus, and the visual area of the cerebral cortex of the occipital lobe. The fibers of the optic nerves arise from the cells of the ganglion-cell layer of the retinæ. The fibers which arise in the mesial or nasal halves of each retina cross in the chiasma to find their nuclei of termination in the

gray substance of the opposite side, while those from the outer or lateral halves terminate on the same side (figs. 748, 783).

The **optic chiasma** (optic commissure) is adherent upon the structures of the optic portion of the hypothalamus adjacent to it. It is formed by the approach and fusion of the two optic nerves, and is knit together by the decussating fibers from ganglion cells of the nasal halves of each retina, and, in addition, by the fibers of Gudden's commissure which is contained in it.

Beyond the chiasma the optic fibers continue as the **optic tracts** which course posteriorly around the cerebral peduncles to attain their entrance into the thalamencephalon and mesencephalon. Upon reaching the pulvinar of the thalamus each optic tract divides into two roots, a lateral and medial (figs. 745, 747, 748).

The *lateral root* contains practically all of the true visual fibers—fibers arising from the lateral half of the retina of the same side and the nasal half of the retina of the opposite side. These

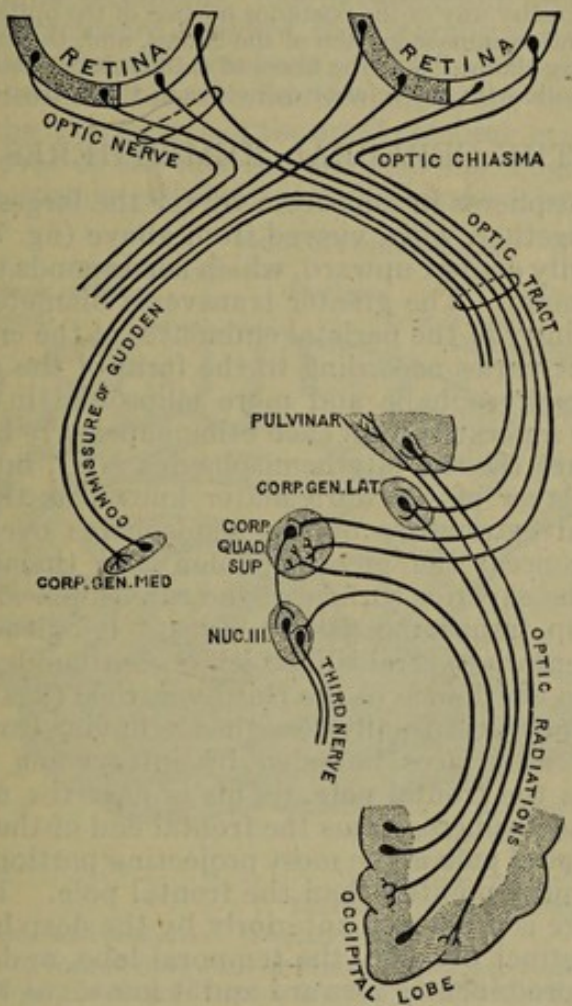

FIG. 748.—DIAGRAM OF THE PRINCIPAL COMPONENTS OF THE OPTIC APPARATUS. (After Cunningham.)

fibers are distributed to three localities:—(1) part of them terminate in the lateral geniculate body; (2) a portion pass over and around the lateral geniculate body and enter the pulvinar; (3) a portion enter the superior quadrigeminal brachium and course in it to terminate in the nucleus of the superior quadrigeminate body. The most evident function of this latter portion is to bear impulses which, by way of the neurones of the quadrigeminate body, are distributed to the nuclei of the oculomotor, trochlear, and abducent nerves, and thus mediate eye-moving reflexes. It has been suggested that the optic tracts carry a few visceral efferent fibers arising in the nuclei of the superior quadrigemina. The cells of the lateral geniculate body chiefly and the pulvinar, about which the retinal fibers terminate, give off axones which terminate in the cortex of the visual area, chiefly the gyri about the calcarine fissure of the occipital lobe. In reaching this area they curve upward and backward, coursing in a compact band of white substance known as the optic radiation (radiatio occipitothalamica, fig. 774). This band also is in part composed of fibers arising from the cells of the visual area, which pass from the cortex to the pulvinar, superior quadrigeminate bodies, and possibly some to the medulla oblongata and spinal cord. The superior quadrigeminate bodies probably send no fibers to the visual cortex, although they receive fibers from it.

Experimental and clinical evidence indicates that the great majority of the retinal fibers carrying the impulses which enter consciousness terminate in the lateral geniculate body instead of in the pulvinar of the thalamus. If so, the abundance of fibers of the lateral root which apparently pass around, over and under the lateral geniculate to reach the pulvinar may be, instead, largely fibers arising in the lateral geniculate and terminating in the thalamus to serve

in associational and reflex retinal functions. It is claimed that the pulvinar has chiefly to do with eye movements and pupillary reactions in response to light, and with stereoscopic vision and sensations of distance. In animals with monocular vision, the lateral geniculate consists of a dorsal, large-celled nucleus and a ventral one of smaller cells. The dorsal one serves as the especial nucleus of termination of fibers from the macula lutea and it contributes chiefly those fibers afferent to the visual cortex via the 'optic radiation,' while the ventral nucleus serves in light reflexes via the midbrain. In animals with complete binocular vision, including man, the dorsal or large-celled nucleus is so increased in relative size as to disperse the ventral one to loss of identity. In the latter condition it has been determined that the fibers arising from the upper or temporal half of the retina are distributed to the ventral part of the lateral geniculate body while those from the lower half terminate in the dorsal part of it.

The medial root of the optic tract contains few true visualfibers. It runs into the medial geniculate body, and neither it nor this body are appreciably affected after extirpation of both eyes. Instead, this body is concerned in the auditory apparatus. The root may be considered as largely representing the fibers of **Gudden's commissure** (inferior cerebral commissure). This commissure consists of fibers which correlate the medial geniculate bodies of the two sides with each other, and which, instead of crossing the midline through the mesencephalon, course in the optic tracts and cross by way of the posterior portion of the optic chiasma. It consists of fibers which both arise and terminate in each of the bodies, and, therefore, of fibers coursing in both directions. It is also claimed that the fibers of Gudden's commissure connect the medial geniculate body of each side with the inferior colliculus of the opposite side.

THE CEREBRAL HEMISPHERES

The cerebral hemispheres in man form by far the largest part of the central nervous system. Together, when viewed from above (fig. 756), they present an ovoid surface, markedly convex upward, which corresponds to the inner surface of the vault of the cranium. The greater transverse diameter of this surface lies posteriorly in the vicinity of the parietal eminences of the cranium. The outline of the superior aspect varies according to the form of the cranium, being more spheroidal in the brachycephalic and more ellipsoidal in the dolichocephalic. The hemispheres are separated from each other superiorly by a deep median slit, the **longitudinal fissure** (fissura interhemisphærica NK), into which fits a duplication of the inner layer of the dura mater known as the falx cerebri. The posterior or occipital extremities of the hemispheres overlap the cerebellum, and thus entirely conceal the mesencephalon and thalamencephalon. They are separated from the superior surface of the cerebellum and the corpora quadrigemina by the deep **transverse fissure** (fissura telodiencephalicaNK). This is occupied by the tentorium cerebelli, which is continuous with the falx cerebri and also with the tela chorioidea of the third ventricle (figs. 704, 765).

Each of the hemispheres is usually described as having three poles or projecting extremities, and three surfaces bounded by intervening borders. The most anterior projection is the **frontal pole.** This is near the midline and, with its fellow of the other hemisphere, forms the frontal end of the ovoid contour of the cerebrum. The **occipital pole** is the most projecting portion of the posterior and inferior end, and is more pointed than the frontal pole. The inferolateral portion of the hemisphere is separated anteriorly by the deep **lateral fissure** (fissure of Sylvius) into a distinct division, the temporal lobe, and the anterior portion of this lobe projects prominently forward and is known as the **temporal pole.**

The **surfaces** of the hemisphere are—(1) the lateral or *convex surface;* (2) the *medial surface;* and (3) the *basal surface.* The convex surface comprises the entire rounded aspect of the hemisphere visible previous to manipulation or dissection, and is the surface subjacent to the vault of the cranium. The medial surface is perpendicular, flat, and parallel with that of the other hemisphere, the two bounding the longitudinal fissure and for the most part in contact with the falx cerebri. The **superomedial border** intervenes between the convex and medial surfaces, and is thus convex and extends from the frontal to the occipital pole.

The more complex *basal surface* fits into the anterior and middle cranial fossæ, and posteriorly rests upon the tentorium cerebelli. Thus it is subdivided into—(*a*) an *orbital area,* which is slightly concave, since it is adapted to the orbital plate of the frontal bone, and is separated from the convex surface by the necessarily arched **superciliary border** and from the medial surface by the **medial orbital border,** the latter being straight and extending from the frontal pole medial to the olfactory bulb and tract; (*b*) a *tentorial area* or surface, which is arched in conformity with the dorsal surface of the cerebellum. This is separated from the convex surface by the **inferolateral border,** which runs from the occipital to the temporal pole; and from the medial surface by the **medial occipital border,** which is a more or less rounded ridge extending from the occipital pole obliquely

upward in the angle formed by the junction of the perpendicular falx cerebri and the horizontal tentorium cerebelli. This border is best seen in brains which have been hardened with the membranes *in situ*. The remainder of the basal surface includes the optic portion of the hypothalamus already considered, and the small depressed and punctate area, the anterior perforated substance, which is penetrated by the anterolateral group of the central branches of the anterior and middle cerebral arteries and into which the striæ of the olfactory trigone disappear. In addition to the orbital area, the basal surface of the hemisphere shows signs of the impress of the petrous portion of the temporal bone and of the great wing of the sphenoid.

The corpus callosum.—In their early development as lateral dilations of the anterior primary brain-vesicle, the hemispheres are connected with each other only at the anterior end of the thalamencephalon, where they are both continuous with the unpaired lamina terminalis. As development proceeds and the hemispheres extend upward, backward, forward, and laterally to conceal completely the base, and as the pallium, or cortex, thickens and its folds begin to appear, the two hemispheres become united across the midline above the thalamencephalon and the third ventricle by the intergrowth of the great cerebral commissure, the **corpus callosum.** After removal of the falx cerebri from the longitudinal fissure, the dorsal surface of the corpus callosum may be exposed by drawing apart the

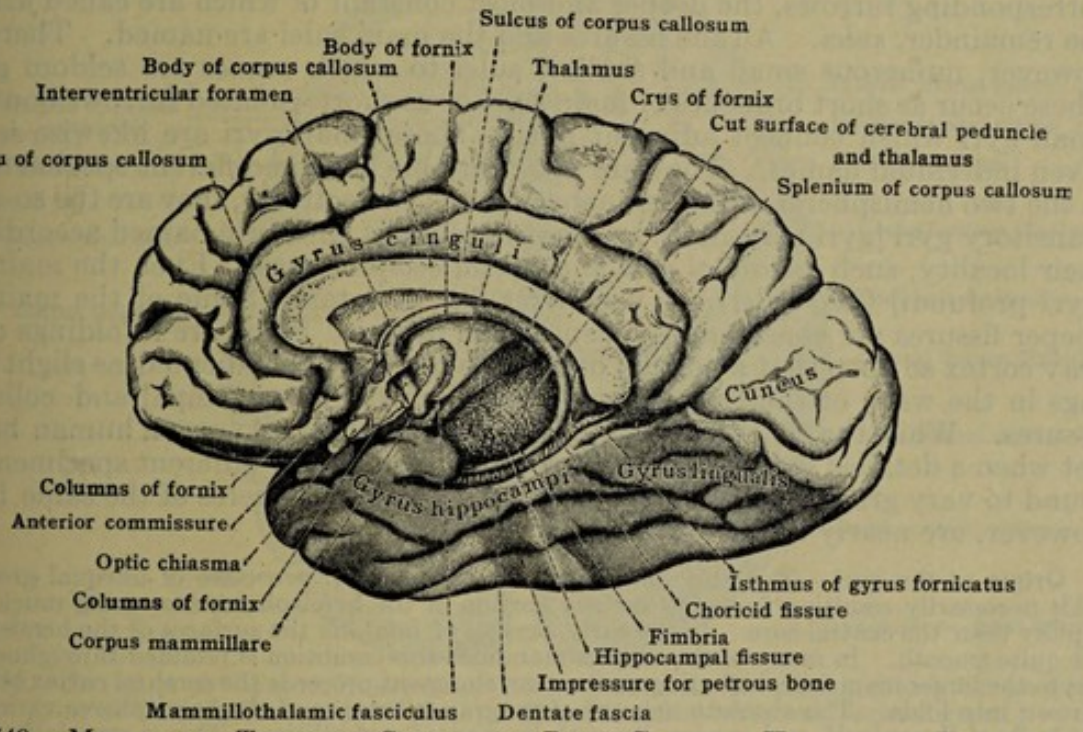

FIG. 749.—MEDIAL AND TENTORIAL SURFACES OF RIGHT CEREBRAL HEMISPHERE, VIEWED FROM THE LEFT. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

contiguous medial surfaces of the hemispheres (fig. 750). It consists of a dense mass of pure white substance coursing transversely, and arises as outgrowth from the cortical cells of both hemispheres. Thus it is the great pathway which correlates the cortex of the two sides of the telencephalon. Only the smaller middle portion of the body lies free in the floor of the longitudinal fissure, by far the greater part being concealed in the substance of the hemispheres, where its fibers radiate to and from different localities of the pallium, forming the *radiations of the corpus callosum.*

The surface of the corpus callosum shows numerous transverse markings the *transverse striæ*, which indicate the course of its component bundles of fibers. In addition there may be seen on each side of the midline two delicate, variable longitudinal bands running over its surface (fig. 750). The **medial longitudinal stria** (*stria Lancisii*) runs close to the median plane, around the anterior end from the gyrus subcallosus, and over the posterior end downward and lateralward to disappear in the hippocampal gyrus of the base of the telencephalon. The **lateral longitudinal stria** is more delicate than the mesial stria, courses lateral to the medial stria, and can be seen only within the sulcus of the corpus callosum. Both striæ are composed largely of axones having to do with the olfactory apparatus.

When severed along the median plane, it may be seen that the anterior margin of the corpus callosum is turned abruptly downward, forming the **genu,** and that

this turn continues, so that the tapering edge of the genu points posteriorly and constitutes the **rostrum** (figs. 746, 749). The rostrum is in contact with the lamina terminalis of the third ventricle below by a short, thin, frontal continuation of this lamina, known as the **rostral lamina.** The rostral lamina may be considered as beginning at the anterior cerebral commissure with the anterior aspect of which it is in contact, and extending to the rostrum. Beginning with the rostrum and genu, the corpus callosum arches backward as the **body of the corpus callosum,** and ends over the quadrigeminate region in its rounded, thickened posterior margin, the **splenium.** It is bounded above by the sulcus of the corpus callosum, and attached to its concave inferior surface are the choroid tela of the third ventricle, the fornix, and the septum pellucidum.

Each cerebral hemisphere includes—(1) a superficial and much folded mantle or *pallium*, divided into lobes and gyri, and consisting of gray substance, the *cortex*, covering an abundant mass of white substance; (2) a modified portion, the *rhinencephalon*, having especially to do with the olfactory impulses; (3) a cavity, the *lateral ventricle;* and (4) a buried mass of gray substance, the *caudate* and *lenticular nuclei*, which together with the *internal capsule* of white substance, are known as the *corpus striatum.*

Gyri, fissures and sulci.—The cerebral pallium is thrown into numerous and variable folds or *gyri* (convolutions). These are separated from each other by corresponding furrows, the deeper and most constant of which are called *fissures;* the remainder, *sulci.* All the fissures and the main sulci are named. There are, however, numerous small and shallow sulci to which names are seldom given. These occur as short branches of main sulci or as short, isolated furrows bounding small gyri which connect adjacent gyri. These small gyri are likewise seldom given individual names. They are very variable both in different specimens and in the two hemispheres of the same specimen. Collectively, they are the so-called transitory gyri [gyri transitivi]. Certain groups of them are named according to their locality, such as *orbital gyri* and *lateral occipital gyri.* Even the main gyri [gyri profundi] (and sulci) are very irregular in detail. Some of the main and deeper fissures are considerably deeper than others. Some are infoldings of the gray cortex so deep that a portion of their course may be indicated as slight bulgings in the walls of the lateral ventricles, e. g., the hippocampal and collateral fissures. While the general surface pattern is similar for all normal human brains, yet when a detailed comparison is made, the given gyri of different specimens are found to vary greatly. The main gyri of the two hemispheres of the same brain, however, are nearly alike.

Origin of the gyri.—The gyri (and sulci) are the result of processes of unequal growth—folds necessarily resulting from the surface portion of the hemispheres increasing much more rapidly than the central core. In the early periods of fetal life the surfaces of the hemispheres are quite smooth. In many of the smaller mammals this condition is retained throughout life, but in the larger mammals, including man, as development proceeds the cerebral cortex becomes thrown into folds. The absolute amount of the gray substance of the hemispheres varies with the bulk of the animal, and apparently with its mental capabilities. This is especially true of the cortex, for in the larger brains, and that of man especially, by far the greater amount of the cerebral gray substance lies on the surface. Therefore, in either the growth or evolution of a small animal into a large one the amount of cerebral gray substance is increased, and in this increase the surface area of the brain is especially enlarged. It is a geometrical law that in the growth of a body the surface increases with the square, while the volume increases with the cube of the diameter. The cerebral hemisphere is a mass the increase of whose volume does not keep the required pace with the increase of its surface area or cortical layer. The white substance of the hemisphere arises in large measure as outgrowths from the cells of the cortical layer, and thus it can only increase in a certain proportion to the gray substance. Therefore, the surface mantle of gray substance of a hemisphere, enlarged in accordance with an increased bulk of body, is greater than is necessary to comprise the surface of the geometrical figure formed by the combined white and gray substance. Consequently, in order to possess the preponderant amount of gray substance, the surface of the hemisphere is of necessity thrown into folds. It follows also that the thinner the cortical layer in proportion to the volume of the hemisphere, the greater and more folded will be the surface area. In accordance with this theory small animals have smooth or relatively smooth hemispheres, and that independently of their position in the animal scale while large animals have convoluted cortices.

The sulci in general begin to appear with the fifth month of fetal life, the larger of them, the fissures, appearing first and in a more or less regular order. Up to the fifth month the encephalon, due to its rapid growth, closely occupies the cranial capsule. During the fifth month the cranium begins to grow more rapidly than the encephalon, and a space is formed between the cerebrum and the inner surface of the cranium. This space allows further expansion of the pallium, and at the time the space is relatively greatest (during the sixth month) the form and direction of the principal gyri and sulci begin to be indicated. As growth proceeds the unrestricted expansion of the pallium results in the gyri again approaching the wall of the cranium,

and during the eighth month of fetal life they again come in contact with it. Finally, the later relative growth of the cranium results in the space found between it and the cortex in the adult. It is obvious that the relation of the cranium may be a factor in the causation of the gyri, for the increase of surface area necessitated by the increased amount of cortical gray substance might be limited by a cranial cavity of small size. It is probable that the second contact of the cortex with the cranium (during the eighth month) may at least cause a deepening and accentuation of the sulci already begun. Evidently the form of the cranium modifies the gyri, and to a certain extent probably determines their direction, for in long, dolichocephalic crania the anteroposterior gyri are most accentuated, and in the wide, brachycephalic crania the transverse gyri are most marked. At birth all the main fissures and sulci are present, but some of the smaller sulci appear later. In the growing pallium both the bottoms of the sulci as well as the summits of the gyri move away from the geometrical center of the hemisphere, the summits more rapidly, and hence the sulci or fissures first formed grow gradually deeper as long as growth continues.

The mechanical factors in the growth processes which result in the more or less regular arrangement of the gyri of the hemispheres of a given group of animals have not been satisfactorily determined. It has been suggested that the differences in arrangement of the gyri in different groups of animals may be in part dependent upon the functional importance of the various regions—the amount of gray substance of a region varying with the functional importance, and the consequent local increases being accompanied by resultant local foldings. This

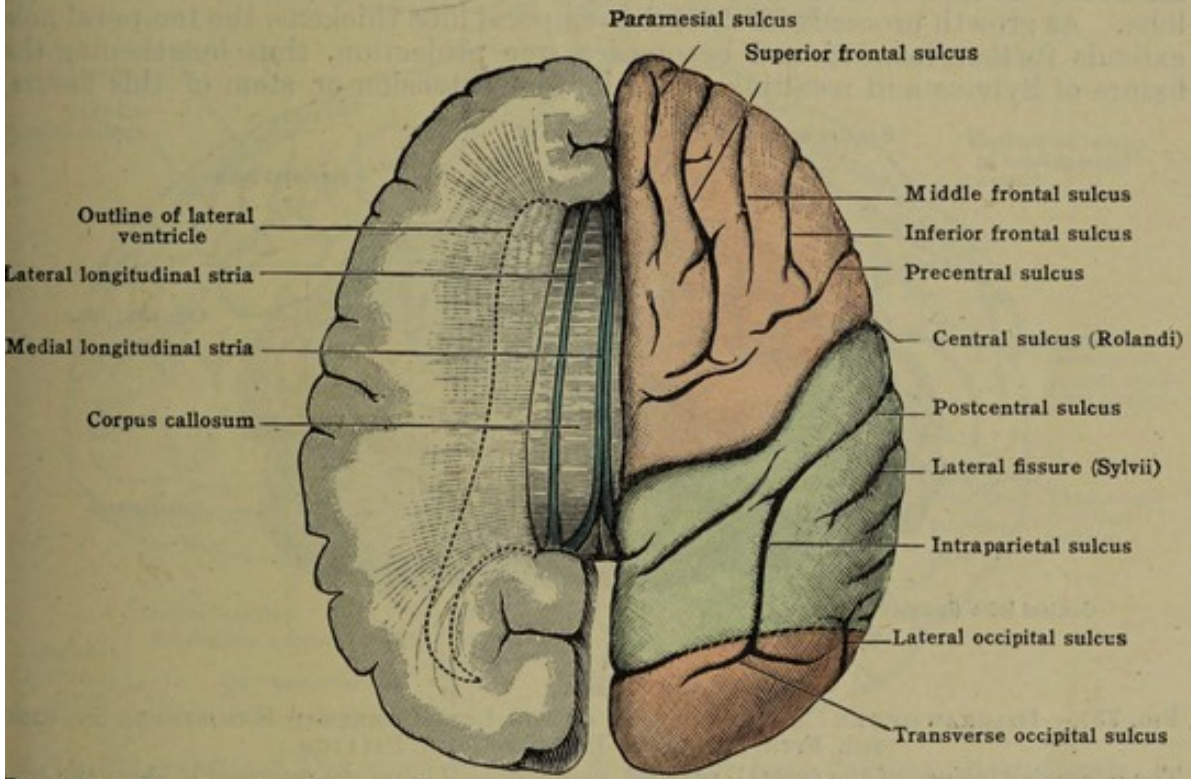

FIG. 750.—DIAGRAM OF CONVEX SURFACE OF RIGHT CEREBRAL HEMISPHERE AND UPPER SURFACE OF CORPUS CALLOSUM. (Temporal and occipital lobes red, parietal green.)

idea is supported by the fact that while the somesthetic (sensory-motor) area of the cortex varies with the bulk of the body, the frontal gyri, so much developed in man and which are one of the chief regions of the associational phenomena, are relatively independent of and do not vary with the weight of either the body or the brain.

Surface area.—The total surface area of the adult human telencephalon is about 2300 sq. cm. Of this area almost exactly one-third is contained on the outer or exposed surfaces of the gyri, while the other two-thirds is found in the walls of the sulci and fissures.

LOBES OF THE TELENCEPHALON AND THE GYRI AND SULCI

The folded pallium of each hemisphere is arbitrarily divided into lobes, partly by the use of certain of the main fissures and sulci as boundaries and partly by the use of imaginary lines (figs. 750–752). These divisions are six in number, themselves subdivided into their component gyri:

(1) Temporal lobe.
(2) Insula (Central lobe or Island of Reil).
(3) Frontal lobe.
(4) Parietal lobe.
(5) Occipital lobe.
(6) Olfactory brain or rhinencephalon (including structures comprised in the other lobes and often grouped under the names *olfactory* and *limbic lobes*.

This division of the cortex of the hemisphere is largely merely topographical. With the exception of the temporal lobe and the rhinencephalon, it has little of either morphological or functional value. The occipital lobe contains the recognized visual area of the cortex, but this area, as such, does not involve all of the lobe. In their functional significance, the frontal and parietal lobes, especially, overlap each other.

The temporal lobe.—This is the first lobe whose demarcation is indicated. During the second month of intrauterine life there appears a slight depression on the lateral aspect of the then smooth hemisphere. As the pallium further grows, this depression deepens into a well-marked fossa with a relatively broad floor. This fossa marks the beginning of the lateral cerebral fissure or fissure of Sylvius, and is, therefore, known as the *Sylvian fossa.* As the pallium continues to project outward, the folds which form the margins of the Sylvian fossa increase in size and height and begin to overlap and conceal its broad floor, which is the beginning of the insula. The overlapping folds thus become the **opercula,** and as their lips approach each other, there results the deep fissure of Sylvius, which marks off anteriorly an inferolateral limb of the pallium, termed by position the temporal lobe. As growth proceeds further, the temporal lobe thickens, the temporal pole extends further forward and becomes a free projection, thus lengthening the fissure of Sylvius and resulting in the inferior extension or stem of this fissure,

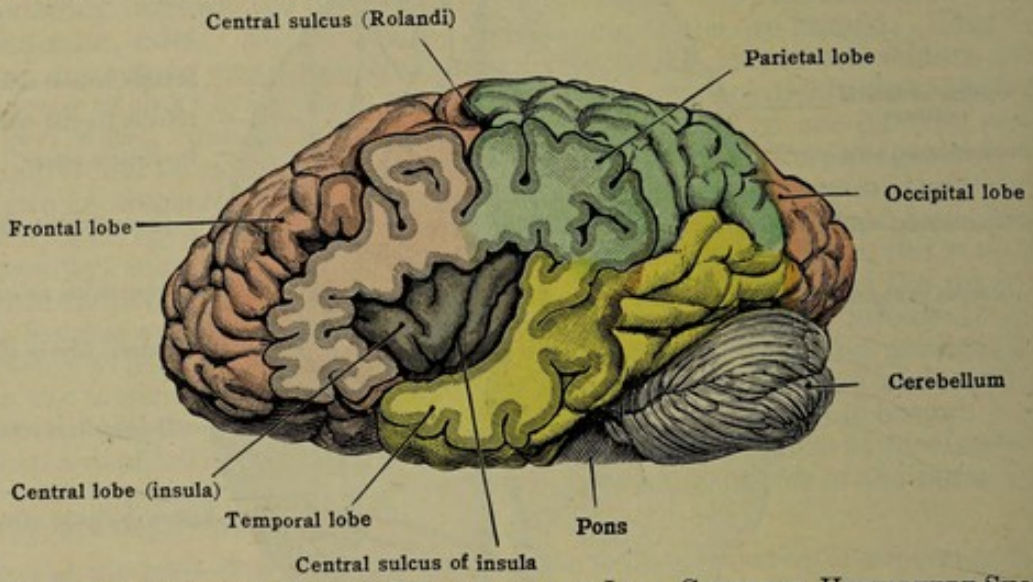

FIG. 751.—DIAGRAM OF THE CONVEX SURFACE OF THE LEFT CEREBRAL HEMISPHERE SHOWING THE FIVE PRINCIPAL LOBES OF THE PALLIUM.

The opercular regions of the frontal, parietal, and temporal lobes are removed to show the central lobe or island of Reil.

which runs between the temporal pole and the frontal lobe and curves under so as to appear on the basal surface of the hemisphere (fig. 758). Finally the cortex of the temporal lobe itself is thrown into folds or gyri. Its posterior end is never marked off from the lobes above and behind, except by arbitrary lines which will be mentioned in connection with those lobes.

The temporal lobe forms part of the lateral convex and tentorial surfaces of the hemisphere, and its anterior portion is adapted to the surface of the middle cranial fossa. It thus has a lateral surface and a basal and tentorial surface. In these surfaces are the following gyri with their intervening and bounding sulci (fig. 752):

The **superior temporal gyrus** is bounded by the posterior ramus of the lateral fissure, and extends from the temporal pole backward into the supramarginal region belonging to the parietal lobe above. The upper margin of this gyrus constitutes the **temporal operculum,** in that it aids in overlapping and enclosing the insula in the floor of the lateral fissure (fig. 753). This margin is mostly smooth, being occasionally interrupted by a few weak twigs of the lateral fissure. It is separated from the gyrus below by the **superior temporal sulcus,** which is parallel with the posterior ramus of the lateral fissure and is frequently called the *parallel sulcus.* The posterior extremity of this sulcus divides the angular gyrus of the parietal lobe, and its anterior end disappears in the temporal pole, sometimes as a continuous groove, sometimes in isolated pieces.

The **middle temporal gyrus** likewise begins in the temporal pole and is continuous backward into the angular gyrus of the parietal lobe.

The **inferior temporal gyrus** forms the inferolateral border of the temporal lobe, and is usually more broken up than the two gyri above it. It usually begins continuous with them in the frontal pole, and extends horizontally backward into the lateral gyri of the occipital lobe. It is separated from the middle gyrus by the **middle temporal sulcus,** which likewise is never so continuous a furrow as the superior temporal sulcus. Frequently this sulcus occurs in detached portions and often terminates within the temporal lobe.

The **fusiform gyrus** is in the basal and tentorial surface of the temporal lobe (fig. 754). Its usual somewhat spindle-shape suggests its name, and it is continuous backward into the occipital gyri, or its posterior end may be completely isolated by a union of the *inferior temporal sulcus* and the **collateral fissure,** which two furrows separate it from its neighbors on either side. Anteriorly the fusiform gyrus runs into the common substance of the other three gyri at the temporal pole.

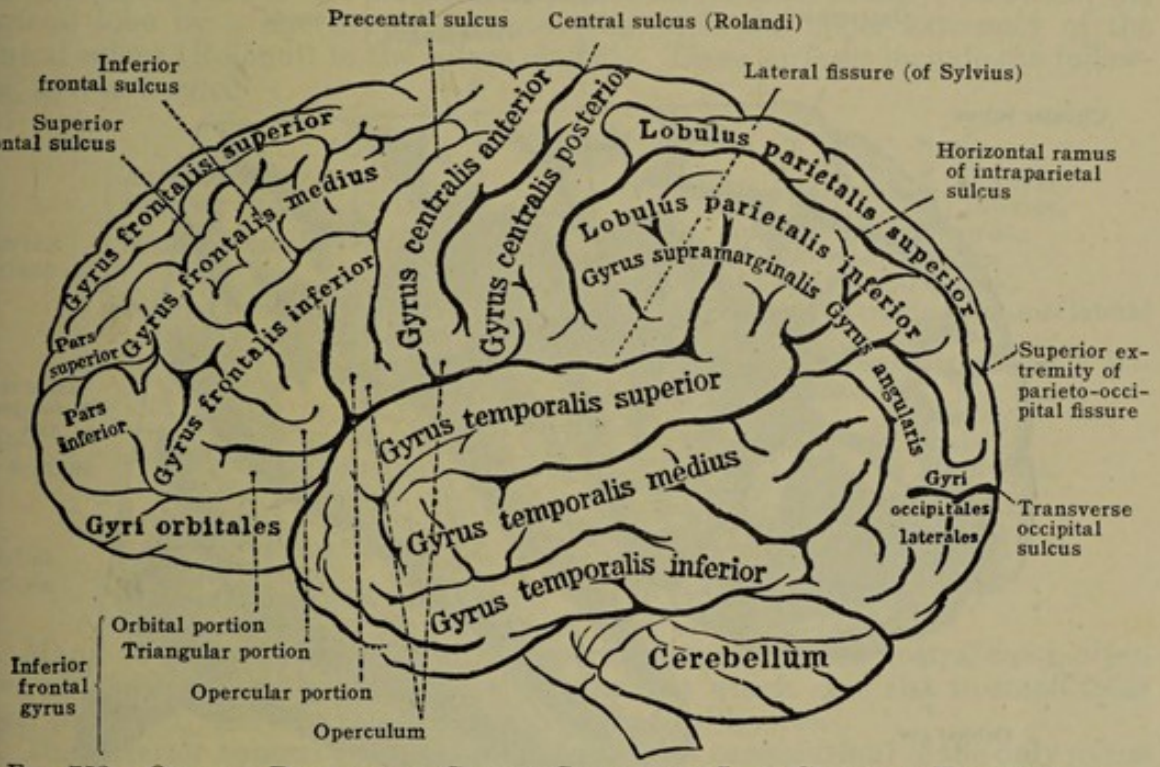

FIG. 752.—OUTLINE DRAWING OF CONVEX SURFACE OF LEFT CEREBRAL HEMISPHERE. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

The **lingual gyrus** (fig. 754) is usually included in the tentorial surface of the temporal lobe, though some regard it as a part of the occipital lobe. Its larger, posterior portion lies within the boundaries of the occipital lobe. Bounded laterally by the collateral fissure, it is continuous anteriorly into the hippocampal gyrus of the rhinencephalon.

All of the sulci give off occasional lateral twigs (*transverse temporal sulci*) which themselves may or may not branch, and which tend to divide the main gyri into **transverse temporal gyri.**

The lateral fissure (fissure of Sylvius) (vallecula cerebri lateralis NK).—On account of its origin by the overlapping and enclosing of the broad floor of the Sylvian fossa by the adjacent folds of the pallium, the lateral fissure is the deepest and most conspicuous fissure of the cerebral hemisphere (figs. 752–754). Its main divisions are a short stem and three main branches. The **stem** lies in the basal surface of the hemisphere, where it begins in a depression in the anterior perforated substance, the *vallecula Sylvii*, and passes forward and upward between and separating the temporal pole and the superciliary border of the frontal lobe. It corresponds in direction with the posterior border of the lesser wing of the sphenoid bone, which projects backward into it, and it contains the middle cerebral artery, the Sylvian vein, and the sinus alæ parvæ. It coincides on the lateral surface with a point known in cranial topography as the *Sylvian point*, where it divides into its three main branches (fig. 752):

(1) The **posterior ramus** is the linear continuation of the fissure, and runs horizontally backward and upward to terminate in the supramarginal gyrus of the parietal lobe.

(2) The **anterior ascending ramus** passes upward for about 10 mm., subdividing the inferior gyrus of the frontal lobe.

(3) The **anterior horizontal ramus** passes forward from the stem of the fissure about 10 mm., and likewise into the inferior frontal gyrus, but parallel with the superciliary border.

These branches, together with certain smaller collateral twigs, divide the overlapping or opercular portions of the adjacent pallium into (*a*) the *temporal operculum*, which lies below the posterior ramus; (*b*) the frontoparietal operculum, or *operculum proper*, which lies above and behind the anterior ascending ramus; (*c*) the *frontal operculum*, between the latter and the anterior horizontal ramus; (*d*) and the *orbital operculum*, below the anterior horizontal ramus. Collectively the opercula are known as the *opercula of the insula*.

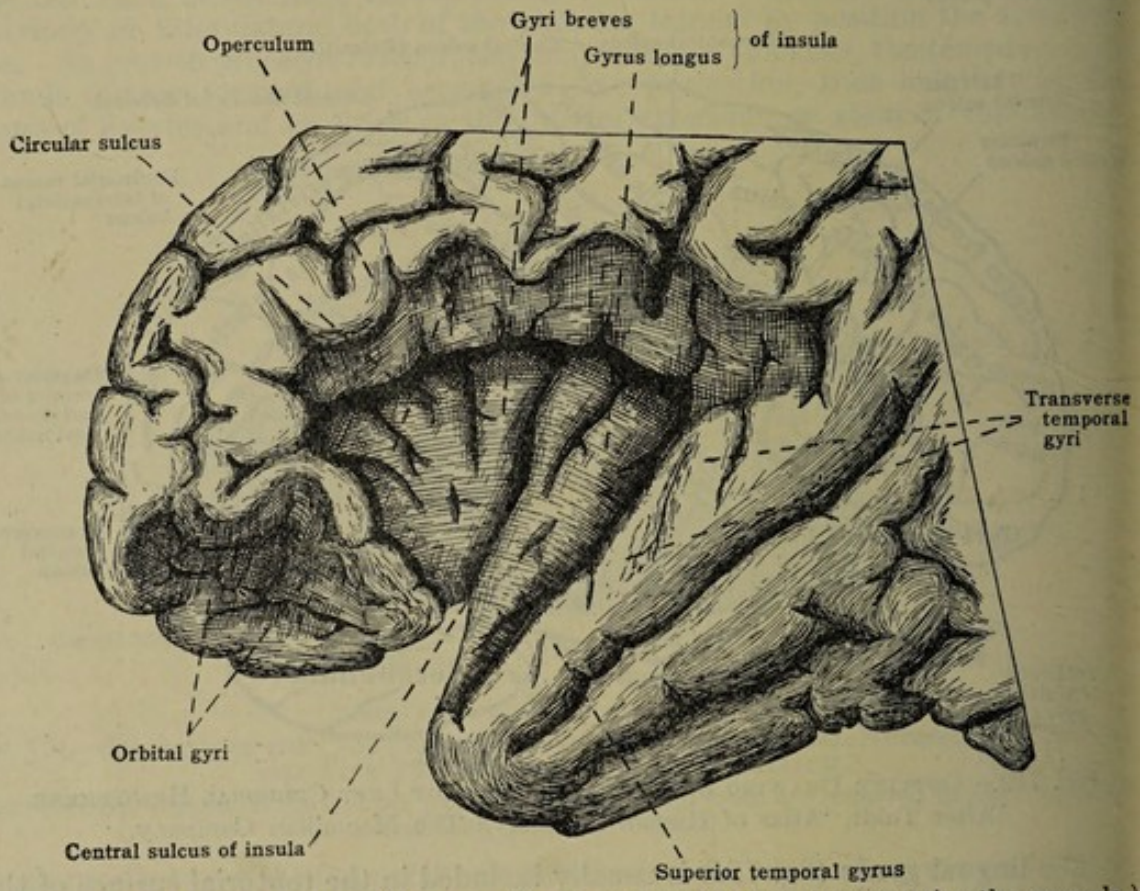

FIG. 753.—THE INSULA WITH ITS GYRI AND SULCI. (Shown by widely separating the opercula.)

The insula (central lobe).—The insula or island of Reil (figs. 751, 753) is a triangular area of the cerebral cortex lying in the floor of the lateral fissure, and concealed by the opercula. Of these, the temporal operculum overlaps the insula to a greater extent than either the frontal or parietal. More than half of it may, therefore, be exposed, by gently pressing away the temporal lobe. The insula corresponds to the broad floor of the Sylvian fossa of the fetal brain. In the developed condition its surface is convex lateralward and is itself folded into gyri. The apex of the triangle appears upon the basal surface of the hemisphere (fig. 754), and is the only portion which may be seen without disturbing the specimen. The apex appears as the end of a small gyrus under the temporal pole, and in close relation with the anterior perforated substance and the vallecula Sylvii, and is known as the **limen of the insula.** In the folding process by which the opercula accomplish the overlapping and enclosing of the island, there results a deep sulcus which surrounds its entire area except at the limen insulæ. This is known as the **circular sulcus,** or limiting sulcus of Reil. The gyri (and sulci) of the insula radiate from the apex of the triangle. The **central sulcus** of the insula is the deepest. It runs from below backward and upward, parallel with the central sulcus (of Rolando) above and divides the insula into a larger anterior and

a longer posterior portion. The anterior portion consists of from three to five short irregular **gyri breves** or precentral gyri, separated by **sulci brevis**; the posterior portion consists of a single, slightly furrowed gyrus, which is long and arched and extends from the apex to the base of the triangle, the **gyrus longus.**

In a thorough study of the insula of more than 200 human brains, including a few of idiots and paralytics and a series of young fetuses, Nelidoff finds that the left island is more deeply marked by sulci and averages 11 mm. longer than the right; that, of the sulci in the island, the central sulcus is the first to appear, is the most persistent sulcus in defective brains, though occasionally absent in microcephalic idiots, and that on the average it is more pronounced in males than in females.

The frontal lobe (figs. 750–757).—This is the most anterior of the lobes of the hemisphere and, like the two lobes behind, it has a convex or lateral, a basal, and a medial surface. The convex surface begins with the frontal pole, and is bounded posteriorly by the *central sulcus* (*Rolandi*). The basal surface extends backward to the stem of the lateral fissure which is covered by the frontal pole. The medial surface is separated from the gyrus cinguli of the rhinencephalon (limbic lobe) by the subfrontal part of the **sulcus cinguli** (callosomarginal fissure), and from the parietal lobe by a line drawn perpendicular from the upper extremity of the central sulcus (Rolandi) to the sulcus cinguli. These surfaces include the following, gyri and sulci:—

	Gyri.	Sulci.
Convex surface	Anterior central gyrus.	
	Superior frontal gyrus.	
	Middle frontal gyrus: Superior portion.	Precentral sulcus: Superior.
	Middle frontal gyrus: Inferior portion.	Precentral sulcus: Inferior.
		Superior frontal sulcus.
		Middle frontal sulcus.
	Inferior frontal gyrus: Opercular portion.	Inferior frontal sulcus.
	Inferior frontal gyrus: Triangular portion.	Anterior ascending ramus of lateral fissure.
	Inferior frontal gyrus: Orbital portion.	Anterior horizontal ramus of lateral fissure.
Basal surface	Orbital gyri: Lateral.	Orbital sulci: Lateral
	Orbital gyri: Anterior.	Orbital sulci: Medial.
	Orbital gyri: Posterior.	Orbital sulci: Transverse.
	Orbital gyri: Medial.	
	Gyrus rectus	Olfactory sulcus.
Medial surface	Superior frontal gyrus.	
	Marginal gyrus.	
	Paracentral lobule (anterior part).	Rostral sulci.

Many of the sulci, especially the superior frontal and the rostral sulci, often give off twigs or are broken into short furrows which give rise to small folds [gyri transitivi], too inconstant to be given special names.

The **anterior central gyrus** (ascending frontal convolution) is the only gyrus of the frontal lobe having a vertical direction. It lies parallel to the central sulcus (Rolandi), and thus extends obliquely across the convex surface from the posterior ramus of the lateral fissure (frontal operculum) to the superomedial border, and is continuous on the medial surface with the anterior portion of the *paracentral lobule.* It comprises the larger part of the motor portion of the somesthetic (sensory-motor) area of the cerebral cortex. It is separated from the horizontal frontal gyri in front of it by the **precentral sulcus**

This sulcus is developed in three parts, but the upper and middle parts in the fetal brain usually fuse together, so that in the later condition it consists of a superior and an inferior segment. The superior cuts the superomedial border of the hemisphere and appears on the medial surface in the paracentral lobule. On the convex surface it is usually connected with the posterior end of the superior frontal sulcus (fig. 752).

The **superior frontal gyrus** is a relatively broad, uneven convolution, comprising the anterior portion of the superomedial border of the hemisphere and therefore extends horizontally from the precentral sulcus to the frontal pole. It is sometimes imperfectly divided into a superior and an inferior part by a series of detached, irregular furrows, spoken of collectively as the *paramedial sulcus.* The resulting transitory gyri are of considerable interest in that they are peculiar to the human brain, and are said to be more marked in the higher than in the lower types.

The **middle frontal gyrus** is likewise a broad strip of pallium extending from the precentral sulcus to the temporal pole. It is separated from the superior frontal gyrus by the **superior frontal sulcus,** which is usually continuous into the

superior segment of the precentral sulcus and thence extends horizontally to the frontal pole. The middle frontal gyrus is in most cases subdivided anteriorly into a *superior* and an *inferior portion* by a **middle frontal sulcus.** This sulcus begins above and runs into the frontal pole, where, upon reaching the superciliary border, it frequently bifurcates into a transverse furrow, known as the *fronto-marginal sulcus.*

The **inferior frontal gyrus** forms the superior wall of the lateral fissure, and is separated from the middle frontal gyrus by the **inferior frontal sulcus.** This sulcus usually begins continuous with the inferior section of the precentral sulcus, and extends, very irregularly and frequently interrupted, toward the frontal pole. The gyrus abuts upon the anterior central gyrus, and its posterior portion is divided into three parts (the frontal opercula) by the anterior ascending and horizontal rami of the lateral fissure. The part behind the anterior ascending

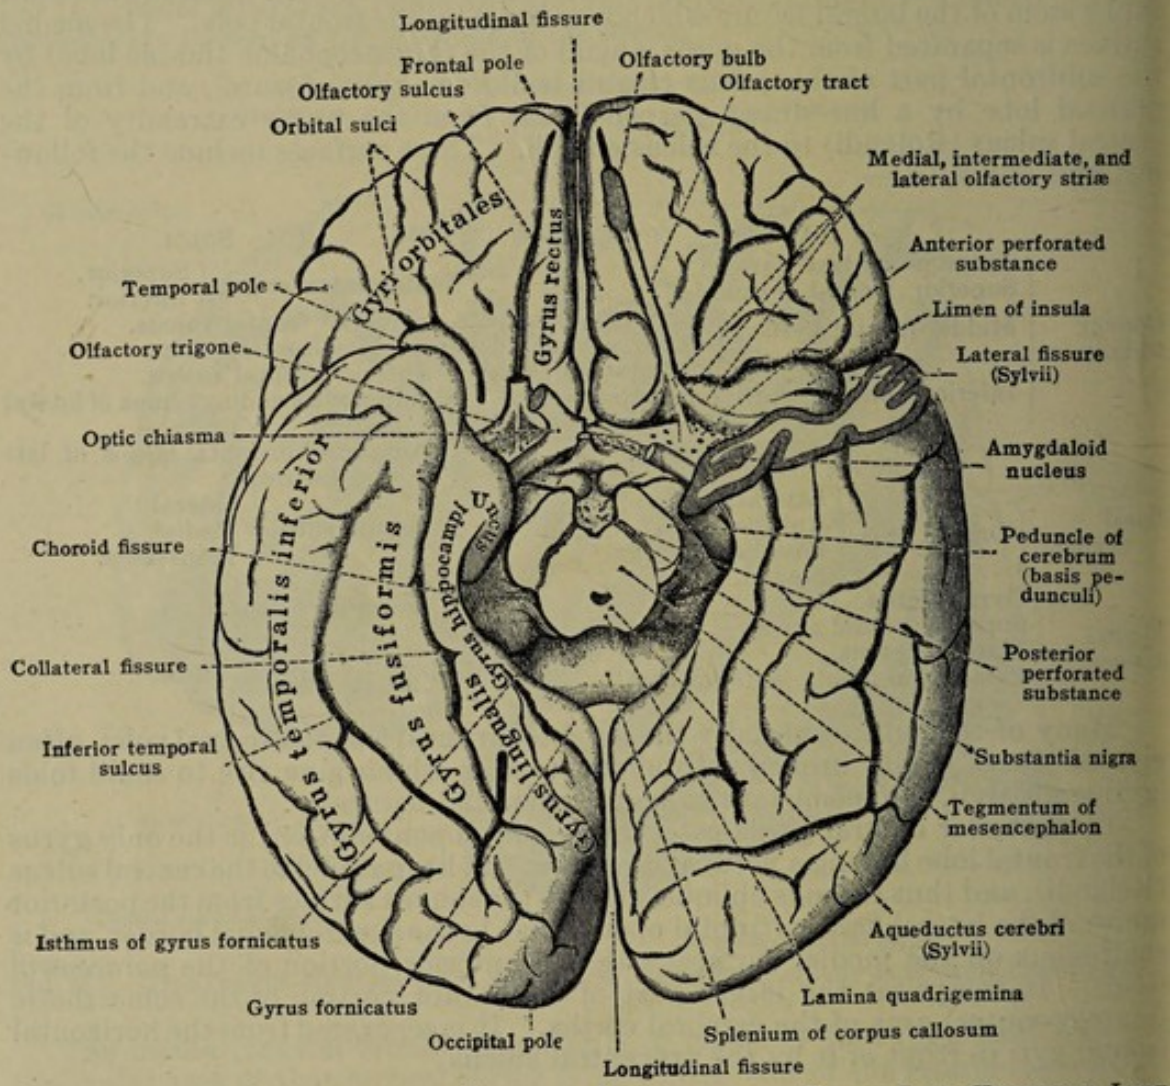

FIG. 754.—BASAL SURFACE OF THE CEREBRAL HEMISPHERES. TIP OF LEFT TEMPORAL LOBE REMOVED. (After Toldt, 'Atlas of Human Anatomy,' The Macmillian Company.)

ramus is the **opercular portion** (a part of the frontoparietal operculum or operculum proper), sometimes referred to as the *basilar portion.* In most brains this part is traversed by a short oblique furrow, the **diagonal sulcus.** The part between the two anterior rami of the lateral fissure is the cone-shaped **triangular portion.** This portion frequently involves one and sometimes two descending twigs of the inferior frontal sulcus. The part below the anterior horizontal ramus is by position the **orbital portion.**

It is seen that the inferior frontal gyrus gives rise to the whole of the frontal operculum and the anterior half of the frontoparietal operculum. The opercular portion is of special interest in that in the left hemisphere it constitutes the historic **convolution of Broca,** the motor area for the function of speech. The area controlling speech, however, involves that part of the triangular portion bounding the anterior ascending ramus of the lateral fissure as well, and both these parts often appear more developed on the left hemisphere. The development of the opercula of the inferior frontal gyrus is a distinctive characteristic of the human brain.

This gyrus does not develop opercula even in the highest varieties of apes. The development of the function of speech in man no doubt has influenced the development of the frontal opercula.

On the *basal surface* (fig. 754) of the frontal lobe is the orbital area and the gyrus rectus. The more pronounced of the **orbital sulci** are often so joined with each other as to form an H-shaped figure standing parallel to the medial plane, and thus they comprise a *medial*, a *lateral* and a *transverse orbital sulcus*. This figure naturally divides the orbital area into four gyri:—(1) The **lateral orbital gyrus** is the basal continuation of the inferior frontal gyrus, and is thus related to the orbital portion of the frontal operculum; (2) the **anterior orbital gyrus** is continuous at the pole with the middle frontal gyrus; (3) the **posterior orbital gyrus** is closely related to the limen insulæ and the stem of the lateral fissure, and its outer part is in relation with the orbital portion of the operculum; (4) the **medial orbital gyrus** is continuous over the superciliary border with the superior frontal gyrus. It frequently contains one or two short, isolated sulci. Its medial boundary is the straight **olfactory sulcus,** in which lie the olfactory bulb and tract of the rhinencephalon. This sulcus marks off a narrow straight strip of cortex between it and the medial border of the lobe known as the **gyrus rectus.** The posterior portion of the gyrus rectus comprises a part of the **parolfactory area** or Broca's area, which functionally belongs to the rhinencephalon. As an area or field, this appears mesially lying between the anterior and posterior parolfactory sulci.

On the *medial surface* (fig. 757) of the frontal lobe the superior frontal gyrus is separated from the gyrus cinguli of the rhinencephalon (limbic lobe) by the well-marked **sulcus cinguli.** Anteriorly the superior frontal gyrus is subdivided by the main stem of the **rostral sulci** into a **marginal gyrus,** and what may be termed a **submarginal gyrus.** The marginal gyrus is usually broken into smaller parts by twigs of the rostral sulci, most of which are perpendicular to the main stem, while the submarginal gyrus is less frequently interrupted. Posteriorly the superior frontal gyrus constitutes the anterior portion of the *paracentral lobule,* a part of the somesthetic area of the medial surface of the hemisphere. This lobule is usually marked off anteriorly by a vertical twig from the sulcus cinguli.

The **sulcus cinguli** (callosomarginal fissure) is the longest and one of the most prominent sulci on the medial surface of the hemisphere. It divides the anterior portion of the medial surface into a marginal part above and a callosal part below —in other words, it separates the superior frontal gyrus from the gyrus cinguli. Its **subfrontal portion** begins below the rostrum of the corpus callosum and curves forward and upward around the genu, and then turns backward above the body of the corpus callosum. Before it reaches the level of the splenium, it turns upward and cuts and terminates in the superomedial border of the hemisphere, as the next sulcus behind the upper termination of the central sulcus. This upward turn is the **marginal portion** of the sulcus cinguli. It is sometimes an abrupt curve and sometimes curves gradually, but its marginal relation to the upper end of the central sulcus is so constant that it serves as a means by which either of the sulci may be identified. The marginal portion separates the paracentral lobule from the precuneus (quadrate lobule), and is wholly within the parietal lobe. One of the most constant twigs of the sulcus cinguli is that which marks off the paracentral lobule from the superior frontal gyrus. Another sometimes divides the paracentral lobule into its frontal and parietal portions.

The sulcus cinguli is developed from two and sometimes three (anterior, middle, and posterior) separate furrows, which later extend and fuse into continuity. This method of its development may explain the irregularities frequently met with and the fact that sometimes in the adult the sulcus occurs in separate pieces.

The **central sulcus** (fissure of Rolando) (figs. 752, 755, 756) is one of the principal landmarks of the convex surface of the hemisphere. It separates the frontal from the parietal lobe, and likewise divides the somesthetic area of the pallium. Its upper end terminates in and usually cuts the superomedial border of the hemisphere immediately in front of the termination of the marginal portion of the sulcus cinguli. Thence it pursues an oblique though sinuous course forward across the convex surface of the hemisphere, forming on the average an angle of about 72° with the superomedial border (**Rolandic angle**), and terminates in the frontoparietal operculum immediately above the posterior ramus, and about 2.5 cm. behind the point of origin of the two anterior rami of the lateral fissure. It rarely cuts

through the frontoparietal operculum. In its sinuous course, varying from the line of its superomedial end, two bends are marked (fig. 755):—(1) The **superior genu** occurs at about the junction of the upper and middle thirds of the sulcus and is concave forward. It accommodates the greater part of that portion of the cortex which is the motor area for the muscles of the leg and trunk, and the development of this area in man probably aids in producing it. (2) The **inferior genu** occurs below, is concave forward and is commonly a little more marked than the superior genu. It is probably in part a result of the superior genu—the turn of the sulcus in resuming its general course, but it may further result from the development of the shoulder and arm area of the cortex which occupies its concavity.

The **central sulcus (Rolandi)** appears in the pallium of the fetus during the latter part of the fifth month. It then consists of a lower longer and an upper shorter part. Usually these two parts become continuous before birth; very rarely do they remain separate in the adult. The point of their fusion is sometimes manifest within the depth of the sulcus. If the lips of the sulcus be pressed widely apart at about the region of the junction of its middle and upper thirds, it will be found that the opposing walls give off a number of protuberances or lateral gyri, which dovetail into each other when the sulcus is closed. Sometimes two of these lateral gyri appear fused across the floor of the sulcus, so as to form a bridge of gray substance known as the **deep annectant gyrus.** This interruption of the continuity of the sulcus, when present, represents the point at which the two parts of the sulcus in the fetal brain joined each other without the continuity becoming wholly completed in the adult. The genua of the adult sulcus may often be due to the precedent parts not being in line at the time of their fusion.

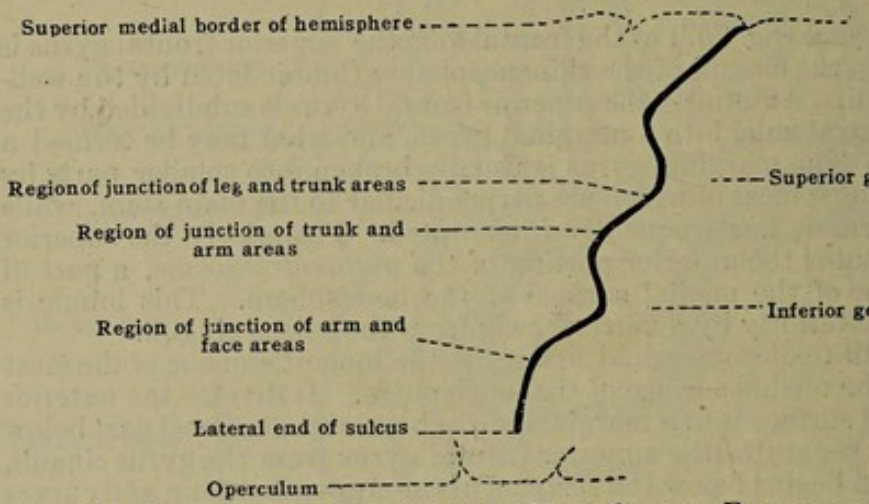

FIG. 755.—DIAGRAM REPRESENTING THE MOST COMMON FORM OF THE CENTRAL SULCUS AND INDICATING THE REGIONS OF JUNCTION UPON IT OF THE AREAS OF THE PRECENTRAL GYRUS DEVOTED TO THE DIFFERENT REGIONS OF THE BODY (SYMINGTON AND CRYMBLE).

From a special study of the central sulcus of 237 normal adult hemispheres, Symington and Crymble (1913) give the following details: (1) that the most common course of the sulcus is that illustrated in fig. 755, above; (2) that it varies in depth both in a given specimen and in different specimens—the greatest variations in depth reported for a given sulcus being from 22 to 12 millimeters, the shallowest part being in the region of the deep annectant gyrus; (3) that the average length from the superomedial border of the hemisphere to the opercular end of the sulcus is about 9 cm. in direct line and 10.4 cm. following the curves of the sulcus. The average length of the curved floor is 7.9 cm. (4) From the superomedial end of the sulcus to the points of junction of the general areas of the precentral gyrus, direct line measurements give averages, (a) to the junction of leg and trunk areas, 3.5 cm.; (b) to junction of trunk and arm areas, 4.5 cm.; (c) junction of arm and face areas, 7.5 cm.

The parietal lobe.—The parietal lobe (figs. 749–752, 756, 757) occupies a somewhat smaller area of the human telencephalon than either the frontal or the temporal lobe. It has a lateral convex and a medial surface, but no basal surface. It is separated from the frontal lobe in front by the central sulcus; from the occipital lobe behind, on the medial surface by the *parietooccipital fissure*, and, on the convex surface, by an arbitrary line drawn transversely around the convex surface of the hemisphere from the superior extremity of this fissure to the inferolateral border, and it is separated from the temporal lobe below by the horizontal part of the posterior ramus of the lateral fissure, and by a line drawn in continuity with this horizontal part to intersect the transverse line drawn to limit it from the occipital lobe.

The preoccipital notch.—*In situ*, the inferolateral border of the posterior portion of the hemisphere rests over a small portion of the parietomastoid suture of the cranium, and upon this suture occurs a fold or vertical thickening of the dura mater, which slightly indents the

inferolateral border of the hemisphere. This indentation occurs about 4 cm. from the occipital pole, and is considered one of the points of limitation of the parietal from the occipital lobe, and is therefore called the preoccipital notch. While during late fetal life and early childhood it is well marked, it is usually very slight in the adult brain, and is, as a rule, evident only in brains hardened *in situ*. When it is visible, the arbitrary transverse line from the superior extremity of the parietooccipital fissure, used as a boundary between the convex surfaces of the parietal and occipital lobes, should be so drawn as to bisect the preoccipital notch.

The *convex surface* of the parietal lobe comprises the following gyri and sulci:—

The **posterior central gyrus** (ascending parietal) extends obliquely across the hemisphere parallel with the anterior central gyrus of the frontal lobe, from which it is separated by the central sulcus. Its inferior end is bounded by the posterior ramus of the lateral fissure, and constitutes the posterior or parietal portion of the frontoparietal operculum. Its upper end takes part in the superomedial border of the hemisphere, and is bounded posteriorly by the tip end of the marginal portion of the sulcus cinguli. Its posterolateral boundary consists of the two

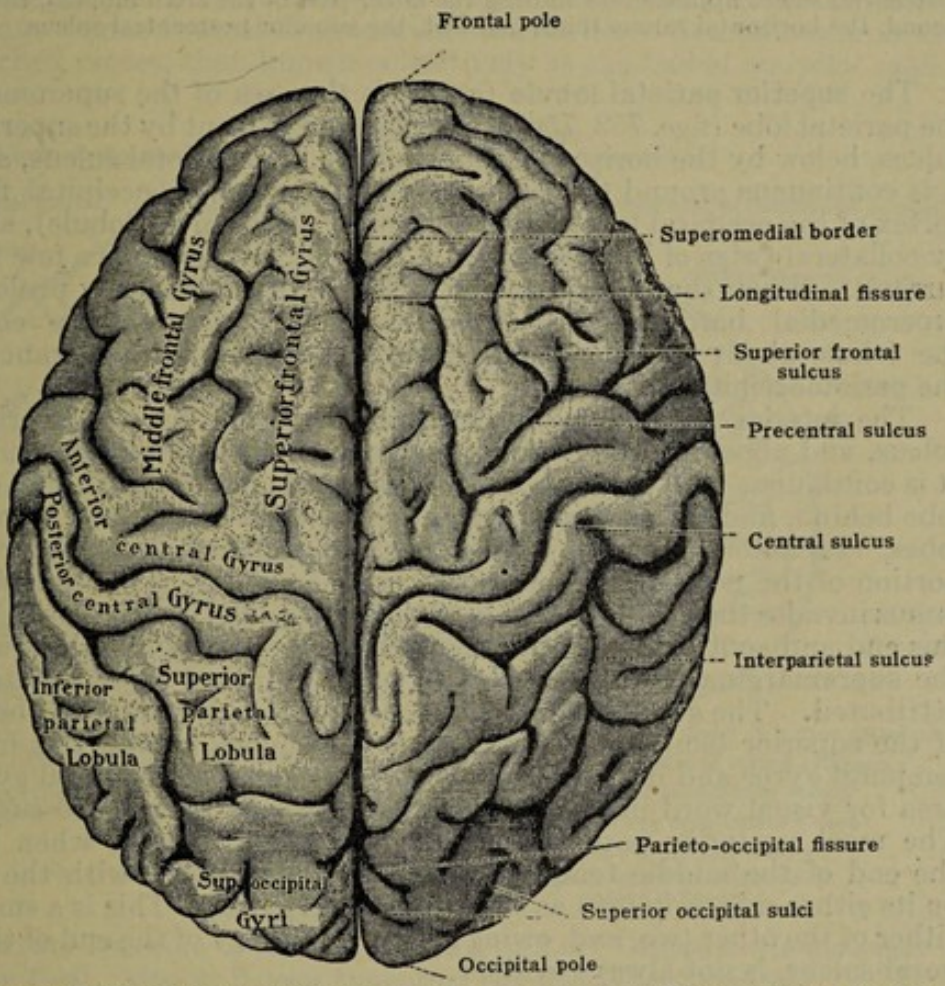

FIG. 756.—CONVEX SURFACE OF THE CEREBRAL HEMISPHERES AS VIEWED FROM ABOVE. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

more or less vertical rami or factors of the interparietal sulcus, viz., the inferior and superior portions of the *postcentral sulcus*, either continuous with each other or detached.

The **interparietal sulcus** (intraparietal) is often the most complicated sulcus of the pallium. Its development usually begins as four different furrows in the fetal brain, and the difficulty with which it is traced in the adult brain depends upon the extent to which these four factors become continuous in the later development. When continuity of the furrows is well established, the entire sulcus may be described as consisting of an anterior end and a convex *horizontal ramus*, which gives off a few short collateral twigs and whose either end is in the form of an irregular, reclining ⊣. The transverse bar of the anterior end arises from two of the four factors of the entire sulcus:—(1) an inferior furrow, the *inferior postcentral sulcus*, commencing above the posterior ramus of the lateral fissure and ascending as the boundary of the lower half of the posterior central gyrus, and (2) a superior furrow, the *superior postcentral sulcus*, lying behind the upper portion of the posterior central gyrus, and which, upon approaching the superomedial

border, may turn backward a short distance parallel with the horizontal ramus, as in fig. 752. When confluent, these two factors form together a continuous **postcentral sulcus.** In the adult the superior of the two is always continuous with the horizontal ramus; when confluent, the two join so as to form the transverse bar of the anterior end of this ramus. The horizontal ramus, which represents the third of the primary furrows, is continued backward past the superior extremity of the parietooccipital fissure into the occipital lobe, where it usually joins the *occipital ramus*, the fourth of the primary furrows. This ramus divides shortly into two branches which run at right angles to the stem, forming the *transverse occipital sulcus*, and thus arises the transverse bar of the posterior end of the interparietal sulcus.

The occipital ramus may, however, consist of little more than the transverse bar, which may or may not be joined by the horizontal ramus. The occipital ramus is more frequently separate from the horizontal than is the postcentral sulcus. In their development the inferior postcentral sulcus appears first (during the latter part of the sixth month), the occipital ramus second, the horizontal ramus third, and last, the superior postcentral sulcus.

The **superior parietal lobule** (*gyrus*) is the area of the superomedial border of the parietal lobe (figs. 752, 756). It is limited in front by the superior postcentral sulcus, below by the horizontal ramus of the interparietal sulcus, and posteriorly it is continuous around the superior end of the parietooccipital fissure into the cortex of the occipital lobe. It is a relatively wide area (lobule), always invaded by collateral twigs of its limiting sulci, and usually contains a few short, isolated furrows. When the parieto-occipital fissure is considerably prolonged over the superomedial border (*external parietooccipital fissure*), the continuation of the lobule about the end of this fissure presents the appearance described as the **parietooccipital arch.**

The **inferior parietal lobule** is limited in front by the inferior postcentral sulcus, and above by the horizontal ramus of the interparietal sulcus (fig. 752). It is continuous with the cortex of the temporal lobe, and with that of the occipital lobe behind, and is therefore invaded by the ends of the sulci belonging to these lobes. Its anterior portion is separated from the temporal lobe by the horizontal portion of the posterior ramus of the lateral fissure. The upturned end of this ramus invades the anterior portion of the lobule and the broad fold, arched around this end and continuous behind it into the superior temporal gyrus, is known as the **supramarginal gyrus**—an area to which auditory word- and tone-images are attributed. The **angular gyrus** is the portion which embraces the posterior end of the superior temporal sulcus, and is continuous behind this into the middle temporal gyrus and in front usually with the superior temporal gyrus. It is the area for visual word images. Its shape is usually such as to suggest its name. The most posterior part of the inferior parietal lobule, when arching about the end of the middle temporal sulcus and continuous with the temporal gyri on its either side, is known as the **postparietal gyrus.** This is a smaller area than either of the other two, and, owing to the variability of the end of the middle temporal sulcus, is not always evident.

The *medial surface* of the parietal lobe is divided into two parts by the marginal portion of the sulcus cinguli. The anterior and smaller part is the medial continuation of the posterior central gyrus, and comprises the posterior portion of the **paracentral lobule** (fig. 757). It is limited from the part of this lobule belonging to the frontal lobe by a vertical line drawn from the marginal extremity of the central sulcus. The **precuneus** (*quadrate lobule*) is the posterior and larger part of the medial surface of the parietal lobe. It is separated from the cuneus of the occipital lobe by the parietooccipital fissure, and is imperfectly separated from the gyrus cinguli (limbic lobe) below by the *subparietal sulcus* (postlimbic fissure), branches of which invade it extensively.

The occipital lobe.—This is a relatively small, trifacial, pyramidal segment, comprising the posterior extremity of the hemisphere, its apex being the occipital pole. Though one of the natural divisions of the cerebral hemisphere, it is very indefinitely marked off from the lobes anterior to it. Though it contains the cortical area of the visual apparatus, only in the brains of man and the apes does it occur as a well-defined posterior projection of the hemisphere. In most of the mammalia it is not differentiated at all. Its three surfaces comprise a convex, a medial, and a tentorial surface.

Its *convex surface* is separated from that of the parietal and temporal lobes by the superior and external extremity of the parietooccipital fissure and by an arbitrary line drawn transversely from this extremity to the inferolateral border of the hemisphere, or so drawn as to bisect the preoccipital notch when this is evident. The sulci which occur on the convex surface may be described as two, though both of these are very variable in their extent and shape, and their branches are inconstant both as to number and length. (1) The **transverse occipital sulcus** is the most constant in shape. It extends a variable distance transversely across the superior portion of the lobe, and, as noted above, it is frequently continuous with the interparietal sulcus through its occipital ramus, and when so, it appears as the posterior terminal bifurcation of this sulcus (fig. 752). When detached, it often occurs merely as a definite furrow with few rami, and sometimes the ramus by which it otherwise would join the interparietal sulcus is entirely absent. (2) The **lateral occipital sulcus** is always short, and has its deepest portion below the transverse sulcus. It usually has a somewhat oblique course toward the superomedial border. Sometimes it occurs in several detached pieces, then known collectively as the *lateral occipital sulci*.

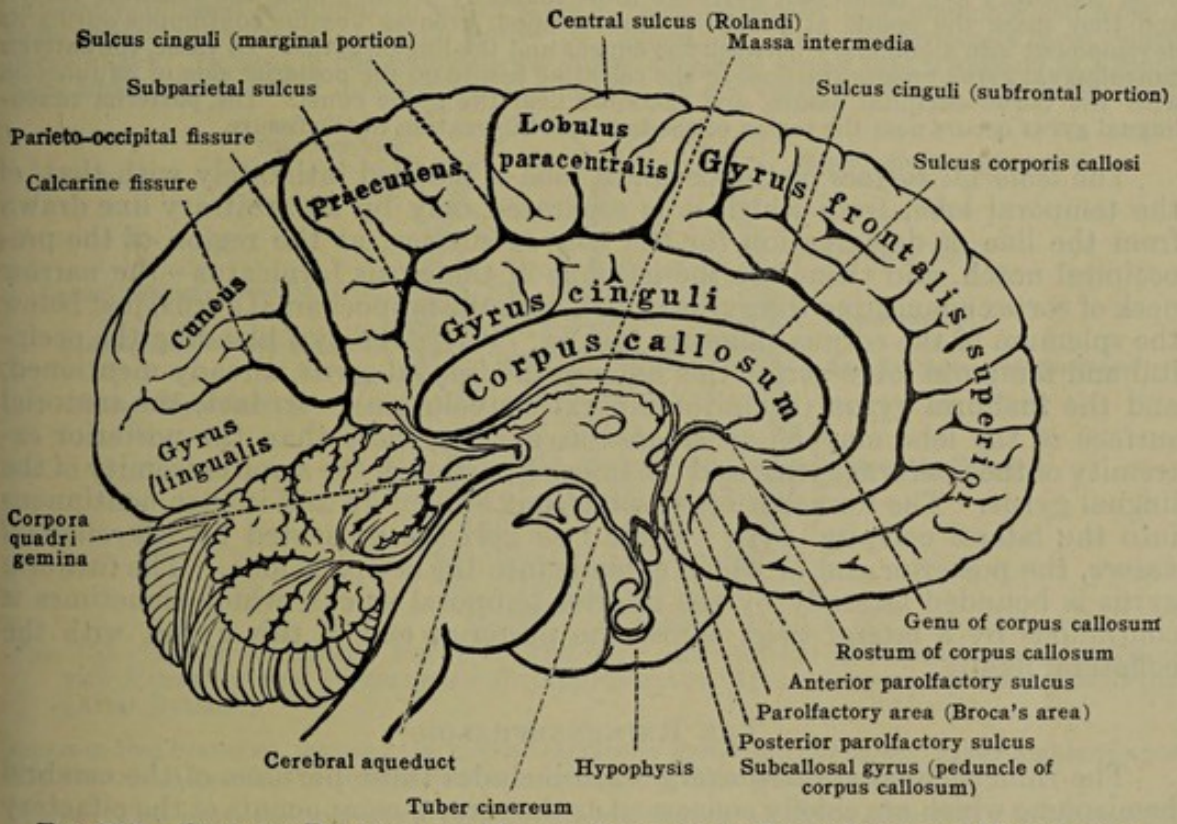

FIG. 757.—OUTLINE DRAWING OF MEDIAL SURFACE OF LEFT CEREBRAL HEMISPHERE. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

Therefore, the gyri of the convex surface of the lobe are also variable. They are not sufficiently constant to merit individual names. The lateral occipital sulcus or sulci roughly divide them into an inferior and lateral area, known as the **lateral occipital gyri,** and into a superior area, the **superior occipital gyri.** The lateral area is continuous into the gyri of the temporal lobe, while the superior area is continuous into the gyri of the parietal lobe.

The *medial surface* of the occipital lobe is separated from that of the parietal lobe (precuneus) and from the gyrus cinguli of the limbic lobe by the well-marked parietooccipital fissure. It comprises the constantly defined, wedge-shaped lobule known as the **cuneus,** and the posterior and medial extremity of the **lingual gyrus.** Since the greater portion of the length of the lingual gyrus is involved in the basal surface of the temporal lobe, this gyrus as a whole has been considered as belonging to the temporal lobe (see figs. 749, 754). The cuneus is separated from the lingual gyrus by the posterior portion of the **calcarine fissure,** which always terminates in a bifurcation, one limb of which invades the cuneus near the superomedial border. In addition the cuneus may contain other twigs from both the fissures bounding it, and also, when wide, may contain one or more short, detached **sulci cunei.**

The **calcarine fissure** and the **parietooccipital fissure** are almost invariably joined in the human brain, forming a Y-shaped figure, the prongs of which give the cuneus its shape. The calcarine fissure begins on the tentorial surface in the posterior portion of the hippocampal gyrus of the limbic lobe, below the splenium of the corpus callosum, and extends backward across the medial occipital border of the hemisphere. It then bends downward and proceeds to its terminal bifurcation in the polar portion of the occipital lobe. The stem or hippocampal portion of the fissure is deeper than the posterior or occipital portion. It produces a well-marked eminence in the medial wall of the posterior cornu of the lateral ventricle, known as the *calcar avis* or *hippocampus minor*. It is developed separately from the posterior portion, which itself first appears as two grooves. All three parts are usually continuous with each other before birth.

The **parieto-occipital fissure** usually appears from the first as a continuous groove. It begins in the superomedial border of the hemisphere, rarely extending into the convex surface more than 10 mm. (*external parieto-occipital fissure*), thence it extends vertically downward across the mesial surface (*internal parieto-occipital fissure*), and terminates by joining the calcarine fissure at the region of the downward bend of the latter, or at about the junction of its anterior and middle thirds. In certain of the lower apes and in the brain of the chimpanzee there is no junction between the two fissures, they being kept apart by a narrow neck of cortex, the **gyrus cunei**. Neither are they joined in the human fetus. If in the adult human brain the region of their junction be opened widely, there will be found a submerged transitory gyrus (deep annectant gyrus), which is the gyrus cunei, superficial in the fetus. In the higher apes and in microcephalic idiots this gyrus may be on the surface or partially submerged. Two other transitory gyri (annectant gyri) are to be found by pressing open the calcarine fissure, and they mark the points at which its three original grooves became continuous during its development into a boundary between the cuneus and the lingual gyrus. Of these, the **anterior cuneolingual gyrus** crosses the floor of the calcarine fissure on the posterior side of its junction with the parietooccipital fissure, and therefore near the gyrus cunei. The **posterior cuneolingual gyrus** occurs near the region of the terminal bifurcation of the fissure.

The *tentorial surface* of the occipital lobe is blended intimately with that of the temporal lobe, from which it is separated only by an arbitrary line drawn from the line of demarcation for the convex surface, at the region of the preoccipital notch, and thence to the isthmus of the gyrus fornicatus—the narrow neck of cortex connecting the gyrus cinguli with the hippocampal gyrus, just below the splenium of the corpus callosum (see fig. 749). The gyri blending the occipital and temporal lobes across this line are the *lingual gyrus*, already mentioned, and the **fusiform gyrus** (occipitotemporal convolution). In fact, the tentorial surface of the lobe may be considered as nothing more than the posterior extremity of the fusiform gyrus, and the inferior portion of the same extremity of the lingual gyrus. The former is often somewhat broken up and is then continuous into the lateral occipital gyri. These two gyri are separated by the *collateral fissure*, the posterior end of which extends into the occipital lobe. The fusiform gyrus is bounded laterally by the inferior temporal sulcus, which sometimes is continuous by a lateral twig, across the posterior end of this gyrus, with the collateral fissure.

The Rhinencephalon

The rhinencephalon or *olfactory brain* includes those portions of the cerebral hemisphere which are chiefly concerned as the central components of the olfactory apparatus. Owing to the preponderant development of the other divisions of the hemisphere, the parts comprising this division appear relatively but feebly developed in the human brain. In most of the mammals the sense of smell is relatively much more highly developed, and in many of the larger mammals the parts comprising the rhinencephalon are of greater absolute size than in man, though their cerebral hemispheres may be considerably smaller. In the human fetus the parts of the rhinencephalon are relatively much more prominent than after the completed differentiations into the adult condition. In the broader sense of the term the rhinencephalon includes those parts of the hemisphere usually classed as comprising two lobes, viz., the **olfactory lobe** and the **limbic lobe**. Neither of these is a 'lobe' in the sense of comprising a definite segment of the hemisphere, as do the other lobes, and therefore the rhinencephalon cannot be called a distinct lobe. It is so strung out that by one or the other of its parts it is either in contact or continuity with each of the other lobes of the hemisphere. Morphologically, the olfactory lobe and adjacent structures form the *anterior division*, and the limbic lobe forms the *posterior division* of the rhinencephalon.

The anterior division—the *olfactory lobe* proper—belongs almost wholly to the base of the encephalon, and consists of the following parts:—

(1) The **olfactory bulb** is an elongated, oval enlargement of gray substance which lies upon the lamina cribrosa of the ethmoid bone, and, practically free, it

is pressed into the anterior end of the olfactory sulcus in the basal surface of the frontal lobe. The numerous thin filaments of non-medullated axones of the *olfactory nerve* enter the cranium through the foramina of the lamina cribrosa and pass into the inferior surface of the bulb to form synapses with its cells.

(2) The **olfactory tract** is a triangular band of white substance which arises in the olfactory bulb, and continues backward about 20 mm. to the region of the anterior perforated substance. It appears triangular in transverse section from the fact that its upper side fits into the olfactory sulcus. It becomes somewhat broader at its posterior end. In the human fetus and in the adult of many of the lower vertebrates the tract retains considerable gray substance.

(3) The **olfactory trigone** (*olfactory tubercle*) is the small triangular ridge, the posterior continuation of the olfactory tract joining the anterior perforated substance. In it the olfactory tract breaks up into three roots, the *lateral*, *intermediate*, and *medial olfactory stria* (*gyri*). The lateral olfactory stria emphasizes the lateral portion of the trigone into the **lateral olfactory gyrus**, a portion of which is directly continuous into the *limen insulæ* (figs. 754, 758).

While a few of the fibers of the lateral stria penetrate this region, the greater mass of them pass obliquely lateralward over it and gradually disappear in the anterolateral portion of the anterior perforated substance, in which some of them terminate, but through which most of them pass to curve into the anterior end of the hippocampal gyrus and terminate there, chiefly in the uncus. In most of the mammals the lateral stria is so strong that it appears as a superficial white band passing directly into the uncus. In the early fetus it is seen to enter the

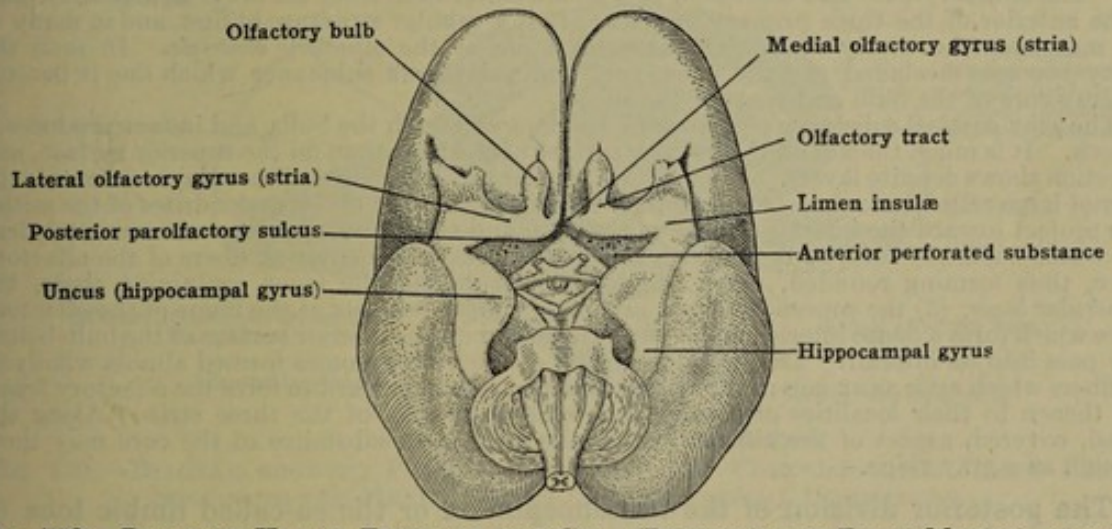

FIG. 758.—BRAIN OF HUMAN FETUS OF 22.5 CM. (BEGINNING OF FIFTH MONTH), SHOWING THE PARTS OF THE DEVELOPING RHINENCEPHALON APPARENT ON THE BASAL SURFACE. (After Retzius.)

uncus in two branches, forming the medial **semilunar gyrus** and the lateral **gyrus ambiens** upon the uncus. A portion of the *limen insulæ* belongs to the rhinencephalon.

(4) The **parolfactory area** (Broca's area) (area adolfactoria NK) involves the mesial extension of the olfactory trigone, and is concerned with the *medial olfactory* stria. On the basal surface of the hemisphere this area involves the posterior extremity of the gyrus rectus—a portion of which is sometimes separated from the remainder of the gyrus by a ventral prolongation of the *anterior parolfactory sulcus* of the medial surface (figs. 757, 762). This prolongation when present has been called the **fissura serotina.** On the medial surface the parolfactory area appears as a definite gyrus. In front this is separated from the superior frontal gyrus by the *anterior parolfactory sulcus*, and from the subcallosal gyrus behind by the deeper *posterior parolfactory sulcus* (fig. 757). It is continuous above into the gyrus cinguli of the limbic lobe, a portion of the posterior division of the rhinencephalon.

A large portion of the fibers of the medial stria are lost in the parolfactory area, and are known to terminate about the cells there. This stria or root of the olfactory tract forms a slight ridge on the ventral surface of the area, which is frequently prominent enough to retain the name **medial olfactory gyrus** applied to it in the fetal brain (fig. 758).

(5) The **subcallosal gyrus** (peduncle of the corpus callosum) is the narrow fold of the pallium which lies between the posterior parolfactory sulcus and the rostral lamina and the ventral continuation of the latter into the lamina terminalis. It begins above, in part fused to the rostrum of the corpus callosum, and in part

continuous with the gyrus cinguli, and ventrally it goes over lateralward and posteriorly into that portion of the anterior perforated substance known as the *diagonal band* of Broca, and in this way it extends into the uncus. Medially, it approaches its fellow of the opposite side so closely that the groove separating the two is known as the *median subcallosal sulcus* of Retzius. Some fibers of the medial olfactory stria disappear in the substance of the subcallosal gyrus.

(6) The **anterior perforated substance** (area olfactoria NK) must be considered with the rhinencephalon, but, like the limen insula, it can only be considered as belonging in part to this division of the brain. It comprises the basal region between the optic chiasma and optic tract and the olfactory trigone. Usually the posterior parolfactory sulcus (*fissura prima* of the embryo) is sufficiently evident to separate it more or less distinctly from the latter. Its posterolateral area is occupied by the *diagonal band* of Broca. A few fibers from the medial stria are known to disappear within its depths, and, as mentioned above, many fibers from the lateral stria also pass into it. The intermediate *olfactory stria* is always much the weakest of the three striæ, and in many specimens is apparently absent. The fibers of this stria run almost straight backward and plunge directly into the anterior area of the anterior perforated substance, where some of them are known to terminate, while others continue into the uncus.

On embryological grounds, the subcallosal gyrus and the anterior perforated substance are classed with the posterior part of the 'olfactory' lobe or anterior division of the rhinencephalon. The olfactory bulb and tract arise as a hollow outgrowth from the lower and anterior part of the anterior of the three primary vesicles. It is a tubular structure at first, and in many of the mammals the cavity maintains throughout life as the *olfactory ventricle*. In man the cavity becomes occluded and the ependyma and gelatinous substance which line it become the gray core of the bulb and tract of the adult.

The gray cortical substance persists and develops chiefly in the bulb, and in fact produces it as such. It is much thicker on the inferior surface of the bulb than on the superior surface, and in section shows definite layers. From within outward, the principal of these layers are—(1) the layer of large cells whose shape suggests their name, *mitral cells;* (2) large dendrites of the mitral cells project toward the inferior surface of the bulb and there break up into numerous telodendria which copiously form synapses with like telodendria of the entering fibers of the olfactory nerve, thus forming rounded, much tangled glomeruli and the layer containing these, the *glomerular layer;* (3) the superficial layer, or *olfactory layer*, consists of the fibers of the olfactory nerve which form a dense interlacement with each other on the inferior surface of the bulb before they pass into its interior. The superior surface of the bulb becomes formed almost wholly of the fibers which arise as axones of the mitral cells and pass backward to form the olfactory tract, and thence to their localities of termination, chiefly by way of the three striæ. Along the dorsal, covered, aspect of the olfactory tract the gelatinous substance of the core may show through as a gray ridge.

The posterior division of the rhinencephalon or the so-called **limbic lobe** (a name introduced by Broca in 1878) takes part in both the medial and tentorial surfaces of the hemisphere (fig. 759). Seen from the medial surface, it forms an irregular elliptical figure which encloses the corpus callosum and the extremities of which approach each other at the anterior perforated substance, where they are continous with the structures of the anterior division of the rhinencephalon. The figure is bounded externally by the sulcus cinguli above, by the subparietal sulcus (postlimbic sulcus) and the anterior limb of the calcarine fissure behind, and by the collateral fissure below. These respectively separate it from the frontal, parietal, occipital, and temporal lobes. It comprises the following structures which are either wholly or in part devoted to the functions of the olfactory apparatus:—

1. Gyrus fornicatus
   - Part of gyrus cinguli and cingulum.
   - Isthmus of the gyrus fornicatus.
   - Hippocampus
     - hippocampal gyrus.
     - uncus.
     - dentate gyrus (fascia).
     - fimbria.
2. The medial and lateral longitudinal striæ upon the corpus callosum.
3. The fornix.
4. The mammillary body, the mammillothalamic fasciculus to the anterior nucleus of the thalamus and the mammillopeduncular fasciculus.
5. Part of anterior cerebral commissure.
6. Part of septum pellucidum.
7. Part of medullary stria of thalamus.
8. Most of habenular nucleus.

The **gyrus fornicatus** comprises the greater mass of the limbic lobe. As seen above, it is a term used to represent collectively a number of conjoined structures. Being an incomplete ellipse in form, its two ends are united to form a closed ring by means of the connection of the parolfactory area with the gyrus cinguli and the connection of the anterior perforated substance with the uncus of the hippocampal gyrus. It is best described in terms of its three component parts indicated above:

The **gyrus cinguli** begins in junction with the area parolfactoria below the anterior end of the corpus callosum, and curves above so as to embrace entirely the upper surface of the latter It is separated from the frontal lobe by the sulcus cinguli (callosomarginal fissure), from the parietal lobe by the subparietal sulcus, and from the corpus callosum below by the **sulcus of the corpus callosum**. By the latter it is separated from the longitudinal stria of the upper surface of the corpus callosum.

The gyrus cinguli covers over, and its cells are closely associated with, the **cingulum**, a well-marked arcuate band of white substance, which follows the gyrus in its bend around the rostrum and backward to turn around the splenium of the corpus callosum in the isthmus of the gyrus fornicatus, and then to course forward into the hippocampal gyrus and the uncus. The cingulum is largely an association fasciculus between the gyri of the temporal lobe and those gyri on the

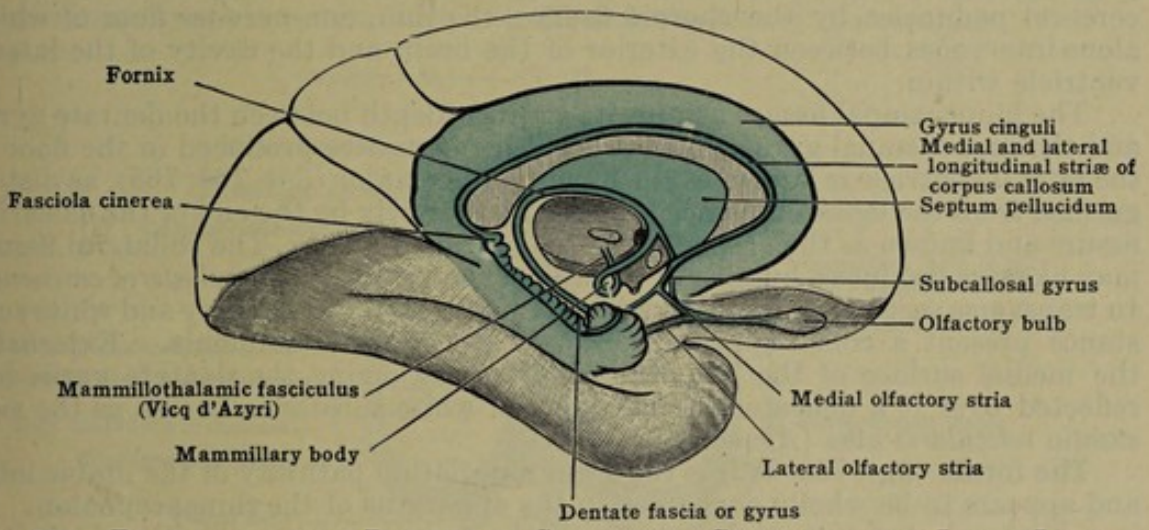

FIG. 759.—DIAGRAM SHOWING POSITION OF STRUCTURES COMPRISING THE LIMBIC LOBE AS SEEN FROM THE MEDIAL ASPECT OF THE CEREBRAL HEMISPHERE.

medial surface of the cerebral hemisphere in which it runs, its fibers for the most part running short courses, being continually added to it and continually leaving it. However, it contains olfactory axones running in two directions: (1) fibers from the medial olfactory stria and fibers arising in the parolfactory area, the gyrus subcallosus and the anterior perforated substance which course posteriorly for distribution in the cortex of the gyrus cinguli and hippocampal gyrus; (2) fibers arising in the hippocampal gyrus, especially the uncus, to course dorsalward through the isthmus and forward as association fibers. Some fibers arising from the cortical cells of the gyrus cinguli pass inferiorly through the cingulum, through the corpus callosum and, anteriorly, through the septum pellucidum to join the fornix below (*perforating fibers of the fornix*).

The **isthmus of the gyrus fornicatus** is the constricted portion connecting the posterior end of the gyrus cinguli with that of the hippocampal gyrus (figs. 749, 754). It is bounded externally by the anterior end of the calcarine fissure, and incloses the posterior turn of the cingulum.

The **hippocampus** is the name applied to the curved appearances produced in the floor of the lateral ventricle by the peculiar foldings of this part of the cerebral cortex. The *hippocampal gyrus* (gyrus of the hippocampus) is the main gyrus of the tentorial surface of the limbic lobe. Externally it is separated from the fusiform gyrus by the collateral fissure, and it is bounded internally by the **hippocampal** or, more inclusive, the **choroid fissure.** Posteriorly it is partially divided by the calcarine fissure into the lingual gyrus (of the temporal lobe) and the isthmus of the gyrus fornicatus. Its anterior extremity is hooked backward and is known as the **uncus** (*gyrus uncinatus*). This is almost entirely separated from the temporal lobe by a groove, the **temporal notch.** If the hippocampal fissure be opened up, the **dentate gyrus** or fascia and the *fimbria* will be seen. These lie side by side, separated by the shallow **fimbriodentate sulcus** (fig. 766).

The free edge of the dentate gyrus presents a peculiarly notched appearance, produced by numerous parallel grooves cutting it transversely. Its posterior end, sometimes called the *fasciola cinerea*, continues backward over the splenium of the corpus callosum, and upon the upper surface of the corpus callosum appears as a thin strip of gray substance which contains embedded in it the ends of the *medial* and *lateral longitudinal striæ*. This strip is called the **supracallosal gyrus** (*gyrus epicallosus, induseum griseum*), and is thought to represent a vestigial part of the hippocampal gyrus. Closely beneath the splenium of the corpus callosum, on the superomedial side of the hippocampal gyrus and medial to the dentate gyrus, there sometimes occur suggestions of round or oval elevations of the gray substance which have been called the **'callosal convolutions'** or *gyri Andreæ Retzii*. Rarely are they strongly developed, but when so they often produce a spiral appearance.

The **fimbria** is but the fimbriated, free border of the posterior end or origin of the fornix, so folded as to project into the hippocampal fissure, parallel with the dentate gyrus (fig. 766). It is a conspicuous band composed almost entirely of white substance, continuous laterally with the thick stratum covering the ventricular surface of the hippocampus. It begins anteriorly in the hook or recurved extremity of the uncus. Traced backward, it is seen to curve upward, and within the ventricle it becomes part of the general accumulation of the white substance (*alveus*) of the ventricular surface of the hippocampus, which accumulation is the beginning of the fornix. The free border of the fimbria (seen in section) is known as the *tenia fimbriæ*, or better, *tenia fornicis*. The fimbria is separated from the cerebral peduncles by the **choroid fissure,** the thin, non-nervous floor of which alone intervenes between the exterior of the brain and the cavity of the lateral ventricle within.

The hippocampal fissure attains its greatest depth between the dentate gyrus and the hippocampal gyrus, and the resulting eminence produced in the floor of the lateral ventricle is known as the **hippocampus major** (figs. 764, 765), as distinguished from the lesser eminence produced posteriorly by the end of the calcarine fissure and known as the *hippocampus minor* [calcar avis]. The collateral fissure may likewise produce a bulging in the wall of the ventricle, the *collateral eminence*. In transverse sections of the hippocampus major, the layers of gray and white substance present a coiled appearance known as the **cornu ammonis.** Externally the medial surface of the hippocampal gyrus adjoining the dentate gyrus has reflected over it a delicate reticular layer of white substance known as the *substantia reticularis alba* (*Arnoldi*).

The fornix (figs. 760–762) is the great association pathway of the limbic lobe, and appears to be wholly concerned in the apparatus of the rhinencephalon. It is a bilateral structure arched beneath the corpus callosum, with which it is connected anteriorly by the septum pellucidum. Posteriorly it passes in contact with the splenium. It consists of two prominent strips of white substance, one for each hemisphere, the ends of which are separate from each other, while their intermediate parts are fused across the midline. These fused parts run above the choroid tela of the third ventricle, and their lateral edges (*teniæ fornicis*) rest, on each side, along the line of the tenia chorioidea. The posterior, separate ends are known as the posterior pillars or crura of the fornix; the fused, intermediate portion is the body, and the separate, anterior ends are the anterior pillars or columns of the fornix.

The crura (posterior pillars) of the fornix.—When seen from the medial aspect of the hemisphere, the fused portion of the fornix, in the separation of the hemispheres, is split along the midline (fig. 749). The half under examination may be seen to course obliquely lateralward under the splenium of the corpus callosum, and then, continuous into the fimbria, to curve forward and ventralward toward the uncus. The greater mass of the fibers coursing in the fornix arise as outgrowths of the cells of the uncus, hippocampal gyrus, and dentate gyrus. They accumulate as a dense stratum on the ventricular surface of these gyri, termed the **alveus,** which crops outward as the fimbria and which passes backward and upward; upon reaching the region of the splenium it turns obliquely forward under the latter and approaches the midline, to fuse with the like bundle from the gyri of the hippocampus of the opposite side. The bundles thus arising from the two sides are the crura (posterior pillars) of the fornix. They appear as two flattened bands of white substance which come in close contact with and even adhere to the splenium.

The angle formed by the mutual approach of the crura of the fornix is crossed by a lamina of commissural fibers connecting the hippocampal gyri of the two hemispheres (fig. 761).

This lamina is the **hippocampal commissure** or *transverse fornix*. Like those of the fornix, its fibers arise from the cortex of the hippocampal gyri, but they serve as commissural fibers between the hippocampal gyri of the two hemispheres. Being of a different functional direction, it should not be considered a part of the fornix. The angle formed by the two crura of the fornix as traversed by the hippocampal commissure gives a picture named the **psalterium or lyra**. Usually the hippocampal commissure and the crura are in close contact with the under surface of the splenium. When occasionally they do not adhere, the space between is known as **Verga's ventricle**. According to recent studies of brains with degenerated corpus callosum (Shimazono), further commissural fibers between the limbic lobes course in the posterior angle of the septum pellucidum, transverse to the body of the fornix.

The body of the fornix [corpus fornicis] appears as a triangular plate of white substance produced by the fusion of the pillars. Its base or widest portion is behind. It is not always bilaterally symmetrical. Its upper surface is attached by the septum pellucidum to the lower surface of the corpus callosum. Below, it lies over the choroid tela of the third ventricle, which separates it medially from the cavity of the third ventricle and laterally from the upper surfaces of the thalami. Its sharp lateral edge or margin (tenia fornicis) projects into the lateral ventricle of either side in relation with the choroid plexus of that ventricle, and thus the lateral portion of its upper surface forms part of the floor of the lateral ventricle—an arrangement to be expected, since the crura arise from the floor of the ventricle, viz., the hippocampus. The ventricular portion is covered by a layer of ependyma in common with that lining the rest of the ventricle.

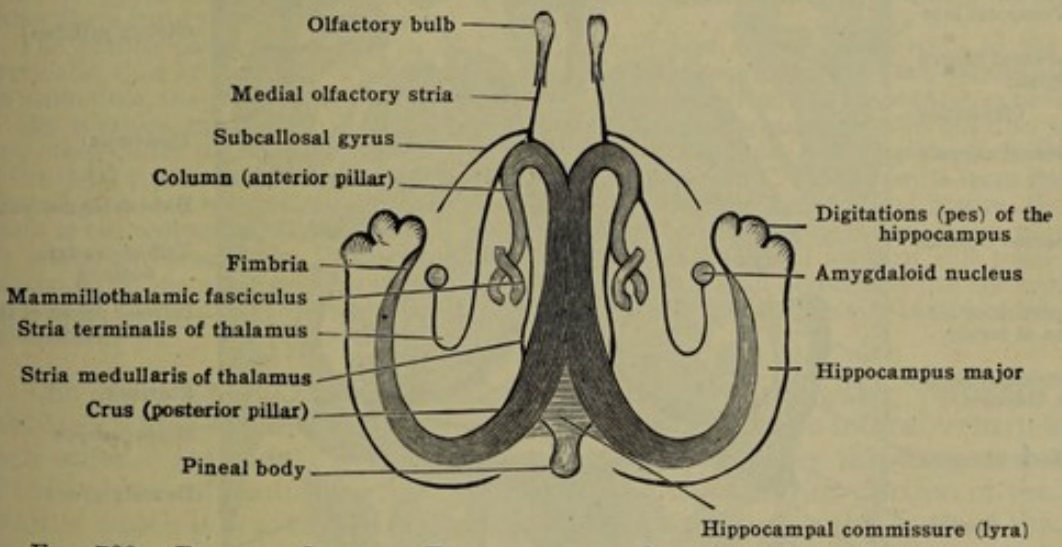

FIG. 760.—DIAGRAM SHOWING FORNIX AND ITS CONNECTIONS AS SEEN FROM ABOVE.

Along its body the fornix receives fibers arising from the cells of the cortex of the gyrus cinguli and fibers from the longitudinal stria upon the dorsal surface of the corpus callosum. These pass through the latter and are the **perforating fibers of the fornix** (fig. 762). In their ventral course, they pass obliquely forward through the corpus callosum and, anteriorly, through the posterior angle of the septum pellucidum to join the fornix and course in its functional direction. The fibers arising in the cortex of the gyrus cinguli may course short distances in the cingulum before perforating the corpus callosum.

The columns (anterior pillars) of the fornix [columnæ fornicis] are two separate, cylindrical bundles which pass forward from the apex of the body of the fornix and then turn sharply downward along the anterior boundary of the third ventricle, just behind the anterior cerebral commissure. A part of each column, the *free portion* [pars libera], forms the anterior boundary of the interventricular foramen (Monroi). Thence the *covered portion* [pars tecta] sinks into the gray substance of the lateral wall of the third ventricle, and passes downward to the base of the brain, where it appears on the exterior as the **mammillary body** [corpus mammillare] (fig. 749).

Some fornix fibers are interrupted in the nuclei of the mammillary body; probably most of them merely double back, forming the genu. From the mammillary body the fibers are disposed in at least three ways: (1) The greater part perhaps pass directly upward and are lost in the *anterior nucleus of the thalamus*, where they ramify freely and terminate about its cells. These fibers form the bundle known as the **mammillothalamic fasciculus**, or bundle of Vicq d'Azyr; (2) A portion of the fibers go to form a **mammillomesencephalic fasciculus** (*tegmentomammillary fasciculus, mammillopeduncular fasciculus*). This begins in the mammillary body and passes caudalward into the mesencephalon to terminate about cell-bodies in, or in the region of, the so-called *nucleus of the medial longitudinal fasciculus and posterior commissure*. Fibers given by these cell-bodies may convey impulses by way of the medial longitudinal fasciculus or the gen-

eral reticular formation to the nuclei in the mesencephalon, rhombencephalon and perhaps into the spinal cord. Some of this portion of the fibers from the mammillary body are said to pass caudalward through the mesencephalon without interruption there. (3) A portion of the fibers decussate in the superior parts of the mamillary bodies and are distributed to both the thalamus and the mesencephalon of the opposite side. This decussation is the **supramammillary commissure.**

As seen above, the fornix as a whole is composed of longitudinally directed fibers, some of which, however, cross the midline in the region of its body and course in the columns of the opposite side. For the greater part, its fibers rise from the cells of the hippocampal gyri, but it is known to contain some fibers which arise in the anterior perforated substance and subcallosal gyrus and course through the fornix to the hippocampal gyri.

The **medial** and **lateral longitudinal striæ** upon the corpus callosum consist of olfactory fibers coursing in both directions: (1) fibers arising in the parolfactory area, the subcallosal gyrus and the anterior perforated substance (diagonal band of Broca) course posteriorly and

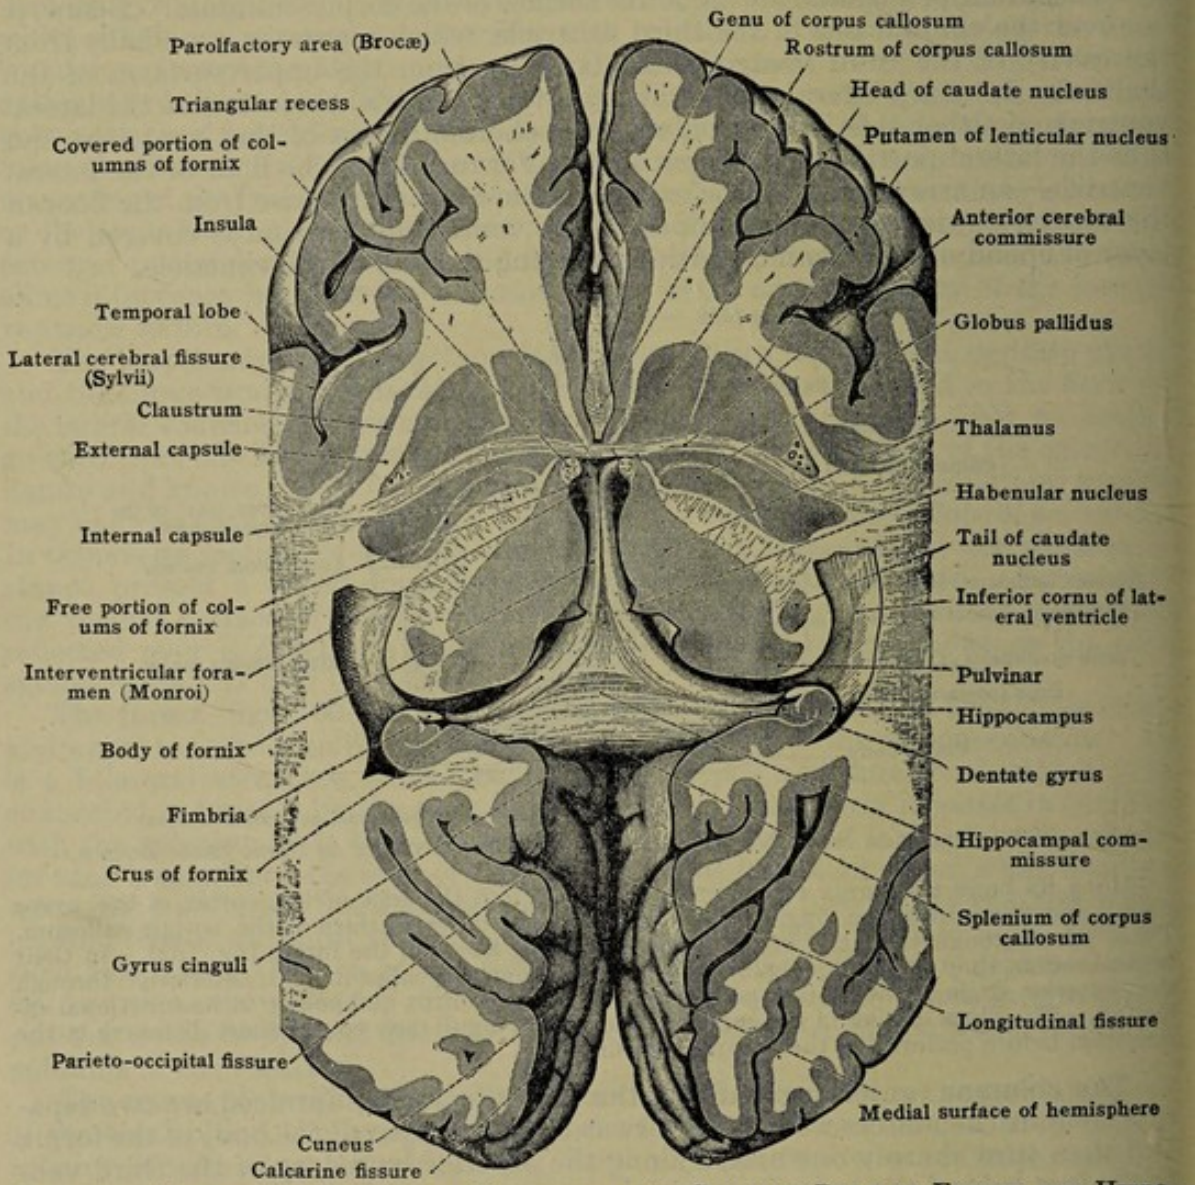

FIG. 761.—HORIZONTAL SECTION OF TELENCEPHALON SHOWING BODY OF FORNIX AND HIPPOCAMPAL COMMISSURE AS SEEN FROM BELOW AND THE ANTERIOR COMMISSURE, IN SECTION. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

then inferiorly in them to the gray substance of the gryi of the hippocampus; (2) and chiefly, fibers from the hippocampal gyri course in them anteriorly and inferiorly around the rostrum of the corpus callosum, through the ventral part of the septum pellucidum, to join the fornix. It is suggested that the stria, especially the medial, may be considered as a part of the fornix detached upon the dorsal surface of the corpus callosum during the projection of the latter between the cerebral hemispheres. The medial stria is often called the *stria Lancisii*. The two striæ are sometimes called the *dorsal fornix*.

The anterior cerebral commissure is largely concerned in the rhinencephalon; the remainder includes commissural fibers connecting the two temporal lobes. It forms one of the five commissures of the telencephalon, the other four being the corpus callosum, the hippocampal, inferior cerebral, and supramammillary commissures. It is a bundle of white substance with a slightly twisted appearance,

which crosses the midline in the anterior boundary of the third ventricle between the lamina teminalis and the columns of the fornix (figs. 749 and 761), just below the interventricular foramen (foramen of Monro). In each hemisphere its main or temporal portion passes lateralward and slightly backward beneath the head of the caudate nucleus and through the anterior end of the lenticular nucleus, and thence is dispersed to the gray substance of the temporal lobe and hippocampal gyrus.

It contains fibers both to and from the temporal lobe of each side. In addition to these fibers, the anterior commissure carries in its frontal side three sets of fibers belonging to the olfactory apparatus:—(1) fibers arising in the olfactory bulb of one side, which pass by way of the medial olfactory stria through it to the olfactory bulb of the opposite side; (2) fibers which pass through it from the medial stria (olfactory bulb) of one side to the uncus of the opposite side; (3) commissural fibers between the hippocampal cortex, especially the uncus, of the two sides.

The anterior commissure is a more primitive commissure than the corpus callosum, in that it is present in the lower forms when the latter is absent, and diminishes in relative size and importance as the corpus callosum appears and increases in size. In man the appearance of the anterior commissure precedes but little that of the corpus callosum. During the fifth month the lamina terminalis, which then alone unites the anterior ends of the two hemispheres, develops a thickening of its dorsal portion. In a part of this thickening, transverse fibers begin to appear and their increase in number results in the partial separation posteriorly of the part containing them from the rest of the lamina, and then follows the differentiation of this part into the anterior commissure. The remainder of the thickening of the lamina continues to increase in size with the increase of the hemispheres; its upper edge is directed posteriorly, and fibers begin to appear in it which arise in the cortex of one side and cross over to that of the other side. These fibers form the corpus callosum.

The corpus callosum, a growth of fibers in the upper, expanded portion of the lamina terminalis, thus bridges over a portion of the longitudinal fissure between the hemispheres. In the mean time, the *fornix* arises as two bundles of fibers, one from the hippocampus of each side. In the complex mechanics of the development of the cerebrum these two bundles approach each other under the corpus callosum, fuse for a certain distance, and together arch the cavity of the third ventricle and come to acquire their adult position. There results from these processes of growth a completely enclosed space, a portion of the longitudinal fissure, the roof of which is the corpus callosum, its floor, the body of the fornix, and its lateral walls, portions of the mesial surfaces of the two cerebral hemispheres. The lateral walls of this space do not thicken as do the other regions of the pallium, but remain thin and constitute the *septum pellucidum* of the adult, the space itself being the so-called *fifth ventricle* or cavity of the septum pellucidum.

The **septum pellucidum** is a thin, approximately triangular, vertically placed partition which separates the anterior portions of the two lateral ventricles from each other. Its widest portion lies in front, bounded by the genu and rostrum of the corpus callosum, the rostral lamina, and the anterior portion of the fornix, to all of which it is attached. Prolonged backward under the body of the corpus callosum, it narrows rapidly and terminates at the line of adherence between the posterior portion of the fornix and the splenium of the corpus callosum. It consists of two thin layers, the **laminæ of the septum pellucidum,** arrested developments of mesial portions of the cerebral pallium. The laminæ enclose a narrow median cavity known as the **fifth ventricle** [cavum septi pellucidi]. This cavity is of very variable size, is completely closed, and does not merit the term 'ventricle,' as applied to the other cavities of the brain, in that it has no communication with the ventricular system and has a different lining from the other ventricles.

Each lamina of the septum pellucidum consists of a layer of undeveloped gray substance next to the fifth ventricle and a layer of white substance next to the lateral ventricle, the latter covered by a layer of ependyma common to that ventricle. The white substance consists in part of fibers belonging to the general association systems of the hemispheres, and in part of four varieties of fibers concerned with the rhinencephalon:—(1) fibers from each medial olfactory stria are known to reach the septum pellucidum and thence go by way of the fornix to the hippocampus major; (2) fibers are thought to be contributed by the fornix to the septum pellucidum, and through it reach the subcallosal gyrus and perhaps the parolfactory area and even the olfactory bulb; (3) the posterior angle of the septum pellucidum is perforated by some commissural fibers passing from the body of the fornix and by some perforating fibers of the fornix, passing from above through it to the fornix below; (4) anteriorly, some fibers from the longitudinal stria upon the corpus callosum pass through its posterior portion to join the fornix.

The medullary stria of the thalamus [stria medullaris thalami] (*stria pinealis, tenia thalami, habenula*), already described as to position, receives fibers from three sources, the majority at least of which belong to the rhinencephalon: (1) fibers from the fornix nearby and thus from the cortex of the hippocampal gyrus and gyrus cinguli (a corticohabenular tract); (2) fibers from the parolfactory area and the anterior perforated substance, through the septum pellucidum and lamina terminalis (a more direct olfactohabenular tract); (3) fibers arising from the cell-bodies in the thalamus, supposedly chiefly from its anterior (olfactory) nucleus. These latter fibers make a thalamohabenular tract. .

The majority of the fibers of the medullary stria terminate in the habenular nuclei, situated at the two sides of the stalk of the pineal body. Most terminate in the habenular nucleus of the same side. Some cross in the *habenular commissure* (dorsal part of the posterior cerebral commissure) and terminate in the nucleus of the opposite side. A few are claimed to pass to the nuclei of the quadrigeminate bodies and a few others to join the association tracts of the mesencephalon. Axones given off by the cells of the habenular nucleus curve anteriorly, inferiorly, and then course posteriorly (fasciculus retroflexus) to terminate in the *interpeduncular nucleus* (*habenulopeduncular tract*), and fibers arising in this latter nucleus pass to the cells about the central gray substance of the mesencephalon (an interpedunculotegmental tract). The two mesencephalic paths here noted and the mammillomesencephalic fasciculus noted above give three anatomical possibilities for olfactory reflex activities, visceral (or sympathetic) and somatic, involving the motor cranial nerves and possibly the spinal nerves. Fibers arising in the cortex of the hippocampal gyrus, uncus especially, may pass by way of the cingulum and thence by any suitable association fasciculus of the cerebral hemisphere to the motor area of the cerebral cortex; also fibers may arise from the anterior nucleus of the thalamus and pass to the motor cortex by way of the internal capsule. From the motor cortex, the descending pyramidal fibers give the possibilities for any higher cortical reactions induced by smell.

A more direct mesencephalic path has been suggested by Wallenberg, namely, that cells in the olfactory trigone and anterior perforated substance, about which terminate fibersaof the olfactory tract, send axones directly posteriorly, around the tuber cinereum, to termin te in the mammillary body and thence the impulses may go to the mesencephalon. Such fibers, if they exist, would form an *olfactomammillary tract.* A path is described in the hedge-hog

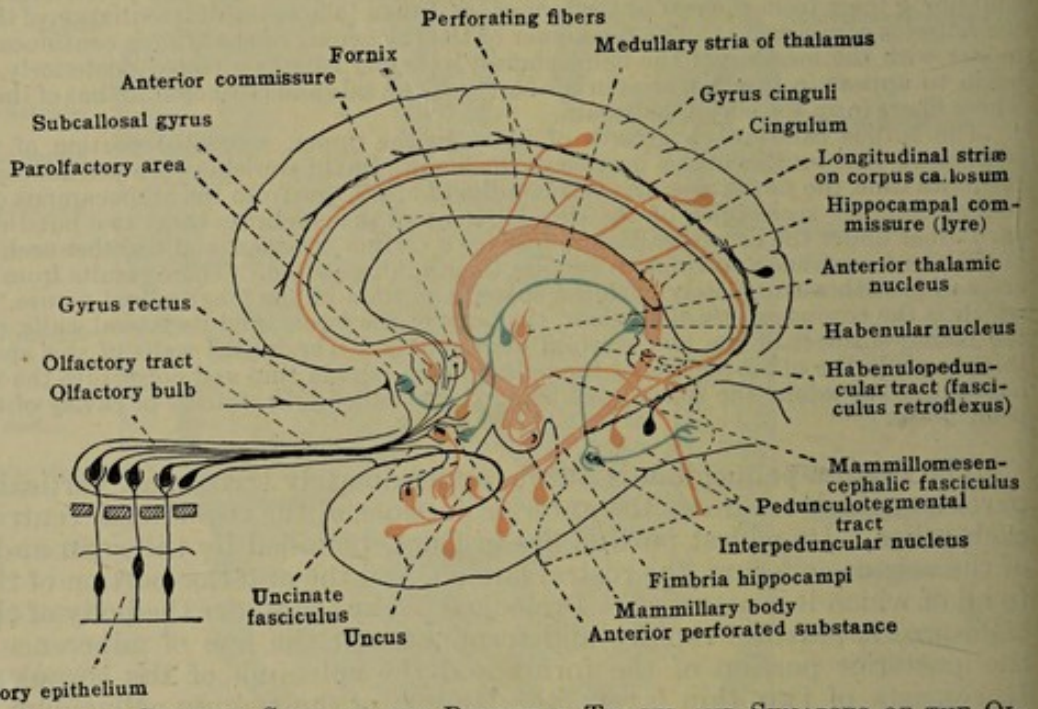

FIG. 762.—DIAGRAM SHOWING SOME OF THE PRINCIPAL TRACTS AND SYNAPSES OF THE OLFACTORY APPARATUS.

which arises from cells in the olfactory trigone and passes directly posteriorly to terminate in the gray substance of the mesencephalon—an *olfactomesencephalic tract.*

To the complicated central connections of the sense of smell, Dejerine adds yet another path, namely, a portion at least of the terminal stria [stria terminalis] of the thalamus. This contains fibers arising from cells in the anterior perforated substance and in the septum pellucidum and fibers from the opposite side by way of the anterior commissure. It runs a crescentic course posteriorly, bounding the thalamus from the caudate nucleus, turning downward and then anteriorly in the wall of the inferior cornu of the lateral ventricle to terminate in the amygdaloid nucleus, which latter is a more or less detached bit of the cortex of the extreme anterior portion of the hippocampal gyrus (uncus). The stria is said also to contain fibers which arise in the amygdaloid nucleus and course in it forward to be given off to the thalamus and probably to the internal capsule and thence to the cerebral cortex above. For a more detailed description of what may be called the fornix-system of fibers, the work of Shimazono may be consulted.

SUMMARY OF THE OLFACTORY APPARATUS

I. Peripheral part.

(1) Olfactory area of nasal epithelium containing the cell-bodies and peripheral processes of olfactory neurones (*olfactory ganglion*).

(2) Non-medullated central processes of olfactory neurones, the *olfactory nerve*, passing as numerous filaments through the cribriform plate of the ethmoid, to terminate in contact with the dendrites of the 'mitral cells' (stratum glomerulosum) in the olfactory bulb.

II. The rhinencephalon.

A. The anterior division.

(1) Olfactory bulb, olfactory tract, olfactory trigone (tubercle), lateral olfactory stria (gryus), medial and intermediate olfactory stria.

(2) The parolfactory area, subcallosal gyrus, anterior perforated substance including the diagonal band of Broca.

B. The posterior division.

(1) Part of anterior commissure, septum pellucidum, uncinate fasciculus, hippocampal gyrus (uncus especially), dentate gyrus, gyrus cinguli and cingulum.

(2) Fimbria, hippocampal commissure, fornix, longitudinal striæ upon corpus callosum, mammillary body, mammillothalamic fasciculus, mammillomesencephalic fasciculus.

(3) The anterior nucleus of the thalamus.

(4) The medullary stria of the thalamus, habenular nucleus, fasciculus retroflexus, interpeduncular nucleus, and interpedunculotegmental tract.

(5) Probably an olfactomammillary and an olfactomesencephalic tract, and a part of the terminal stria of the thalamus with the amygdaloid nucleus.

THE LATERAL VENTRICLES

Two of the four cavities of the ventricular system of the brain are in the telencephalon. From their position, one in each cerebral hemisphere, they are known as the **lateral ventricles** (figs. 763–766). They arise as lateral dilations of the cavity of the anterior of the primary vesicle, and, just as the fourth ventricle remains in communication with the third by way of the aqueduct of the cerebrum, so the lateral are connected with the third by the two interventricular foramina (Monroi). The whole ventricular system, including the central canal of the spinal

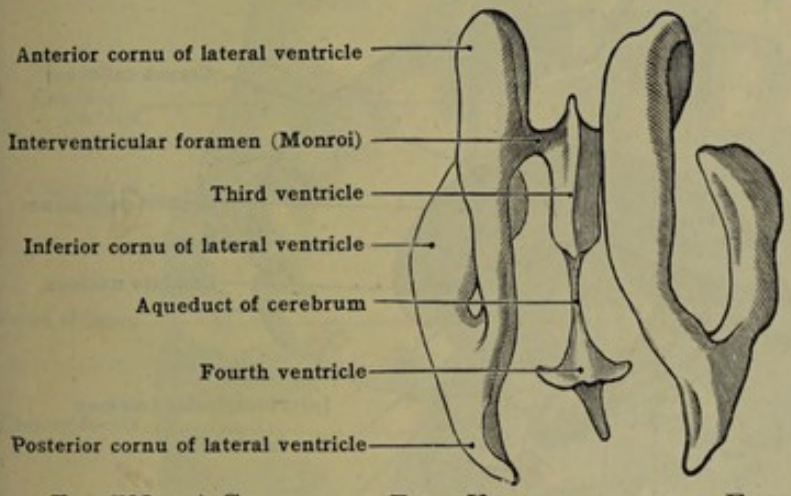

FIG. 763.—A CAST OF THE FOUR VENTRICLES OF THE ENCEPHALON. (After Welcker.)

cord, is lined by a continuous layer of ependyma and contains a small quantity of liquid known as the cerebrospinal fluid.

Each lateral ventricle is of an irregular, horseshoe shape. It consists of a *central portion* or body and three cornua, which correspond to the three poles of the hemisphere. The portion projecting into the frontal lobe is known as the *anterior cornu*, that projecting into the occipital lobe is the *posterior cornu*, and the portion which sweeps anteriorly downward into the temporal lobe is the *inferior cornu*. The ventricles of different individuals vary considerably in capacity, and the cavity of a given ventricle is not uniform throughout. In some localities the space may be quite appreciable, while in other places the walls may be approximate or even in apposition. Each lateral ventricle is a completely closed cavity except at the interventricular foramen. However, a strip of the floor of the inferior cornu is separated from the exterior of the brain by only the thin, non-nervous lamina forming the floor of the choroid fissure.

The **interventricular foramen** (foramen of Monro), by which the lateral ventricle is continuous with the cavity of the third ventricle, is a small, roundish channel, 2 to 4 mm. wide, which opens into the mesial side of the posterior end of the anterior cornu. It is bounded in front by the free portion of the columns (anterior pillars) of the fornix, and behind by the anterior tubercle of the thalamus. That the greater part of the lateral ventricle is posterior to it is due to the backward extension of the hemispheres during their growth and elaboration. Through the two foramina indirectly, the cavities of the two lateral ventricles are in communication with each other by way of the cavity of the third ventricle.

The walls of the lateral ventricle.—The **anterior cornu** (recessus frontalis NK) is a bowl-like cavity, convex forward and extending downward and medialward into the frontal lobe. Above and anteriorly it is bounded by the lower surface of the corpus callosum and the radiations of its genu into the substance of the

frontal lobe. Its medial boundary is the septum pellucidum; the head of the caudate nucleus (part of the corpus striatum) gives it a bulging, inferolateral wall, and the remainder of its floor is formed by the white substance of the orbital part of the frontal lobe.

The **central portion** or body of the ventricle is more nearly horizontal. It lies within the parietal lobe and extends from the interventricular foramen to the level of the splenium of the corpus callosum. Its roof is formed by the inferior surface of the body of the corpus callosum, and its medial wall consists of the posterior part of the septum pellucidum, attaching the fornix to the lower surface of the corpus callosum. Like the anterior horn, it is given an oblique, inferolateral wall by the narrower, middle part of the caudate nucleus. Several structures contribute to its floor:—(1) the stria terminalis of the thalamus, a line of white substance conforming to the genu of the internal capsule within, and constituting the boundary between the caudate nucleus and the thalamus, and containing (2) the vena terminalis (vein of the corpus striatum); (3) the lamina affixa, a medial continuation of the stria terminalis upon the surface of (4) the lateral part of the thalamus; (5) the medial edge of the lamina affixa, the tenia chorioidea, and the choroid plexus continuing under (6) the edge (tenia) of the body and the beginning crura (posterior pillars) of the fornix (fig. 765).

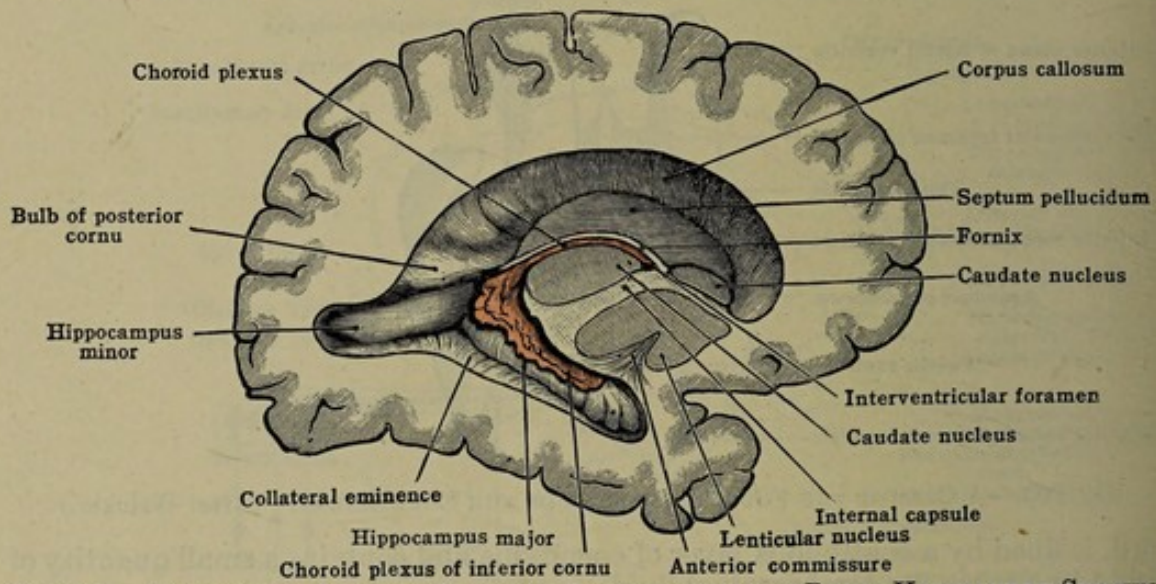

FIG. 764.—DIAGRAM OF LATERAL SAGITTAL SECTION THROUGH RIGHT HEMISPHERE SHOWING LATERAL VENTRICLE FROM THE MESIAL SIDE OF THE SECTION.

The choroid plexus of the lateral ventricles (figs. 765, 799) is continuous with that of the third ventricle. The choroid tela of the third ventricle (velum interpositum) continues under the tenia of the fornix into the lateral ventricle, and there, along the line of the tenia chorioidea, becomes elaborated into a varicose, convoluted, villus-like fringe, rich in venous capillaries and lymphatics. This fringe is the choroid plexus. It is continuous anteriorly, at the interventricular foramen, with the corresponding plexus of the opposite lateral ventricle and with the choroid plexus of the third ventricle. The latter consists of two similar but smaller fringes, which project close together into the cavity of the third ventricle from the medial portion of the ventral surface of its choroid tela. Behind, the choroid plexus of the lateral ventricle curves posteriorly and inferiorly into the inferior cornu, being especially well developed at the region of its entrance into the latter, into what is called the **choroid glomus.** It extends into neither posterior nor anterior cornu.

Though apparently lying free in the ventricle, the choroid plexus is invested throughout by a layer of ependyma, the **epithelial choroid lamina,** which is adapted to all its unevennesses of surface and which is a continuation of the ependymal lining of the remainder of the ventricle —continuous, on the one hand, with that of the lamina affixa and thalamus, and, on the other, with the epitheloid covering upon the upper surface of the tenia of the fornix and fimbria.

The **posterior cornu** (recessus occipitalis NK) of the lateral ventricle is a crescentic cleft of variable length, convex lateralward, which is carried backward from the posterior end of the body of the ventricle and, curving medialward, comes to a point in the occipital lobe. Its *roof* and *lateral wall* are formed by a

portion of the posterior radiation of the corpus callosum, which forms a layer, from its appearance known as the **tapetum.** In transverse sections of the occipital lobe (fig. 774) the tapetum appears as a thin lamina of obliquely cut white substance immediately bounding the cavity, while lateral to the tapetum occurs a thicker layer of more transversely cut fibers, the occipitothalamic radiation. In the medial or *inner wall* of the posterior cornu run two variable longitudinal eminences:—(1) The superior of these is the **bulb of the posterior cornu,** and is formed by the occipital portion of the radiation of the corpus callosum (splenium), which bends around the impression of the deep parieto-occipital fissure, and, hook-like, sweeps into the occipital lobe. In horizontal sections these fibers, together with the fibers of the splenium and the similar fibers into the opposite occipital lobe, form the figure known as the **forceps major.** (2) The inferior and thicker of the eminences is the **hippocampus minor** [**calcar avis**] (cock's spur),

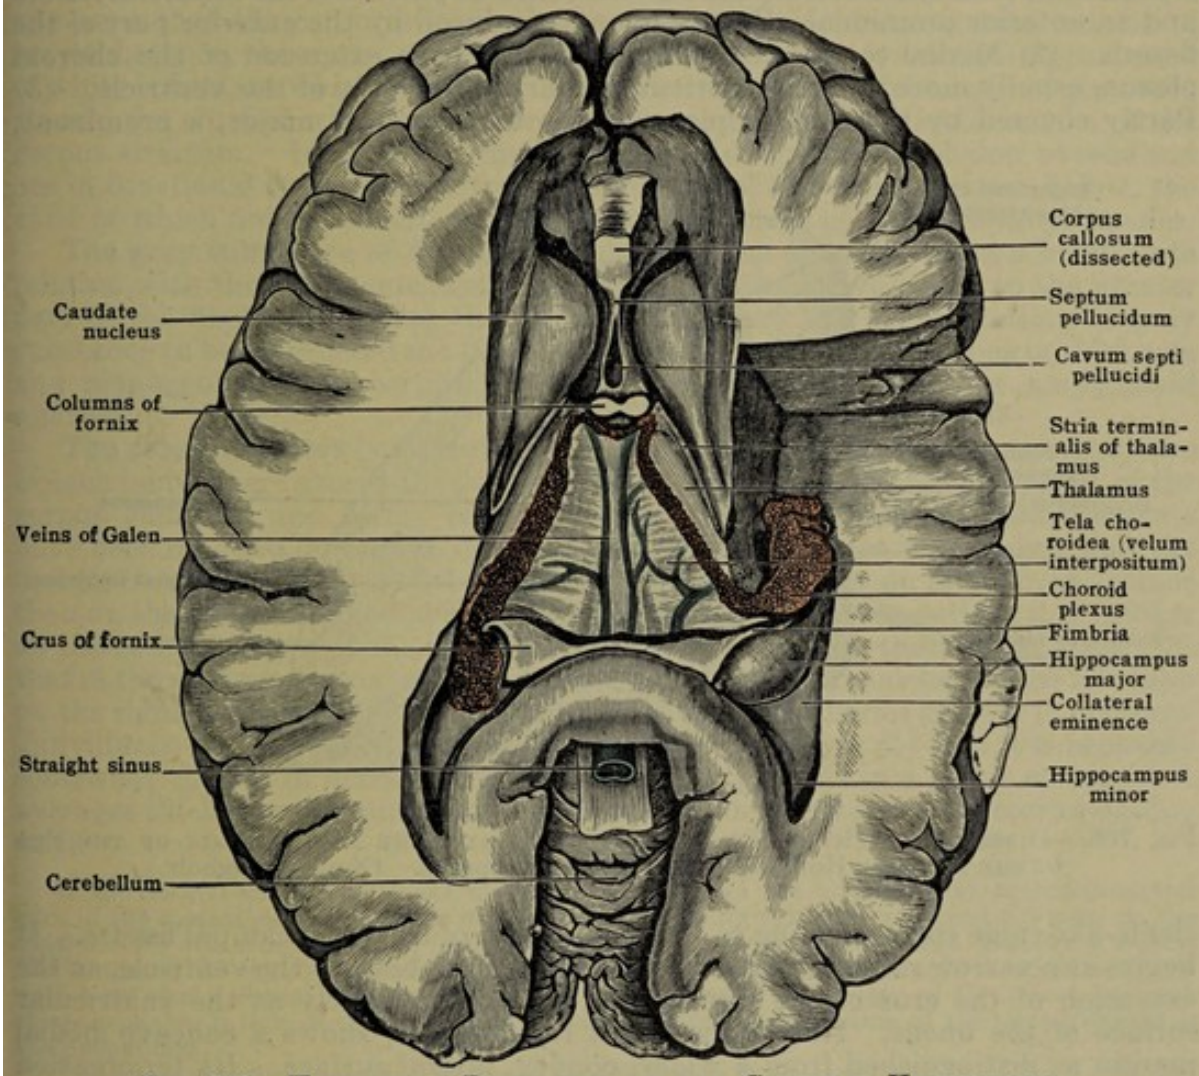

FIG. 765.—HORIZONTAL DISSECTION OF THE CEREBRAL HEMISPHERES.
The fornix has been removed to show the relation of the tela chorioidea of the third ventricle to the choroid plexus of the lateral ventricles. (From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)

and it is due to the anterior part of the calcarine fissure, by which the wall of the hemisphere is projected into the ventricle. The posterior cornu, like the anterior, is not entered by the choroid plexus.

The inferior cornu (pars temporalis NK).—In its inferior and slightly lateral origin from the region of junction between the body of the ventricle and the posterior cornu, the inferior cornu aids in producing a somewhat triangular dilation of the cavity, known as the **collateral trigone.** Beginning as a part of the trigone, the cavity of this cornu at first passes posteriorly and lateralward, but then suddenly curves anteriorly and inferiorly into the medial part of the temporal lobe nearly parallel with the superior temporal sulcus. Above, it follows the curved crura (posterior pillars) of the fornix and fimbria; below, it does not extend to the temporal pole by from 2 to 3 cm. Its *roof* and *lateral wall* are, for the most part, like those of the posterior cornu, formed by the tapetum, but

medialward a strip of the roof is formed by the attenuated, inferior prolongation, or tail, of the caudate nucleus, together with the inferior extension of the stria terminalis of the thalamus.

At the end of the inferior cornu the roof shows a bulging, the **amygdaloid tubercle,** situated at the termination of the tail of the caudate nucleus. This bulging is produced by the *amygdaloid nucleus*, an accumulation of gray substance continuous with that of the cortex of the hippocampal gyrus, and which gives origin to part of the longitudinal fibers coursing in the stria terminalis of the thalamus.

In the *medial wall* and floor of the inferior cornu the following structures are shown:—(1) In the posterior or trigonal part of the floor is the longitudinal **collateral eminence,** a bulging, very variable in development in different specimens, produced by the collateral fissure. This is often pronouncedly in two parts, a posterior prominence corresponding to the middle portion of the collateral fissure and an anterior prominence (less frequent) produced by the anterior part of the fissure. (2) Medial to this eminence lies the inferior extension of the **choroid plexus,** usually more voluminous than the part in the body of the ventricle. (3) Partly covered by the choroid plexus is the **hippocampus major,** a prominent,

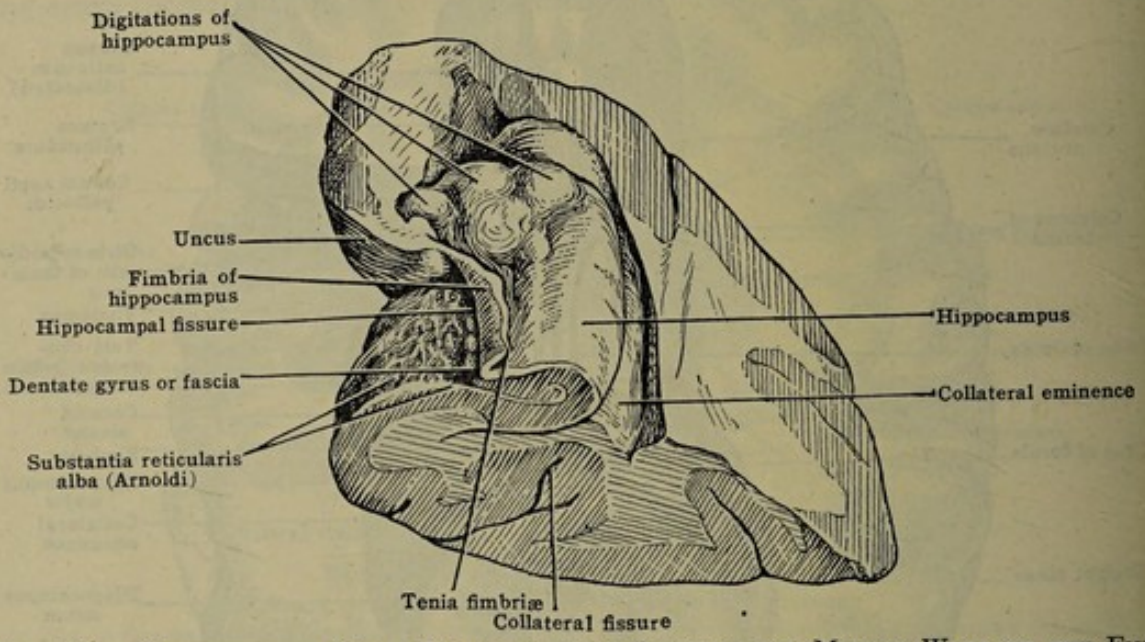

FIG. 766.—DISSECTION OF RIGHT TEMPORAL LOBE SHOWING THE MEDIAL WALL OF THE END OF THE INFERIOR HORN OF THE LATERAL VENTRICLE. (From Spalteholz.)

sickle-like ridge corresponding to the indentation of the hippocampal fissure. It begins as a narrow ridge posteriorly, at the end of the body of the ventricle, as the extension of the crus of the fornix, and expands anteriorly as the ventricular surface of the uncus. Its surface is not regular, but, shows a concave medial margin as distinguished from a wider, convex, lateral surface. Its termination in front (*pes hippocampi*) is divided by two or three flat, radial grooves into a corresponding number of short elevations known as the *hippocampal digitations.* It is covered by a thick stratum of white substance, the *alveus*, arising from its depths and continued mesially into the fimbria. (4) The **fimbria** is so folded that its margin, *tenia fimbriæ*, lies in the cavity of the inferior cornu attached to the choroid plexus and the thin, non-nervous floor of the choroid fissure.

The caudate nucleus (fig. 767).—As realized in the study of the lateral ventricle, the caudate nucleus is a comma-shaped mass of gray substance with a long, much-curved, and attenuated tail. Its *head* forms the bulging lateral wall of the anterior cornu; thence it proceeds posteriorly in the lateral wall of the body of the ventricle and, at the collateral trigone, curves downward and its *tail* becomes a medial portion of the roof of the inferior cornu. It is separated from the thalamus adjacent to it by the stria terminalis of the thalamus (tenia semicircularis). The end of its tail extends anteriorly below to the level of the anterior horn of the ventricle above. Owing to its much curved shape, both horizontal and coronal sections of the hemisphere passing through the inferior cornu may contain the nucleus cut at two places (figs. 768, 773).

The caudate nucleus is the intraventricular of the two masses of gray substance which together are sometimes referred to as the **basal ganglia.** The extraventricular of these masses is the *lenticular nucleus,* which is buried in the substance of the hemisphere, lateral and inferior to the caudate nucleus. The two masses are separated by the *internal capsule,* a thick band of nerve-fibers continuous into the cerebral peduncles, and connecting the gray cortex of the hemisphere with the structures inferior to it. Anteriorly and below, the two nuclei become continuous. The white substance of the internal capsule, in separating them posteriorly, contributes to their striated appearance in sections, known collectively as the *corpus striatum* (figs. 769–773). The corpus striatum as such is described below.

INTERNAL STRUCTURE OF THE PROSENCEPHALON

From the above examinations of their external and ventricular surfaces, it is apparent that the cerebral hemispheres consist of a folded, external mantle of gray substance, the cortex cerebri, spread more or less evenly over an internal mass of white substance which contains embedded within it certain masses of gray substance, the chief of which are known as the caudate and lenticular nuclei of the corpus striatum. In addition, the hemispheres of the telencephalon overlie and are in functional connection with the structures of the diencephalon below, the chief of which are the thalamencephalon and the bases of the cerebral peduncles.

The gray substance of the telencephalon.—The gray substance is in intimate relation with the white substance, and in fact its cells give origin to the greater part of the fibers composing the white substance. The accumulations of gray substance to be considered are the cerebral cortex, with its variations in thickness and arrangement, the corpus striatum, the claustrum, and the amygdaloid nucleus.

The cerebral cortex [substantia corticalis] is distributed over the entire surface of each hemisphere except the peduncular region of the base and the region of the corpus callosum and fornix of the medial surface. Numerous measurements have been made to determine its average thickness. These have shown that the mantle is not uniformly distributed:—(1) that it is thicker on the convex surface than on the basal and medial surfaces; (2) that on the convex surface it is thicker on the central region of the hemisphere, somesthetic area, than at the poles; (3) that in the average normal specimen it averages somewhat thicker on the left than on the right hemisphere; (4) that its average thickness varies greatly in different individuals, and that the thickness decreases with old age; (5) that it is probably somewhat thicker in males than in females, and (6) that in a given specimen it averages thicker on the summits of the gyri than in the floors of the corresponding sulci.

In the normal adult it averages about 4 mm. thick on the anterior and posterior central gyri, in the somesthetic area, while it attains its mimimum thickness of about 2.5 mm. on the basal surface of the occipital and frontal lobes. Its total average thickness is about 2.9 mm. The lamina of the septum pellucidum and the practically non-nervous floor of the third ventricle and that of the choroid fissure are very much thinner. The cortex of the (more ancient) rhinencephalon is termed the **archipallium;** while the remaining cortex of the telencephalon is the **neopallium.**

The cerebral cortex consists of layers of the cell-bodies of neurones, chiefly of the pyramidal type (fig. 684), which receive impulses from the structures below and from other regions of the cortex by way of fibers reaching them through the internal mass of white substance, and which in turn contribute fibers to the white substance. Certain fibers of shorter course and numerous collateral branches of fibers passing out of the cortex are devoted to the association of the region of their origin with the cortex of the immediate vicinity of their origin, and most of these course within the gray cortex itself. In certain gyri, such as the anterior central gyri and those of the medial surface of the occipital lobe, these short association fibers accumulate into strata, and in vertical sections give the cortex a stratified appearance. Two such strata of white substance may be noted in the above localities, one lying about midway in the thickness of the cortex and one slightly internal to this. They are known as the inner and outer **stripes of Baillarger.** In addition, a thin, superficial or *tangential layer* of fibers may often be distinguished lying in the surface of the cortex. Transverse sections through the anterior end of the hippocampus show a coiled arrangement of the layers of white substance, to which has been given the name *cornu ammonis.* The peculiar structure and appearance of the olfactory bulb and tract, parts of the cortex, have already been mentioned.

The corpus striatum is so called on account of the appearance in section of its component parts, the caudate and lenticular nuclei (basal ganglia) and the internal capsule between them. The two nuclei are directly continuous with each other at their anterior ends (fig. 767), and in addition they are connected by

numerous small bands of gray substance which pass from one to the other through the internal capsule, especially its anterior part. Also each nucleus contributes numerous fibers to, and receives fibers from, the internal capsule. These bundles of fibers both arising and terminating within the nuclei, together with the gray substance among the fibers of the capsule, produce the ribbed and striped appearance suggesting the name, corpus striatum. The **caudate nucleus**—the intraventricular part of the corpus striatum—lies with its thicker anterior part (head) closely related to the internal capsule, but its tail passes posteriorly around the posterior border of the capsule and curves downward and anteriorly into the roof of the inferior cornu of the lateral ventricle.

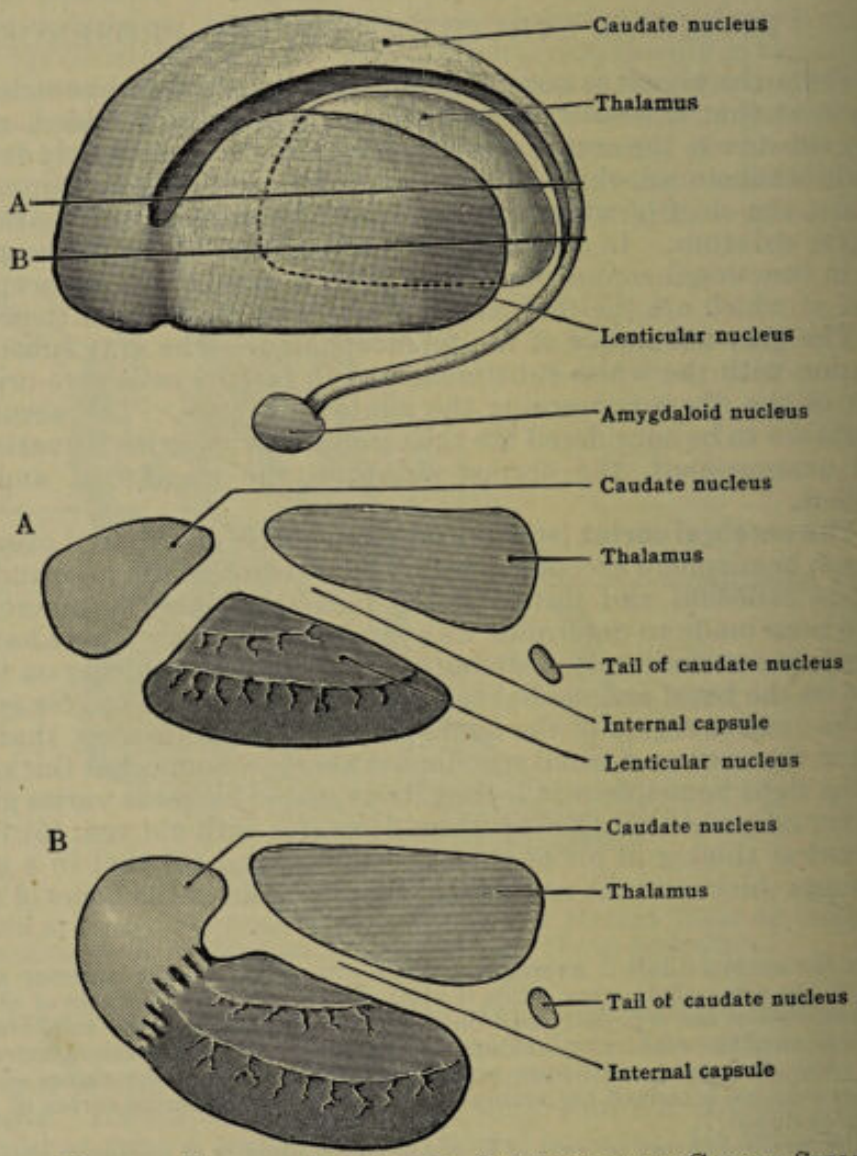

FIG. 767.—DIAGRAMS OF LATERAL VIEW AND HORIZONTAL SECTIONS OF THE CORPUS STRIATUM AND THALAMUS WITH POSITION OF THE INTERNAL CAPSULE.

A and B below represent horizontal sections along the lines A and B in the figure above. The figure also shows the relative position of the thalamus and the amygdaloid nucleus.

The lenticular nucleus [nucleus lentiformis]—the extraventricular part of the corpus striatum—is embedded in the white substance of the cerebral hemisphere. It is somewhat pyriform in shape, not being so long as the caudate nucleus, and neither having a tail nor extending so far anteriorly. Its lower surface is separated from the inferior cornu of the lateral ventricle by the white substance of the roof of that cornu and by the tail of the caudate nucleus, and, further forward, the anterior commissure passes through its base. Its lateral surface is rounded and conforms both in extent and curvature with the surface of the insula, from which it is separated by the fibers of the external capsule and the intervening claustrum. Its oblique superior and medial surface is adapted to the lateral surface of the internal capsule, and it comes to a rounded apex in the angle formed by the internal capsule and a plane parallel with the base of the hemisphere. In both horizontal and coronal (transverse) sections through its middle

it resembles a compound biconvex lens. Internally this appearance is produced by two vertically curving lamina of white substance, an **external** and an **internal medullary lamina,** which divide its substance into three zones:—the two medial zones together form an area, triangular in section, known as the **globus pallidus** (pars pallida NK); the lateral, larger and more gray, concavoconvex zone is the **putamen** (figs. 769, 770). Radiating fibers from the medullary lamina extend into the zones, especially those of the globus pallidus, rendering it a paler gray. These zones disappear in transverse sections of the anterior portion of the lenticular nucleus on account of the fact that the larger putamen alone comprises this portion and alone becomes continuous with the caudate nucleus. (See figs. 767, 771.)

Phylogenetically, the globus pallidus, the most primitive portion of the striate body, is referred to as the *paleostriatum*, with the hypothalamic nucleus and substantia nigra sometimes included in the term. In contrast, the name, *neostriatum*, is used for the putamen and the caudate nucleus. The latter two nuclei are really but a single mass of gray substance separated largely and imperfectly by the invasion of the internal capsule. They increase progressively as the mammalian scale is ascended, reaching their greatest relative size in the primates.

Connections.—Both nuclei of the corpus striatum become continuous with the cortex in the region of the anterior perforated substance, and the putamen of the lenticular nucleus may blend with the anterior part of the base of the claustrum. The following are the principal fiber connections:—(1) Fibers arising in the nuclei which join the internal capsule to reach the cerebral cortex, and fibers arising in the cortex which descend by the same course to the cells of the nuclei. (2) Fibers which pass in both directions between the thalamus and the corpus striatum (caudate nucleus especially). These are more abundant anteriorly, and necessarily pass in the internal capsule. (3) The **ansa lenticularis,** or striosubthalamic radiation, a usually distinct lamina, composed largely of fibers passing inferiorly between the thalamus and lenticular nucleus. It passes from the basal aspect of the anterior tubercle and middle nuclei of the thalamus and curves below through the internal capsule to the basal surface of the lenticular nucleus, and there its fibers are distributed upward through its medullary lamina to the globus pallidus and putamen. Some enter the internal capsule and reach the cortex, chiefly that of the temporal lobe. The ansa lenticularis also contains fibers from the cortex of the temporal lobe to terminate in the inferior and medial parts of the thalamus. The fibers associating the thalamus with the temporal lobe belong to the so-called *inferior peduncle of the thalamus.* (4) Fibers connecting both nuclei (chiefly the lenticular) with the red nucleus and substantia nigra of the mesencephalon. These pass through the hypothalamic region and along the cerebral peduncle.

No definitely localized functions have been with certainty ascribed to either nucleus of the corpus striatum. They serve as relays in the pathways associating the cortical gray substance with the structures below. It is held that some of the descending motor fibers arising from the cells of the cortex give off collaterals, in passing, to the cells of the nuclei and these give fibers which join the internal capsule and cerebral peduncles, increasing the number of fibers bearing impulses from the cortex to the mesencephalon, rhombencephalon and spinal cord. This would make the functions of the nuclei subsidiary to those of the cerebral cortex. In lower vertebrates, the corpus striatum is an important reflex center. It has been established that fibers from the globus pallidus exert control over skeletal muscular activity (S. A. K. Wilson), via the red nucleus (striorubral tract). More recently considerable interest has been directed toward the entire striate body. Research as to the possible extent of striate associations has been done with the hope to obtain anatomical explanations for certain long known and very pronounced nervous symptoms. The investigations have resulted in the fairly well supported assumption of a structural complex referred to as the extrapyramidal system, discussed below (fig. 776).

The claustrum is a triangular plate of gray substance which is embedded in the white substance between the lenticular nucleus and the cortex of the insula. Its medial surface is concave, conforming to the convexity of the putamen. The sheet of white substance intervening between it and the putamen is known as the **external capsule** (pars lateralis of the capsula nuclei lentiformis NK).

The lateral surface of the claustrum shows ridges in section which conform to the neighboring gyri of the insula, and it is spread through a region which quite closely coincides with the area of the insula. Below and anteriorly it becomes continuous with the cortex of the anterior perforated substance and with the lenticular nucleus at the region of the junction of these. Above and posteriorly it gradually becomes thinner, and finally disappears in the white substance about it. In origin it is thought to be a detached portion of the cortical gray substance of the insua.

The amygdaloid nucleus [nucleus amygdalæ] is represented by the amygdaloid tubercle, which has already been described in the extremity of the inferior cornu of the lateral ventricle (fig. 767). It is an almond-shaped mass of cells joined to the tail of the caudate nucleus, continuous above with the putamen and anteriorly continuous with the cortex of the hippocampal gyrus.

The chief connections of the amygdaloid nucleus by way of the *stria terminalis of the thalamus* are noted above under the description of the posterior division of the rhinencephalon. The

amygdaloid nucleus, like the claustrum, is thought to represent a detached portion of the cortex, it being detached from the uncus. Considering this and its chief connections, it, with the stria terminalis of the thalamus, are concerned in the central portion of the olfactory apparatus.

The thalamus and hypothalamus.—The external features of these portions of the prosencephalon have been described previously, but inasmuch as they contain the chief relays between the telencephalon and the divisions of the nervous system caudal to the prosencephalon, the consideration of their internal structure has been deferred until now. The principal gray masses to be considered are the thalamus and the hypothalamic nucleus. The structures comprising the metathalamus and epithalamus have already been mentioned in their relations with the mesencephalon and the optic and auditory apparatus.

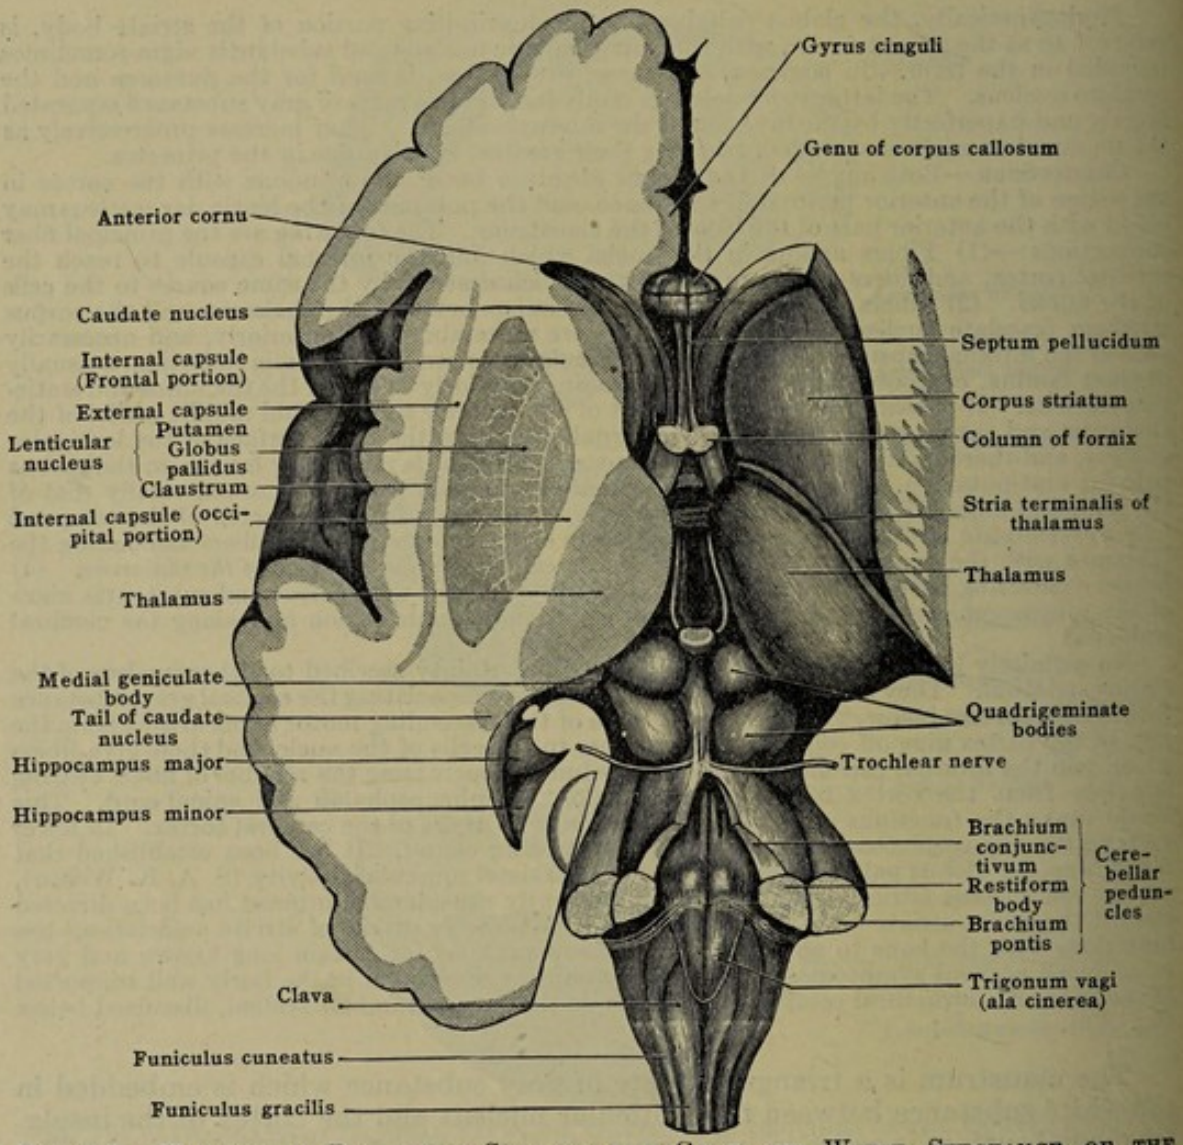

FIG. 768.—HORIZONTAL DISSECTION SHOWING THE GRAY AND WHITE SUBSTANCE OF THE TELENCEPHALON BELOW THE CORPUS CALLOSUM AND THE RELATIVE POSITION OF THE THALAMENCEPHALON. (After Landois and Stirling.)

The thalamus has upon its upper surface, under its ependyma, a thin **stratum zonale** of white substance, derived in part from the incoming fibers but chiefly from its own cells. Its oblique lateral surface conforms to the medial surface of the internal capsule; its vertical medial surface forms the lateral wall of the third ventricle, and below it is continuous into the hypothalamic (tegmental) region and the hypothalamic nucleus. Its upper surface shows a middle, an anterior, and a posterior prominence or tubercle. The **anterior tubercle** (nucleus) forms the posterior boundary of the interventricular foramen; the posterior tubercle is the cushion-like **pulvinar** which projects backward over the lateral geniculate body and the brachium of the superior quadrigeminate body.

A horizontal section through the superomedial edge, splitting the stria medullaris of the thalamus and thus passing above the massa intermedia, shows the gray mass of the thalamus divided into segments or nuclei by a more or less distinct

internal medullary lamina. This extends the whole length of the thalamus, dividing its middle and posterior portion into the **medial** and the **lateral nucleus.** Anteriorly the lamina bifurcates into a medial limb, extending to the medial surface of the thalamus, and a lateral limb, extending forward to join the genu of the internal capsule (figs. 770, 771). This bifurcation results in a cup-like sheet of white substance which encloses the **anterior nucleus.** On the lateral surface of the section, next to the internal capsule, usually there may be distinguished an **external medullary lamina,** separated from the white substance of the capsule by a *reticular layer* of mixed white and gray substance.

The anterior nucleus, lying partially encapsulated in the bifurcation of the internal medullary lamina, is somewhat wedge-shaped and points backward between the anterior portions of the lateral and medial nuclei.

It is composed chiefly of large cells, and constitutes the anterior tubercle of the superior aspect. Its principal connection from below is with the nuclei of the mammillary body of the same and opposite sides, and chiefly with uninterrupted fibers derived from the fornix. The fibers from both sources enter it by way of the *mammillothalamic fasciculus* (figs. 749 and 770). The significance of this connection is mentioned in the description of the limbic lobe.

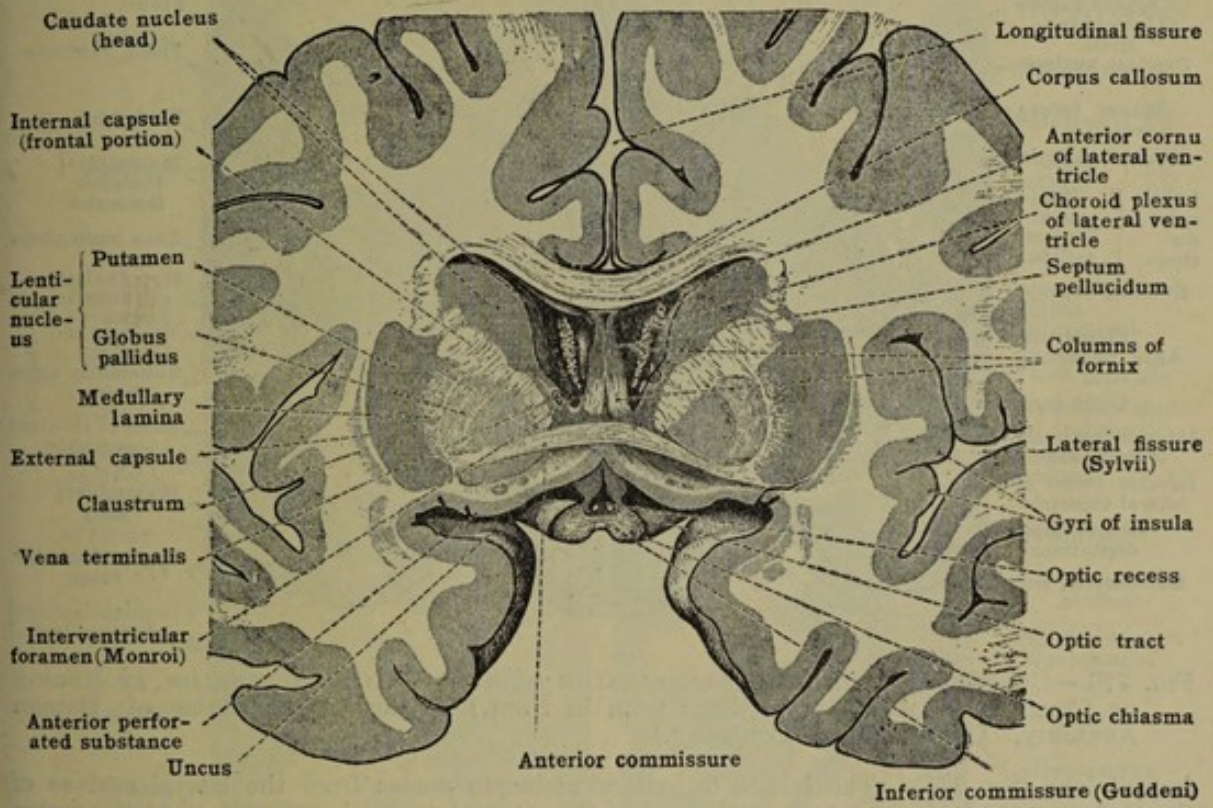

FIG. 769.—CORONAL SECTION OF TELENCEPHALON THROUGH THE ANTERIOR COMMISSURE, OPTIC CHIASMA AND BODY OF CORPUS CALLOSUM. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

The lateral nucleus, lying between the external and internal medullary laminæ, extends posteriorly to include the **pulvinar,** which latter, however, is often called the posterior nucleus of the thalamus.

The neurones of the anterior portion of the lateral nucleus (lateral nucleus proper), together with the entire inferolateral gray substance of the thalamus, receive the terminations of the spinal, medial and trigeminal lemnisci and thus serve as the third links in the neurone chains bearing sensory impulses from the general body to the cerebral cortex. The lateral nucleus also especially receives fibers inferiorly from the red nucleus and from the brachium conjunctivum direct. The pulvinar, as already noted, together with the lateral geniculate body, constitutes the prosencephalic nucleus of termination of the optic tract, and the stratum zonale upon the surface of this nucleus might be called its stratum opticum.

The medial nucleus lies medial to the internal medullary lamina and forms the posterior portion of the lateral wall of the third ventricle (fig. 771). It is shorter than the lateral nucleus, and is less extensively pervaded by fibers.

Its inferior part is thought to receive fibers from the three lemnisci, trigeminal especially, and to send fibers to the cortex. Its dorsal part receives fibers from the olfactory areas of the cortex and contributes fibers to the medullary stria of the thalamus and probably some to the cortex. It is usually continuous across the third ventricle with the opposite medial nucleus by the massa intermedia.

In comparative anatomy, the nuclei of the thalamus have been variously subdivided by the different investigators. All the nuclei are connected with the lenticular nucleus by fibers passing between the two through the internal capsule directly, and by fibers curving from below, chiefly from the anterior, lateral and medial nuclei, and passing in the ansa lenticularis.

The cortical connections of the thalamus are abundant. They consist of fibers both to and from the cortex of the different lobes of the hemisphere, the greater part arising in the thalamus and terminating in the cortex. These fibers collect in the internal and external medullary lamina and the stratum zonale; most of them enter the internal capsule and thence radiate to the different parts of the cortex. Carrying sensory impulses to the cortex received from sensory neurones below, these thalamocortical fibers are the *sensory projection fibers* of the brain.

They form the so-called peduncles of the thalamus, which have been distinguished both by the Flechsig method of investigation, by the degeneration method and by direct dissection. The anterior or **frontal peduncle** passes from the lateral and anterior part of the thalamus through the frontal portion of the internal capsule, and radiates to the cortex of the

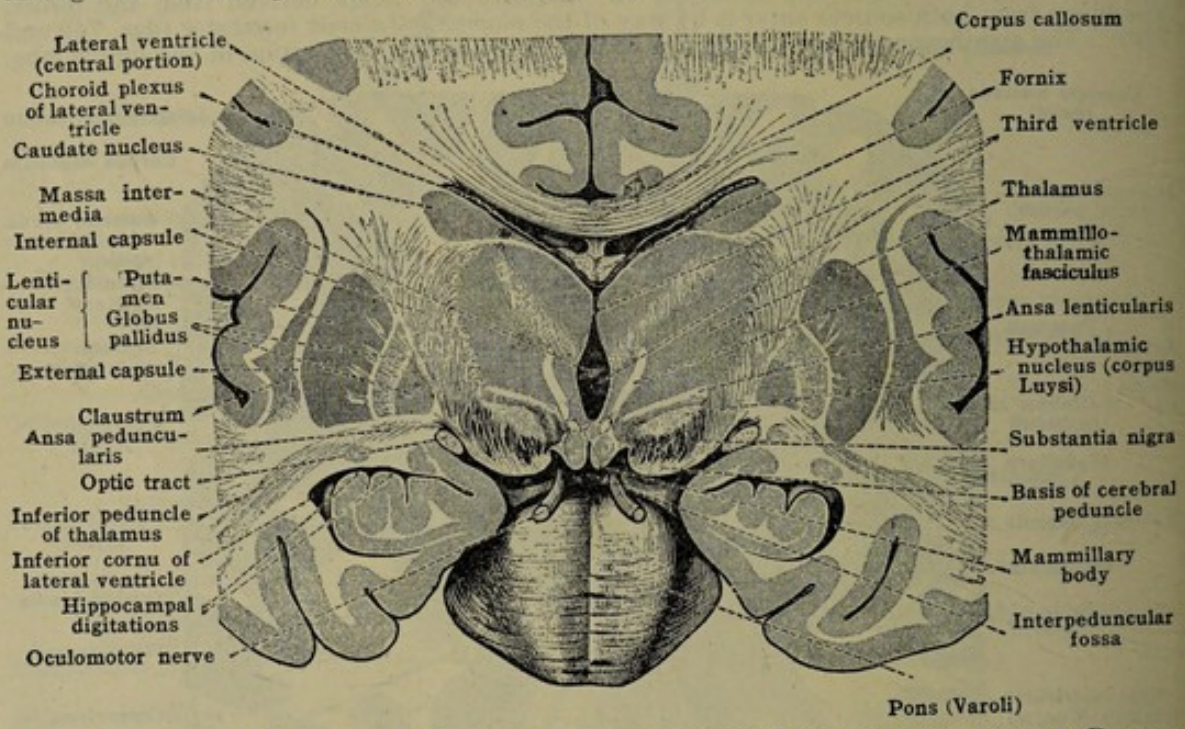

FIG. 770.—CORONAL SECTION OF PROSENCEPHALON THROUGH THALAMENCEPHALON AT REGION OF CORPORA MAMMILLARIA. (Seen from in front.) (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

frontal lobe (fig. 775). The middle or **parietal peduncle** passes from the lateral surface of the thalamus through the intermediate part of the internal capsule, and upward to the cortex of the parietal lobe. The posterior or **occipital peduncle** passes chiefly from the pulvinar, through the occipital portion of the internal capsule, and radiates backward to the occipital lobe by way of the occipitothalamic (optic) radiation (fig. 774). The **inferior peduncle** passes from the medial and basal surface of the thalamus (from the anterior and medial nuclei chiefly), turns outward to course beneath the lenticular nucleus, and radiates to the cortex of the temporal lobe and insula. The fibers of this peduncle course chiefly in the ansa lenticularis (fig. 770). Some turn upward in the external capsule to reach the cortex above the insula; others pass upward through the medullary laminæ of the lenticular nucleus.

The nuclei of the thalamus without doubt serve chiefly as relays in the sensory paths, both general and special, from the periphery of the body to the cerebral cortex. By the several terminal branches of each of the ascending visiting fibers making synapses with the thalamic neurones, the sensory impulses are not only reinforced by the transfer but also the number of neurones bearing them to the cortex is increased in the thalamus.

From the viewpoint of comparative anatomy, the larger, lateral portion of the thalamus, or *neothalamus*, including the pulvinar and the lateral and medial geniculate bodies (detached portions of the thalamus), is considered especially concerned in such relays. In the lower forms, having little or no cerebral cortex, the medial portion of the thalamus persists and serves for the mediation of primitive reflex activities. In man, clinical evidence collected by Head and Holmes and others seem to suggest that some of these primitive reflex functions may be retained in the medial portion; but further, the interesting inference is possible that some activities usually classed as conscious may be mediated by the thalamus, the cerebral cortex not being essential for them. In other words, the thalamus divorced from the cerebral cortex by destructive lesions, seems able to mediate activities in response to sensations of pleasure and pain. The participation of the cerebral cortex, however, seems especially necessary for all analytical, or so-called intellectual and voluntary activities. Such functions of the thalamus give the thalamospinal fasciculus greater functional significance than is usually attributed to it.

The hypothalamic nucleus (body of Luys, subthalamus) (fig. 770) is a biconvex plate of gray substance situated on the basal aspect of the lateral and anterior nuclei of the thalamus, and between these and the basis of the cerebral peduncle. It is the anterior continuation of the substantia nigra, which is spread upon the dorsal surface of the peduncle, and which, though greatly diminished, extends into the hypothalamic region. It is referred to as the hypothalamic nucleus as far

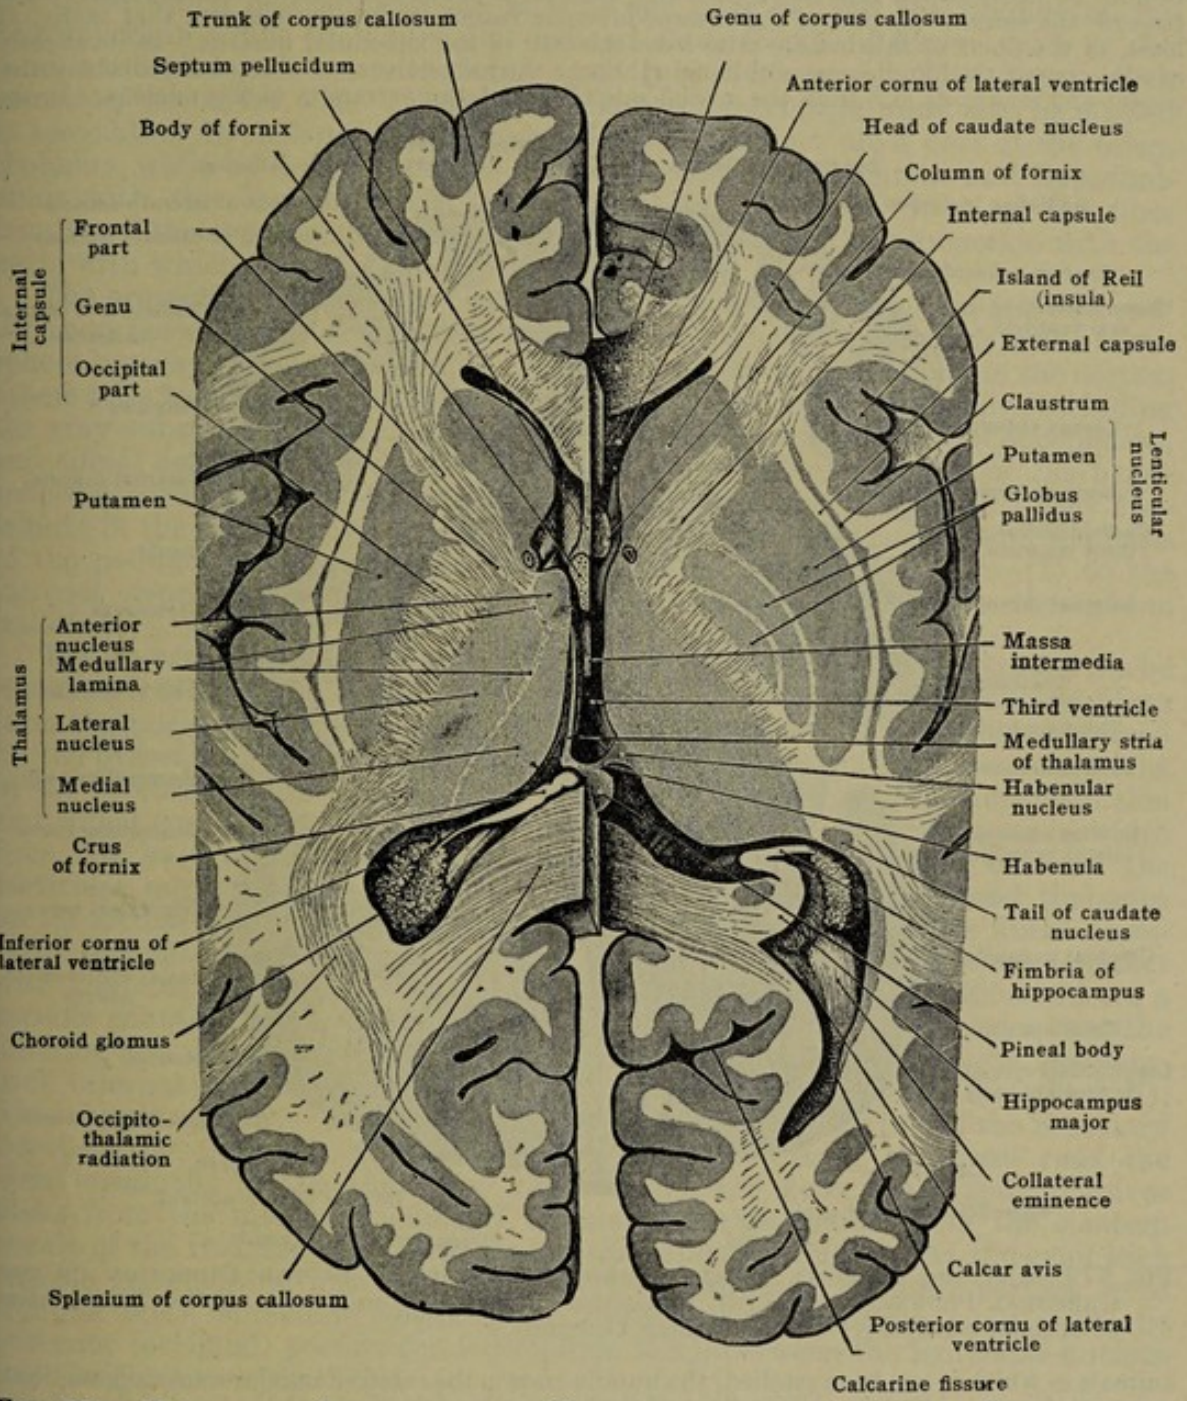

FIG. 771.—HORIZONTAL SECTIONS OF THE PROSENCEPHALON THROUGH THE THALAMUS AND CORPUS STRIATUM.

The plane of the section of the left hemisphere splits the medullary stria of the thalamus about 15 mm. above the plane through which the right hemisphere is cut. (After Toldt.)

posteriorly as the posterior commissure. It presents a brownish-pink color in fresh material, due to pigment in its cells and to its abundant blood-capillaries.

It is enclosed by a thin capsule of white substance, some of the fibers of which seem to decussate with those of the opposite side in the floor of the third ventricle, above and just behind the region of the corpora mammillaria. It is said to receive fibers descending from the cortex and fibers from the thalamus and nuclei of the corpus striatum. Most of the fibers arising from it join the cerebral peduncle. Such relations would suggest that the hypothalamic nucleus serves as a relay in certain paths from the cortex and striate body to the structures below. On the other hand, formerly it was considered the chief nucleus of termination of the medial lemniscus.

The *habenular nucleus* and the *fasciculus retroflexus* of Meynert have been noted in the description of the rhinencephalon. The **habenular nucleus**, a part of the epithalamus, is a small group of nerve cells situated in the habenular trigone just inferolateral to the pineal body. Some fibers of the medullary stria of the thalamus (habenula) terminate about its cells. A small bundle of fibers crossing the midline under the pineal body in the superior aspect of the posterior cerebral commissure is called the *commissure of the habenulæ*, from the fact that it contains fibers correlating the habenular nuclei of the two sides.

The **fasciculus retroflexus (Meynerti)** (tractus habenulopeduncularis) is a relatively strong bundle of fibers which runs downward and then turns caudalward from the habenular nucleus toward the inferior portion of the interpeduncular fossa. It has been shown that many, at least, of the fibers of this bundle arise from the cells of the habenular nucleus. In its slightly caudal course, the bundle passes obliquely through the red nucleus, entering the medial superior aspect and makes its exit from the medial side of the inferior extremity of this nucleus. In the

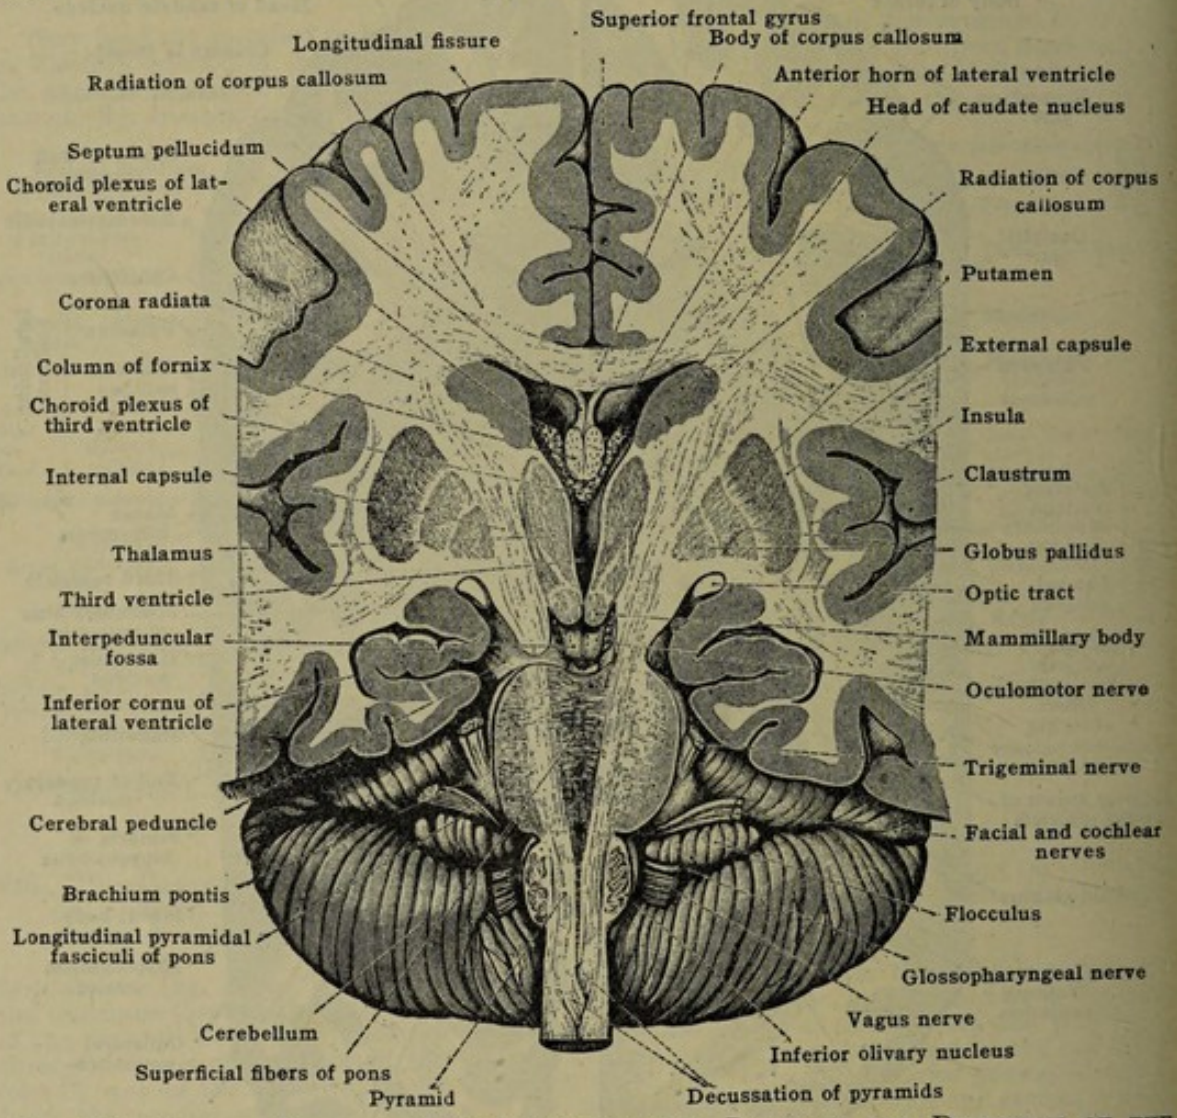

FIG. 772.—OBLIQUE FRONTAL SECTION THROUGH THE BRAIN IN THE DIRECTION OF THE CEREBRAL PEDUNCLES AND THE PYRAMIDS. (Seen from in front.) (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

animals in which it has been studied, the bundle ends in the *interpeduncular nucleus* (ganglion), a group of nerve cells lying in the floor of the interpeduncular fossa at the level of the inferior quadrigemina. In man, the interpeduncular nucleus is not definitely assembled and the bundle seems to disappear in the posterior perforated substance. However, the microscope shows cells dispersed among the fibers of the bundle and these cells probably represent the nucleus. Impulses borne by the fasciculus are presumably transmitted to the cranial and spinal nerves.

The white substance of the telencephalon.—A horizontal section through the upper part of the body of the corpus callosum will pass above the basal gray substance of the corpus striatum, and, aided by the corpus callosum, each hemisphere in such a section will appear as if consisting of a solid, half-oval mass of white substance, bounded without by the gray layer of the cortex (fig. 750). As seen at this level, the white substance of each hemisphere is known as the **centrum semiovale.** Horizontal sections passing below the body of the corpus callosum involve the corpus striatum and thalamus, and the appearance of the white substance is modified accordingly (fig. 768).

In the white substance of the cerebral hemispheres as a whole three main systems of fibers are recognized:—projection fibers, commissural fibers, and association fibers. The *projection fibers* are those of a more or less vertical course, which pass to and from the cortex of the hemisphere, associating it with the structures below the cortex and the confines of the hemisphere. The *commissural fibers* are those of a transverse or horizontal course, which cross the midline and functionally correlate the two hemispheres with each other. The *association fibers* are those which neither cross the midline nor pass beyond the bounds of the hemisphere in which they arise, but instead associate the different parts of the same hemisphere—lobes with lobes and gyri with gyri. The fibers which associate the cortex with the nuclei of the corpus striatum must also be classed as association fibers, since these masses of gray substance are a part of the telencephalon, while by definition those which associate the thalamus and hypothalamus with the cortex belong to the projection system. Some of the fiber bundles of the above systems have already been described in connection with the parts with which they are concerned.

The projection fibers of the hemisphere comprise both ascending and descending fibers between the cerebral cortex and structures below the bounds of the hemisphere proper, i.e., some arise in the structures below and terminate in the cortex; others arise from the cortical cells and terminate in the structures below, including the gray substance of the thalamencephalon, mesencephalon, rhombencephalon, and spinal cord. The projection fibers are given different names in the hemisphere according to their arrangement and the appearances to which they contribute in the dissections. Beginning with the pyramidal fasciculi and the basis of the peduncle, they contribute fibers (both sensory and motor)—(1) to the *internal capsule* and some to the *external capsule* and (2) to the *corona radiata.*

The internal capsule [capsula interna] (pars medialis of the capsula nuclei lentiformis NK) is a band of white substance, consisting of the ascending fibers from the nuclei of the thalamus, hypothalamus, and corpus striatum, reinforced by the descending fibers from the cortex to these nuclei and by those descending in the cerebral peduncle to terminate in the mesencephalon, rhombencephalon and spinal cord. It is a broad, fan-like mass of fibers, which increases in width from the base of the hemisphere upward, and which is spread between the lenticular nucleus on its lateral aspect and the caudate nucleus and thalamus on its medial side. To reach the cortex above, the course of its fibers necessarily intersects that of the radiations of the corpus callosum, and thus, together with the corpus callosum, these fan-like bands of the two hemispheres form a capsule containing the thalami, the third ventricle, the caudate nuclei, and the anterior and central portions of the lateral ventricles. In horizontal sections, each internal capsule appears bent at an angle, the **genu** (genu capsulæ NK), which approaches the cavity of the lateral ventricle along the line of the boundary between the thalamus and the caudate nucleus. Along the genu runs the stria terminalis of the thalamus, and through the genu the capsule receives fibers from the internal medullary lamina of the thalamus, from the stratum zonale of the thalamus and from that of the caudate nucleus. At the genu each capsule is separable into two parts:—(1) the **anterior (frontal) portion** (crus frontale NK), spreading between the caudate and lenticular nuclei; (2) the **posterior (occipital) portion** (crus occipitale NK), between the lenticular nucleus and the thalamus (fig. 775).

Functionally, the internal capsule may be divided into a frontal, a frontoparietal and an occipital part.

The **frontal part** consists of (1) an *anterior segment*, carrying chiefly fibers coursing in both directions between the thalamus and the cortex of the frontal lobe, and (2) a *posterior segment* carrying the frontopontile tract.

The **frontoparietal part** may be considered in four segments:—(1) An anterior segment, the *genu*, carrying impulses from the cortex to the nuclei of the motor cranial nerves; (2) posterior to this is the *corticospinal segment for the arm and thorax*, descending cortical fibers to the spinal cord; also the *corticorubral tract;* (3) next is the *corticospinal segment for the lower extremity;* (4) a posterior segment carrying the *general sensory path* ascending from the ventrolateral part of the thalamus and the red nucleus to the cortex. All the segments of the frontoparietal part carry in addition, fibers in both directions between the cortex above and the thalamus and the nuclei of the striate body.

The occipital part consists (1) of an anterior segment which carries the descending *temporal and occipital pontile paths*, and (2) a posterior segment carrying the *visual fibers* between the occipital cortex and the nuclei of termination of the optic nerve. This segment also carries the

auditory fibers passing to the cortex of the superior temporal gyrus from the regions of termination of the lateral lemniscus. Thus this segment carries a visual and an auditory path.

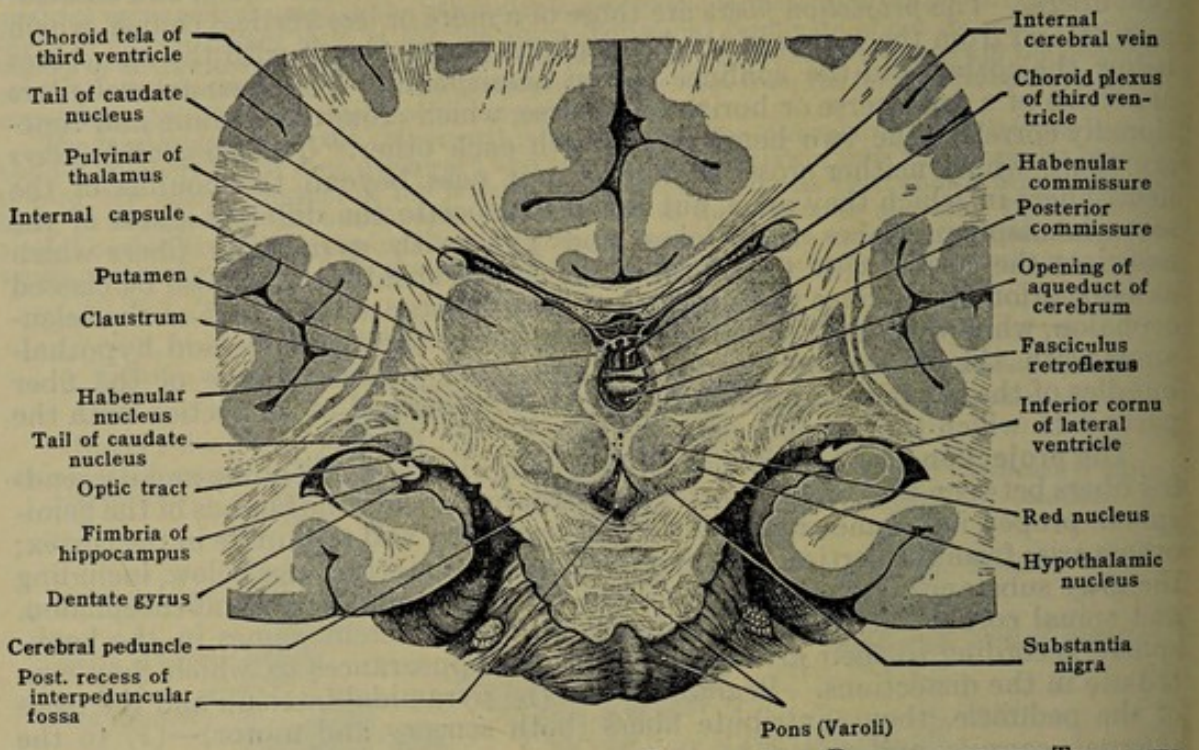

FIG. 773.—CORONAL SECTION OF BRAIN PASSING THROUGH THE PULVINAR OF THE THALAMUS AND THE UNCUS OF THE HIPPOCAMPAL GYRUS. (After Toldt.)

The corona radiata.—Above the corpus callosum and laterally joining its radiations, the fibers of the internal capsule are dispersed in all directions. The appearance known in coronal sections of the hemispheres as the corona radiata is produced by the ascending and descending fibers of the internal capsule combined

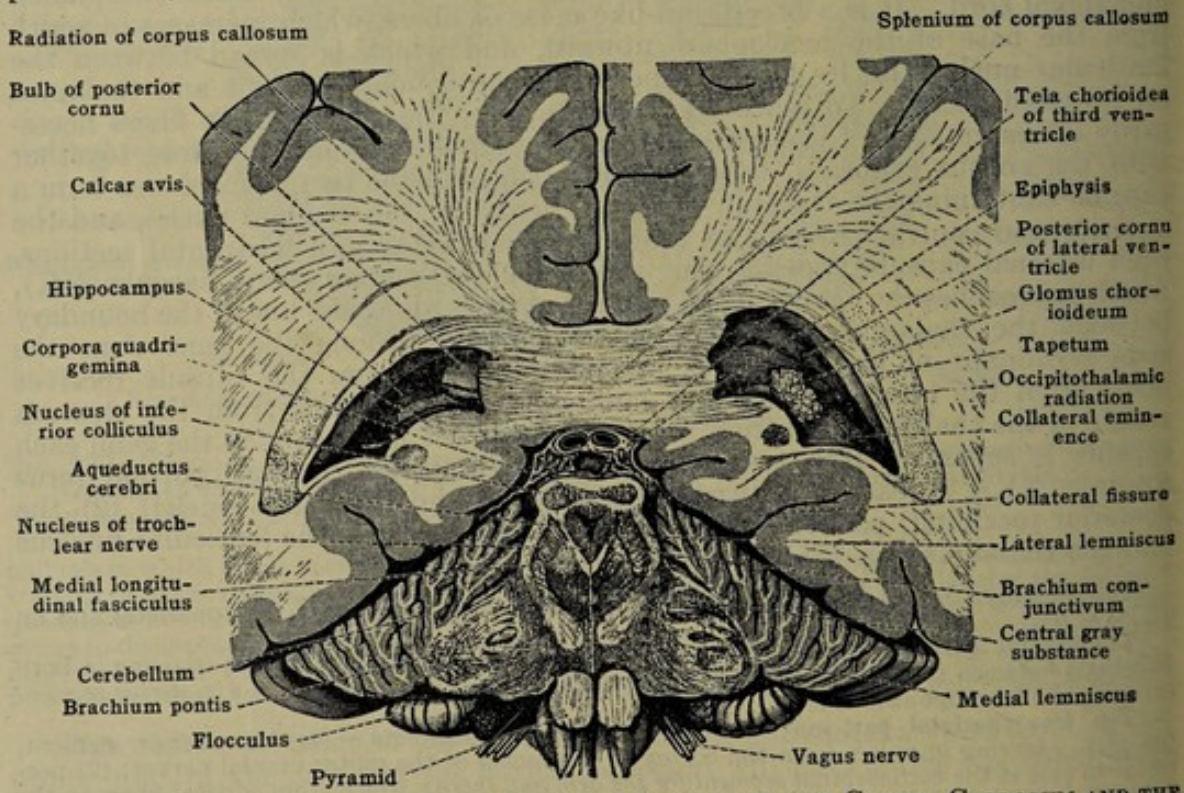

FIG. 774.—CORONAL SECTION THROUGH THE SPLENIUM OF THE CORPUS CALLOSUM AND THE POSTERIOR CORNUA OF THE LATERAL VENTRICLES. (Viewed from behind.) (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

with the radiations of the corpus callosum. The radiations related to the internal capsule may be divided into a frontal, a parietal and an occipital part, corresponding to the frontal, parietal and occipital parts of the internal capsule.

The radiation derived from the posterior segment of the occipital part of the internal capsule, the visual path, accumulates into a well-defined band of fibers which passes posteriorly into the occipital lobe, spreading in the lateral wall of the posterior cornu of the lateral ventricle immediately lateral to the tapetum. This band consists for the most part of fibers arising in the pulvinar of the thalamus and in the lateral geniculate body and going to the visual area of the occipital cortex, and of fibers arising in this cortex to terminate in the thalamus and mesencephalon. Being thus concerned with the optic apparatus, it is known as the **occipitothalamic radiation** or **optic radiation** (fig. 774).

The external capsule is, as already noted, a thin sheet of white substance spread between the claustrum and the lenticular nucleus.

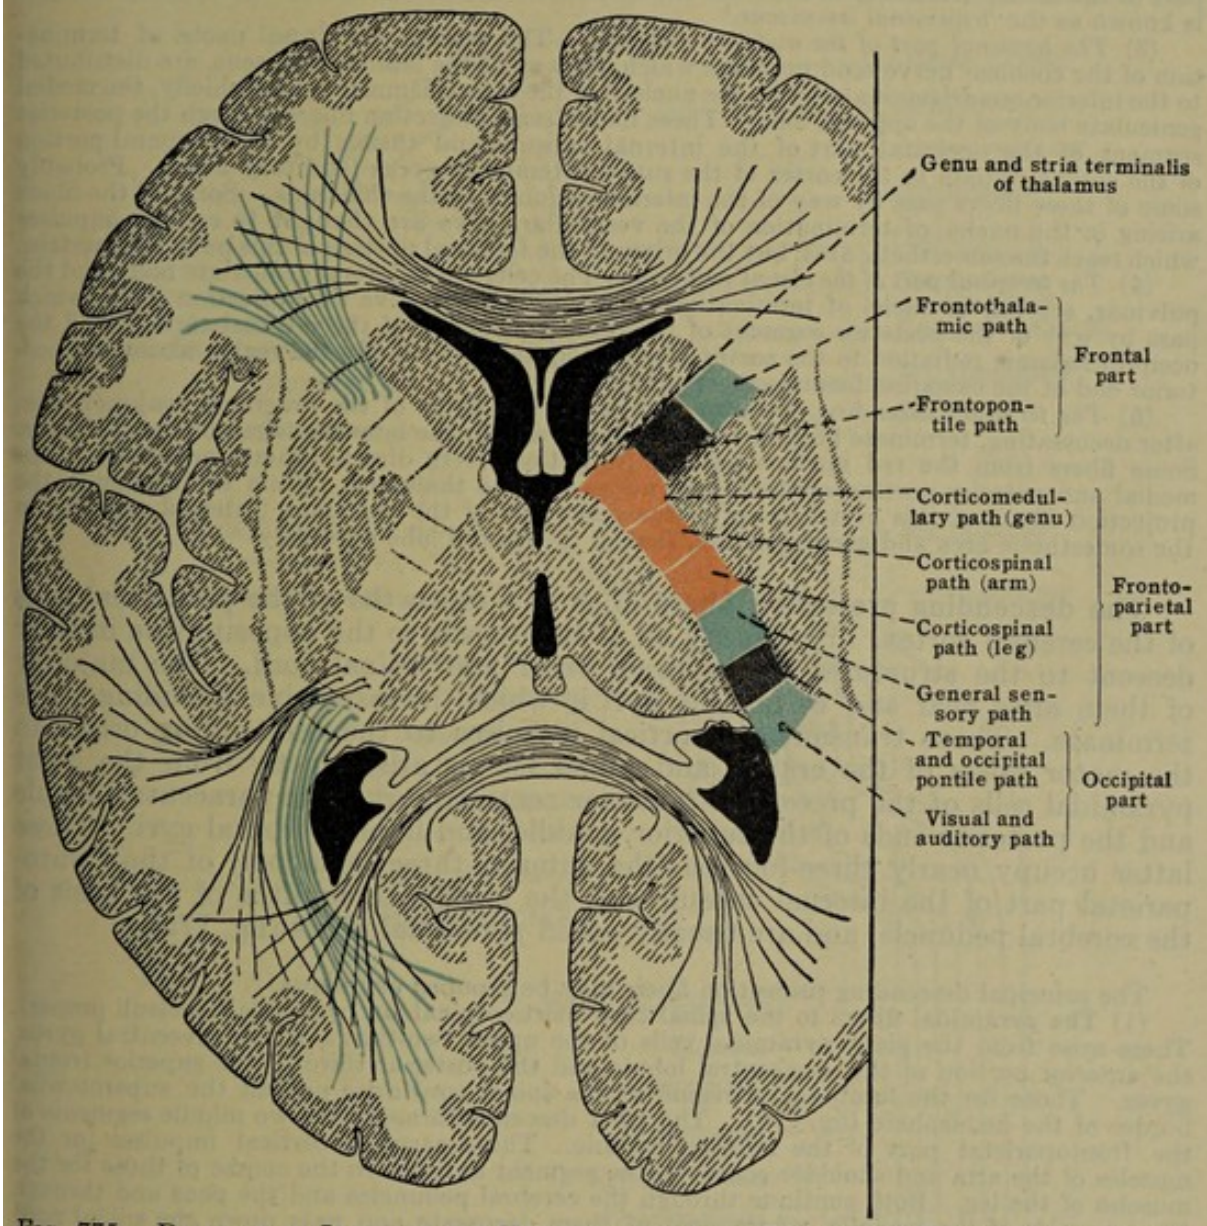

FIG. 775.—DIAGRAM TO INDICATE THE TOPOGRAPHY OF THE PROJECTION FIBERS IN THE INTERNAL CAPSULE. (In part after Villiger.)

It owes its appearance as such to the presence of the claustrum. It joins the internal capsule at the upper, posterior, and anterior borders of the putamen, and below the claustrum it is continuous with the general white substance of the temporal lobe. Thus it contributes to an encapsulation of the lenticular nucleus by white substance. Most of the fibers contained in it belong to the association system. Its projection fibers consist of those of the inferior peduncle of the thalamus, which pass from the basal surface of the thalamus and, instead of continuing below to the cortex of the temporal lobe and insula, turn upward, around the lenticular nucleus to the cortex above the insula. Some of these thalamic fibers are known to pass upward through the laminae of the lenticular nucleus instead of through the external capsule.

The ascending projection fibers arise mostly from the cells of the nuclei of the thalamus; some arise from nuclei in the mesencephalon and from the red nucleus. They may be summarized as follows:—

(1) *The terminal part of the general sensory pathway of the body.* The portion of the medial lemniscus which arises in the nuclei of the fasciculus gracilis and cuneatus, of the opposite side, and the 'spinal lemniscus' (spinothalamic fasciculi), arising in the opposite side of the spinal cord, terminate in the ventral and lateral gray substance of the thalamus. The projection fibers given off by this pass chiefly through the posterior segment of the frontoparietal part of the internal capsule and radiate to and terminate in the somesthetic area of the cortex, chiefly in the posterior central gyrus. Some few may pass outside around the lenticular nucleus, and ascend by way of the external capsule.

(2) *The terminal part of the general sensory pathway of the head and neck.* The nuclei of termination of the sensory portions of the cranial nerves of the rhombencephalon (except the nuclei of the cochlear nerve) give fibers which course upward in the medial lemniscus (fillet) and reticular substance of the opposite side and terminate in the inferolateral portions of the thalamus. Thence arise projection fibers which ascend to the somesthetic area by practically the same route as those of the general sensory system for the body. A large portion of this part of the medial lemniscus arises from the nucleus of termination of the trigeminal nerve and is known as the *'trigeminal lemniscus.'*

(3) *The terminal part of the auditory pathway.* The ventral and dorsal nuclei of termination of the cochlear nerve send impulses which, by way of the lateral lemniscus, are distributed to the inferior quadrigeminate body, the nucleus of the lateral lemniscus and, chiefly, the medial geniculate body of the opposite side. These nuclei send projection fibers through the posterior segment of the occipital part of the internal capsule, and thence by the temporal portion of the corona radiata to the cortex of the superior temporal gyrus (auditory area). Probably some of these fibers pass by way of the inferior peduncle of the thalamus. Some of the fibers arising in the nuclei of termination of the vestibular nerve are thought to convey impulses which reach the somesthetic area, but the origin of the terminal portion of this path is uncertain.

(4) *The terminal part of the visual pathway.* The cells of the lateral geniculate body and the pulvinar, serving as nuclei of termination of the optic tract, give off projection fibers which pass by way of the posterior segment of the occipital portion of the internal capsule and the occipitothalamic radiation to the cortex of the occipital lobe, chiefly the region about the posterior end of the calcarine fissure—the visual area.

(5) *The terminal ascending cerebellar pathway.* The fibers of the brachium conjunctivum, after decussating, terminate both in the red nucleus and in the lateral nucleus of the thalamus. Some fibers from the red nucleus become projection fibers direct, others terminate in the medial and anterior portion of the lateral nucleus of the thalamus. From the thalamus the projection fibers of this system pass in the peduncles of the thalamus (internal capsule) to the somesthetic area and general cortex, that of the frontal lobe especially.

The descending projection fibers arise as outgrowths of the pyramidal cells of the cerebral cortex. Practically all of them cross to the opposite side in their descent to the structures of the brain stem and spinal cord. The majority of them arise near and within the gyri in which the respective ascending fibers terminate. Those transmitting cortical impulses to the cells giving origin to the motor fibers of the cranial and spinal nerves arise chiefly from the giant pyramidal cells of the precentral (anterior central) gyrus, the paracentral lobule and the posterior ends of the superior, middle, and inferior frontal gyri. These latter occupy nearly three-fourths (the anterior three segments) of the frontoparietal part of the internal capsule and the middle three-fifths of the basis of the cerebral peduncle, and are usually called *pyramidal* fibers (fig. 775).

The principal descending projection fibers may be grouped as follows:

(1) **The pyramidal fibers to the spinal cord** (corticospinal or pyramidal fasciculi proper). These arise from the giant pyramidal cells of the upper two-thirds of the precentral gyrus, the anterior portion of the paracentral lobule and the posterior third of the superior frontal gyrus. Those for the lumbosacral region of the spinal cord arise nearest the superomedial border of the hemisphere (fig. 778). The tract descends through the two middle segments of the frontoparietal part of the internal capsule. Those carrying cortical impulses for the muscles of the arm and shoulder course in the segment anterior to the course of those for the muscles of the leg. Both continue through the cerebral peduncles and the pons and through the pyramids of the medulla, where most of them decussate and pass down the spinal cord to terminate about the ventral horn cells (the origin of the motor nerve roots) of the opposite side.

(2) **The pyramidal (cortico-medullary) fibers to the nuclei of origin of the motor cranial nerves** arise from the pyramidal cells in the inferior third of the precentral gyrus, the posterior end of the inferior frontal gyrus, the opercular margin of the posterior central gyrus, and probably some (for eye movements) in the posterior end of the middle frontal gyrus. The locality of the origin of the pyramidal fibers terminating in the nuclei of the facial and hypoglossal nerves only has been determined with certainty. The general tract passes in the genu of the internal capsule, through the cerebral peduncle, and gradually decussating along the brain stem, terminates in the nuclei of the motor cranial nerves of the opposite side.

(3) **The frontal pontile path** (Arnold's bundle) arises in the cortex of the frontal lobe, anterior to the precental gyrus, descends through the frontal part of the corona radiata and posterior segment of the frontal portion of the internal capsule into the frontomedial portion of the cerebral peduncle, and terminates in the nuclei of the pons.

(4) **The temporal pontile path** (Türk's bundle) arises in the cortex of the superior and middle temporal gyri, passes through the anterior segment of the occipital part of the internal capsule, enters the cerebral peduncle posterolateral to its pyramidal portion, and terminates in the nuclei of the pons. An occipitopontile path is described as arising in the occipital cortex and

joining the temporal pontile path in the internal capsule to pass to the nuclei of the pons.

(5) **The occipitomesencephalic path** (Flechsig's secondary optic radiation) arises in the cortex of the visual area of the occipital lobe (cuneus and about the calcarine fissure), passes forward through the occipitothalamic radiation, downward in the posterior segment of the occipital portion of the internal capsule, and terminates in the nucleus of the superior quadrigeminate body and the lateral geniculate body. It is probable that some of its fibers terminate directly in the nuclei of the eye-moving nerves.

(6) **Those fibers of the fornix** which arise in the hippocampus may terminate in the corpus mammillare or pass through to the anterior nucleus of the thalamus of the same and opposite side (mammillothalamic fasciculus) or continue into the mescencephalon and probably to structures lower down.

In the frontal part of the internal capsule fibers are said to course in both directions between the medial nucleus of the thalamus and the cortex of the frontal lobe. And in the frontoparietal part of the capsule a tract is claimed to descend from the motor area of the cortex to terminate in the red nucleus—a *'corticorubral tract.'* In addition, as noted in preceding paragraphs, some

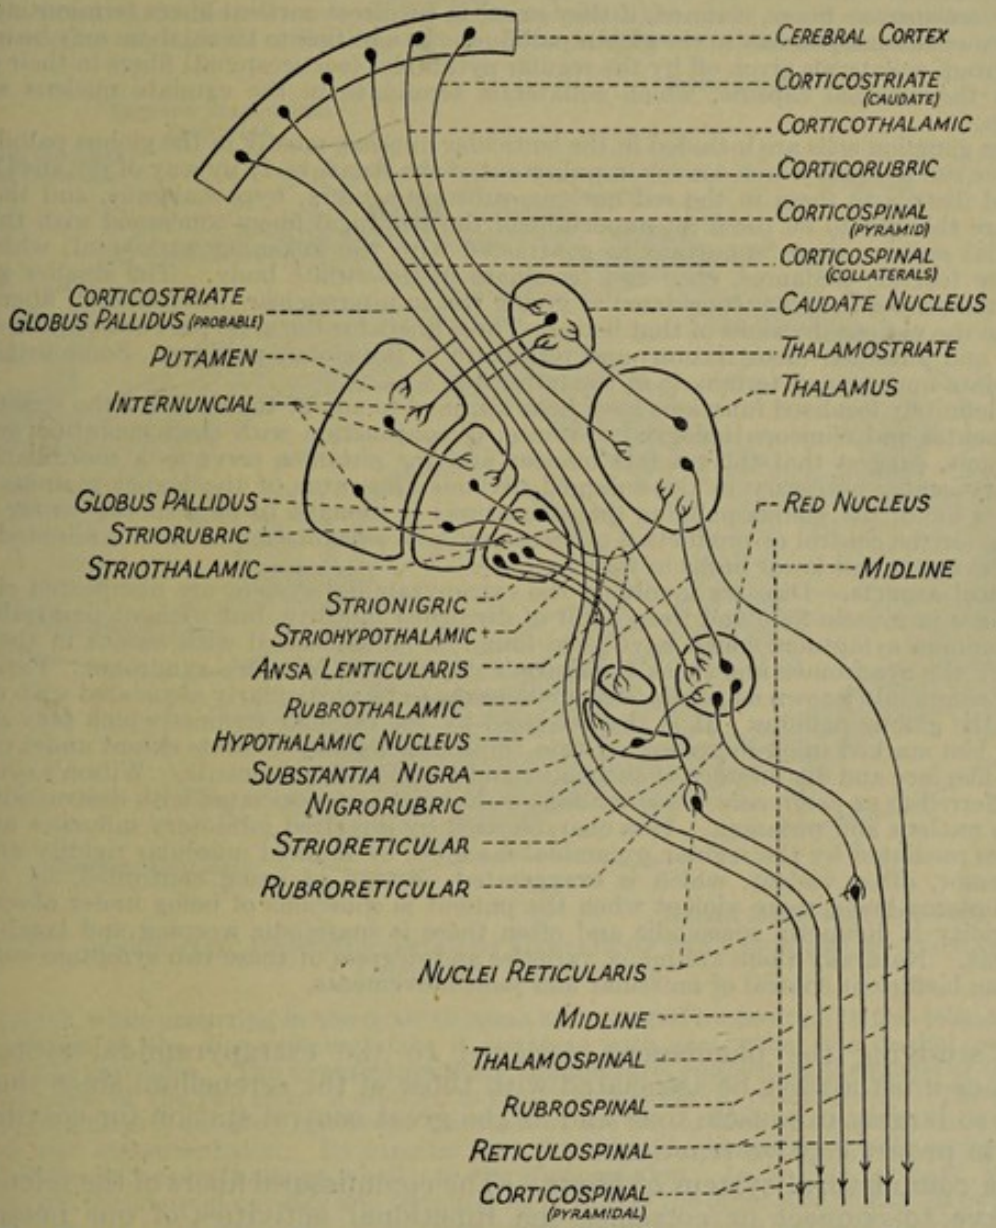

FIG. 776.—DIAGRAM OF THE KNOWN AND SOME OF THE PROBABLE PATHS COMPRISING THE EXTRAPYRAMIDAL SYSTEM.

of the fibers descending from the cortex are described as making synapses in the corpus striatum (basal ganglia), thalamus, hypothalamic nucleus, and substantia nigra. These cortical fibers are claimed for the most part to give off collaterals which terminate in these masses of gray substance instead of terminating wholly within them. Descending fibers arising from these masses have acquired much clinical importance from experimental evidence and from pronounced nervous symptoms found to be associated with pathological lesions involving them, especially the caudate and the lenticular nuclei. These descending fibers, together with the descending cortical fibers concerned, are collectively named the extrapyramidal system.

(7) **The extrapyramidal system.**—Actual structural proof is lacking for anatomical explanations of all the experimental phenomena and all the symptoms associated with pathological lesions which are usually attributed to the extrapyramidal paths. However, it is known that descending fibers do arise in the thalamus, red nucleus and some from the corpus striatum. These extrapyramidal fibers may provide a mechanism for the partial restitution of function

in cases in which lesions involving the regular pyramidal fasciculi have abolished the usual voluntary activities. Also, normally the extrapyramidal fibers are held to coördinate with the regular pyramidal fibers so as to contribute a steadying control in the activities mediated by the latter. The extrapyramidal system includes all descending cortical chains which reach the medulla and spinal cord by a circuitous route instead of following the recognized pyramidal tracts. The paths descending by the way of the cerebellum and chiefly concerned in the apparatuses of equilibration and muscle tone are usually omitted from the extrapyramidal paths. Thus the paths included in the list are:

(a) The *corticorubral* path, which arises in the cortex of the frontal lobe and makes synapses in the red nucleus. Descending fibers from the red nucleus may establish connections with the motor neurones of the brain stem and spinal cord by way of the rubrospinal tract, including the rubroreticulospinal and the rubrothalamospinal paths. (See diagram, fig. 776.)

(b) *Corticothalamic* fibers, which connect the cortex with the thalamus of the same side. Thence the thalamospinal fasciculus serves as intermediate links between the thalamus and the motor neurones of the spinal cord. A thalamostriate path is claimed to exist between the thalamus and caudate nucleus, and possibly the globus pallidus via the ansa lenticularis.

(c) *Corticostriate* fibers, claimed, if they exist, to be direct cortical fibers terminating in the caudate nucleus and possibly in the globus pallidus. In addition to these, there may be included in this group collaterals given off by the regular pyramidal (corticospinal) fibers in their passage through the internal capsule, which collaterals terminate in the caudate nucleus and the putamen.

Large ganglion cells are included in the lenticular nucleus, mostly in the globus pallidus, and these give rise to fibers which convey impulses out of the striate body by way of the ansa lenticularis and distribute them in the red nucleus, substantia nigra, hypothalamus, and thalamus. These are thought to be the most important of the striofugal fibers concerned with the extrapyramidal system, more important as contrasted with the incoming (striopetal) which arise elsewhere (cortex, thalamus, etc.) and terminate in the striate body. The smaller ganglion cells of the striate body are considered as giving rise to internuclear (internuncial) fibers which associate the various divisions of that body. These fibers for the most part arise in the caudate nucleus and putamen (neostriatum) and terminate in the globus pallidus. Some originate in the caudate nucleus and terminate in the putamen.

No definitely localized functions have been ascribed to any of the nuclei of the striate body. Experimental and clinicopathological evidence, in conjunction with their evolution and fiber connections, suggest that the caudate nucleus and the putamen serve as a coordinating and inhibitory center necessary in the enlarged nervous apparatus of the higher mammals. On the other hand, the globus pallidus (paleostriatum) is thought to be a motor center of long standing for the control or production of associated movements such as the coordinated swinging of the upper and lower limbs in walking.

Clinical aspects.—Diseases involving the extrapyramidal system are manifested clinically by changes in muscle tone and some form of disturbed motility, but without paralysis. The more common symptoms which have been found to be associated with lesions in the striate body are the syndromes known as Parkinson's disease and Wilson's syndrome. Parkinson's disease, commonly known as *paralysis agitans*, seems to be particularly associated with destruction of the globus pallidus. It is characterized by the familiar tremors which may cease or become less marked upon increased volition (muscular rigidity to some extent under control), a mask-like face and disturbance of automatic and associated movements. Wilson's syndrome, often referred to as *progressive lenticular degeneration*, is more associated with destruction of the caudate nucleus and putamen. It is characterized by impaired inhibitory influence upon the activities mediated by the regular pyramidal fasciculi, by marked muscular rigidity and complex tremor, often violent, which is exaggerated, instead of being controlled, by volition, the symptoms being more violent when the patient is conscious of being under observation. The rigidity is distinctly spasmodic and often there is spasmodic weeping and laughter and dysphasia. Naturally there are many varieties and degrees of these two symptom complexes involving inefficient control of muscular and joint movements.

In studying the phenomena assigned to the extrapyramidal system, its functions must always be associated with those of the cerebellum since the latter serves so largely in muscle tone and as the great central station for coördination paths in proprioceptive reactions.

The commissural system of fibers.—The commissural fibers of the telencephalon serve to connect or correlate the functional activities of one hemisphere with those of the other. They consist of three groups:—The corpus callosum, the anterior commissure and the hippocampal commissure.

(1) The **corpus callosum** is the great commissure of the brain. A general description of this with the medial and lateral striæ running over it has already been given. It is a thick band of white substance, about 10 cm. wide, which crosses between the two hemispheres at the bottom of the longitudinal fissure. Its shape is such that in a median sagittal section of the brain its parts are given the names *splenium*, *body*, *genu*, and *rostrum* (figs. 746 and 757). Its lower surface is medially joined to the fornix, in part by the septum pellucidum and in part directly. Posterolaterally, it forms the tapetum of the lateral ventricle of either side. The majority of its fibers arise from the cortical cells of the two hemispheres and terminate in the cortex of the side opposite that of their origin. In dissections, its fibers are seen to radiate toward all parts of the cortex—the radiation of the corpus callosum. These radiations may be divided into frontal, parietal, temporal and occipital parts. The occipital parts curve posteriorly in two strong bands from the splenium into the occipital lobes, producing the figure known as the

forceps major. Anteriorly, the frontal parts are two similar but lesser bands which curve from the genu forward into the frontal lobe, producing the **forceps minor.**

(2) The **anterior commissure** (commissura rostralis NK) has been described in connection with the rhinencephalon. In addition to the olfactory fibers coursing through it from the olfactory bulb and parolfactory area of one hemisphere to the uncus and olfactory bulb of the opposite hemisphere, and its commissural fibers between the two hippocampal gyri, comprising its greater part, it also carries fibers which arise in the cortex of the temporal lobe, the uncus chiefly, of one side and terminate in that of the opposite side. It crosses in the substance of the anterior boundary of the third ventricle, and through the inferior portions of the lenticular nuclei, and can be seen only in dissections (figs. 761, 769). It is a relatively small, round bundle, and its midportion between its terminal radiations presents a somewhat twisted appearance.

(3) The **hippocampal commissure** (*transverse fornix*) belongs wholly to the limbic lobe (rhinencephalon), and has been described there. It connects the hippocampal gyri of the two sides, and crosses the midline under and usually adhering to the inferior surface of the splenium of the corpus callosum. Crossing the body of the fornix, it thins anteriorly, its edge crossing in the posterior angle of the septum pellucidum.

With these three commissures of the telencephalon, the three other commissures of the prosencephalon should be called to mind. **The inferior cerebral commissure** (Gudden's

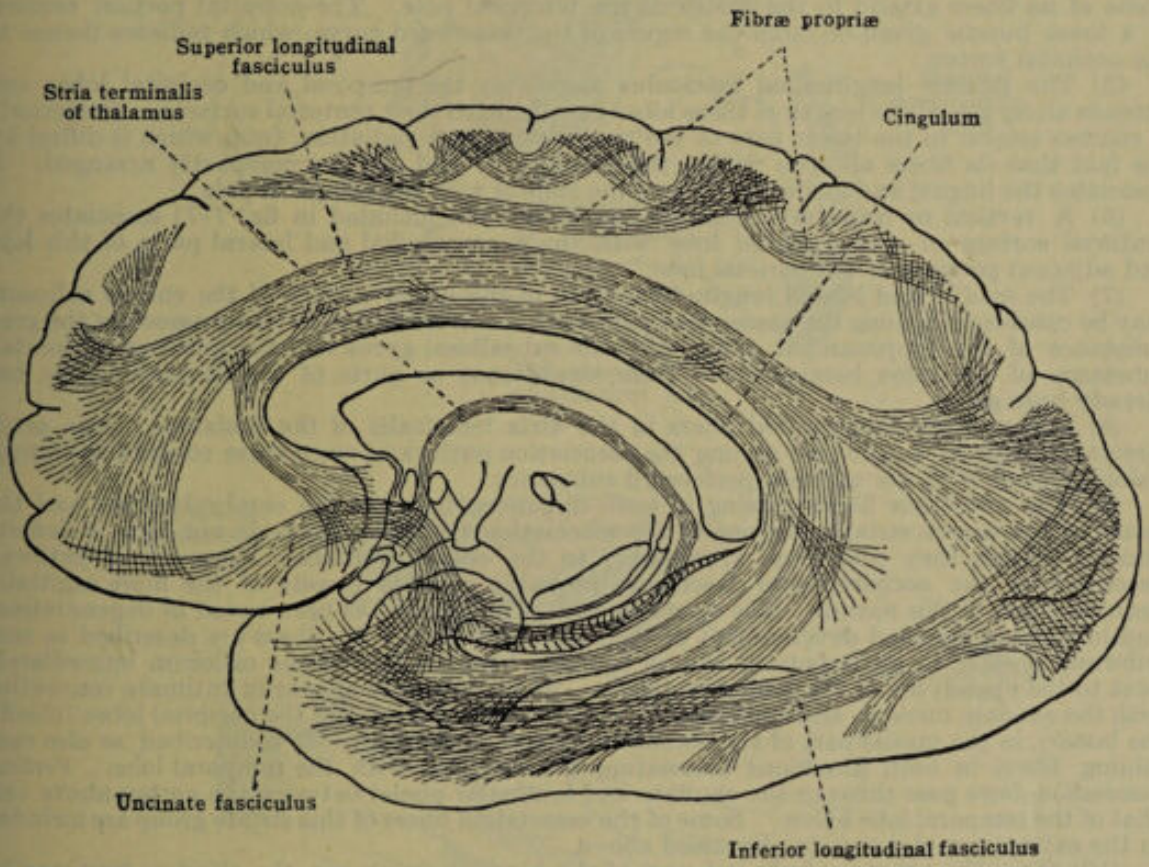

FIG. 777.—SCHEMATIC REPRESENTATION OF CERTAIN OF THE ASSOCIATION-PATHWAYS OF THE CEREBRAL HEMISPHERE.

commissure), while occurring in the optic chiasma and allotted by position to the telencephalon, really belongs to the diencephalon since it connects with each other the medial geniculate bodies of the two sides. **The supramammillary commissure,** connecting the nuclei of the mammillary bodies of the two sides, is allotted to the diencephalon (hypothalamus). **The posterior cerebral commisure,** situated just below the stalk of the pineal body, belongs to both the diencephalon and mesencephalon. Its superior part, the *habenular commissure*, connecting the two nuclei of the habenulæ, belongs wholly to the diencephalon. In its inferior part, the fibers arising in the thalamus of one side and terminating in that of the other side belong likewise to the diencephalon, but those passing between the superior quadrigeminate bodies of the two sides and between the so-called nuclei of the medial longitudinal fasciculi belong to the mesencephalon.

The association system of the hemisphere.—The possibilities for association-bundles connecting the different parts of the same hemisphere with each other are innumerable, though only a few are designated by names. They serve for the distribution or diffusion of impulses brought in from the exterior by the ascending projection system, and it is by means of them that the different areas of the cortex may function in harmony and coördination. Most of the association-bundles are supposed to contain fibers coursing in both directions. Several of them have already been described in company with the gray masses with which they are concerned. They may be summarized as follows (see fig. 777):—

(1) Those of short course, the **fibræ propriæ,** which associate contiguous gyri with each other. These arise from the cells of a gyrus and loop around the floor of a sulcus, continu-

ally receiving and losing fibers in the cortex they associate. The stripes of Baillarger within the gray cortical layer might be included among the short association-bundles, these largely associating different regions of the same gyrus.

(2) The **cingulum** (girdle) lies in the gyrus cinguli and is shaped correspondingly. It extends from the anterior perforated substance and the subcallosal gyrus around the genu of the corpus callosum, then under cover of the gyrus cinguli and around the splenium, and thence downward and forward in the hippocampal gyrus to the uncus. It is chiefly an aggregation of fibers of short course—fibers which associate neighboring portions of the cortical substance beneath which they course, and which, by continually overlapping each other, form the bundle.

(3) The **uncinate fasciculus** is a hook-shaped bundle which associates the uncus and anterior portion of the temporal lobe with the olfactory bulb, parolfactory area and anterior perforated substance and perhaps the frontal pole with the orbital gyri. Its shape is due to its having to curve medialward around the stem of the lateral cerebral fissure.

(4) The **superior longitudinal fasciculus** is the longest of the association-paths, and associates the frontal, occipital, and temporal lobes. From the frontal lobe it passes laterally in the frontal and parietal operculum, transverse to the radiations of the corpus callosum and the lower part of the corona radiata, and above the insula to the region of the posterior end of the lateral fissure, and thence it curves downward and forward to the cortex of the temporal lobe. Some of its fibers extend to the cortex of the temporal pole. The occipital portion consists of a loose bundle given off from the region of the downward curve, which radiates thence to the occipital cortex.

(5) The **inferior longitudinal fasciculus** associates the temporal and occipital lobes and extends along the whole length of these lobes parallel with their tentorial surfaces. Posteriorly it courses lateral to the lower part of the occipitothalamic radiation, from which it differs by the fact that its fibers all arise within the hemisphere and are less compactly arranged. It associates the lingual and fusiform gyri and the cuneus with the temporal pole.

(6) A vertical or **transverse occipital fasciculus** (not included in fig. 777) associates the tentorial surface of the occipital lobe with the superomedial and lateral parts of this lobe and adjacent portions of the parietal lobe.

(7) The medial and lateral **longitudinal striæ** of the upper surface of the corpus callosum may be considered among the association pathways, since most of their fibers associate the gray substance of the hippocampal gyrus with the subcallosal gyrus and the anterior perforated substance of the same hemisphere. Their significance as parts of the rhinencephalon has already been given.

(8) Likewise the longitudinal fibers in the **stria terminalis of the thalamus** (tenia semicircularis) may be considered among the association pathways, since these connect the amygdaloid nucleus with the anterior perforated substance.

(9) The numerous fibers passing in both directions between the cerebral cortex and the nuclei of the corpus striatum belong to the association system. These do not form a definite bundle, though they contribute appreciably to the corona radiata. However, a pathway described as the **occipitofrontal fasciculus** probably consists largely of the more sagittally running fibers of this nature. The existence of this fasciculus has been noted in degenerations and in cases of arrested development of the corpus callosum. Its fibers are described as contributing greatly to the tapetum, and as coursing beneath the corpus callosum immediately next to the ependyma of the lateral ventricle. As a mass, they appear in intimate connection with the caudate nucleus, and are spread toward both the frontal and the occipital lobes (chiefly the latter), in the mesial part of the corona radiata of those lobes. It is described as also containing fibers in both directions associating the occipital with the temporal lobe. *Vertical association-fibers* pass through the caudate and lenticular nuclei between the cortex above and that of the temporal lobe below. Some of the association fibers of this striate group are included in the extrapyramidal system, discussed above.

(10) Since the olfactory bulb is a part of the hemisphere proper, the *olfactory tract* may be considered an association pathway connecting the olfactory bulb with the parolfactory area, the subcallosal gyrus, the anterior perforated substance, and the uncus. As already shown, a portion of the fibers of the tract belongs to the commissural system.

THE FUNCTIONAL AREAS OF THE CEREBRAL CORTEX

The definitely known areas of specific function of the human cerebral cortex are relatively small. They comprise but little more than a third of the area of the entire hemisphere. They are—(1) the general sensory-motor or somesthetic area, and (2) the more specific areas for the organs of special sense. They represent portions of the cortex in which terminate sensory or ascending projection-fibers bearing impulses from the given peripheral structures, and in which arise motor or descending projection-fibers bearing impulses in response.

Knowledge of the location of the areas has been obtained—(1) by the Flechsig method of investigation, and to a considerable extent by Flechsig himself; (2) from clinicopathological observations, largely studies of the phenomena resulting from brain-tumors, cerebral thrombi and traumatic lesions; (3) by experimental excitation of the cortex of monkeys and apes, the resulting phenomena being correlated with the anatomical findings and compared with the observations upon the human brain. The remaining larger and less known areas of the cortex are referred to as '*association-centers*' or *areas* of the 'higher psychic activities.'

In development, the sensory fibers to the specific areas acquire their medullary sheaths first, before birth, and then the respective motor fibers from each become medullated. It is not until a month after birth that the association-centers show medullation and therefore acquire active functional connection with the specific areas.

In defining an area it is not claimed that all the fibers bearing a given type of impulse terminate in that area, nor that all the motor fibers leading to the given reaction originate in the area. It can only be said that of the fibers concerned in a given group of reactions, more terminate and arise in the areas cited than in any other areas of the cortex. The corresponding

motor fibers arise both in the region of the termination of the sensory fibers (sensory area) and also in a zone (motor area) either partially surrounding or bordering upon a part of the region of the termination.

There is yet much lack of agreement among observers both as to the number of localized functional areas and as to the exact position of certain of the areas claimed. Some of the more recent and more trustworthy observations upon the human cortex are those made by Forester (1927). These were made upon chance cases in which the operation could be performed under local anesthesia, the patient fully conscious. The cortex was excited by electrical stimulus with the patient able to describe sensations experienced. Stimulation of an area resulting in a more instant and marked contraction of a muscle or group of muscles established the cortical area concerned with the muscles responding to it. Upon stimulation of a sensory area, the patient would report a sensory experience, 'an aura,' similar to that induced by a stimulation

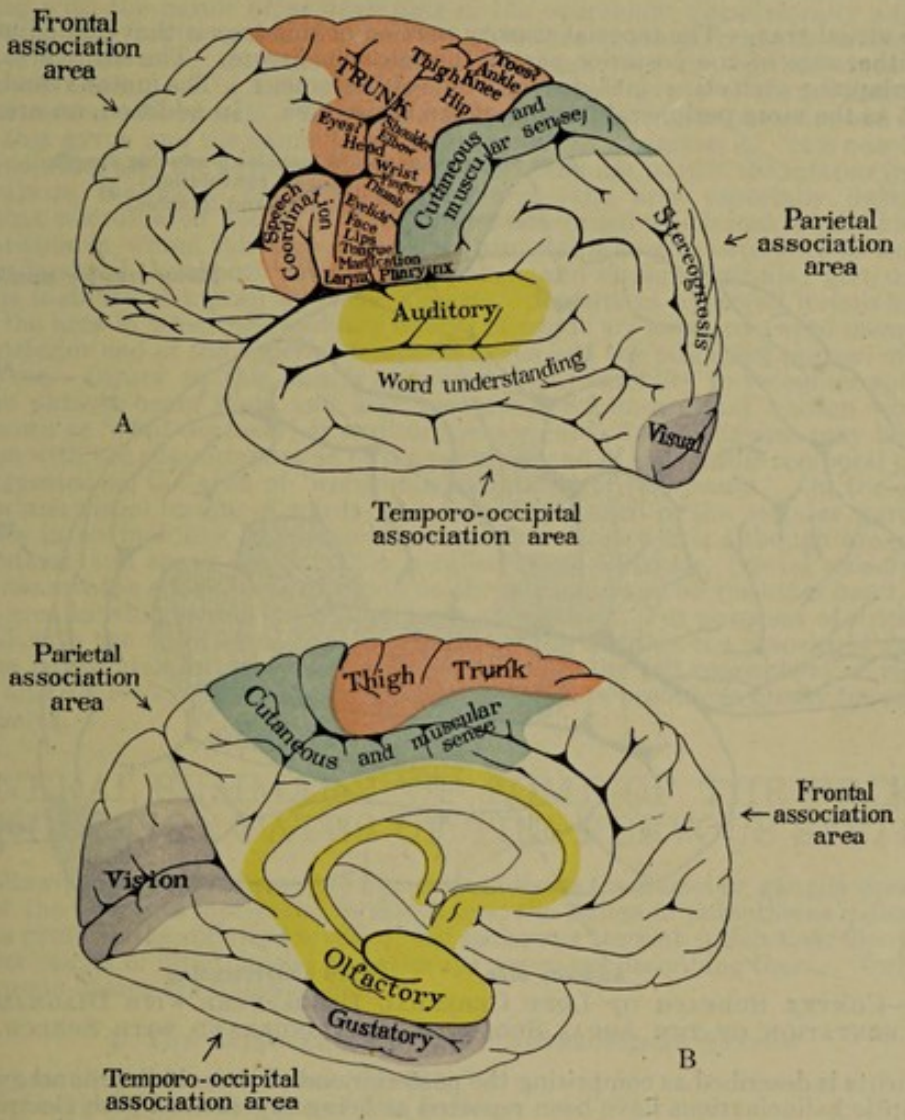

FIG. 778.—DIAGRAMS SUGGESTING THE GENERAL MOTOR, GENERAL AND SPECIAL SENSORY AND THE ASSOCIATION AREAS OF (A) THE CONVEX AND (B) THE MEDIAL SURFACE OF THE CEREBRAL HEMISPHERE. THE DIFFERENT SENSORY AREAS OF THE POSTERIOR CENTRAL GYRUS ARE LOCATED APPROXIMATELY OPPOSITE THEIR CORRESPONDING MOTOR AREAS AS NAMED.

of an organ or region of the general body normally related to that area of the cortex. Stimulation of a purely motor areas did not give an aura, while stimulation of a 'sensory' area was often followed first by an aura and then by a contraction of muscles normally occurring in response to sensations when aroused in the corresponding region of the body. The following are considered the more generally accepted of the areas:—

(1) The **somesthetic (sensory-motor) area,** the area of general sensibility, and the area in which arise the larger part of the cerebral motor or pyramidal fibers for the cortical control of the general muscular system. As is to be expected, it is the largest of the specific areas. It includes the anterior central gyrus, posterior central gyrus, the posterior ends of the superior, middle, and inferior frontal gyri, the paracentral lobules, and the immediately adjacent part of the gyrus cinguli. The ascending or sensory fibers are found to terminate most abundantly in the part posterior to the central sulcus (Rolandi), the posterior central gyrus being the special *area of cutaneous sensibility* of the human cortex, and the adjacent anterior ends of the horizontal parietal gyri have been designated as the area of '*muscular sense.*' Both these areas are carried over upon the medial surface to involve the lower part of the paracentral lobule and a part of the gyrus cinguli. The anterior central gyrus gives origin to relatively more motor fibers than

the other portions of the somesthetic area. In distribution, the muscles furthest away from the cortex are innervated from the most superior part of the area, the leg area being in the superomedial border of the hemisphere, while that for the head is in the anterior and inferior part of the area (fig. 778). The muscles of mastication and the laryngeal muscles are controlled from the frontoparietal operculum. Broca's convolution, the opercular portion and part of the triangular portion of the inferior frontal gyrus of the left hemisphere, constitutes the especial motor coördination-area of speech, and Mills extended this area to include the superoanterior portion of the insula below. The various authorities differ considerably as to the exact locations of many of the areas for the cortical control of given sets of muscles. Further observations must be skillfully made for localization of areas of the human cortex in detail and further correlations must be determined between the experiments upon the cortex of anthropoid apes and the functions of that of man. The accompanying diagrams (figs. 778, 779) are compiled from several of the diagrams more usually given and must be considered as only approximately correct.

(2) **The visual area.**—The especial sensory portion of this area is that immediately bordering upon either side of the posterior part of the calcarine fissure. The entire area, motor and sensory overlapping each other, includes the whole of the cuneus. The motor visual area proper is described as the more peripheral portion of the entire area. In addition, an area producing

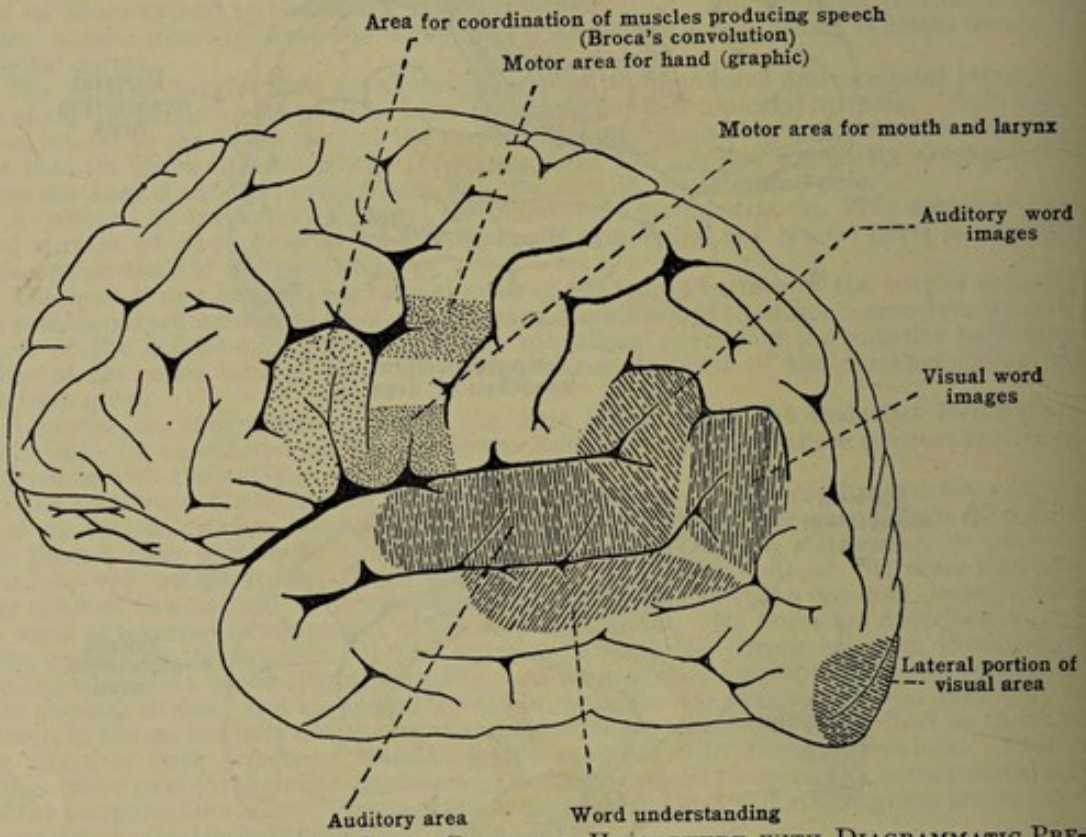

FIG. 779.—CONVEX SURFACE OF LEFT CEREBRAL HEMISPHERE WITH DIAGRAMMATIC PRESENTATION OF THE AREAS SUGGESTED AS CONCERNED WITH SPEECH.

eye movements is described as comprising the posterior end of the middle frontal gyrus. Optic aura and optic hallucinations have been reported as being experienced with electrical stimulation of the region of the lateral occipital gyri just inferior to the lateral end of the parieto-occipital fissure.

(3) **The auditory (cochlear) area** comprises the middle third of the superior temporal gyrus and the transverse temporal gyri of the temporal operculum. This area has been determined not only by lesions and degenerations but also by auditory aura experienced upon its stimulation. The motor portion of this area lies in its inferior border. The fibers arising in the area course downward in the temporal pontile path to the motor nuclei of the medulla.

(4) **The olfactory area** consists of the olfactory trigone, the parolfactory area, the subcallosal gyrus, part of the anterior perforated substance, the hippocampal gyrus (especially the uncus), and the callosal half of the gyrus cinguli. Its motor or efferent area lies chiefly in the hippocampal gyrus, the fibers from which pass out from the telencephalon by way of the fornix and cingulum.

(5) **The gustatory area** is supposed to comprise the anterior portion of the fusiform gyrus and the zone (motor portion) about the anterior extremity of the inferior temporal sulcus. The area has been claimed to extend through the isthmus of the gyrus fornicatus to include a part of the callosal margin of the gyrus cinguli.

(6) **The association-areas.**—The relatively large areas allotted at present to the so-called higher psychic activities are indicated in fig. 778. The great relative extent of these is one of the characteristics of the human brain. They probably merely represent the portions of the cortex of which little is known, and may eventually be subdivided into more specific areas. They are considered to be connected with the structures below by fewer projection fibers than are the recognized areas named above, while, on the other hand, they are rich in association fibers. By means of the latter they are in intimate connection with the specific areas and have

abundant means of correlating and exercising a controlling influence upon the functions of these areas. According to Flechsig, they consist of—(1) a *parietal association-area*, comprising that part of the parietal cortex between the somesthetic area and the visual area; (2) an *occipito-temporal association-area*, including the unspecified portions of the temporal lobe and the adjoining portion of the occipital lobe not included in the visual area; (3) a *frontal association-area* including all the frontal lobe anterior to the somesthetic and olfactory area. A large frontal area is especially distinctive of man. In the folds of the inferior parietal lobule of the parietal association-area such intellectual activities as the optic discrimination of words, letters, numbers, and objects generally are supposed to take place, while the superior parietal lobule continued into the posterior part of the præcuneus is the general region for the perception of form and solidity of objects—the stereognostic center. No sensory aura are experienced in stimulation of the frontal association area.

The *insula* is suggested as the area in which auditory, olfactory and gustatory impulses are associated with the motor areas beginning in the operculum dorsolaterally adjacent to it.

Observations of symptoms and the position of lesions accompanying them have made it possible to arrive at some trustworthy conclusions regarding the **cortical areas controlling speech.** Broca announced in 1861 that the inferior frontal gyrus of the *left* hemisphere was peculiarly concerned with speech. This area was later confined to the posterior end or opercular portion of this gyrus and the name 'Broca's Convolution' was given it. It is now known that Broca's convolution and the adjacent portion of the triangular part of the inferior frontal gyrus as well comprise the *motor* or *emissive speech-area*—the area especially devoted to the control of that coördinated action of the muscles concerned which makes possible articulate speech. Patients in whom this area is impaired are unable to give utterance to words though they may understand them both written and spoken, and though they may give utterance to sound. This inability is known as *motor aphasia*. Results of observed lesions have further shown that the area in which the *auditory images* of words are retained (word memories) comprises the posterior end of the superior temporal gyrus and the adjoining portion of the supramarginal gyrus. Injury to this area is accompanied by inability to recognize spoken words although the patient hears them and may recognize and understand written words, a phenomenon known as 'word-deafness' or auditory *sensory aphasia*. This area may be considered as continuous with the superior portion of the posterior end of the middle temporal gyrus which has been suggested as the area of 'word-understanding,' or *'lalognosis.'* On the other hand, the area in which visual images of words are retained is located as the angular gyrus. Injury to this results in an inability to recognize printed or written words although the patient may hear, understand and speak them. This is called *'word-blindness*, (visual sensory aphasia). This area is nearest the special area of vision on the one hand and on the other hand, is continuous into the area to which word-understanding is attributed. For purposes of writing, it must be associated with the motor area for the muscles of the hand in the precentral gyrus.

While the motor area for speech is most functional in the left hemisphere of right-handed individuals, and *vice versa*, the remaining areas concerned are probably equally functional in the two hemispheres.

III. GENERAL SUMMARY OF SOME OF THE PRINCIPAL CONDUCTION-PATHS OF THE NERVOUS SYSTEM

In the following summary the arabic numerals indicate the nuclei or ganglia containing the cell-bodies of the neurones interposed in the chains; the letters in parentheses indicate the different names given to the different levels of the pathways through which their fibers run. For detailed descriptions of either nuclei or pathways see pages describing them. Only the more common neurone-chains are followed here.

I. The Spinocerebral and Cerebrospinal System

A. *The ascending path of neurones* (fig. 780).

1. Spinal ganglion—neurone of first order.
   (*a*) Terminal corpuscles and peripheral process of T-fiber.
   (*b*) Dorsal or afferent root of spinal nerve.
   (*c*) Ascending branch of bifurcation of dorsal root fiber in fasciculus gracilis or fasciculus cuneatus of spinal cord.
2. Nucleus of fasciculus gracilis or nucleus of fasciculus cuneatus in medulla oblongata —neurone of second order.
   (*a*) Internal arcuate fibers.
   (*b*) Decussation of medial lemniscus.
   (*c*) Interolivary stratum of opposite side.
   (*d*) Medial lemniscus.
3. Inferior and lateral nuclei of thalamus—neurone of third order.
   (*a*) Internal capsule, posterior segment of frontoparietal portion.
   (*b*) Corona radiata, frontoparietal part.
4. Posterior central gyrus of somesthetic area of cerebral cortex.
   (*a*) Association and commissural fibers of cortex.

1*x*. Spinal ganglion—neurone of first order.
   (*a*) Terminals, especially in skin, and peripheral process of T-fiber.
   (*b*) Dorsal or afferent root of spinal nerve.
   (*c*) Collaterals and terminal branches of bifurcation of dorsal root-fiber within spinal cord.

2*x*. Gray substance of spinal cord, dorsal horn especially—neurone of second order.
   (*a*) Decussation of fibers to opposite side within spinal cord.
   (*b*) Spinothalamic and spinotectal paths (*spinal lemniscus*).

3x. Inferolateral nuclei of thalamus—neurone of third order.
(*a*) Internal capsule (medial side of frontoparietal portion).
(*b*) Corona radiata.
4x. Posterior central gyrus of cerebral cortex—neurone of fourth order.
(*a*) Association and commissural fibers of cortex.

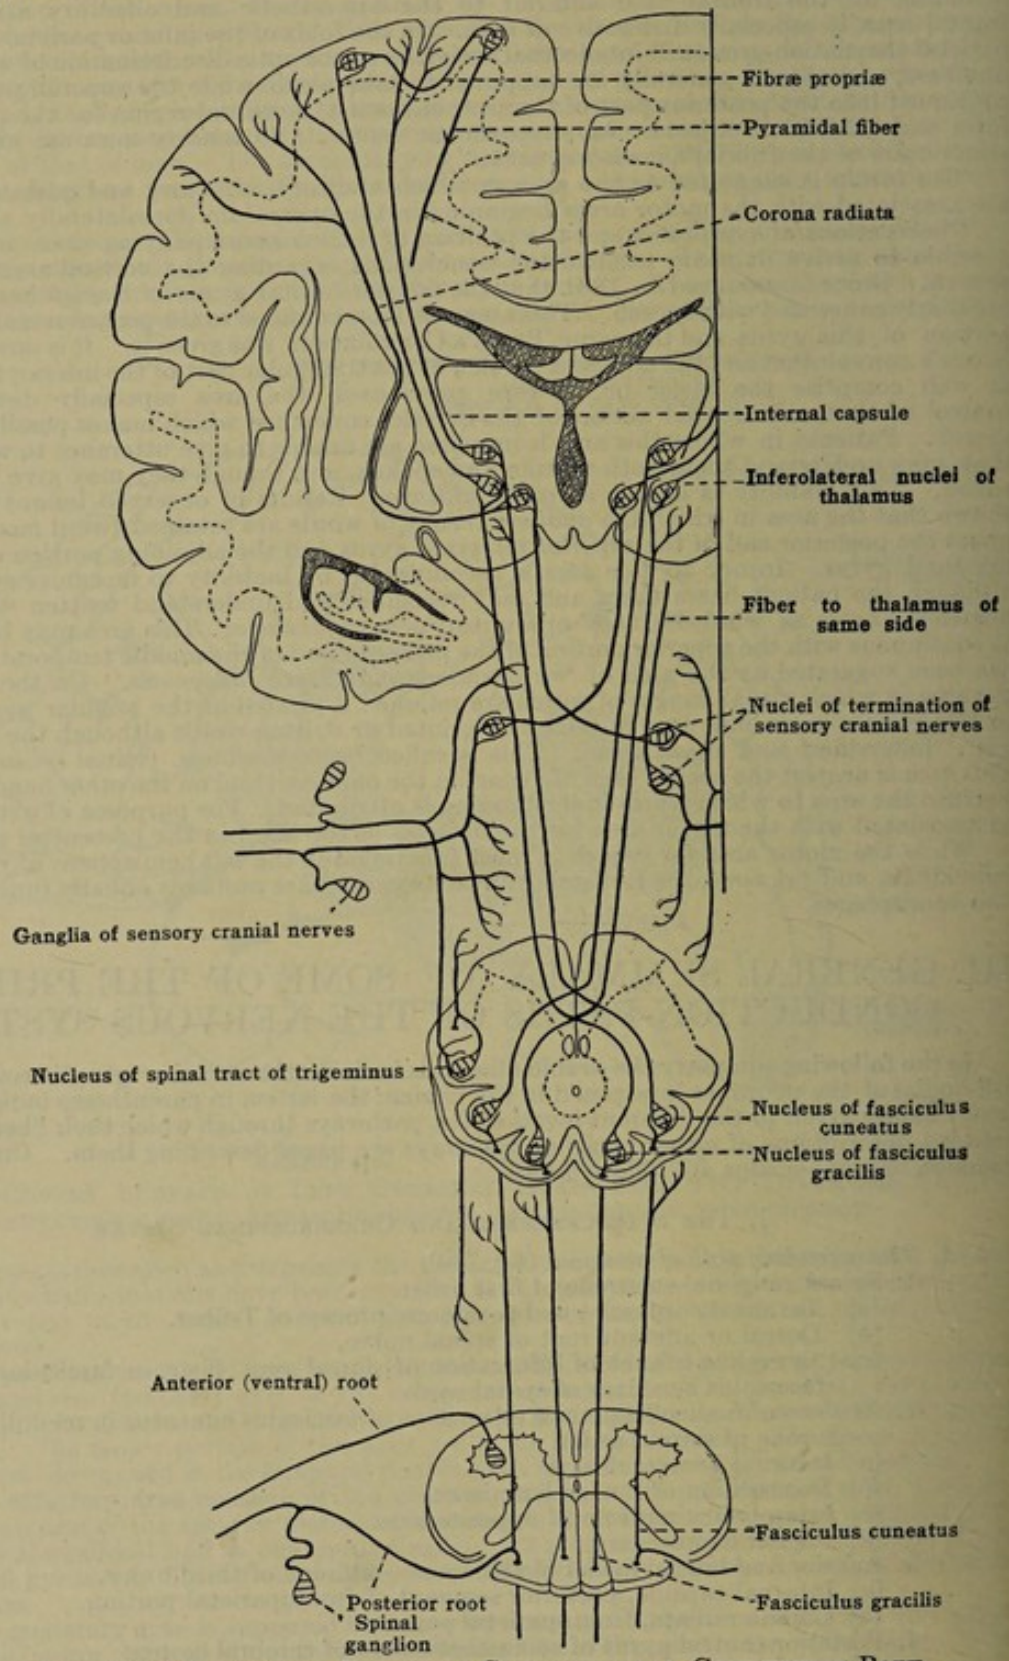

FIG. 780.—SCHEME OF PRINCIPAL SPINOCEREBRAL CONDUCTION-PATH.

B. Descending path of neurones (fig. 781).

1. Giant pyramidal cells of precentral gyrus of somesthetic area.
(*a*) Corona radiata, frontoparietal part.
(*b*) Internal capsule, middle segments of frontoparietal portion.
(*c*) Cerebral peduncle.
(*d*) Pyramid of medulla oblongata.
(e^1) Decussation of pyramids.

(f^1) Lateral cerebrospinal fasciculus (crossed pyramidal tract).
(e^2) Ventral cerebrospinal fasciculus (direct or uncrossed pyramidal tract).
(f^2) Gradual decussation of latter in cervical and upper thoracic regions of spinal cord.

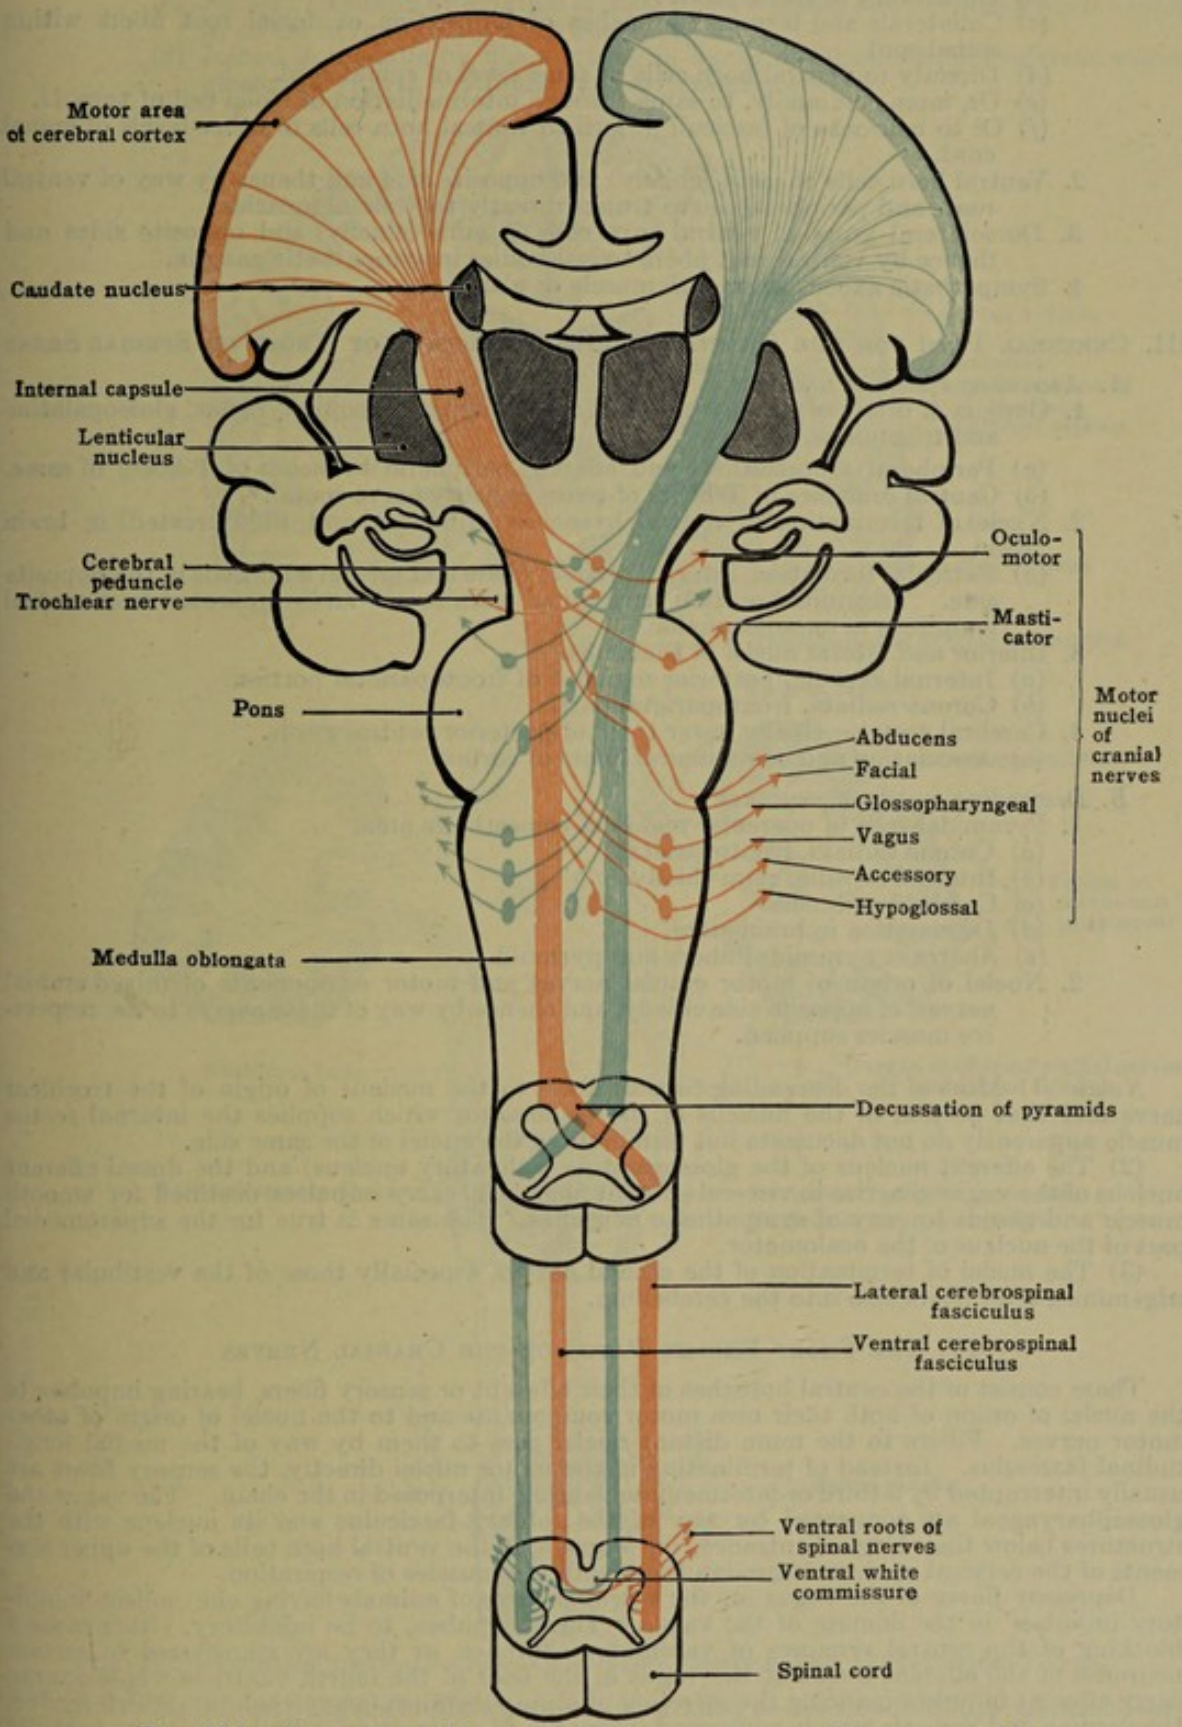

FIG. 781.—SCHEME OF DESCENDING CEREBROSPINAL CONDUCTION-PATH. (Extrapyramidal paths not included.)

1x. Extrapyramidal system, see p. 965.
2. Cells of ventral horn of spinal cord of opposite side.
   (a) Ventral or efferent roots of spinal nerves.
   (b) Peripheral nerve-trunks directly to skeletal muscles or indirectly to smooth muscle or glands by way of sympathetic neurones.

II. Short Reflex Paths of Spinal Cord

1. Spinal ganglia.
   (*a*) Terminal corpuscles and peripheral process of T-fibers.
   (*b*) Dorsal root of spinal nerve.
   (*c*) Collaterals and terminal branches of bifurcation of dorsal root fibers within spinal cord
   (*d*) Directly to ventral horn cells of same level of spinal cord.
   (*e*) Or, more commonly, to same through intermediation of Golgi cell of type II.
   (*f*) Or to neurones of fasciculi proprii to ventral horn cells of other levels of spinal cord.
2. Ventral horn cells of same (chiefly) and opposite side and thence by way of ventral roots and peripheral nerve trunks directly to skeletal muscles.
3. Dorsolateral group of ventral horn cells of same (chiefly) and opposite sides and thence by ventral root fibers to cell-bodies in sympathetic ganglia.
4. Sympathetic axones to smooth muscle or glands.

III. Cerebral Path for the Cranial Nerves, Exclusive of Those of Special Sense

A. Ascending system of neurones.

1. Ganglia of origin of sensory components of vagus, glossopharyngeus, glossopalatine and trigeminus.
   (*a*) Peripheral arborizations and afferent peripheral branches of T-fibers of same.
   (*b*) Central branches of T-fibers of same (sensory nerve roots).
2. Nuclei of termination of central branches (bifurcated and unbifurcated) in brain stem.
   (*a*) Reticular formation, internal arcuate fibers and medial lemniscus of the opposite side. Trigeminal portion (trigeminal lemniscus) courses separated from medial lemniscus in mesencephalon.
3. Inferior and lateral nuclei of thalamus.
   (*a*) Internal capsule, posterior segment of frontoparietal portion.
   (*b*) Corona radiata, frontoparietal part.
4. Cerebral cortex—chiefly lower third of posterior central gyrus.
   (*a*) Association and commissural fibers of cortex.

B. Descending system of neurones.

1. Pyramidal cells of opercular region of somesthetic area.
   (*a*) Corona radiata, frontoparietal.
   (*b*) Internal capsule, genu chiefly.
   (*c*) Cerebral peduncle.
   (*d*) Decussation in brain-stem.
   (*e*) Aberrant pyramidal fibers and pyramid.
2. Nuclei of origin of motor cranial nerves and motor components of mixed cranial nerves, of opposite side chiefly, and thence by way of these nerves to the respective muscles supplied.

Notes: (1) Most of the descending cortical fibers to the nucleus of origin of the trochlear nerve and that portion of the nucleus of the oculomotor which supplies the internal rectus muscle apparently do not decussate but terminate in the nuclei of the same side.

(2) The efferent nucleus of the glossopalatine (salivatory nucleus) and the dorsal efferent nucleus of the vagus give rise to visceral efferent fibers, i.e., carry impulses destined for smooth muscle and glands by way of sympathetic neurones. The same is true for the superomedial part of the nucleus of the oculomotor.

(3) The nuclei of termination of the cranial nerves, especially those of the vestibular and trigeminus, send fibers also into the cerebellum.

IV. The Short Reflex Paths of the Cranial Nerves

These consist of the central branches of their afferent or sensory fibers, bearing impulses to the nuclei of origin of both their own motor components and to the nuclei of origin of other motor nerves. Fibers to the more distant nuclei pass to them by way of the medial longitudinal fasciculus. Instead of terminating in the motor nuclei directly, the sensory fibers are usually interrupted by a third or intermediate neurone interposed in the chain. The vagus and glossopharyngeal are connected by way of the solitary fasciculus and its nucleus with the structures below their level of entrance, the vagus with the ventral horn cells of the upper segments of the cervical cord, and through these with the muscles of respiration.

Depressor fibers of the vagus (or the *depressor nerve* of animals having one) collect 'inhibitory impulses' in the domain of the vagus. These impulses, to be inhibitory, either cause a blocking of the central synapses of vasomotor neurones, or they are transferred to certain neurones of the efferent nuclei of the vagus in the floor of the fourth ventricle whose axones carry efferent impulses inducing the secretion of some substance (acetylcholine?) which renders the cardiac and smooth muscle concerned incapable of contraction. Probably a sympathetic neurone is a link in such a chain as the latter, but the components of the inhibitory chain are not known with certainty.

V. Conduction-Paths Involving the Cerebellum

A. Ascending cerebellar pathways.

1. Spinal ganglia.
   (*a*) Terminal corpuscles, trunks and dorsal roots of spinal nerves.

(*b*) Collaterals and terminal branches of bifurcation of dorsal root fibers in spinal cord, chiefly those conveying impulses of *muscle-sense*.

2*x*. Dorsal nucleus (Clarke's column).

(*a*) Dorsal spinocerebellar fasciculus (direct cerebellar tract).

(*b*) Restiform body (inferior cerebellar peduncle)—

(*c*) Joined in medulla by external arcuate fibers (crossed and uncrossed fibers arising in nuclei of funiculus gracilis and cuneatus);

(*d*) Joined in medulla by fibers arising in nuclei of termination of afferent vagus, glossopharyngeal, vestibular, and trigeminal nerves;

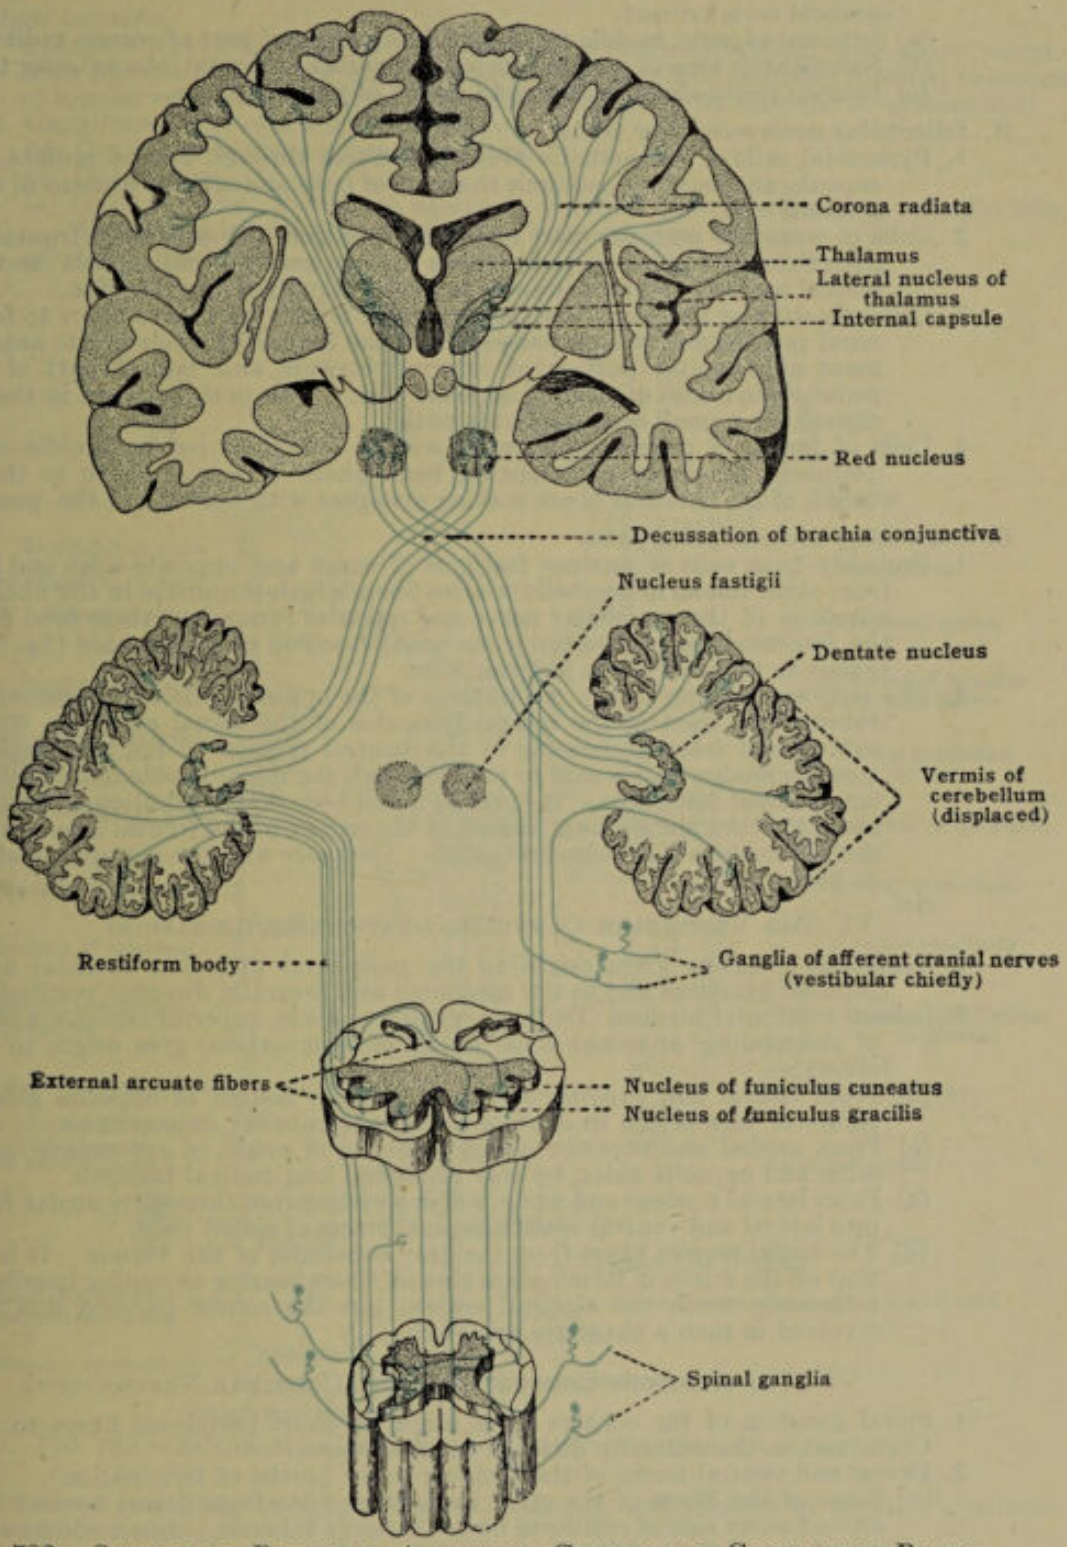

FIG. 782.—SCHEME OF PRINCIPAL ASCENDING CEREBELLAR CONDUCTION-PATHS.

(*e*) Joined by fibers both to and from (ascending and descending) the inferior olivary nucleus of the same and especially opposite sides (*olivo-cerebellar fibers*).

2*y*. Nerve-cells in base of ventral horn of same and opposite side (lumbosacral region).

(*a*) Superficial anterolateral spinocerebellar fasciculus (Gowers' tract), ascending through spinal cord and reticular formation of medulla and pons.

(*b*) Anterior medullary velum and brachium conjunctivum to cerebellar cortex (vermis chiefly).

3. Cerebellar cortex, dentate nucleus, nucleus fastigii, nucleus emboliformis, and nucleus globosus.

(*a*) White substance (corpus medullare) of cerebellum, associating various regions of its cortex and its nuclei with each other.
(*b*) Brachium conjunctivum (superior cerebellar peduncle) arising chiefly from dentate nucleus.
(*c*) Decussation of brachium conjunctivum.

4. Red nucleus and lateral nucleus of thalamus. Most fibers of the brachium conjunctivum terminate in the red nucleus; many merely give off collaterals to it in passing to their termination in the thalamus. Most of the ascending fibers arising in the red nucleus also terminate in the thalamus; some ascend to the cerebral cortex direct.
   (*a*) Internal capsule, middle third, and frontoparietal part of corona radiata.
   (*b*) Somesthetic area of cerebral cortex and cortex of frontal lobe anterior to it.
   (*c*) Inferior peduncle of thalamus to cortex of temporal lobe.

B. *Descending cerebrocerebellar paths.*

1. Pyramidal cells of somesthetic area send fibers through corona radiata, internal capsule, and cerebral peduncle to nuclei of pons and arcuate nucleus of same and opposite side.
2. Cells of cortex of posterior part of frontal lobe give fibers to form frontal pontile path through frontal parts of corona radiata and internal capsule and through medial part of cerebral peduncle to nuclei of pons of opposite side.
3. Cells of cortex of temporal lobe (superior and middle gyri) give fibers to form temporal pontile path which passes under the lenticular nucleus into anterior segment of occipital portion of internal capsule and lateral part of cerebral peduncle to nuclei of pons of opposite side. This path is joined in the internal capsule by a small occipitopontile path.
4. Cells of nuclei of pons send fibers by way of brachium pontis (middle cerebellar peduncle) to cortex of cerebellar hemisphere of side opposite to that of the origin of the cerebral fibers making synapses with the cells of the pons.

C. *Descending cerebellospinal paths.*

1. Probably from cells of nucleus fastigius of same and opposite sides and probably from other nuclei of cerebellum arise fibers which terminate in the nuclei of termination of the vestibular nerve and reticular formation; these send fibers into the intermediate and anterior marginal fasciculi of spinal cord (fig. 698), and thence to the cells of the anterior horn.
2. The pathway arising in the red nucleus of the opposite side and descending in the rubrospinal tract of the lateral funiculus of the spinal cord (fig. 698). The rubrospinal tract decussates in the ventral portion of the tegmentum of the mesencephalon and is said to pass through the medulla oblongata in the medial longitudinal fasciculus. It must be noted here that in addition to the brachium conjunctivum some fibers arising in the cortex of the frontal lobe terminate in the red nucleus (corticorubral path). Compare with the extrapyramidal paths, p. 965.

VI. The Vestibular Conduction-Paths (Equilibration)

1. Vestibular ganglion gives origin to the peripheral utricular, saccular and three ampullar branches and to the combined and centrally directed vestibular nerve.
2. Lateral vestibular nucleus (Deiters'), medial nucleus, superior nucleus, and nucleus of descending or spinal root (nuclei of termination) give origin to fibers as follows:—
   (*a*) From lateral and superior nuclei to nucleus fastigii of opposite side and to cortex of vermis and to dentate nucleus (cerebellar connection).
   (*b*) From medial and superior nuclei to nuclei of origin of eye-muscle nerves of same and opposite sides, by way of medial longitudinal fasciculi.
   (*c*) From lateral nucleus and nucleus of descending root through reticular formation into lateral and ventral vestibulospinal tracts of spinal cord.
   (*d*) The nuclei receive fibers from the gray substance of the vermis. It is possible that all the nuclei of termination give off fibers bearing ascending impulses which ultimately reach the cerebral cortex, but the course pursued and neurones involved in such a chain are uncertain.

VII. The Auditory Conduction-Path (Cochlear Nerve)

1. Spiral ganglion of the cochlea gives origin to short peripheral fibers to organ of Corti, and to the centrally directed cochlear nerve.
2. Dorsal and ventral nuclei of the cochlear nerve (nuclei of termination).
   (*a*) Some of the fibers of the striæ medullares arise from dorsal nucleus and pass around outer side of restiform body (acoustic tubercle), then medianward under ependyma of floor of fourth ventricle to midline, then ventralward into tegmentum, where they decussate and join trapezoid body and lateral lemniscus of opposite side.
   (*b*) Fibers arising in ventral nucleus pass ventrally medianward and some terminate in the superior olivary nucleus of same side; others pass by way of trapezoid body and lateral lemniscus to terminate in superior olivary nucleus, nucleus of lateral lemniscus, medial geniculate body and nucleus of inferior quadrigeminate body of the opposite side.
3. Nuclei of superior olives of both sides and nucleus of lateral lemniscus send fibers to reticular formation and medial longitudinal fasciculus, associating auditory impulses with the nuclei of the motor cranial nerves.

4. Fibers from medial geniculate body and probably some from nucleus of inferior quadri geminate body pass into internal capsule and through temporal part of corona radiata to middle third of superior temporal gyrus and adjacent portions (auditory area).
5. It is probable that fibers from the auditory area of the cerebral cortex are also distributed to nuclei of the motor cranial nerves by way of the inferior quadrigeminate bodies.

VIII. Conduction-Paths of the Visual Apparatus

A. Optic impulses.

1. Synapses of central processes of rods and cones (neuroepithelium) with short (peripheral) processes of bipolar cells of retina and synapses of centrally directed processes of bipolar cells with dendrites of ganglion cells of retina (nucleus of termination).
2. Ganglion-cells of retina give origin to—
   (*a*) Optic (nerve-fiber) stratum of retina.
   (*b*) Optic nerve.
   (*c*) Optic chiasma; fibers from nasal side of retina cross in chiasma to opposite side; fibers from lateral side of retina continue on same side in—
   (*d*) Optic tract to —

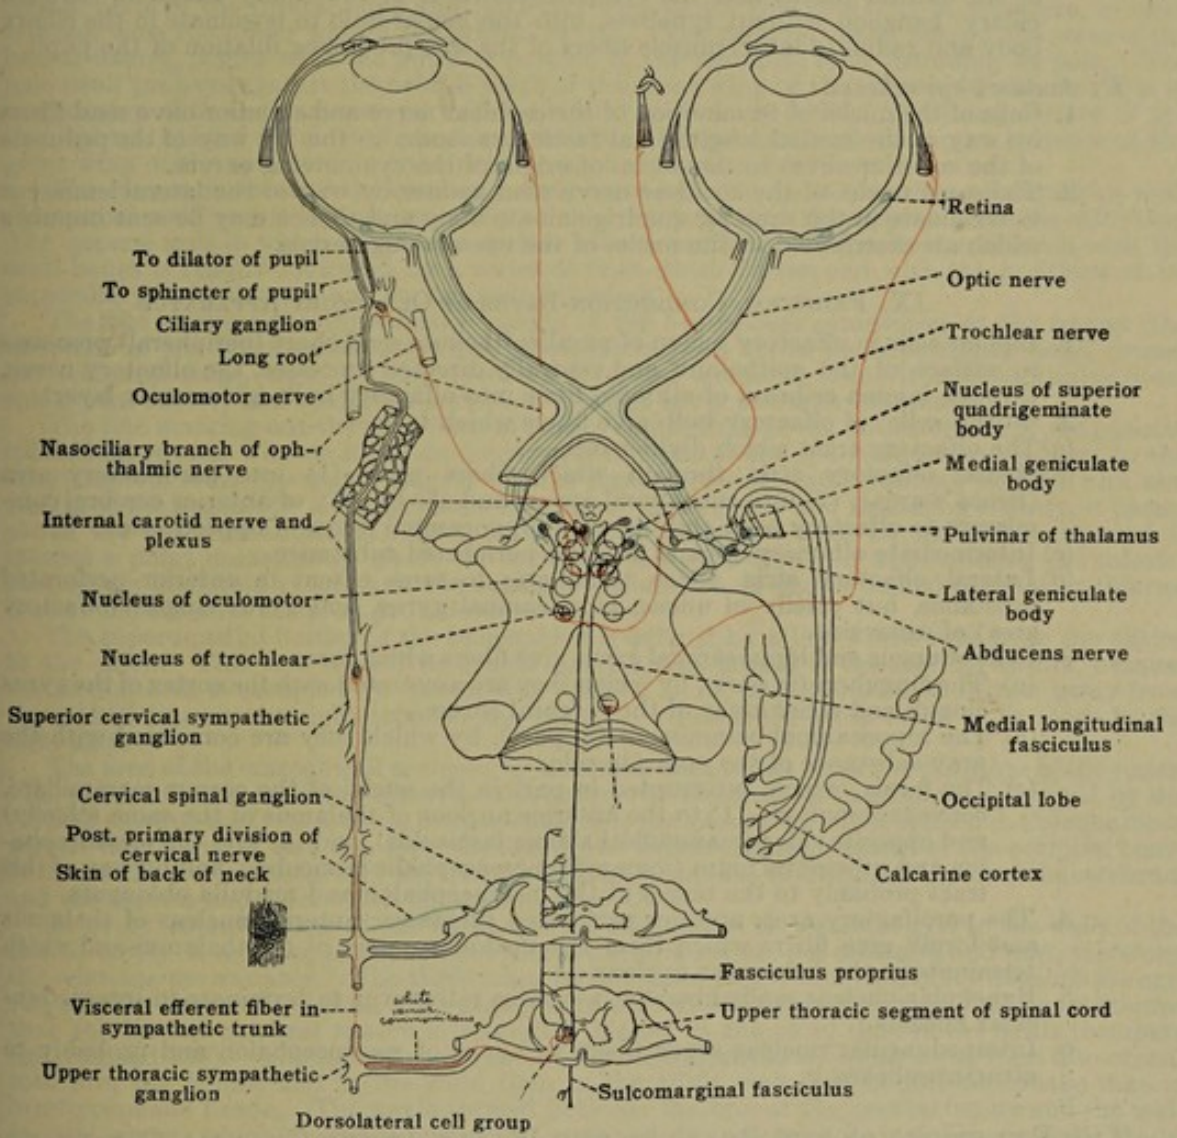

Fig. 783.—Diagram of Principal Pathways of Optic Apparatus.

3. Lateral geniculate body, pulvinar of thalamus, and nucleus of superior quadrigeminate body.
   (*a*) Fibers from nucleus of superior quadrigeminate body pass ventrally, to nuclei of origin of oculomotor and trochlear nerves and to medial longitudinal fasciculus of same and opposite sides, and from it are distributed to nuclei of origin of abducens and facial nerves.
   (*b*) Fibers from lateral geniculate body, chiefly, and pulvinar pass through occipital portion of internal capsule and occipitothalamic radiation (optic radiation) to cortex of occipital lobe (visual area).
4. Cells of visual area of cortex send fibers through occipitothalamic radiation and occipital portion of internal capsule to nucleus of superior quadrigeminate body (occipitomesencephilic fasciculus), and thence, probably interrupted by cells of this nucleus, the impulses are carried to nuclei of eye-muscle nerves.

5. Cells of nucleus of superior quadrigeminate body and pulvinar send fibers by way of medial longitudinal fasciculus into lateral and ventral funiculi of spinal cord (see fig. 698), chiefly of the opposite side. Fibers from the quadrigeminate body cross midline chiefly in decussation of 'optic-acoustic reflex path' (fig. 741) and in fountain decussation.
6. The smaller cells of the superomedial group of the nucleus of the oculomotor nerve (nucleus of Edinger and Westphal) send axones, by way of the trunk of the nerve and the short root of the ciliary ganglion, which terminate about cells in—
7. The ciliary ganglion, whose cells send axones to enter the ocular bulb and terminate upon the smooth muscle fibers of the ciliary body and sphincter of the iris.

B. Spinopupillary ('ciliospinal') reflexes.

1. Peripheral processes of spinal ganglion cells terminating in the skin and central processes of same entering by way of dorsal roots of spinal nerves to bifurcate in spinal cord and give terminal twigs about—
2. Cells of the dorsolateral group of the ventral horn of the same and opposite sides of cervical and upper thoracic regions of spinal cord. These cells send (visceral efferent) axones by way of white rami communicantes of upper thoracic nerves and sympathetic trunk to terminate about cells in—
3. The superior cervical sympathetic ganglion, which cells send axones chiefly by way of the carotid plexus and the sympathetic roots of the ciliary ganglion, through ciliary ganglion without synapses, into the ocular bulb to terminate in the ciliary body and radial (dilator) muscle fibers of the iris, producing dilation of the pupil.

C. Auditory-eye reflexes.

1. Cells of the nuclei of termination of the cochlear nerve and superior olive send fibers by way of the medial longitudinal fasciculus (some to this by way of the peduncle of the superior olive) to the nuclei of origin of the eye-moving nerves.
2. The same nuclei of the cochlear nerve send axones by way of the lateral lemniscus to terminate in the superior quadrigeminate body and thence may be sent impulses which are distributed to the nuclei of the eye-moving nerves.

IX. Principal Conduction-Paths of Olfactory Apparatus

1. Bipolar cells in olfactory region of nasal epithelium send short (peripheral) processes to surface of the epithelium and centrally directed processes, the olfactory nerve, through lamina cribrosa of ethmoid bone into olfactory bulb (glomerular layer).
2. 'Mitral cells' of olfactory bulb give fibers which form—

(*a*) The olfactory tract which divides into—
(*b*) Medial olfactory stria through which fibers pass—(1) into parolfactory area (Broca's area); (2) into subcallosal gyrus; and (3) by way of anterior cerebral commissure to olfactory bulb and uncus of hippocampal gyrus of opposite side.
(*c*) Intermediate olfactory stria to anterior perforated substance.
(*d*) Lateral olfactory stria, which terminates to some extent in anterior perforated substance, but chiefly in uncus, hippocampal gyrus, and gyrus cinguli (olfactory area) of same side.

3. Cells of uncus and hippocampal gyrus give fibers which form—
   (*a*) The cingulum (in part), by which they are associated with the cortex of the gyrus cinguli and other areas of the cerebral cortex.
   (*b*) The hippocampal commissure (in part), by which they are correlated with the gray substance of the opposite side.
   (*c*) The fornix, which, interrupted in part in the nuclei of the corpus mammillare, conveys impulses—(1) to the anterior nucleus of thalamus of the same (chiefly) and opposite sides (mammillothalamic fasciculus), and (2) into the mesencephalon and substantia nigra (mammillomesencephalic fasciculus), and by way of this tract probably to the nuclei of the mesencephalon and medulla oblongata.
4. The parolfactory area, anterior perforated substance, anterior nucleus of thalamus and fornix give fibers which form the medullary stria of the thalamus and which terminate in the habenular nucleus.
5. Habenular nucleus sends fibers in fasciculus retroflexus to terminate in interpeduncular nucleus.
6. Interpeduncular nucleus sends fibers to nuclei of mesencephalon and probably to structures below it.

The Relations of the Brain to the Walls of the Cranial Cavity

The precise methods by which the exact positions of the most important fissures, sulci, gyri, and areas can be ascertained and mapped out on the surface of the head in the living subject are usually described in the textbooks of surgery. Here, only a very general survey of the relations of the brain to the cranial bones is given and from a purely anatomical standpoint (fig. 784).

The parts of the brain which lie in closest relation with the walls of the cranial cavity are the olfactory bulb and tract, the basal and lateral surfaces of the cerebral hemispheres, the inferior surfaces of the lateral lobes of the cerebellum, the ventral surfaces of the medulla and pons, and the hypophysis.

Certain of these portions of the brain lie in relation with the basicranial axis, that is, with the basioccipital, the basisphenoid, and the ethmoid bones, while others are associated with the sides and vault of the cranial cavity. Considering the former portions first, the ventral surface of the medulla oblongata, which is formed by the pyramids, lies upon the upper surface of the basioccipital bone. More superiorly the ventral surface of the pons rests upon the basisphenoid, from which it is partly separated by the basilar artery and the pair of abducens

nerves. In front of the dorsum sellæ the hypophysis (pituitary body) is lodged in the hypophyseal fossa. Still further forward the olfactory tracts lie in grooves on the upper surface of the presphenoid section of the sphenoid bone; and in front of the sphenoid the olfactory bulbs rest upon the cribriform plates of the ethmoid.

Posterior and lateral to the posterior part of the foramen magnum the hemispheres of the cerebellum are in relation with the cranial wall, resting upon the lower parts of the supraoccipital and the posterior parts of the exoccipital portions of the occipital bone, while anteriorly each hemisphere is in relation with the inner surface of the mastoid process and the posterior surface of the petrous portion of the temporal bone. The area of the cranial wall which is in close relationship with the cerebellar hemispheres may be indicated, on the external surface of the skull, by a line which commences at the inferior part of the external occipital protuberance and thence runs upward and lateralward. It crosses the superior nuchal line a little beyond its center, and, continuing in the same direction, crosses the inferior part of the lambdoid suture and reaches a point directly above the asterion (the meeting point of the occipital, temporal, and parietal (bones); thence it descends, just in front of the occipitomastoid suture, to the tip of the mastoid process, and there turns medialward to its termination at the margin of the foramen magnum, immediately behind the posterior end of the occipital condyle.

The basal surface of each cerebral hemisphere may be said to consist of two parts, an anterior and a posterior, separated by the stem of the lateral cerebral (Sylvian) fissure. The anterior part, formed by the orbital surface of the frontal lobe, rests upon the upper surfaces of the orbital plate of the frontal bone and the lesser wing of the sphenoid. It is, therefore, in close relation with the upper wall of the orbital cavity. The posterior part, behind the stem of the lateral fissure, begins with the anterior portion of the temporal lobe, including its pole. The pole itself projects against the orbital plate of the great wing of the sphenoid bone, and it is in relationship with the posterior part of the lateral wall of the orbit. The basal surface of the hemisphere, behind the pole of the temporal lobe, is in contact with the upper surfaces of the great wing of the sphenoid and the petrous part of the temporal bone.

The convex surfaces of the cerebral hemispheres have the most extensive relationships with the cranial wall, and it is more especially to these surfaces that the surgeon turns his attention. The general area in which the convex surface of each cerebral hemisphere is in relation with the skull bones is readily indicated by a series of lines which correspond with the positions of its superciliary, inferolateral, and superomedial borders.

The line marking the superciliary margin of the hemisphere commences at the nasion (the midpoint of the frontonasal suture); it passes lateralward above the superciliary ridge, crosses the temporal ridge, then, turning posteriorly in the temporal fossa, it reaches the parietosphenoidal suture, and continues backward along it to its posterior extremity.

The line marking out the inferolateral border commences at the posterior end of the parietosphenoidal suture, whence it passes downward, in front of the sphenosquamous suture, to the infratemporal crest (pterygoid ridge); there it turns posteriorly and, running parallel with and medial to the zygomatic arch, it crosses the root of the zygoma, and ascending slightly, it passes above the external auditory meatus. Continuing backward with an inclination upward it reaches a point immediately above the asterion; thence it descends, and, crossing the inferior part of the lambdoid suture and the superior nuchal line, it passes medialward to the inferior part of the external occipital protuberance.

The superomedial border of the hemisphere is defined by a line which runs from the nasion to the inion. This line should be drawn about 5 mm. lateral to the sagittal suture, because the medial area is occupied by the superior sagittal sinus, and it should be further away from the middle line on the right than on the left side, because the sinus tends to lie more to the right side.

The area of the cranial wall enclosed by the three lines which mark the positions of the superciliary, inferolateral, and the superomedial borders of the cerebral hemisphere is formed by the vertical plate of the frontal bone, the parietal bone, the great wing of the sphenoid, the squamous part of the temporal, and the upper section of the supraoccipital segment of the occipital bone. It covers the convex surfaces of the frontal, parietal, temporal, and occipital lobes of the cerebrum and the fissures and sulci which bound and mark them.

In every consideration of the topographical relations of the cerebral gyri to the walls of the cranial cavity it must be borne in mind that the conditions are not constant, and that, therefore, the relations are variable. The three main factors upon which this variability depends are age, sex, and the shape of the skull. As examples of the variations which occur it may be mentioned that the lateral cerebral fissure is relatively higher in the child than in the adult (compare figs. 784 and 785). The superomedial end of the central sulcus is further away from the coronal suture in the female and in the child than in the adult male, and in dolichocephalic than in brachycephalic heads. The angle formed between the line of the central fissure and the midsagittal plane, which averages about 68° in the adult, is more acute in dolichocephalic heads, and the external part of the parietooccipital fissure is further forward in the child, and possibly in the female, than it is in the adult male.

The position of the posterior horizontal limb of the lateral fissure varies even in the adult. Its posterior part is always under cover of the parietal bone, and it terminates either in front of or inferior to the parietal eminence, but the anterior part may be above, parallel with, or inferior to the squamoparietal suture. In the adult the anterior part of the fissure runs upward and backward from the posterior end of the sphenoparietal suture along the anterior part of the squamoparietal suture to its highest point; thence it continues in the same direction beneath the parietal bone toward the lambda, terminating either in front of or below the parietal eminence. In the child, however, the fissure is considerably above the line of the squamoparietal suture (fig. 785), which it gradually approaches, attaining its adult position about the ninth year. This change of position, which occurs during the first nine years, is due partly to the ascent of the sutural line and partly to the descent of the fissure on the surface of the brain.

The frontal bone always covers the superior, middle, and inferior frontal gyri, except their posterior extremities, which are beneath the parietal bone (fig. 784). The ascending limb (ra-

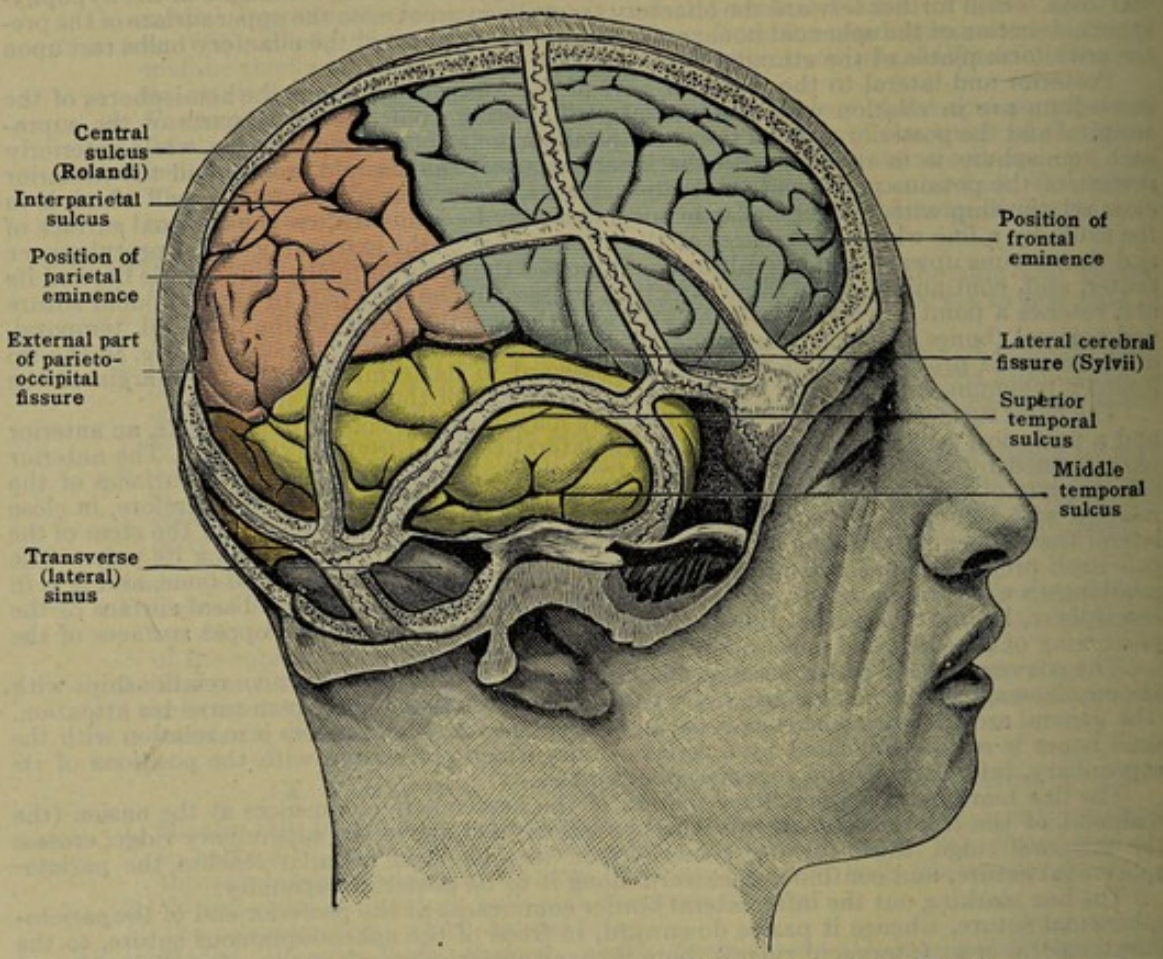

FIG. 784.—DRAWING OF A CAST OF THE HEAD OF AN ADULT MALE.

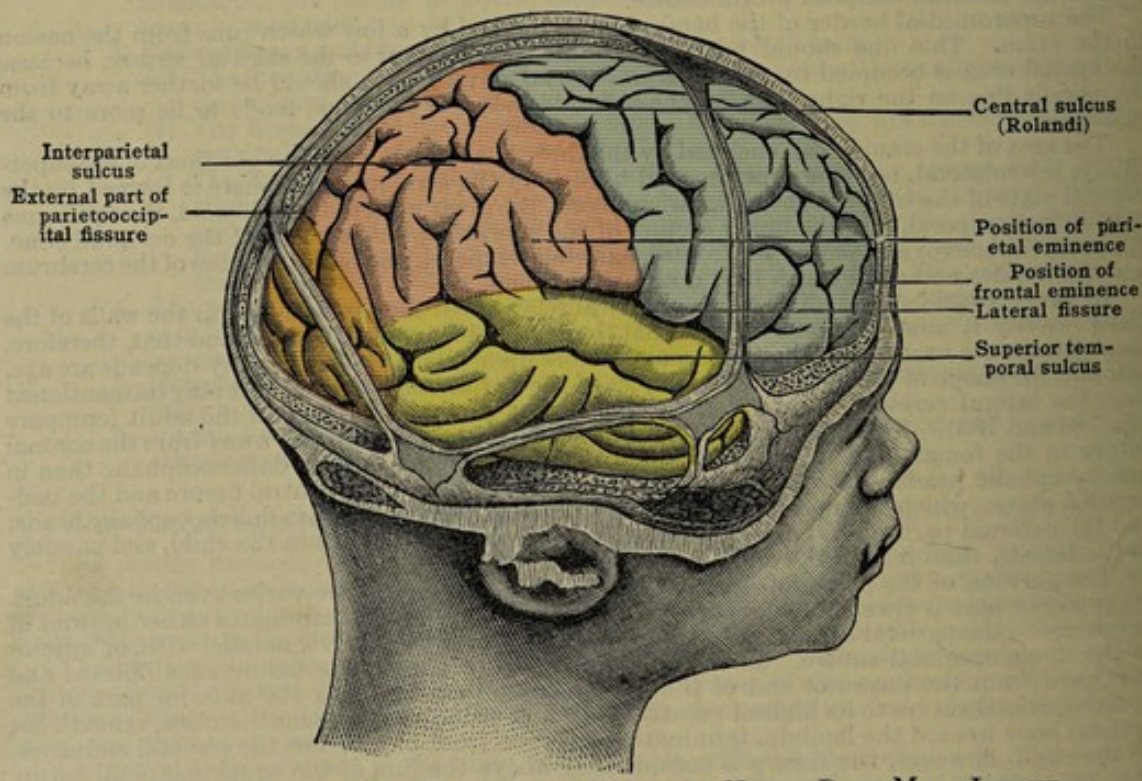

FIG. 785.—DRAWING OF A CAST OF THE HEAD OF A NEWLY BORN MALE INFANT.
(Prepared by Professor Cunningham to illustrate craniocerebral topography.)

mus anterior ascendens) of the lateral fissure, which cuts into the posterior part of the inferior frontal gyrus, runs parallel with and under cover of the lower part of the coronal suture, or immediately in front of it, and the anterior horizontal limb is parallel with and beneath the upper margin of the great wing of the sphenoid.

The parietal bone is in relation with the convex surfaces of four lobes of the cerebrum. Speaking very generally, it may be said that the anterior third covers the posterior part of the frontal lobe, including the anterior central gyrus, the precentral sulcus and the posterior ends of the superior, middle and inferior frontal gyri. The posterior two-thirds of the bone are superficial to the parietal lobe, the posterior part of the temporal lobe, the anterior part of the occipital lobe, the posterior part of the horizontal limb of the lateral fissure, the superior and inferior parts of the postcentral sulcus, the interparietal sulcus, the posterior sections of the superior and middle temporal sulci, and the external part of the parieto-occipital fissure. The central sulcus is beneath the parietal bone at the junction of its middle and anterior thirds (fig. 784).

In the adult, the upper end of the central sulcus is situated at about 55 per cent. of the whole length of the nasoinionic line posterior to the nasion. It is about 4 or 5 cm. from the coronal suture. The inferior end of the sulcus, which extends to near the posterior horizontal limb of the lateral fissure, lies beneath the point of intersection of the auriculobregmatic line with a line drawn from the stephanion (the point where the temporal ridge cuts the coronal suture) to the asterion. This point is about 46 per cent. of the horizontal arc measured from the glabella to the inion.

The superior end of the parieto-occipital fissure usually lies about 5 mm. in front of the lambda, and the course of the fissure may be indicated by a line drawn from 5 mm. in front of the lambda to a point immediately above the asterion, and, as the latter point corresponds with the preoccipital notch on the inferolateral border of the hemisphere, the line in question will indicate the adjacent margins of the parietal, temporal, and occipital lobes.

The occipital bone is in close relation with the cerebellum, as already pointed out, but it also covers the posterior part of the lateral surface of the occipital lobe of the cerebral hemisphere. The great wing of the sphenoid covers the outer surface of the pole of the temporal lobe, and the squamous part of the temporal bone covers the anterior parts of the superior, middle, and inferior temporal gyri and the sulci which separate them.

The Blood-Supply of the Encephalon

The double origin of the continuous arterial system of the brain given by the confluence of the two vertebral arteries and the two internal carotid arteries, together with the description of the general distribution of the different cerebral, mesencephalic, and cerebellar arteries into which the system is divided, and the origin and course of the corresponding veins, are fully dealt with in Section VI. Here attention may be called briefly to the abundant and systematic internal distribution of the terminal branches of the system and their intimate arrangement for the nourishment of the actual nervous tissues within.

The general plan of the blood-supply for the entire encephalon may be summarized as follows:—(1) At their origin the different arteries are so connected, directly or indirectly, on the base of the encephalon, that the blood approaching the brain by way of the vertebral and internal carotid arteries is practically a common supply for all the arteries of the encephalon, and a given part of it may possibly pass into any one of them. (2) In the pia mater of each gross division of the encephalon, the different arteries again become connected with each other in a superficial, freely anastomosing plexus, continuous throughout. (3) From this plexus of the surface, naturally composed in part of the trunks of the different arteries themselves, arise central branches which enter directly into the nervous substance and which break up into twigs that are *terminal;* i.e., twigs that *do not* anastomose internally with the twigs of other central branches. (4) The arterial capillary system arising from the terminal twigs passes over into venous capillaries which converge to form corresponding venous twigs which in their turn pass to the surface and join in forming a peripheral, anastomosing venous plexus superimposed upon the similar arterial plexus. Thrombus or destruction of a central artery deprives of nourishment the domain it supplies, resulting in local necrosis (softening of the brain). (5) From this superficial venous plexus arise the different veins of the encephalon which may or may not accompany the arteries for a short distance, and which finally empty into the sinuses in the cranial dura mater. These, likewise confluent, empty into the internal jugular veins. The choroid plexuses of the ventricles of the brain are modifications of the general anastomosing peripheral plexuses. The choroid plexuses of the lateral and third ventricles are derived largely from the branches of the choroid arteries, which arise separately from the internal carotid arteries.

The blood-supply of the cerebrum may best be taken as an illustration of the general plan of the blood-vascular system of the encephalon. The terminal or internal branches of the surface plexus, derived from the posterior, middle, and anterior cerebral arteries, are arranged into two groups, a **ganglionic** (nuclear) and a **cortical group.** The **ganglionic** branches themselves form four groups in each hemisphere:—

(1) The *anteromedial group* consists of central branches from the plexus of the domain of the anterior cerebral artery, which pass through the medial part of the anterior perforated substance and supply the head of the caudate nucleus, the septum pellucidum, the columns of the fornix, and the lamina terminalis.

(2) The *anterolateral group* consists of central branches from the domain of the middle cerebral artery. These pierce the anterior perforated substance in two subgroups—(*a*) the internal and (*b*) the external striate arteries (fig. 786). The **internal striate arteries** pass through the segments of the globus pallidus of the lenticular nucleus and through the internal capsule, to both of which they give branches, and they terminate in the caudate nucleus and thalamus. The **external striate arteries** are larger and more numerous. They pass upward between the external capsule and the putamen, and then through or around the upper part of the putamen into the internal capsule, where they form two groups, the *lenticulothalamic*

and the *lenticulocaudate groups*. The former terminate in the thalamus and the latter in the caudate nucleus. On account of its larger size at its origin and its direct linear continuation with the internal carotid, emboli (*thrombi*) pass more frequently into the middle cerebral artery than into the anterior cerebral artery. One of the lenticulocaudate arteries which is larger and longer than the others and which is a direct branch from the middle cerebral artery has been called the **'artery of cerebral hemorrhage'** (Charcot), on account of the greater frequency with which it is blocked and ruptured.

(3) The *posteromedial* arteries are central branches of the posterior cerebral artery. They also enter the anterior perforated substance, but supply the floor of the third ventricle, the posterior part of the thalamus, and the hypothalamic region.

(4) The *posterolateral group* are also central branches of the posterior cerebral artery. They supply the posterior part of the internal capsule, the pulvinar of the thalamus, the geniculate bodies, the corpora quadrigemina and their brachia, the pineal body, and the cerebral peduncles.

The *cortical group* of the cerebral arteries arise from the anastomosing plexus in the pia mater of the cortical surfaces of the hemisphere. They pass into the cortical substance both from the summits of the gyri and from the walls of the sulci. They consist of short, medium, and long central branches, and pass at right angles into the gyri. The short branches terminate in the cortical substance; the medium branches supply the more adjacent white substance, and the longer branches pass more deeply into the general medullary center of the hemisphere.

All of both the ganglionic and the cortical arteries are terminal in the sense that they do not anastomose in the substance of the cerebrum. (Pfeifer, however, describes such anastomoses.)

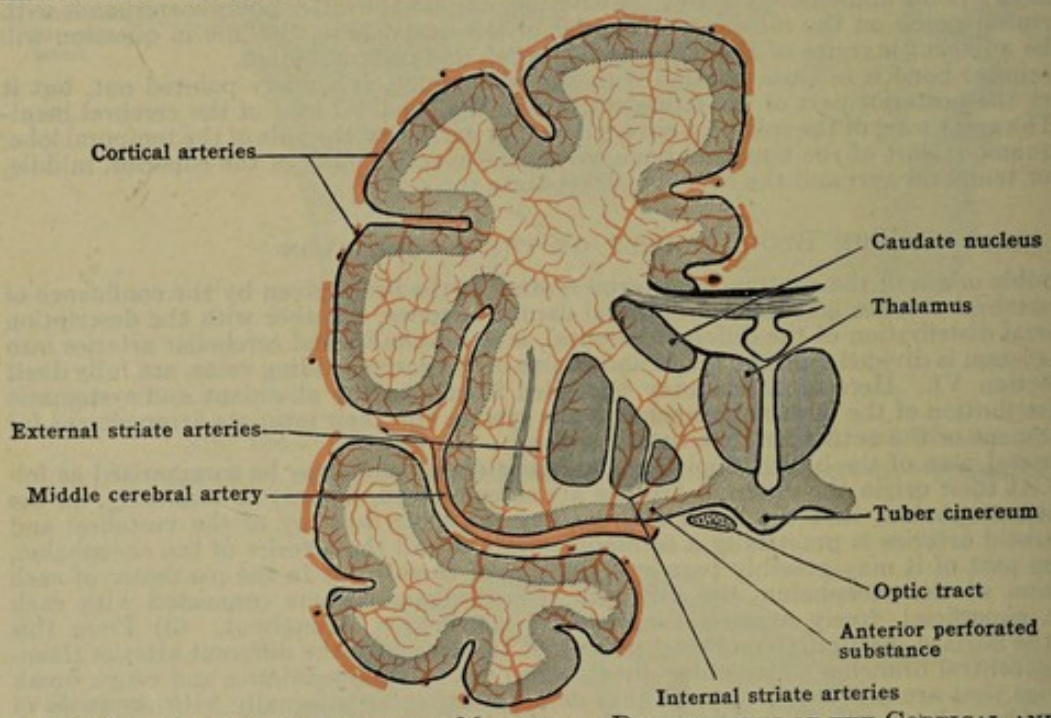

FIG. 786.—DIAGRAM SHOWING THE MANNER OF DISTRIBUTION OF THE CORTICAL AND CENTRAL BRANCHES OF THE CEREBRAL ARTERIES.

The blood-vascular system of the other divisions of the encephalon is in accordance with the same general plan of that of the cerebrum. Slight individual modifications of the general plan are to be expected.

The **blood-vessels of the mesencephalon,** in addition to the supply derived from the posterolateral group of ganglionic arteries, include the vessels of the quadrigeminate bodies and those of the cerebral peduncles. The **arteries** of the quadrigeminate bodies are usually six in number, three for each side—the **superior, middle,** and **inferior quadrigeminate arteries.** The superior and middle are branches of the posterior cerebral and the inferior are branches of the superior cerebellar arteries. The superior supply the superior quadrigeminate bodies and the pineal body; the middle supply both the superior and inferior quadrigeminate bodies, and the inferior the inferior quadrigeminate bodies. They all anastomose in the pia on the surface of the stratum zonale, forming a fine-meshed plexus, and from this superficial plexus the central branches pass into the substance of the bodies. The **veins** terminate in the vein of Galen (v. cerebri magna.)

The **arteries of the cerebral peduncles** form two groups, medial and lateral. The **medial peduncular arteries** are branches of the basilar and the posterior cerebral arteries. They pass to the medial sides of the peduncles and supply the superior and medial part of the tegmentum. The vessels of this group which accompany the fibers of the oculomotor nerves are known as the radicular arteries; they supply the root-filaments and the nuclei of the nerves, which receive no other branches. The **lateral peduncular arteries** are branches of the posterior cerebral and superior cellebellar arteries. They supply the lateral portions of the peduncles and the lateral part of the tegmentum. The **veins** of the midbrain terminate in the basilar veins and the vein of Galén.

The blood-vessels of the cerebellum.—Six **arteries** supply the cerebellum; two, the **posterior inferior cerebellar,** are derived from the vertebral arteries and the remaining four, two **anterior inferior** and two **superior cerebellar,** from the basilar artery. The course and

general distribution of the arteries are described in Section VI, but here it must be noted that the branches of these six vessels form a rich network in the pia mater on the surfaces of the cerebellar lobes, and that extensions of the plexus pass with the folds of the pia mater into the sulci and fissures. From the superficial plexus central branches pass into the interior of the cerebellum and their collaterals from capillary plexuses in the white and gray substance. These branches of the surface plexus are of three lengths:—(1) a longer set, which pass through the cortex of the cerebellum and supply the white substance of the corpus medullare; (2) a set of shorter arterioles which pass through the molecular layer of the cortex and break up in its granular layer; (3) the shortest set pass into the cortex and immediately break up in its molecular layer. The meshes of the capillary plexuses in the gray substance are ovoidal and their axes run radially. The meshes of the plexuses in the white substance are elongated parallel with the nerve-fibers. In addition to the vessels mentioned, a distinct central branch is distributed to each dentate nucleus. This springs either from the superior cerebellar or from the anterior inferior cerebellar artery of the corresponding side.

The **efferent veins** of the cerebellum do not accompany the arteries; they form a plexus in the pia mater which receives tributaries from the capillaries of the terminal branches of the central arteries in the interior, and they form two groups on each cerebellar surface, the vermian veins and the lateral veins. The **superior vermian vein** runs forward on the superior surface of the vermis and terminates in the vein of Galen. The **inferior vermian vein** runs posteriorly and ends in one of the transverse sinuses. The **superior lateral veins** open into the superior petrosal or transverse sinuses, and the **inferior lateral veins** into the inferior petrosal and transverse sinuses. The vein from the dentate nucleus usually joins the inferior lateral veins.

The blood-vessels of the pons.—The arteries to the pons are branches of the basilar artery, and of its anterior inferior and superior cerebellar branches. The plexus in the pia mater is comparatively unimportant, and the branches which enter the substance of the pons form two main groups, the central and the peripheral. The **central arteries** spring directly from the basilar. They pass backward along the raphe, giving branches to the adjacent parts, and they terminate in the nuclei of the pons and those in the floor of the fourth ventricle. The **peripheral arteries** are radicular and intermediate. The *radicular branches* spring from the peripheral plexus and from the anterior inferior cerebellar arteries; they accompany the roots of the trigeminus, abducens, facial, vestibular, and cochlear nerves, supply their fibers and the adjacent parts, and they end in the gray nuclei with which the nerve-fibers are connected. Of the radicular branches, the *internal auditory artery* is often quite large, arising directly from either the basilar artery (usually, figs. 536, 794) or from the anterior inferior cerebellar artery. For further details, see pp. 636, 1189. The *intermediate arteries* enter the surfaces of the pons irregularly and break up into capillaries in its substance, just as the central arteries. **The veins** form a plexus on the surface. The dorsal and lateral part of this plexus is drained into the basilar vein on each side, and the inferior part is connected by efferent channels with the inferior petrosal sinus and the cerebellar veins.

The blood-vessels of the medulla oblongata.—The **arteries of the medulla** are derived directly from the vertebral arteries, from their anterior and posterior spinal and posterior inferior cerebellar branches, and from the basilar artery. The branches of these vessels form a plexus in the pia mater from which, and from the arteries themselves, three main groups of vessels pass into the medulla—the choroidal, the central, and the peripheral. The **choroidal arteries** are derived chiefly from the posterior inferior cerebellar arteries. They supply the choroid plexus of the fourth ventricle. The **anterior central arteries** rise from the anterior spinal artery, from the basilar artery, and from the peripheral plexus; they pass caudalward along the raphe, supplying the adjacent parts of the ventral funiculi and the olivary bodies and they break up into fine terminals in the gray substance of the floor of the fourth ventricle around the nuclei of the cranial nerves. The **posterior central arteries** spring from the posterior spinal arteries; they pass down the median septum of the inferior part of the medulla and supply the adjacent nervous substance. The **peripheral arteries,** like those of the spinal cord, are separable into radicular and intermediate groups. The *radicular arteries* pass from the anterior and posterior spinal branches and from the trunks of the vertebral arteries and accompany the fibers of the last six cranial nerves into the substance of the medulla. They supply the nerve-roots and adjacent white substance and they terminate in capillaries in the gray substance of the lateral part of the floor of the ventricle. The *intermediate peripheral arteries* spring from the arteries previously named and from the peripheral plexus, and they pass directly into the funiculi of the medulla, where they terminate in a capillary plexus which supplies the white substance and the gray nuclei; some of these arteries, more especially those derived from the posterior inferior cerebellar and the posterior spinal arteries, extend inward to the lateral part of the floor of the fourth ventricle. Twigs of all peripheral arteries anastomose with the common superficial plexus in the pia mater with which all central arteries are connected.

The veins which issue from the medulla form a peripheral plexus in the pia mater in which there are two main longitudinal channels, and **anterior median** and a **posterior median vein.** The former communicates posteriorly with the anterior median vein of the cord, and anteriorly with the veins of the pons and with the veins which accompany the hypoglossal nerves. The latter veins empty into the internal jugular veins. The posterior median vein is continuous caudally with the corresponding vein of the cord, and anteriorly, in the region of the calamus scriptorius, it divides into branches which join the radicular veins. The blood is carried away from the peripheral plexus mainly by the **radicular veins,** which pass along the roots of the last six cranial nerves. Those which accompany the hypoglossal nerves have already been referred to. The others end in the terminal parts of the transverse sinuses, the inferior petrosal sinuses, or the inferior part of the occipital sinuses.

The **nerve supply of the blood-vessels** of the brain consists of a perivascular plexus of sympathetic nerve-fibers upon the walls of the vessels and medullated fibers which accompany the vessels and apparently terminate, for the most part, in the connective tissue about them. The former are thought to be vasomotor in function; the latter probably sensory fibers of the craniospinal type. Sensory nerve endings were first described only for the larger vessels by

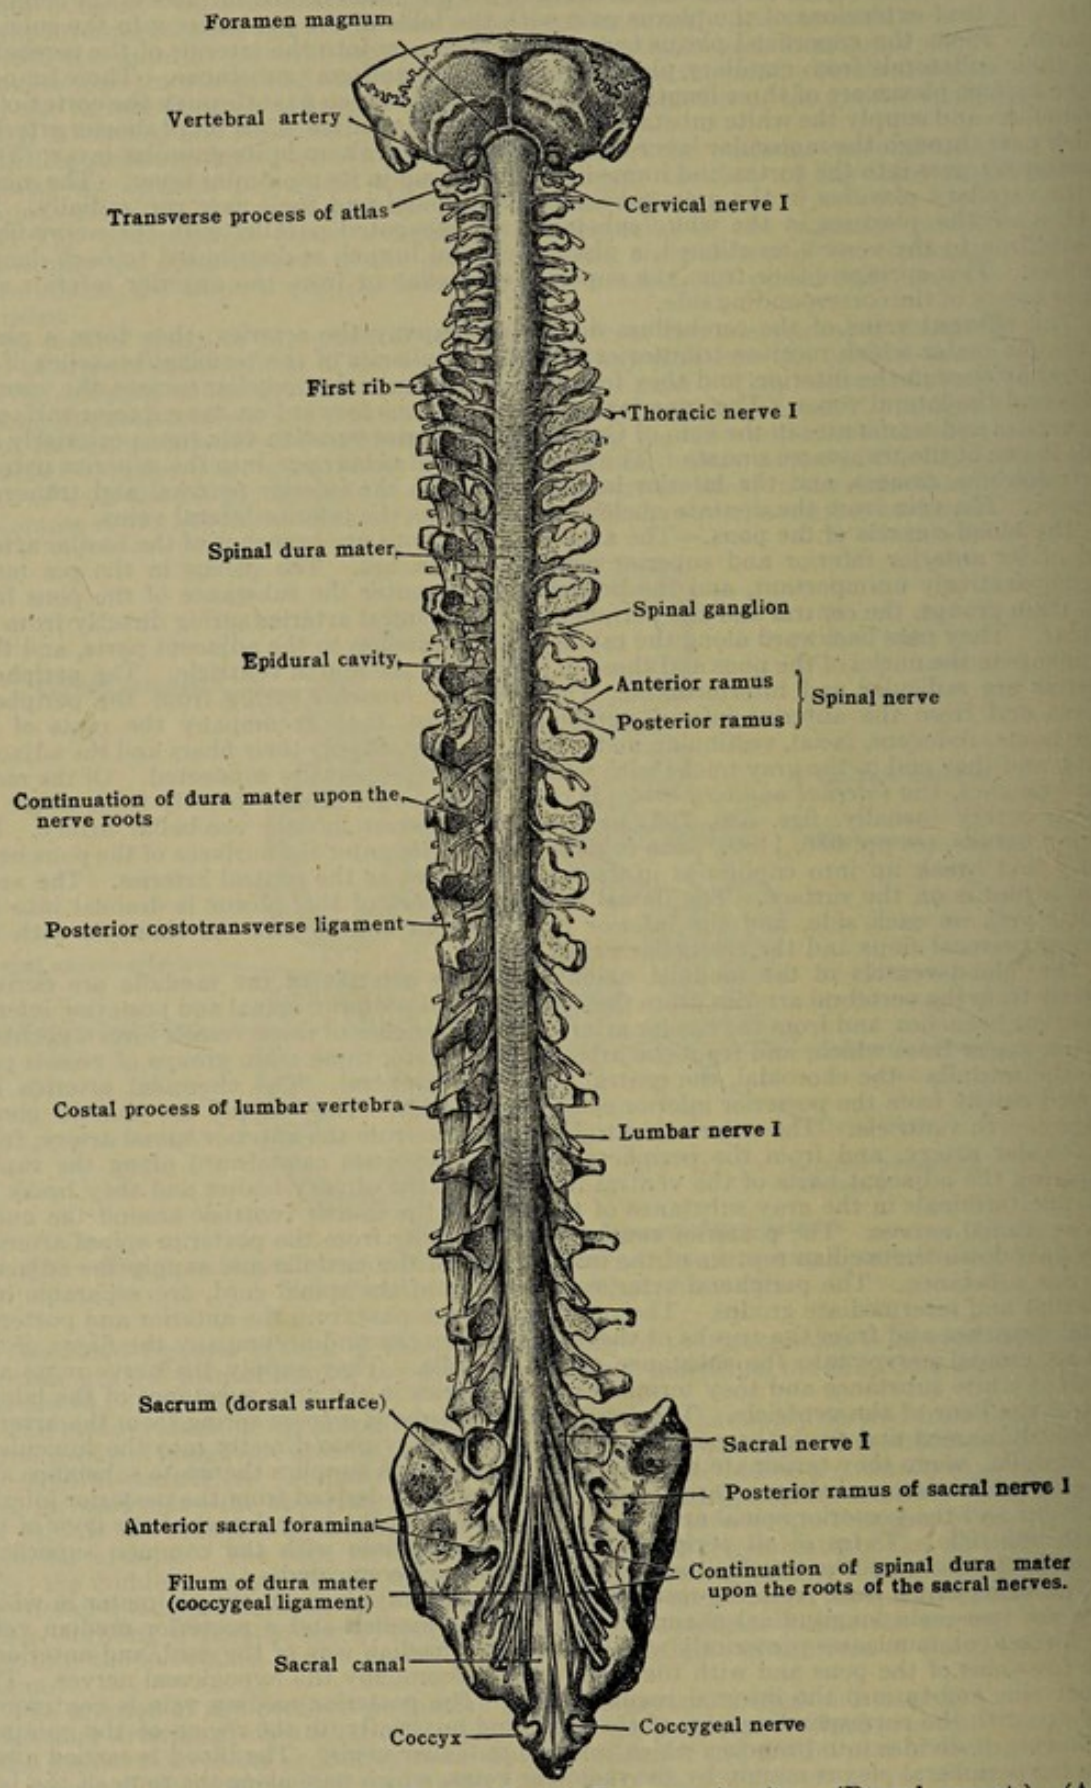

FIG. 787.—SHOWING THE SPINAL DURA MATER EXPOSED *in situ*. (Dorsal aspect.) (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

Huber. Certain headaches are explained by sensory nerve endings in the walls of the central vessels especially. The muscular coat of the arteries of the brain is peculiarly thin.

IV. THE MENINGES

Three membranes, collectively called the **meninges,** envelope the entire central nervous system, separate it from the walls of the bony cavities in which it lies, and aid in its protection and support. They consist of feltworks in which white fibrous connective tissue predominates, and through them pass the blood-vessels which supply the central nerve-axis and the nerves by which the axis is connected with the periphery. Though there are definite spaces or cavities between them, the membranes are not wholly separated from each other, and they are both continuous with and contribute to the walls of the blood-vessels and the sheaths (epineurium) of the nerves passing through them. Beginning with the outermost, they are—(1) the *dura mater*, the thickest, most dense and resistant of the membranes (pachymeninx); (2) the *arachnoid*, the much less dense, web-like middle membrane (leptomeninx); and (3) the *pia mater*, a thin, compact membrane, closely adapted to the surface of the central system, into which it sends numerous connective tissue processes. The pia is highly vascular, containing the rich superficial plexuses of blood-vessels from which the intrinsic blood-supply of the central system is derived. The space between the dura mater and the arachnoid is known as the *subdural cavity*, and that between the arachnoid and the pia mater is the *subarachnoid cavity*.

The Dura Mater

In the fresh condition the dura mater (or pachymeninx NK) appears as a bluish-white, exceedingly resistant membrane, forming the outermost envelope of the entire central nervous system. Its external surface or that next to the bony wall is rough, while its internal surface appears smooth, due to the fact that the subdural cavity partakes of the nature and has the lining of a lymph-space. The cranial dura mater consists of two distinct, closely associated layers, the outermost of which serves as the internal periosteum of the cranial bones. The spinal dura mater is described as consisting of but one layer. The internal periosteum of the spinal canal, though continuous at the foramen magnum with the outer layer of the cranial dura mater, is not considered a part of the spinal dura mater, from the fact that it is so widely separated from the layer actually investing the spinal cord by the epidural space. Thus, since the cranial and spinal portions of the dura mater differ, they are described separately.

The spinal dura mater is a fibrous tube with funnel-shaped caudal end which encloses and forms the outermost support of the spinal cord. It consists of but one layer and this corresponds to the inner layer of the cranial dura mater. It begins at the foramen magnum and terminates in the spinal canal at about the level of the second piece of the os sacrum. It is firmly attached to the internal periosteum of the surrounding bones of the vertebral canal only in certain localities:—

(1) The upper end of the tube blends intimately with the internal periosteum of the cranium at the margin of the foramen magnum, and thus in this locality it becomes continuous with the outer layer of the cranial dura mater. Also in this locality it is attached firmly, though less intimately, to the periosteum of the posterior surfaces of the second and third cervical vertebræ. This locality may be considered the upper fixation-point of the spinal dura mater. (2) It extends laterally and contributes to the connective tissue investments of each pair of spinal nerves, and as such it passes into the intervertebral foramina and becomes continuous with the periosteum lining each. (3) Along its ventral aspect the spinal dura mater is attached by numerous processes to the posterior longitudinal ligament of the vertebral canal. These latter attachments are more or less delicate, loose, and irregular, and are easily torn or cut in removing the specimen. They are stronger and more numerous in the cervical and lumbar regions than in the thoracic. (4) In the space between the dura and the walls of the vertebral canal (*epidural* or *extradural cavity*) lies the rich *internal vertebral venous plexus*, and along the lateral aspect the dura is occasionally connected with the periosteum through the tissue of the walls of the vessels of this plexus, especially in case of the vessels which penetrate the dura. Along its dorsal aspect the spinal dura mater is practically free from the wall of the vertebral canal. (5) At its lower and funnel-shaped extremity, opposite the second sacral vertebra, the dura suddenly contracts into a filament extending through the sacral canal and onto the coccyx and breaking up into a number of processes which become continuous with the periosteum of the dorsal surface of the coccyx. This filament is the **coccygeal ligament** or **filum** of the dura mater, and its attachment may be considered the lower fixation-point of the spinal dura mater. (See figs. 692 and 787.) The extent of the tube is maintained chiefly by means

of the two fixation-points, for all the other attachments are sufficiently loose to permit of the movements of the vertebral column.

The *inner surface* of the spinal dura mater appears smooth, but upon closer examination it is found to be connected with the arachnoid by a few delicate subdural trabeculæ—occasional fine stands of connective tissue bridging the subdural space (fig. 797). Along its lateral aspects the inner surface is at intervals quite firmly attached to the pia mater by the dentations of the **ligamenta denticulata,** which are prolonged from the pia through the arachnoid.

Further, it is continuous at intervals with both the pia mater and arachnoid by way of the connective-tissue sheaths of the nerve-roots which are prolonged from the pia and blend with the dura mater in the passage of the nerve-roots through it. The dura is also pierced by the spinal rami of the vertebral arteries, and the connective tissue of the outer walls of these vessels

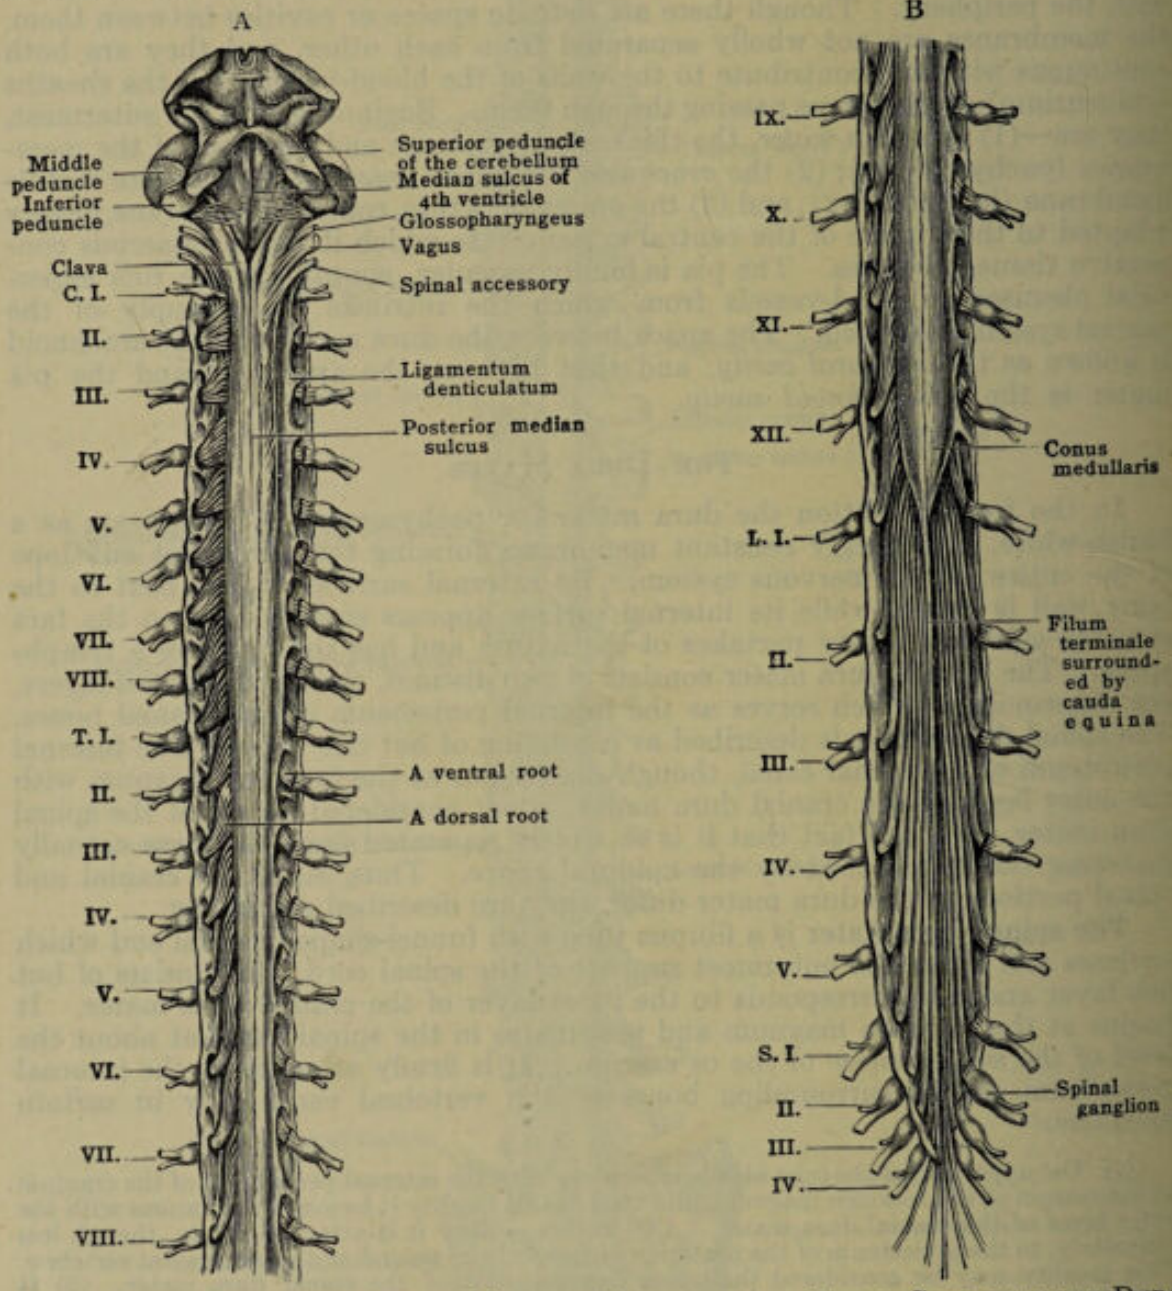

FIG. 788.—DORSAL ASPECT OF THE MEDULLA OBLONGATA AND SPINAL CORD WITH THE DURA MATER PARTIALLY REMOVED. (Hirschfeld and Leveillé.)

blends with all three of the meninges. The filum terminale of the pia mater extends below the termination of the spinal cord into the point of the funnel-shaped end of the dura mater, and there blends with it in line with the coccygeal ligament of the outer surface.

The tube of the spinal dura mater varies in caliber with the variations in the diameter of the spinal cord. However, the termination of its cavity occurs about seven segments below the termination of the spinal cord. This extension contains the long intradural nerve-roots forming the cauda equina, and the caliber of this part, before its sudden contraction, is about as great as that found in any other region. As each pair of the nerve-roots of the cauda equina pass outward, they lie free for a variable distance in this tubular cavity of the dura before the latter blends with and contributes to the thickness of their sheaths.

The **subdural cavity,** the space between the dura mater and the arachnoid, is the thinnest of the meningeal spaces. Along the ventral aspect especially, the spinal arachnoid is quite closely applied to the inner surface of the dura mater. It

contains a small amount of cerebrospinal fluid (lymph) which prevents friction between the opposing surfaces, and is continuous with the fluid in the like space of the cranial meninges.

The space is projected into the venous sinuses of the cranium in the region of the Pacchionian bodies (fig. 796), and its fluid is likewise in contact with the blood-vessels passing through it. It is probably continuous with the lymph-spaces of the nerve-roots passing through it, for colored fluids injected into it pass into the nerve-roots. The arachnoid is so thin and gauze-like that a ready interchange of fluids between the subdural and the subarachnoid spaces is possible by simple transfusion.

The cranial dura mater [dura mater encephali].—The dura mater investing the brain performs a double function—it serves as an internal periosteum for the cranial bones and gives support and protection to the brain. In conformity with its double function it consists of two layers, easily separable in the child, but closely adhering to each other in the adult, except in occasional localities, where there exist small clefts lined with mesothelium. The large blood-sinuses and venous lacunæ, corresponding to the internal vertebral venous plexus of the vertebral canal, are placed between the two layers and the semilunar ganglia of the trigemini also lie between them. The cranial dura begins with the adhesion of the spinal dura mater to the periosteum at the foramen magnum, and it forms a sac-

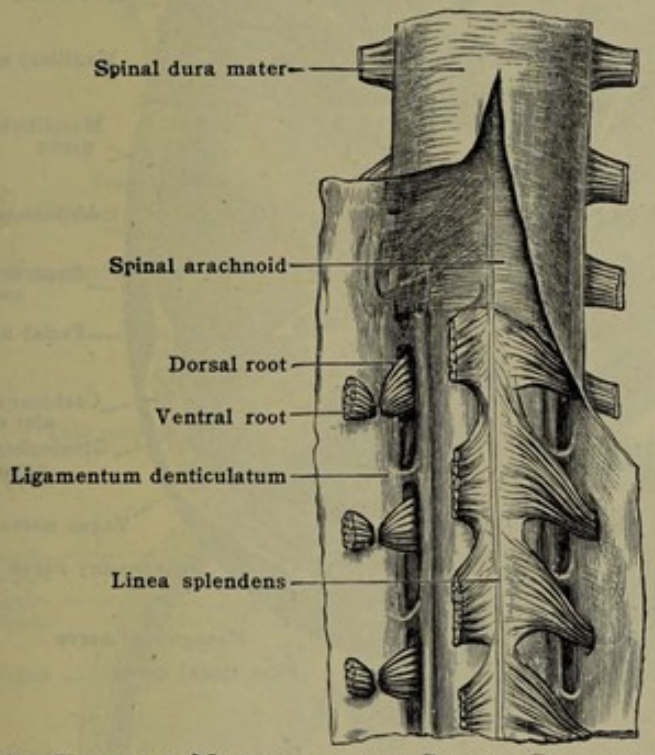

FIG. 789.—VIEW OF MEMBRANES OF SPINAL CORD FROM VENTRAL ASPECT. (Ellis.)

like envelope about the entire encephalon. Consisting of two layers, it is a much thicker membrane than that of the spinal cord.

The *outer surface* of the cranial dura mater when torn away from the cranial bones appears very uneven, and when placed in water presents a flocculent appearance due to its numerous filaments drawn from their small apertures in the bone.

This is due to the many fine bundles of connective tissue and the small blood-vessels which pass between the dura and the cranial bones and which are partially pulled out of their openings in the latter in the process of separation. The abundance of these connections, and, therefore, the degree of adhesion to the bones, varies in different localities. The separation is much less difficult from the inner table of the bones of the vault of the cranium than from the bones of the base of the cavity. The adhesions to the vault of the cranium are most firm along the lines of the sutures. This is due to the fact that during the period before the sutures are closed the outer layer of the dura mater (internal periosteum) is directly continuous with the external periosteum, and, in consequence of this condition during development, the connective tissue connection is more abundant along these lines and some is caught in the closure of the sutures. Along the vault there are occasionally noticed small lymph-spaces between the bone and the dura mater. The stronger adherence to the base of the cranial cavity is due to the numerous foramina in the floor, through which all the larger cranial blood-vessels and the cranial nerves pass, and the dura mater is continuous with the connective tissue investments of these as well as with the periosteum lining the foramina. Also the floor of the cavity is more uneven than the

vault, and the projections of the bones here tend to increase the firmness of attachment. The weight of the brain upon the floor may contribute to the greater adhesion.

The *inner surface* of the inner layer of the cranial dura mater forms the outer boundary of the subdural cavity. Except for the occasional delicate subdural trabeculæ and the passage of blood-vessels and nerve-roots, this surface appears smooth and glistening, being lined by a layer of mesothelium and containing a small amount of the cerebrospinal fluid.

The subdural cavity of the base of the brain is prolonged a short distance along the roots of the various cranial nerves before it is obliterated by the blending of the dura mater with the sheaths of the nerves. This outward extension of the space is most marked about the optic and auditory nerves. In the optic especially, the dura mater remains separate from the nerve throughout its length, only fusing with its sheath upon the posterior surface of the ocular bulb (fig. 790).

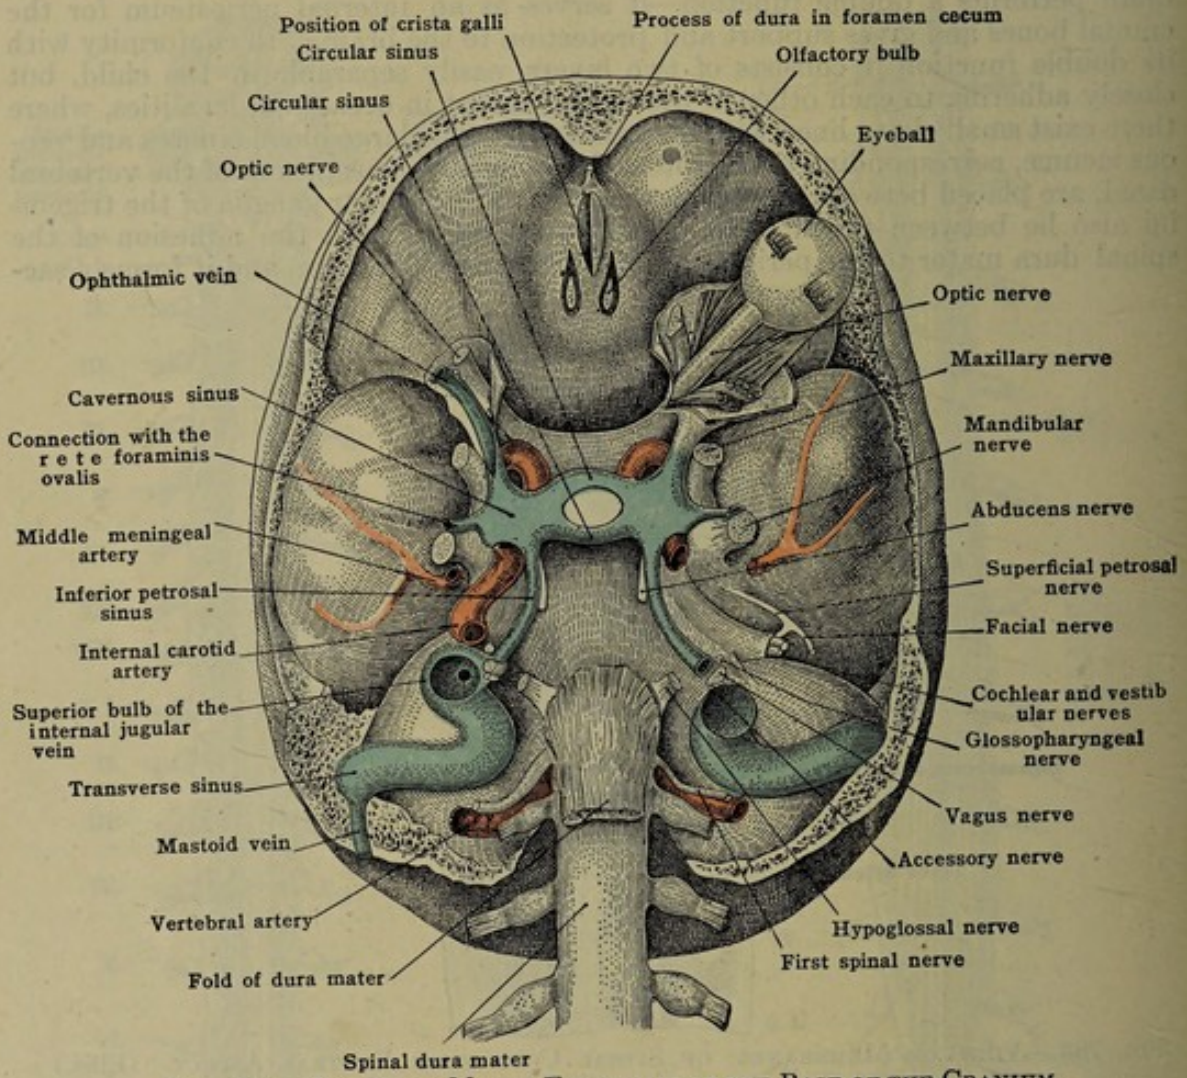

FIG. 790.—THE DURA MATER ENCEPHALI OF THE BASE OF THE CRANIUM.
(After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

In addition to its two layers, one of the most striking differences between the cranial dura mater and that of the spinal cord is that the inner layer of the former undergoes striking septa-like duplications or folds, forming exceedingly strong partitions which project between the larger subdivisions of the encephalon. These are four in number, two large and two small—the falx cerebri and the tentorium cerebelli; the falx cerebelli and the diaphragma sellæ. The larger enclose within their folds the great venous sinuses, into which most of the blood of the encephalon collects to pass outward by way of the internal jugular veins (figs. 792, 793).

The **falx cerebri** is the most striking of these partitions. It is a sickle-shaped fold which projects vertically from the vault into the longitudinal fissure between the cerebral hemispheres. It begins attached to the crista galli in front, and arches to terminate by blending with the superior surface of the transversely placed tentorium cerebelli. Its convex, superior border joins the outer layer of the dura along the medial plane of the vault, and encloses the superior sagittal sinus. Its concave border is free and contains in its posterior two-thirds the smaller inferior sagittal sinus.

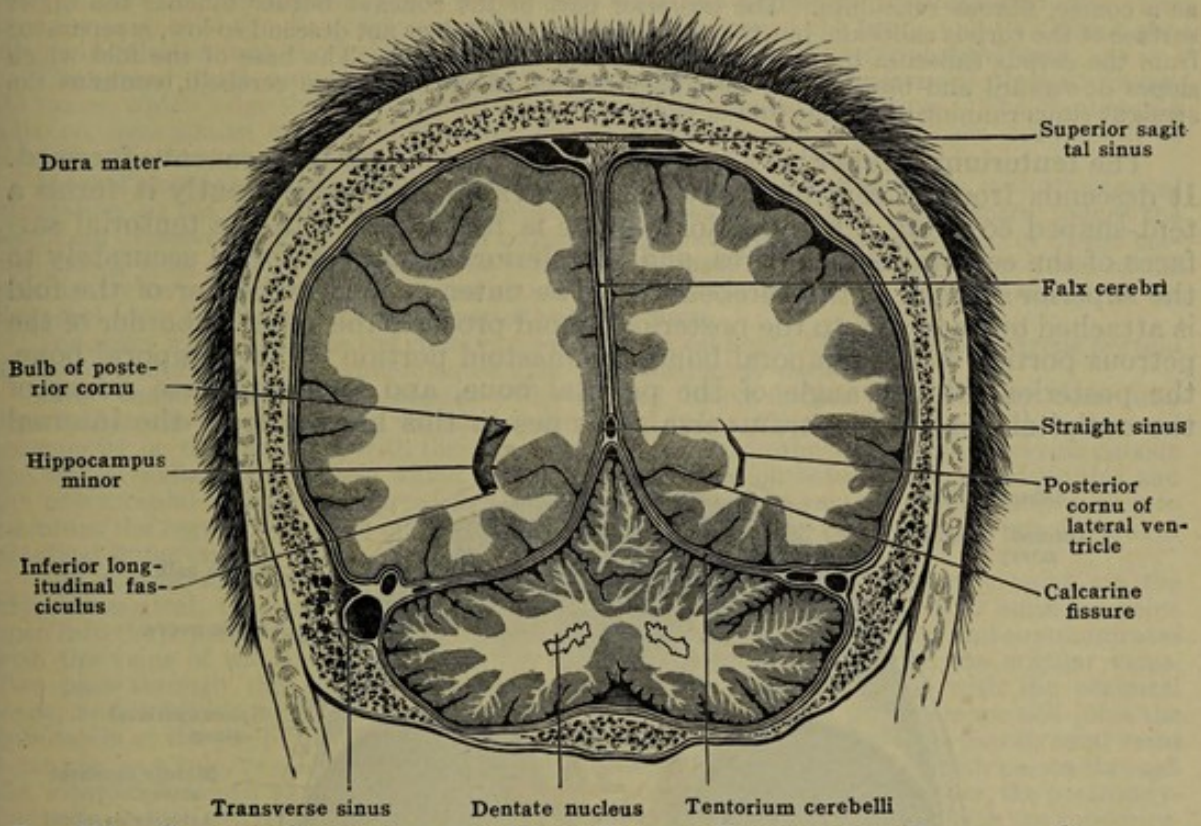

FIG. 791.—CORONAL SECTION OF THE HEAD, PASSING THROUGH THE POSTERIOR CORNUA OF THE LATERAL VENTRICLES.

(From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)

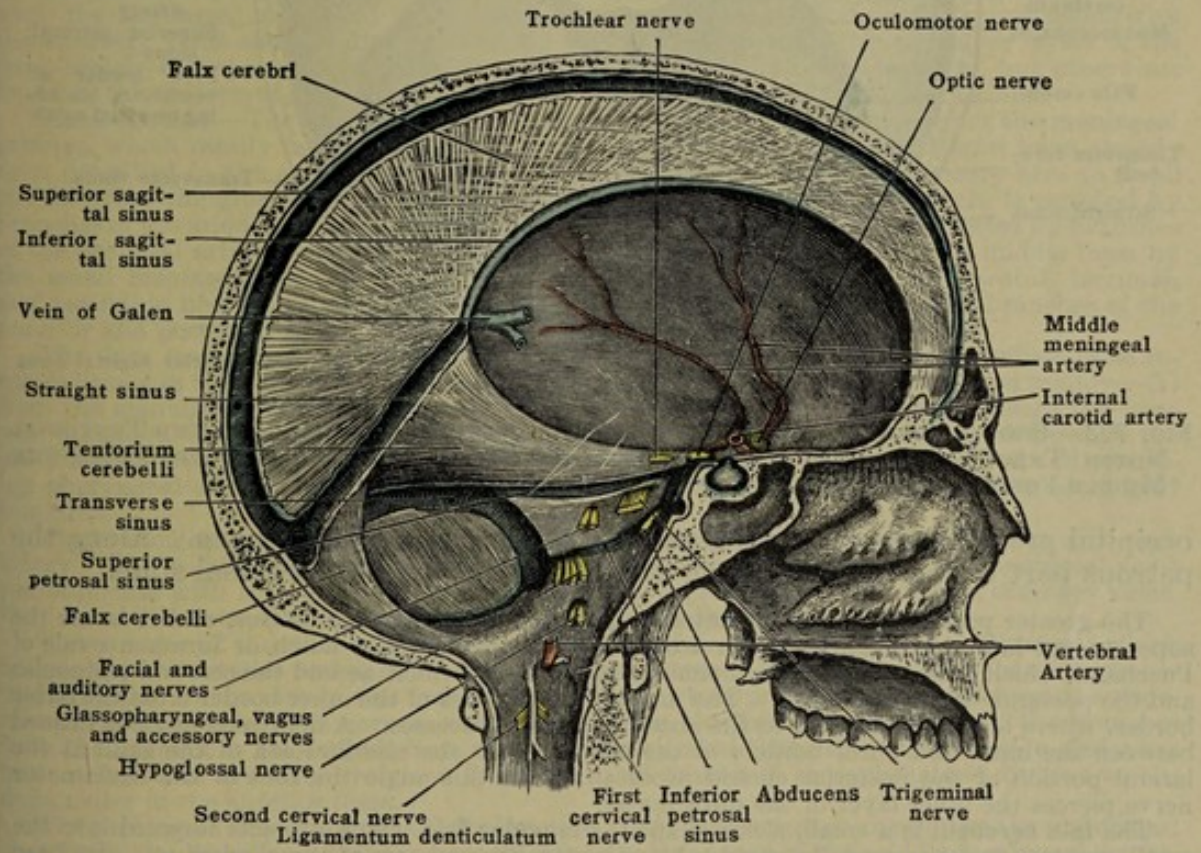

FIG. 792.—THE CRANIUM WITH ENCEPHALON REMOVED TO SHOW THE FALX CEREBRI, THE TENTORIUM CEREBELLI, AND THE PLACES WHERE THE CRANIAL NERVES PIERCE THE DURA MATER. (Sappey.)

The anterior and narrower end is often perforated and occasionally so much so as to appear as a coarse, fibrous reticulum. The posterior part of the concave border touches the upper surface of the corpus callosum, but the anterior part, which does not descend so low, is separated from the corpus callosum by a part of the subarachnoid space. The base of the fold which slopes downward and blends with the upper surface of the tentorium cerebelli, contains the straight sinus running along the line of the blending.

The **tentorium cerebelli** is a large transverse, semilunar fold, concave forward. It descends from its central part which is elevated, and consequently it forms a tent-shaped covering. Its superior surface is in relation with the tentorial surfaces of the cerebral hemispheres, and its inferior surface conforms accurately to the superior surface of the cerebellum. The outer or convex border of the fold is attached on each side to the posterior clinoid process, the superior border of the petrous portion of the temporal bone, the mastoid portion of the temporal bone, the posterior inferior angle of the parietal bone, and the transverse ridges of the occipital bone. The transverse sinus lies in this border, from the internal

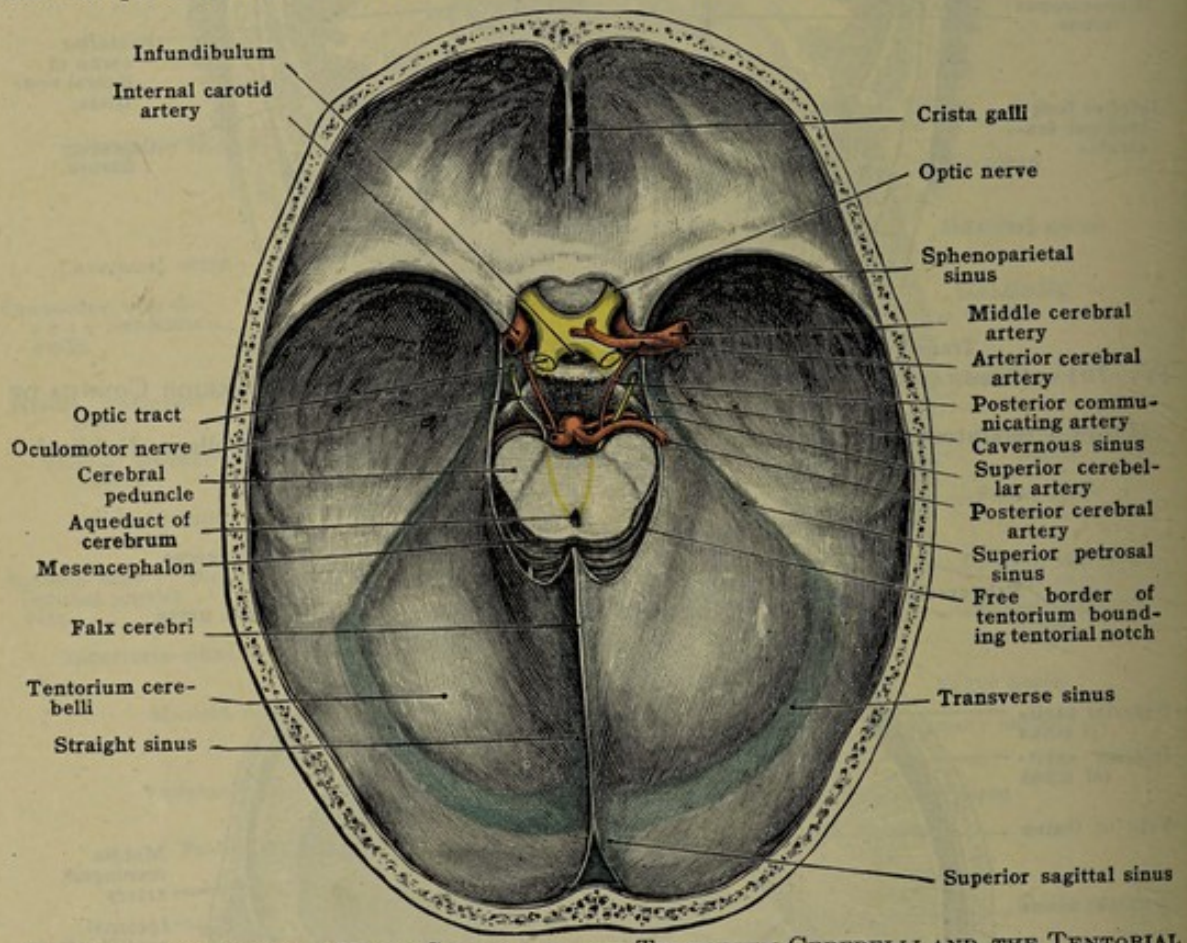

FIG. 793.—SHOWING THE UPPER SURFACE OF THE TENTORIUM CEREBELLI AND THE TENTORIAL NOTCH THROUGH WHICH THE MIDBRAIN AND POSTERIOR CEREBRAL ARTERIES ENTER THE MIDDLE FOSSA OF THE CRANIUM.

occipital protuberance to the mastoid portion of the temporal bone. Along the petrous part of the temporal bone it encloses the superior petrosal sinus.

The greater part of the inner or anterior border of the tentorium is free, and it forms the superior and lateral boundaries of an arched cavity, the **tentorial notch** or foramen ovale of Pacchioni, which encloses the mesencephalon, and through which ascend the cerebral peduncles and the posterior cerebral arteries. The anterior extremities of the inner border cross the outer border, where both are attached to the anterior clinoid processes. A depressed angle is formed between the inner and outer borders of the tentorium in the middle fossa of the skull at the lateral portion of the posterior clinoid process, and in this angle the root of the oculomotor nerve pierces the inner layer of the dura mater.

The **falx cerebelli** is a small, sickle-shaped, triangular fold which projects forward into the small groove (*posterior cerebellar notch*), between the hemispheres of the cerebellum. Its base is attached to the tentorium; its posteroinferior border, along which runs the occipital sinus, is attached to the internal occipital crest. Its anterior border is free, and its apex, which lies immediately above the foramen magnum, usually bifurcates as it disappears anteriorly, clasping the foramen magnum from behind. Bifurcation is always the case when the internal occipital crest splits below to enclose a vermiform fossa.

The **diaphragma sellæ** is a small circular fold, with a foramen in the center, which projects horizontally from the margins of the hypophyseal fossa or sella turcica. Its lateral border is

attached to the clinoid processes and the limbus of the sphenoid, and its medial border forms the boundary of the *foramen of the diaphragma sellæ* and surrounds the infundibulum. The superior surface of the diaphragm is in relation with the base of the brain, and its inferior surface is in relation with the hypophysis, which it binds down in the hypophyseal fossa.

The spaces which remain between the layers of the cranial dura mater are Meckel's caves, the spaces which lodge the endolymphatic sacs, the blood-sinuses and lacunæ. The diaphragma sellæ consists almost entirely of the inner layer of the dura, and thus the sella itself might be classed with these spaces.

Meckel's caves are two cleft-like spaces or niches which lie, one on each side, in the trigeminal impression on the apex of the petrous portion of the temporal bone. Each space lodges the semilunar (Gasserian) ganglion and the adjacent trigeminus and masticator nerves of the corresponding side, and it communicates with the subdural space in the posterior fossa of the cranium by an oval opening, which lies above the superior border of the petrous portion of the temporal bone and inferior to the superior petrosal sinus.

The space which contains the endolymphatic sac on each side lies behind the petrous portion of the temporal bone and communicates with the aqueductus vestibuli.

The venous sinuses and lucunæ.—The cranial blood-sinuses have already been fully described in the account of the vascular system, and it is sufficient to note here that they are continuous, on the one hand, with the meningeal veins, and, on the other, with the veins outside the cranial walls. The vessels which establish communication between the blood-sinuses and the extracranial veins are referred to collectively as **emissary veins.** They possibly help to maintain the regularity of the cranial circulation, and they have therefore a certain amount of practical importance.

The sinuses which are connected with the extracranial veins by emissary veins are the superior sagittal, the transverse (lateral), and the cavernous. Three or four emissary veins open into the superior sagittal sinus:—one passes through the foramen cecum and communicates with the veins of the roof of the nose, or, through the nasal bones, with the angular veins. Two pass through the parietal foramina and establish communications with the occipital veins, and a fourth, which is very inconstant, pierces the occipital protuberance and joins the tributaries of the occipital veins. Connecting each transverse sinus with the extracranial veins there are, as a rule, two emissary veins:—one, the mastoid emissary vein, which passes through the mastoid foramen to the occipital or posterior auricular vein; and the other, the postcondyloid vein, which traverses the condyloid (posterior condyloid) foramen and joins the suboccipital plexus. The cavernous sinus is in communication anteriorly with the superior ophthalmic vein, and through the latter with the angular vein; it is connected with the pterygoid plexus by emissary veins which pass either through the foramen ovale or the foramen Vesalii, and with the pharyngeal plexus by small venous channels which accompany the internal carotid artery through the carotid canal.

The **venous lacunæ** or spaces are small clefts lined by endothelium which communicate with the meningeal veins and with the blood-sinuses. They also have communications with the emissary veins and the diploic veins. They lie between the outer and inner layers of the dura mater, the majority of them at the sides of the superior sagittal sinus, but others are found in the tentorium associated with the transverse sinuses and the straight sinus.

Blood-vessels.—The blood-supply of the cranial dura mater is derived from the **meningeal arteries,** which ramify in its outer layer. The more important of these arteries have already been described in the account of the vascular system, and it is only necessary here to recall the fact that the greater part of the dura mater above the tentorium cerebelli is supplied by branches of the middle meningeal arteries. These are reinforced—(1) at the vertex by branches of the occipital arteries which enter through the parietal foramina; (2) in the middle fossa by the small meningeal arteries and by meningeal branches of the internal carotid, lacrimal, and ascending pharyngeal arteries; and (3) in the anterior fossa by meningeal branches of the anterior and posterior ethmoidal arteries.

The dura mater in the posterior fossa of the skull, below the tentorium cerebelli, also receives branches from the middle meningeal arteries, but its blood-supply is derived mainly—(1) from the meningeal branches of the vertebral arteries which enter the fossa through the foramen magnum, (2) from meningeal branches of the occipital arteries which enter through the mastoid and hypoglossal foramina, and (3) from meningeal branches of the occipital and ascending pharyngeal arteries which enter through the jugular and hypoglossal (anterior condyloid) foramina.

The **meningeal veins** accompany the arteries as *venæ comitantes*, usually one vein with each artery. The middle meningeal artery usually has two venæ comitantes. The meningeal veins communicate with the venous sinuses and with the diploic veins, and, unlike ordinary veins, they do not increase much in caliber as they approach their terminations.

The **nerves** of the dura mater are partly derived from the sympathetic filaments which accompany the arteries and partly from the cranial nerves. The nerves, other than sympathetic filaments, which supply the cranial dura mater are sensory fibers derived from the trigeminus (chiefly) and vagus nerves, and possibly from the first cervical nerves. The branches from the trigeminus are derived from the three divisions of that nerve on either side, and it has been stated that branches are given from the nasal branch of the ophthalmic division to the dura mater in the anterior fossa.

The meningeal branch of the opathalmic division of the trigeminus supplies the tentorium; that from the maxillary division accompanies the branches of the middle meningeal artery. The meningeal branch of the mandibular division (nervus spinosus) passes into the skull through the foramen spinosum and is distributed to the dura mater over the great wing of the sphenoid and to the mastoid cells. The '*recurrent branch of the hypoglossal nerve*' passes to the dura mater of the posterior fossa of the cranium. This recurrent or meningeal branch of the hypoglossal nerve really consists of fibers derived from the superior cervical ganglion of the sympathetic, and contains sensory fibers from the first and second cervical nerves. The meningeal branch of the vagus springs from the ganglion of the root of the nerve, and is distributed in

the posterior cranial fossa. The sympathetic filaments are distributed to the smooth muscle in the walls of the blood-vessels.

The cranial **subdural cavity** is not of uniform thickness throughout, being quite thin along the basal aspect of the encephalon. The lymph contained in it is usually but little more than is sufficient to keep moist its bounding surfaces. It is continuous with the lymph-spaces of the nerves and those of all the tissues bathed, and it is continuous with the similar cavity of the vertebral canal. Its lymph is in free contact with the blood-vessels passing through it, and it is replenished by filtration through their walls. Though extensive, the subdural space is thin at best, for the dura mater is quite closely applied to the second of the three meninges.

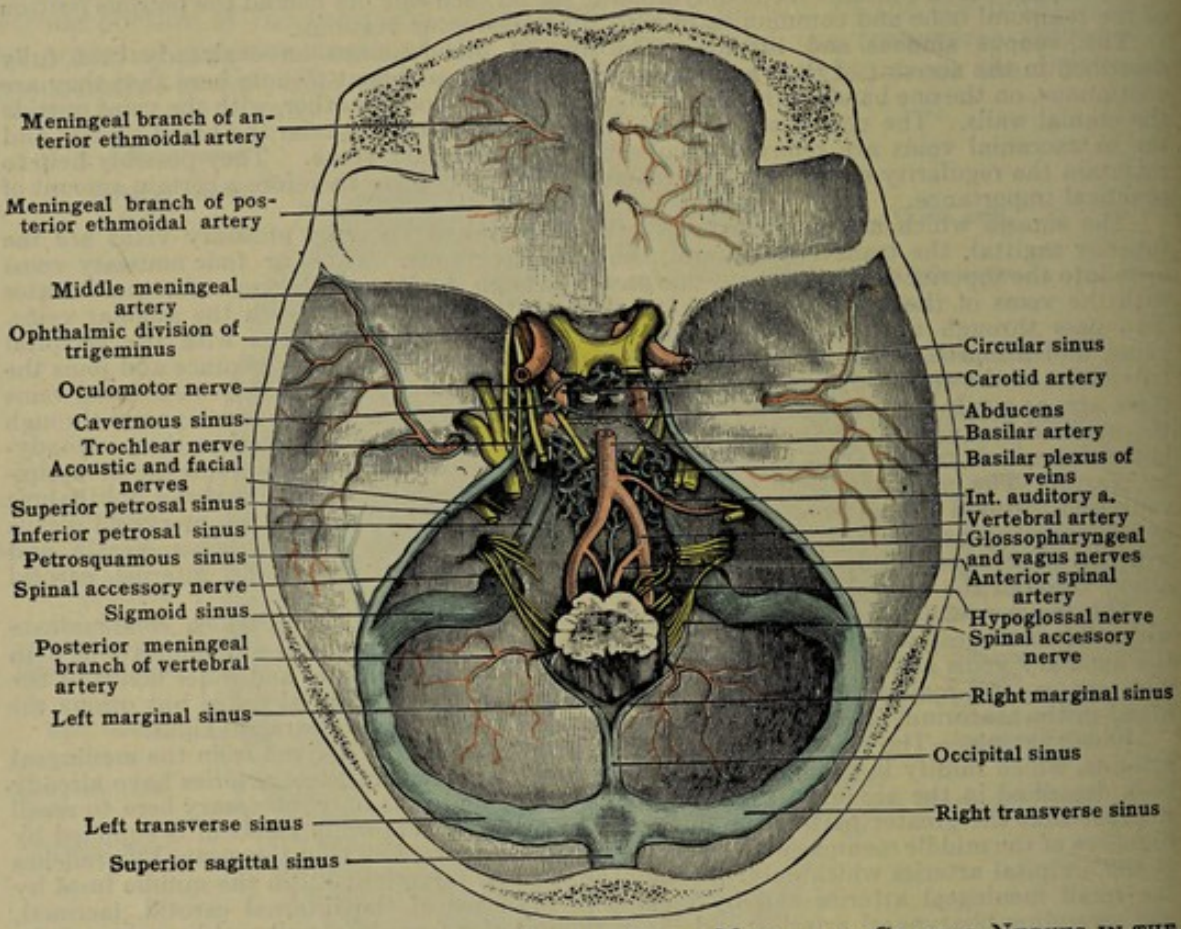

FIG. 794.—SHOWING BLOOD-VESSELS OF CRANIAL DURA MATER AND CRANIAL NERVES IN THE BASE OF THE SKULL.

(On the left side the dura mater has been removed from the middle fossa.)

THE ARACHNOID

The arachnoid or 'serous' membrane is the middle of the three meninges of the central nervous system. As in the case of the other two, an attempt is made to give this membrane a name descriptive of its texture. It is a gauzy reticulum of almost web-like delicacy, which in reality pervades the space it occupies. The term *leptomeninx* (NK) includes both the arachnoid and the pia mater.

Its *outer surface*, or that closely related to the dura mater and bounding the subdural cavity alone shows a sufficiently organized structure to merit the name of membrane. This surface is covered by a layer of mesothelium which is identical with that lining the inner surface of the dura mater and is continuous with the latter by way of the mesothelial covering the blood-vessels, the nerve-roots, the ligamenta denticulata of the spinal cord, and the occasional delicate trabecula passing between the dura mater and the arachnoid. Immediately under the mesothelium, the connective-tissue fibers of the arachnoid are woven into a very thin, more or less compact web. This, however, quickly grades into a loose, spongy reticulum which pervades the thick subarachnoid cavity throughout, and the strands of which are directly continuous into the more compact tissue of the pia mater. Thus an *inner surface* can hardly be claimed. This loose, sponge-like arachnoid tissue holds the cerebrospinal fluid of the subarachnoid cavity, the meshes of the sponge constituting a reticular web of intercommunicating spaces lined by mesothelial cells covering the strands of the web. In addition, the cavity is traversed by the spinal and cranial nerves, by the blood-vessels passing to and from the pia, and, in the vertebral canal distinctively, it is traversed by the ligamenta denticulata and the filum terminale.

Through these the arachnoid is further continuous with the pia mater. The cranial subarachnoid cavity is larger, and the strands of the web are relatively more abundant than in that of the vertebral canal.

The cranial arachnoid is directly continuous with that of the spinal cord, and in the two localities does not differ as much as does the dura mater. Within the cranium, the arachnoid does not closely follow the surface of the encephalon. It is folded in between the cerebellum and cerebral hemispheres, following the contour of the tentorium cerebelli, but it does not fold into the fissures and sulci except the anterior part of the longitudinal fissure and slightly into the lateral (Sylvian) fissure. Otherwise its spongy reticulum fills in the inequalities of surface of the encephalon, its outer surface forming a sheet enveloping the whole and bridging over the sulci and the deeper grooves between the gross divisions (fig. 703). Upon the summits of the gyri it is more closely applied to the pia mater, and there its reticulum becomes more dense. The sulci, occupied by its reticulum, form a continuous system of channels filled more abundantly by the cerebrospinal fluid.

The arachnoid folds in between the cerebellum and medulla oblongata, and at the base of the brain it enshrouds the olfactory bulbs and tracts, and its outer surface forms a continuous sheet stretching from one temporal lobe to the other

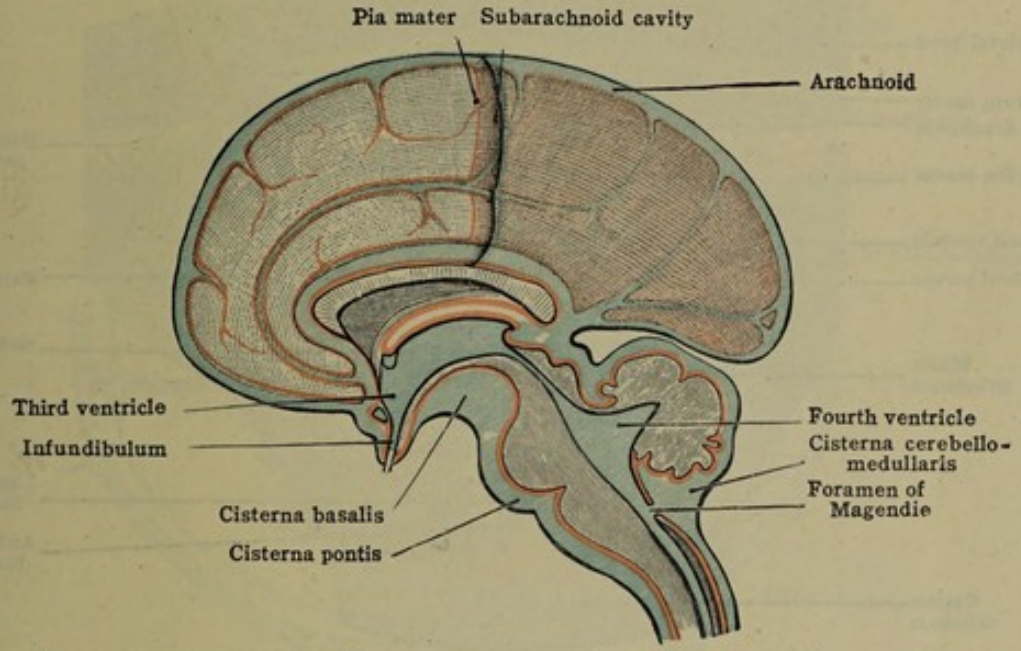

FIG. 795.—DIAGRAM SHOWING THE RELATIONS OF THE PIA MATER, THE ARACHNOID, AND THE SUBARACHNOID CAVITY TO THE BRAIN.

and bridging over the interpeduncular fossa and the inequalities of surface in the region of the optic chiasma and the stems of the lateral fissures. Obviously, therefore, the subarachnoid cavity between its outer surface and the pia mater is of considerable depth in certain localities. These localities comprise the *subarachnoid cisternæ*. These occur where the cavity at the base of the brain is especially large, and make possible a web-invaded 'water-bed' which serves to protect the brain from injurious contiguity with the bones.

The following cisterns are distinguished (fig. 795):—

(1) **The cisterna basalis** lies at the base of the cerebrum and is divided by the optic chiasms into two parts —(*a*) the *cisterna chiasmatis* and (*b*) the *cisterna interpeduncularis*.

(2) **The cisterna pontis** is situated about the pons, especially in its basilar sulcus and the transverse fissures of either border, and is continuous anteriorly with the cisterna basalis and posteriorly with the subarachnoid cavity about the medulla. As a protective device, it is known as 'Hilton's waterbed.'

(3) **The cisterna superior** lies in the angle between the splenium of the corpus callosum and the superior surfaces of the cerebellum and the mesencephalon, and is connected ventrally, around the cerebral peduncles, with the cisterna basalis.

(4) **The cisterna cerebellomedullaris** (cisterna magna) is the cavity between the inferior surface of the cerebellum and the dorsal surface of the medulla oblongata. It is continuous below into the spinal subarachnoid space. The fluid in this cavity is directly continuous with that in the fourth ventricle by way of the foramen of Magendie (median aperture), and the lateral apertures of the fourth ventricle.

Pacchionian bodies [granulationes arachnoideales] (granula meningica NK) (figs. 703, 796).—In certain situations, especially along the margins of the longitudinal fissure, particularly in the frontal region of this, and to a much less extent upon the superior surface of the vermis of the cerebellum, the subarachnoid tissue elaborates numerous small, ovoid or villus-like projections, the Pacchionian bodies. Each arachnoid villus consists of a retiform network of subarachnoid connective tissue whose meshes are filled with cerebrospinal fluid. The Pacchionian bodies on the vertex of the brain project through the inner layer of the dura mater, both into the superior sagittal sinus and into the venous lacunæ or **parasinoidal sinuses** which lie at the sides of that sinus, and, as they become larger, they press against the outer layer of the dura and produce ovoid depressions in the inner plate of the cranium. Within the sinuses they are covered by the endothelium lining the sinuses.

They serve to increase the surface through which passes the lymph from the subarachnoid cavity into the blood-sinuses, and thus may aid in relieving pressure within. Similarly through

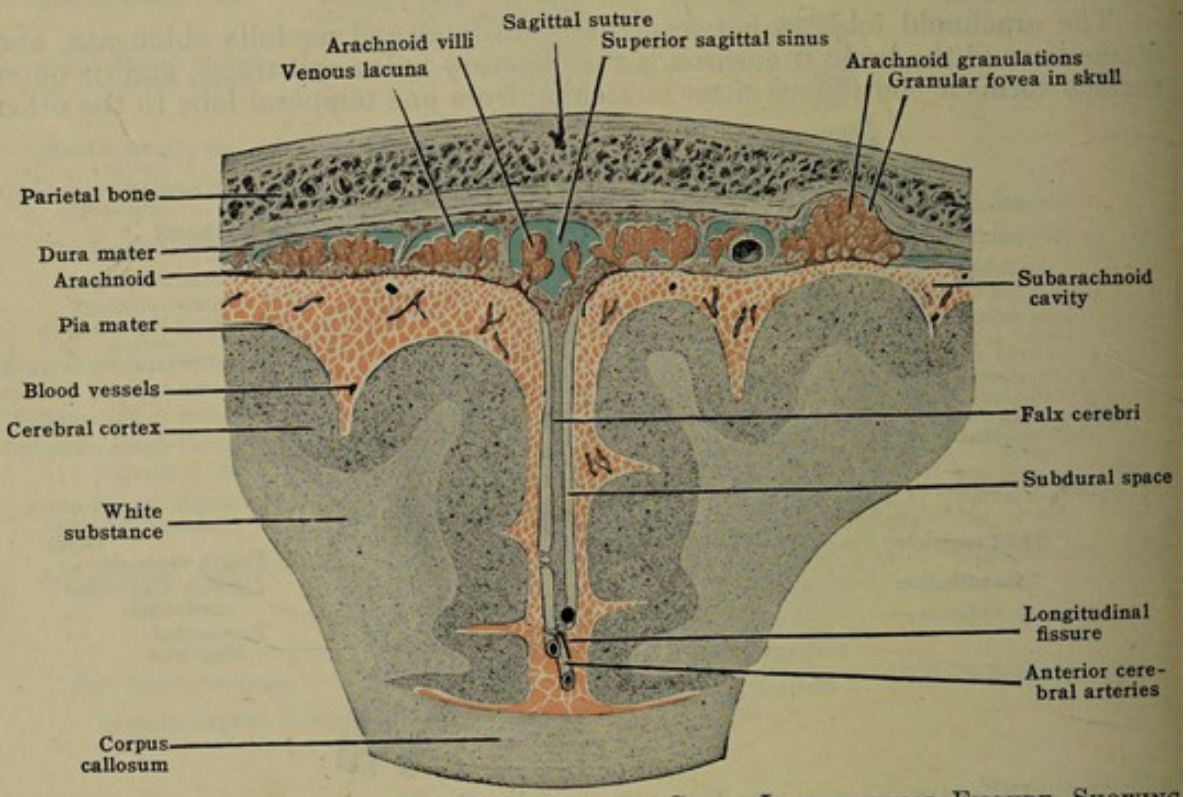

FIG. 796.—CORONAL SECTION TRANSVERSE TO THE GREAT LONGITUDINAL FISSURE, SHOWING THE MENINGES. (Spalteholz.)

them the cerebrospinal fluid may be replenished at need from the blood plasma, though it is chiefly replenished by transfusion through the walls of the small arteries and capillaries of the choroid plexuses and those subjacent to the ependyma of the ventricles. These villi are not present at birth, but they appear at the tenth year and increase in number and size with advancing age. They are less marked in the female than in the male.

The spinal arachnoid (figs. 797, 798) is a loose, reticular sac which is most capacious about the lumbar enlargement of the spinal cord and about the cauda equina. Like that of the encephalon, the portion next to the dura mater alone resembles a membrane, being a loosely organized feltwork, covered on the side of the subdural cavity by a layer of mesothelium common to that cavity. Throughout its length the spinal subarachnoid cavity is relatively wide, and, as in the cranium, contains a fine, spongy, web-like reticulum, numerous threads of which are continuous with the pia mater. This spongy tissue is the inner modification of the arachnoid, and its meshes are occupied by the cerebrospinal fluid. It is not so abundant as in the cranial subarachnoid cavity.

In addition to the delicate threads, the arachnoid is more firmly attached to the pia mater by three imperfect partitions. The most continuous of these is arranged along the dorsal mid-line and is known as the **septum posticum** of Schwalbe (subarachnoid septum). This may be described as a linear condensation of the spongy tissue which pervades the subarachnoid space. It is most incomplete in the upper cervical region, where it becomes merely a line of threads connecting with the pia. It is most complete as a septum in the lower cervical and in

the thoracic region, but at best it maintains a spongy character. The other two partitions are formed by the **denticulate ligaments**, which extend laterally from either side of the spinal cord, connecting the pia and dura mater and involving the arachnoid in passing through it. Within the subarachnoid cavity these form more or less complete septa, though outside the arachnoid they are attached to the dura only at the intervals of their pointed dentations. They belong to the pia mater and will be described with it. The arachnoid is further continuous with the pia by way of the connective tissue sheaths of the roots of the spinal nerves and the blood-vessels passing through the subarachnoid cavity.

Vessels and nerves.—The arachnoid has no special blood-supply and probably no special nerves other than those supplying the walls of the blood-vessels passing through it.

The cerebrospinal fluid.—The subarachnoid cavity is the great lymph-space of the central nervous system. That of the spinal region is directly continuous into that of the cranium, and the fluid contained communicates freely with that in the ventricles of the brain and the central canal of the medulla and spinal cord by way of the foramen of Magendie or medial aperture into the fourth ventricle. In addition, there are the lateral apertures into the fourth ventricle and there is possibly an interchange of fluid between the lateral ventricle and the subarachnoid cavity of the base of the brain by diffusion through the thin floor of the choroid fissure. The arachnoid is not a membrane sufficiently compact to mechanically seriously oppose diffusion between the fluid contained in its cavity and that contained in the subdural cavity, though

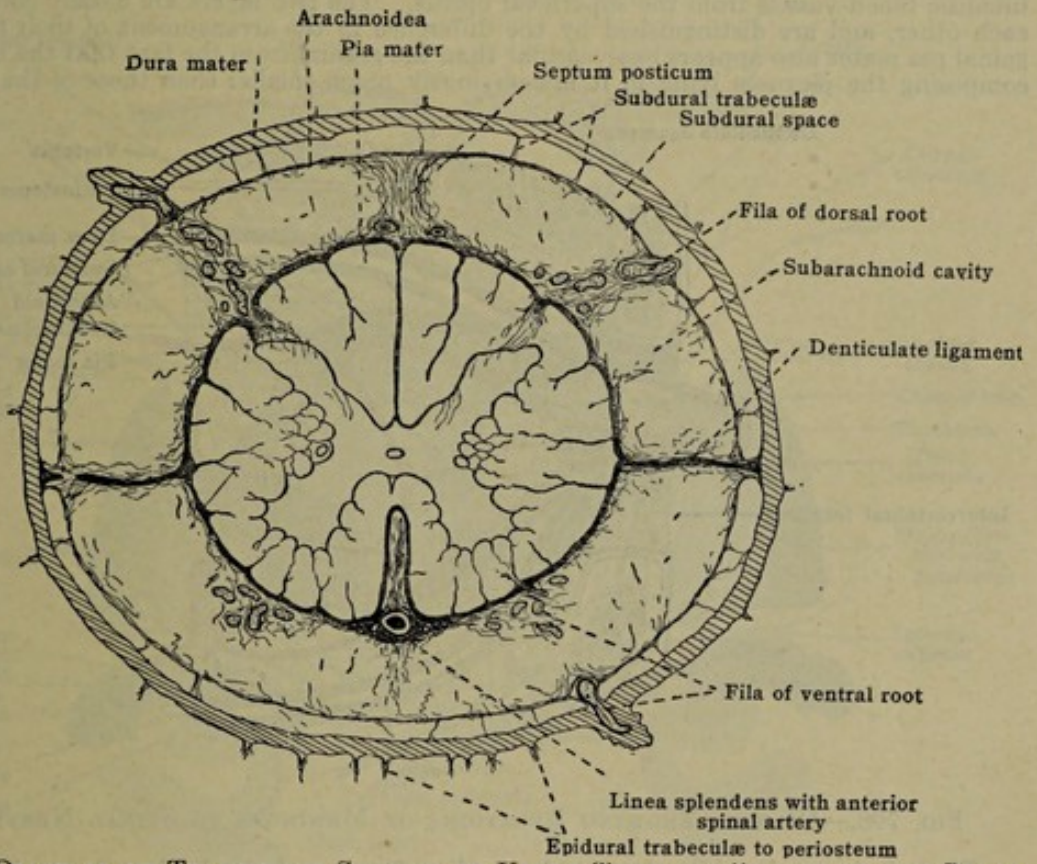

FIG. 797.—DIAGRAM OF TRANSVERSE SECTION OF UPPER THORACIC REGION OF THE SPINAL CORD SHOWING THE RELATIONS OF THE SPINAL MENINGES AND THEIR CAVITIES.

the mesothelium covering it probably controls such activities. The cerebrospinal fluid occupying the cavities is a transparent fluid of a slight yellow tinge, characteristic of the lymph in other lymph-spaces of the body. It is not very great in amount, probably never exceeding 200 c.c. in normal conditions. It is greatest in amount in old age, when the cavities are larger, due to atrophy and shrinkage of the nervous tissues. It collects by transfusion through the walls of the blood-vessels of the choroid plexuses, those in the walls of the ventricles and probably, but in less amount, through the walls of the sinuses, the ependyma lining the ventricles and the mesothelium on the meninges doubtless acting as semipermeable membranes in controlling its osmosis. Its amount may be temporarily increased by a period of increased blood-pressure in the cranial vessels. Pressure due to its abundance may be relieved by diffusion through the membranes containing it, and especially through the villi of the Pacchionian bodies into the venous sinuses and lacunæ, and thence into the veins.

The functions ascribed to the cerebrospinal fluid are the absorption of vibrations, the regulation of intracranial blood pressure and the drainage of waste products from the ever-active central system. Abnormal increase of the fluid in the cerebral ventricles is known as *internal hydrocephalus*. To relieve injurious pressure in the ventricles, surgeons usually employ one or the other of three locations for trephine and needle: (1) the inferior cornu by way of the middle temporal gyrus or sulcus; (2) the anterior cornu through the temporal lobe; and (3) by puncture of the corpus callosum. The approach to the corpus callosum is made through the anterior half, where it is thinner, usually at a point 2 cm. behind the bregma and to the side of the midline to avoid the superior sagittal sinus.

The Pia Mater

The **pia mater,** the third of the meninges, is a thin membrane which envelopes and closely adheres to the entire central nervous system and sends numerous processes into its substance. It likewise contributes the most proximal and compact portion of the sheaths of the nerve-roots in their passage through the meningeal spaces. It is very vascular in that the superficial plexuses of blood-vessels of the pia of both the brain and spinal cord ramify in it as they give off the central branches into the nervous substance. The structure and arrangement of the membrane vary somewhat in the cranial and spinal regions.

The spinal pia mater consists of two layers, an inner and an outer. It is thicker and more compact than that of the encephalon, due to the extra development of its outer layer, which is in the form of a strong, fibrous layer with the fibers arranged for the most part longitudinally.

Its inner layer is a thin feltwork of connective-tissue fibers which is closely adherent to the surface of the spinal cord throughout, sending numerous processes into it which contribute to the support of the nervous tissues. The larger of these processes carry with them the numerous intrinsic blood-vessels from the superficial plexus. The two layers are closely connected with each other, and are distinguished by the difference in the arrangement of their fibers. The spinal pia mater also appears less vascular than the cranial from the fact that the blood-vessels composing the plexuses lying in it are obviously much smaller than those of the encephalon.

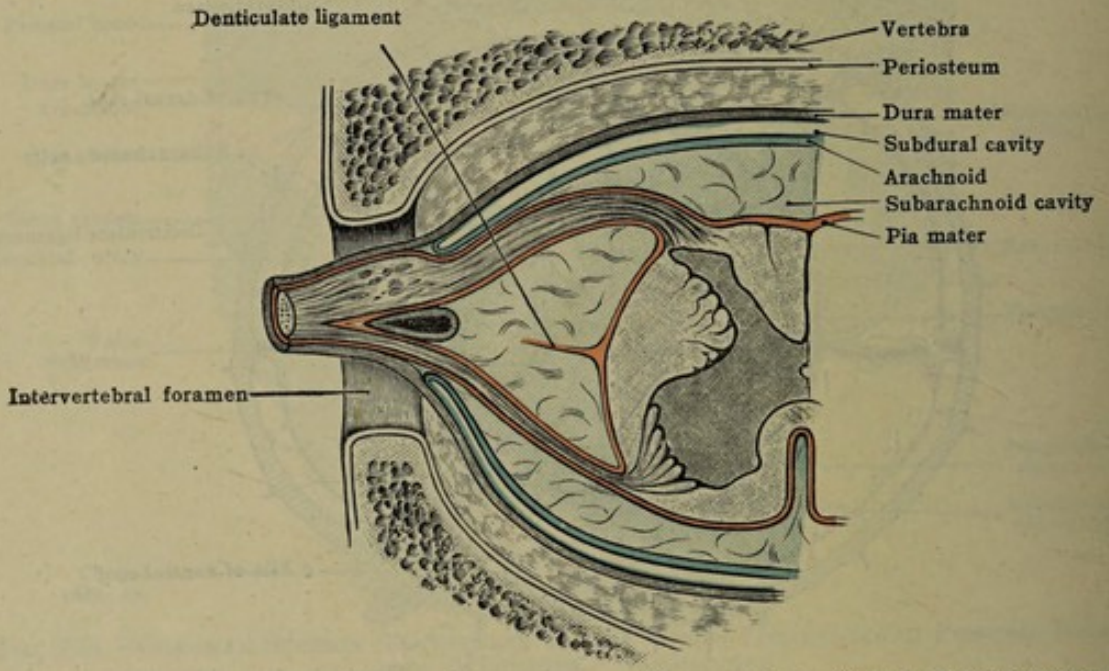

Fig. 798.—Diagram showing Relations of Meninges to Spinal Nerve-roots.

The membrane dips into the anterior median fissure and also bridges it over by forming an extra thickening along it. This thickening appears as a band along the midline of the ventral surface of the cord, the **linea splendens** (fig. 789). It carries, or ensheathes, the anterior spinal artery, the largest of the arterial trunks of the superficial plexus (figs. 702, 797).

The pia mater contributes the innermost and most compact portion of the epineurium of each of the nerve-roots, and thus, upon the roots, it is prolonged laterally into the intervertebral foramina, where the dura mater blends with it in producing the increased thickness of the epineurium.

Nerve fibers are distributed to the spinal pia from the dorsal nerve roots and from the ventral roots (mostly via meningeal rami when present), and some fibers are contributed from the white substance of the cord. These form plexuses in the pia composed of some medullated fibers but chiefly of nonmedullated. For the most part at least, they represent the vasomotor innervation of the blood-vessels in the pia and cord; but nerve endings of sensory type have been described in the pial tissue, as well as in the walls of the blood vessels of the cord and medulla of the cat (S. L. Clark). Presumably such is true for the cranial pia also.

From each side of the cord the pia mater gives off a shelf-like fold, the **denticulate ligament** (figs. 788, 789, 797), which spreads laterally toward the dura mater midway between the lines of attachment of the dorsal and ventral nerve-roots. The outer edge of this fold is dentate or scalloped into about twenty-one pointed processes, which extend through the arachnoid for their points to become continuous with the inner surface of the dura mater. The dentations are usually attached along the line between the roots of the spinal nerves, the uppermost

one a little cephalad to the first cervical nerve and the region where the vertebral artery perforates the dura mater; the most caudal one between the last thoracic and first lumbar nerves, or, between the last two thoracic nerves. The ligaments, aided slightly by the subarachnoid trabeculæ and the nerve roots, serve to hold the spinal cord more or less suspended in the subarachnoid cavity.

Below, at the sudden, conical termination of the spinal cord in the lumbar portion of the vertebral canal, the pia mater is spun out into a thin, tubular filament, the **filum terminale,** which continues caudalward into the sac formed by the dura mater about the cauda equina, and at the end fuses with the dura mater in line with the filum of the spinal dura mater (coccygeal ligament) of the outside (figs. 692, 787).

The cranial pia mater is closely applied to the external surface of the brain, dipping into all the fissures, furrows, and sulci. It is connected with the arachnoid by numerous filaments of the spongy subarachnoid tissue and by the blood-vessels traversing the subarachnoid cavity. It is also pierced by the cranial nerves, and furnishes them their sheaths, which become continuous with the arachnoid and dura mater.

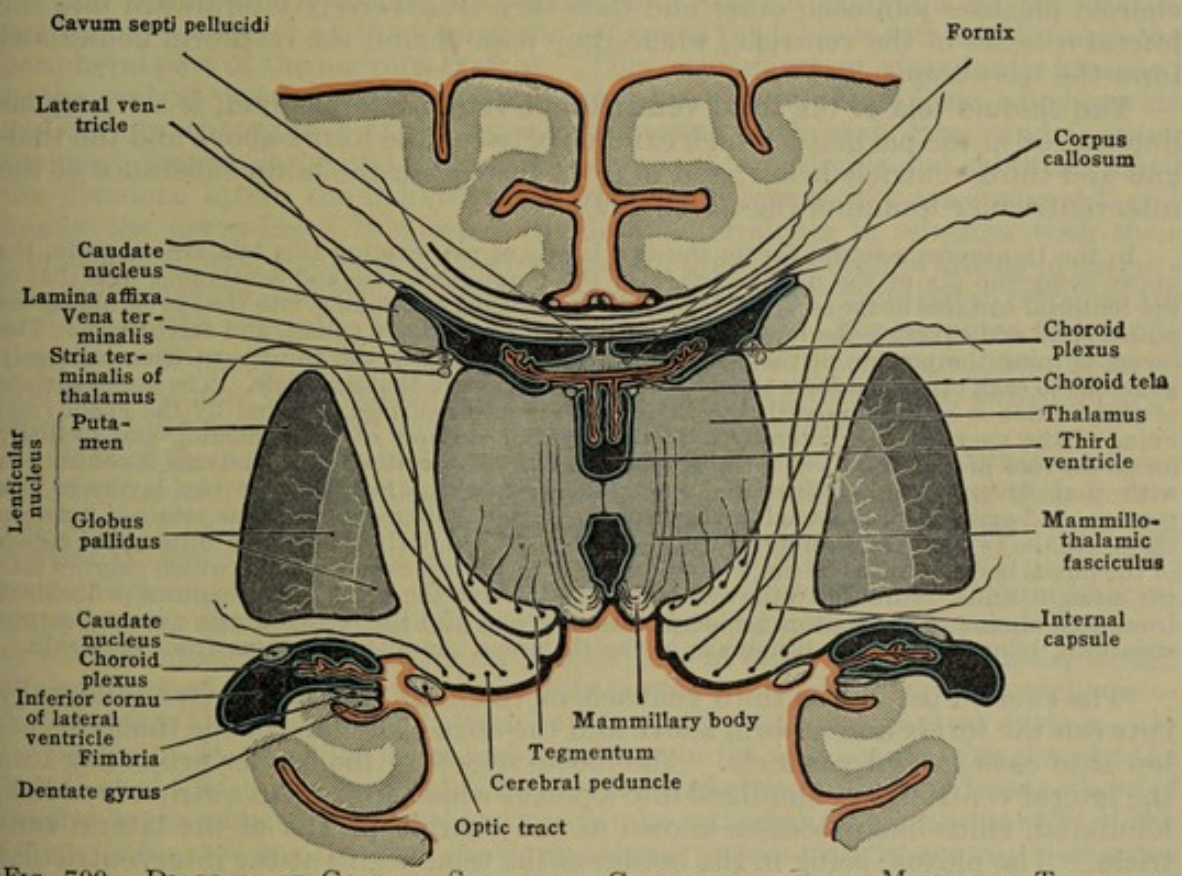

FIG. 799.—DIAGRAM OF CORONAL SECTION OF CEREBRUM THROUGH MIDDLE OF THALAMENCEPHALON SHOWING RELATIONS OF PIA MATER ENCEPHALI AND CHOROID PLEXUSES OF THIRD AND LATERAL VENTRICLES.

Its *outer surface* bounds the subarachnoid cavity. It is with difficulty separable into two layers of mixed white fibrous and elastic connective tissue, with slightly pigmented connective-tissue cells enmeshed between them. Its *inner surface* sends a large number of fibrous processes into the nervous substance, which blend with the neuroglia and aid in the support of the nervous elements. The larger of these processes accompany the central arterial and venous branches of the rich superficial plexuses of blood-vessels contained in the pia on the surface of the brain. Pieces of the pia when pulled off the brain and placed in water present a flocculent appearance, especially as to their inner surfaces, due to these processes having been pulled out.

The cranial pia mater sends strong, vascular duplications into two of the great transverse fissures of the encephalon; viz., the *transverse cerebellar fissure,* between the cerebellum and the medulla oblongata, and the *transverse cerebral fissure,* between the cerebellum, mesencephalon, and thalamencephalon below, and the overhanging cerebral hemispheres. These duplications are spread over the cavities of the fourth and third ventricles, and are known as the *choroid telæ* of these ventricles respectively.

The tela chorioidea of the fourth ventricle is that duplication which extends into the transverse cerebellar fissure, between the inferior surface of the cerebellum (vermis chiefly) and the dorsal surface of the medulla (fourth ventricle). The two layers of this fold of the pia remain separate and a portion of the cisterna cerebello-medullaris of the subarachnoid cavity lies between them.

The inferior of the layers is the tela chorioidea proper (fig. 718). It is triangular in shape, with its base cephalad at the nodule of the vermis and its apex below at the level of the tuber vermis. The superior layer of the fold is the pia mater of the inferior vermis. The tela chorioidea proper is strengthened by the epithelioid roof (ependyma) of the fourth ventricle and is continuous with the pia mater of the medulla oblongata and spinal cord. In roofing over the calamus scriptorius it constitutes the obex. A little above the calamus scriptorius it is pierced by the foramen of Magendie and the two lateral apertures into the fourth ventricle occur in its superolateral regions.

In front of the foramen of Magendie the vessels of the choroid tela, which are derived from the posterior inferior cerebellar arteries, form two longitudinal, lobulated strands occupying invaginations of the ependymal roof of the ventricle, projecting into its cavity, one on either side of the midline. These form the **choroid plexus of the fourth ventricle.** At the base of the triangular tela the two choroid plexuses join each other and then turn transversely lateralward into the lateral recesses of the ventricle, where they pass behind the restiform bodies and form the '*cornucopiæ.*'

The choroid tela of the third ventricle, or **velum interpositum,** is a triangular duplication of the pia mater which extends between the fornix above and the thalami and third ventricle below, and in front fuses with the brain substance at the interventricular foramina (figs. 765, 799).

In the transverse cerebral fissure the two layers of pia forming this tela are separate, the upper being the pia of the under surface of the corpus callosum and continuous with that of the tentorial surfaces of the occipital lobes; the lower being continuous into the pia enfolding the pineal body and covering the mesencephalon, anterior medullary velum, and cerebellum. The layers forming the portion of the duplication which roofs over the third ventricle are loosely adherent to each other and form the tela chorioidea proper of that ventricle. The upper surface of this portion is in relation with the fornix and its lower surface, covered by the ependymal lining of the ventricle, lies laterally over the superior surfaces of both thalami, and medially forms the roof of the third ventricle between them. The epithelioid ependyma is continuous with that covering the thalami and lining the ventricles. Between the two layers of this portion, and embedded in a small amount of the spongy subarachnoid tissue retained between them, are the two (internal cerebral) veins of Galen. Posteriorly these veins unite in the region of the pineal body to form the single great cerebral vein (*vena cerebri magna*) which empties into the straight sinus. Anteriorly the veins of Galen receive the veins of the septum pellucidum from each lamina of the septum pellucidum above, and also the terminal vein (vein of corpus striatum), lying in the stria terminalis of the thalamus, empties into them from each side.

The choroid tela of the third ventricle or velum interpositum extends laterally between the fornix and fimbria above and the stria terminalis of the thalamus below into each lateral ventricle. The blood-vessels of the border projecting into the lateral ventricle are amplified into a plexus which appears as a strip of reddish, lobulated, villus-like processes known as the **choroid plexus of the lateral ventricle.** The plexus, being in the border of the tela, begins at the interventricular foramen, extends through the body or central portion of the lateral ventricle, and downward into its inferior cornu. It is most developed at the junction of the body of the ventricle with the inferior cornu, and is there known as the **glomus chorioideum.**

From the inferior surface of the choroid tela of the third ventricle, hanging down on either side of the midline into the cavity of the ventricle, are two other longitudinal, lobulated invaginated strands of blood-vessels which are the **choroid plexuses of the third ventricle.** At the anterior end of the third ventricle these two plexuses join with each other and also with the plexus of the lateral ventricle of each side through the interventricular foramina.

The choroid plexuses of these ventricles are also covered by a layer of ependyma, *epithelial choroid lamina*, which is but a reflection of the ependyma lining the cavities throughout and represents the remains of the germinal layer of the embryonic brain-vesicles. The blood-vessels of the choroid plexus of the lateral ventricle receive blood by the choroid artery (a direct branch of the internal carotid), which enters the plexus through the choroid fissure immediately medial to the uncus, and also by the choroidal branches of the posterior cerebral artery, which supply the plexus of the body of the ventricle. The choroid plexuses of the third ventricle receive blood chiefly by branches from the superior cerebellar arteries. The greater part of the blood of both plexuses passes out by way of the tortuous choroid veins, which, at the interventricular foramina, empty into the venæ terminales (veins of the corpus striatum), which, in their turn, go to form

the greater part of the veins of Galen. Thence the blood passes by way of the vena cerebri magna into the straight sinus. It is probable that the cerebrospinal fluid of the third and lateral ventricles is derived chiefly by diffusion through the walls of the vessels of the choroid plexuses.

Ventricular nerve plexuses.—There is a subependymal nerve plexus demonstrable in all the choroid plexuses and apparently more robust than is required for the smooth muscle of the blood-vessels there. Fibers from this plexus give nerve terminations of sensory type in the ependyma itself as well as in the connective tissue subjacent to it. The latter terminations are described as similar to sensory terminations found in the pia and they may indicate a continuous series of such, from the pia, through the tela choroidea of the ventricles, into the subependyma. Some of the endings in the ependyma may be secretory (efferent) in function. Exclusive of the vasomotor fibers for the blood vessels there, the subependymal nerve nets in the choroid plexuses of the lateral recesses of the fourth ventricle are described in the cat (S. L. Clark) as composed of fibers which arise directly from the dorsolateral margins of the medulla (Benedict's thirteenth cranial nerve), while the fibers of the nerve plexus for the medial portion of this choroid plexus arise from the substance of the medulla via the taenia of the fourth ventricle. Kolmer has described a subependymal nerve plexus in the wall of the brain ventricles of the monkey.

THE PERIPHERAL NERVOUS SYSTEM

The intimate connection and consequent control exercised by the central nervous system over all the tissues and organs of the body is attained through the peripheral part of the nervous system. This part or system, abundantly attached to the central system, consists of numerous bundles of nerve-fibers which divide and ramify throughout the body, anastomosing with each other and forming various plexuses, large and small. The terminal rami divide and subdivide until the divisions attain the individual nerve-fibers of which they are composed, and finally the nerve-fibers themselves divide and terminate in relations with their allotted peripheral elements. It is by means of these that stimuli arising in the peripheral tissues are conveyed to the central system, and that impulses in response are borne from the central system to the peripheral organs. For purposes of description, as well as upon the basis of certain differences in structure, arrangement, and distribution, the peripheral nervous system is separated into two main divisions: (1) **the craniospinal** and (2) **the sympathetic system.**

Both of these divisions include numerous ganglia or peripheral groups of nerve-cells from which arise a considerable proportion of the fibers forming their nerve-trunks, but neither of the divisions may be considered wholly apart from the central system nor are they independent or separate from each other. The sensory or afferent fibers of the craniospinal nerves pass by way of the afferent nerve-roots into the central system and contribute appreciably to its bulk, and the motor or efferent fibers of these nerves have their cells of origin (nuclei) situated within the confines of the central system. The sympathetic system is intimately associated with the craniospinal, and consequently with the central system—(1) by means of fibers which enter and terminate in the craniospinal ganglia and the spinal cord and brain to supply the blood-vessels there; (2) by efferent fibers of central origin which course in the nerve-trunks and terminate in the ganglia of the sympathetic system; (3) also, the sympathetic trunks usually contain numerous afferent and efferent craniospinal fibers which thus pass to their peripheral termination, usually in the so-called 'splanchnic area,' or domain of the sympathetic, in company with the sympathetic fibers. Likewise the peripheral branches of the craniospinal nerves usually carry for varying distances numerous sympathetic fibers which are on their way to terminate upon their allotted peripheral tissue-elements.

The following **differences** between the craniospinal and sympathetic systems of nerves may be cited: (1) The craniospinal nerves are anatomically continuous with the brain and spinal cord; probably no fibers arising in the sympathetic ganglia actually enter the central system other than for the innervation of its blood-vessels. (2) The ganglia of the craniospinal nerves all lie near the central axis, in line on either side of it, and at more or less regular intervals; the sympathetic ganglia are scattered throughout the body, are far more numerous and more variable in size, and many of these ganglia are not symmetrical for the two sides of the body. (3) The craniospinal nerves are paired throughout, and the nerves of each pair are symmetrical as to their origin and also, with certain exceptions (notably the vagus), in their course and distribution; some of the larger and more proximal of the sympathetic nerve-trunks and plexuses are symmetrical for the two sides of the body; many of them are not, and many of the smaller and most of the more peripheral nerves and ganglia, large and small, are not paired at all. (4) Even in their finer twigs, the craniospinal nerves of the two sides probably do not join with each other across the midline of the body; the sympathetic nerves do so abundantly, especially within the body-cavity. (5) The craniospinal nerves are distributed to the ordinary

sensory surfaces of the body and the organs of special sense and to the skeletal, (striated or 'voluntary') muscles of the body; the sympathetic fibers are devoted chiefly to the supply of the so-called involuntary muscles of the body, including the smooth muscle in the walls of the viscera and in the walls of the blood and lymph vascular-systems, and also to (striated) cardiac muscle, while others serve as secretory fibers to the glands. (6) Craniospinal nerve-fibers are characterized in general by well-developed medullary sheaths, making the nerves appear as white strands; most of the sympathetic fibers are non-medullated, some are completely and some partially medullated, but none possess as thick medullary sheaths as those of the craniospinal nerves. Thus sympathetic nerves appear as gray strands in the periphery. However, many unmedullated craniospinal fibers are to be found.

The craniospinal nerves.—There are forty-six pairs of craniospinal nerves, of which thirty-one pairs are attached to the spinal cord (spinal nerves) and fifteen pairs to the encephalon (cranial nerves). The spinal nerves are the more primitive and retain the typical character, i. e., each is attached to the spinal cord by two roots, a dorsal or sensory ganglionated root, and a ventral, which is motor and not ganglionated. Most of the cranial nerves have only one root, which in some cases corresponds to a dorsal root and therefore has a ganglion, and in other cases corresponds, physiologically at least, to a ventral root of a spinal nerve. Among other individual differences, the fibers of the first cranial nerve, for example, do not collect to form a distinct nerve-trunk and its fibers are not medullated.

I. THE CRANIAL NERVES

Customarily, the cranial nerves [nervi cerebrales] are described as comprising twelve pairs and each is referred to by number. However, present knowledge of their origin, central connections and peripheral distribution suggests that those enumerated as the fifth, seventh, and eighth pairs under the old nomenclature are better each separated into its two component nerves, each of which merits a separate description and a separate name. None of the cranial nerves corresponds closely to a typical spinal nerve with its motor and sensory root. The so-called motor portion of the fifth is no more its motor root than is the seventh nerve. The sensory portion of the seventh is not wholly sensory and rather resembles the ninth pair in distribution, and it has long been commonly referred to as a separate nerve. The two parts of the eighth nerve, both sensory, are known to be wholly different in functional character and are so named. Further, the names of the nerves, descriptive of their function, are pedagogically much more efficient than the use of numbers in referring to them.

Separating the three pairs mentioned, each into its two nerves, gives fifteen pairs instead of twelve. Their names and functional nature are given in the following table. The Roman numerals given in parentheses correspond to the serial numbers given when twelve pairs only are considered. It is also customary to enumerate the cranial nerves from in front backward and caudalward, and this custom is followed here, but again it would be pedagogically better to take them in the reverse order. Then each in its turn could be directly considered as in continuous series with the spinal nerves below and the similarities to and progressive modifications from the spinal type could be better realized. It will be remembered that *somatic efferent* or *motor* fibers are those which terminate directly upon the fibers of skeletal muscle while *visceral efferent* or motor fibers transfer their impulses to sympathetic neurones, and the axones of the latter terminate upon gland cells and upon the fibers of cardiac and smooth muscle.

Name	Nature	General Distribution
Olfactory (I)	Sensory	Olfactory region, nasal epithelium.
Optic (II)	Sensory	Retina.
Oculomotor (III)	Motor: Somatic	Eye-moving muscles.
	Motor: Visceral	Ciliary body, iris.
Trochlear (IV)	Motor-somatic	Eye-moving muscles.
Abducens (VI)	Motor-somatic	Eye-moving muscles.
Trigeminus (V)	Sensory	Face, mouth, and scalp.
Masticator (*minor part or motor root of trigeminus*)	Motor-somatic	Muscles of mastication.
Facial (VII)	Motor: Somatic	Facial muscles.
	Motor: Visceral (?)	Salivary glands, vessels (?).
Glossopalatine. (*Intermediate part of facial.*)	Sensory: Somatic visceral	Tongue, palate.
	Motor-visceral	Salivary glands.

Name	Nature	General Distribution
Cochlear (*auditory*) (VIII).	Sensory	Internal ear (cochlea)
Vestibular (*equilibrator*) (VIII).	Sensory	Semicircular canals, utriculus, sacculus.
Glossopharyngeal (IX)	Sensory { Somatic / Visceral }	Tongue, palate, pharynx.
	Motor { Somatic	Pharynx.
	Visceral	Glands and vessels.
Vagus (X)	Sensory { Visceral / Somatic }	Alimentary canal, lung, heart, ear.
	Motor { Somatic	Larynx, pharynx.
	Visceral	Alimentary canal, heart, larynx, trachea, lung.
Hypoglossal (XII)	Motor-somatic	Tongue-moving muscles.
Spinal accessory (XI)	Motor { Somatic	Neck and shoulder-muscles.
	Visceral	Pharynx, larynx, heart.

The cranial nerves, like the spinal nerves, are developed from cells of the primitive neural tube and, beginning with the trigeminus downward, all the sensory nerves are developed from the cells corresponding to those of the ganglion crest which give origin to the spinal ganglia and the sensory components or dorsal roots of the spinal nerves. Otherwise between the cranial nerves and the spinal nerves there are many important differences. Each spinal nerve has a dorsal or sensory root, which springs from the cells of a spinal ganglion; a ventral or motor root, whose fibers are processes of the nerve-cells which are situated in the walls of the central system, and at their attachment to the surface of the cord the two roots are some distance apart. Only one of the (usually recognized) twelve pairs of cranial nerves corresponds at all closely with typical spinal nerves. This one is the trigeminus which possesses a sensory ganglionated root and near its attachment is accompanied by a small motor nerve, the masticator, which serves in very small part as a corresponding motor root of the trigeminus. But even in this case where the similarity between the cranial and spinal nerves is greatest, there are still points of anatomical difference, which if not essential are very obvious, for the so-called motor root joins not the whole but only with one branch of the sensory portion. The two are only slightly separated from each other at their attachment to the surface of the brain. All the other cranial nerves differ in a still more marked manner from typical spinal nerves. The olfactory nerve is an afferent nerve whose cells of origin (olfactory ganglion) are scattered in the mucous membrane of the nose, an organ of special sense, and its fibers are not collected together into a nerve-trunk, but pass, as a number of small bundles, through the lamina cribrosa of the ethmoid bone directly into the olfactory bulb. The optic nerve is also a nerve of special sense. Its fibers form a very distinct bundle, similar in appearance to an ordinary nerve, from which, however, it differs essentially, both with regard to structure and development; for, unlike an ordinary nerve, its connective tissue consists to a large extent of neuroglia instead of ordinary connective tissue, and its component nerve-fibers are of much smaller caliber than those of an ordinary nerve. It represents the location of the original optic stalk, a diverticulum from the neural tube, and it associates the retina (optic cup), a bit of modified cortex, with the encephalon. The optic nerve, therefore, corresponds more closely with an association tract of the central system than with an ordinary nerve. Its ganglion of origin is a layer of the retina.

The oculomotor, trochlear, abducens and hypoglossal nerves are practically purely motor nerves, and thus correspond only with the ventral roots of spinal nerves. The spinal accessory is purely motor. Its fibers arise from the cells of the anterior horn of the spinal cord and from a nucleus of the medulla which represents an upward extension of that horn, but they do not leave the surface of the spinal cord and brain in the usual situation of ventral roots. On the contrary, they emerge as a series of rootlets from the lateral funiculus of the cord on the dorsal side of the ligamentum denticulatum, and from the upward prolongation of this funiculus.

The cochlear and vestibular are nerves of special sense, and in some respects both correspond closely with the dorsal root of a typical spinal nerve, and the ganglia of both represent spinal ganglia, but their peripheral distribution is limited to the membranous labyrinth.

The vagus and glossopharyngeal nerves contain both motor and sensory fibers, but they differ from typical spinal nerves in that the motor fibers, in company

with the sensory, issue from the posterolateral sulcus of the medulla, and they are intimately intermingled, from their origin, with the sensory fibers, which latter arise from ganglia interposed in the trunks of the nerves and otherwise correspond with the fibers of the dorsal root of a typical spinal nerve.

Superficial attachments and origins.—It is customary to speak of the area where the nerve-fibers leave or enter the brain substance as the superficial attachments of the cranial nerves, and the groups of cells from which their fibers spring, and about which they terminate, as their nuclei of origin and of termination, respectively.

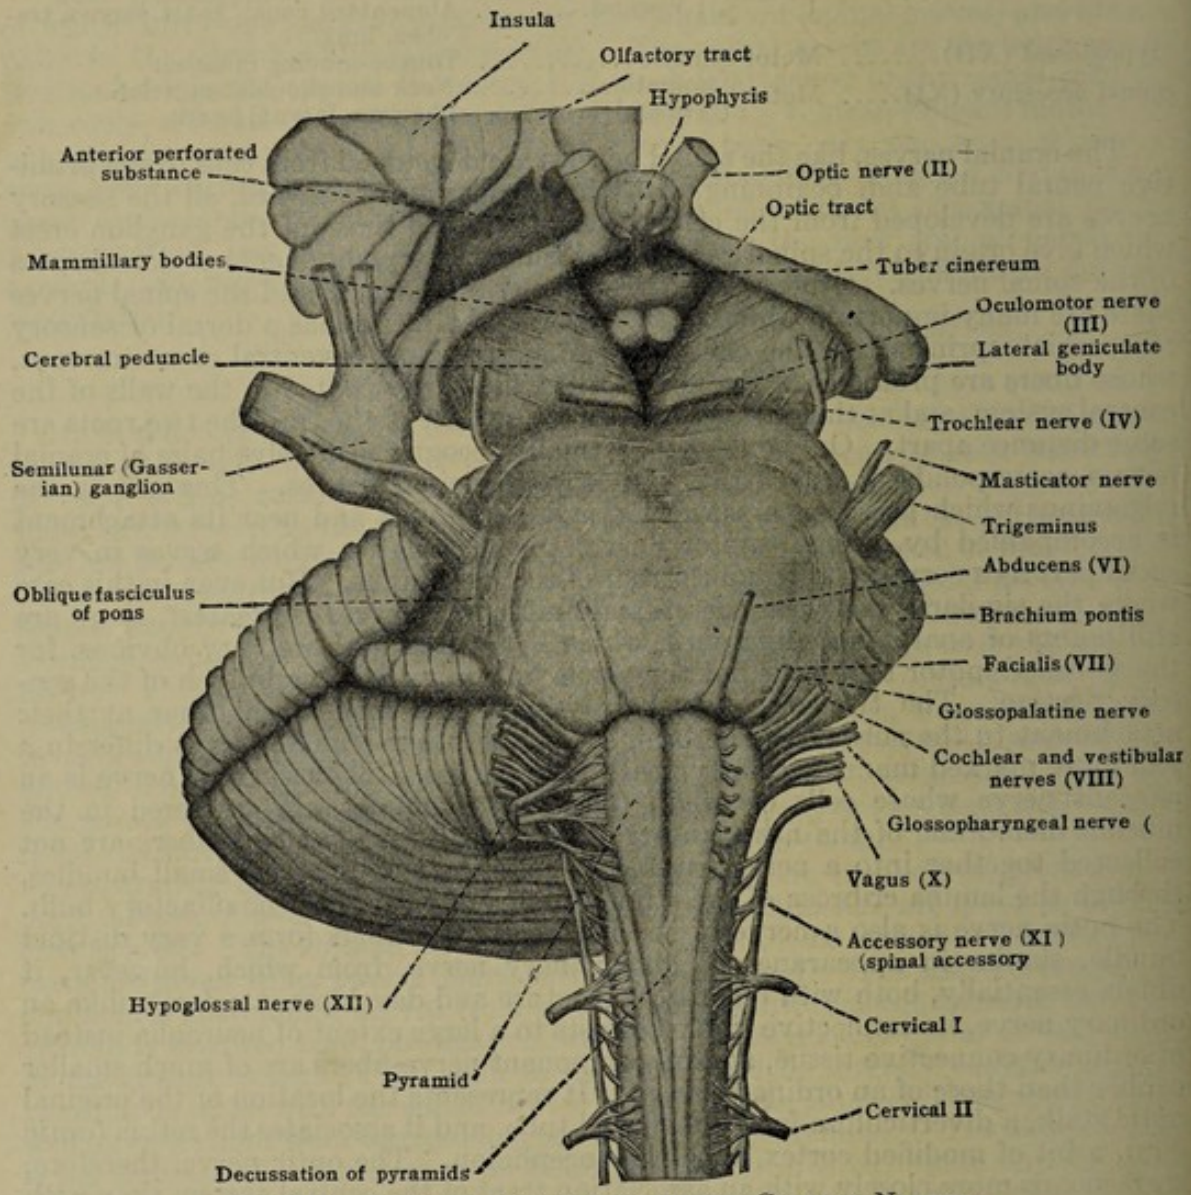

FIG. 800.—SURFACE ATTACHMENT OF THE CRANIAL NERVES.
(After Allen Thomson modified.)

THE OLFACTORY NERVES

The **olfactory nerve-fibers** (fila olfactoria NK) (fig. 801) are the central processes of the bipolar olfactory nerve cell-bodies situated in the olfactory region of the nasal mucous membrane. In man, the olfactory region comprises the epithelium upon the superior third of the nasal septum and that upon practically the whole of the superior nasal concha. The area is relatively small as compared with that of other mammals and, as in other mammals, is characterized by an increased thickness of the epithelium and a yellowish brown color when fresh. The peripheral processes of the olfactory cell-bodies (the olfactory ganglion) are short and extend only to the surface of the olfactory epithelium. As the central processes pass upward from their cells of origin they form subepithelial plexuses in the mucous membrane, and from the upper parts of these plexuses, immediately below the lamina cribrosa of the ethmoid, about twenty filaments

issue on each side. These filaments comprise the **olfactory nerve.** They are non-medullated. They pass upward, through the foramina in the lamina cribrosa, into the anterior fossa of the cranium in two rows, and after piercing the dura mater, the arachnoid, and the pia mater, they enter the inferior surface of the olfactory bulb.

They contribute to the superficial stratum of nerve-fibers on the inferior surface of the olfactory bulb, ending in the *glomeruli* formed by the terminal ramifications of the olfactory nerve-fibers in synapsis with the similar ramifications of the main dendrites of the large mitral cells which lie in the deeper part of the gray substance of the olfactory bulb.

The olfactory nerve-fibers are gray fibers, since they do not possess medullary sheaths, and they are bound together into bundles by connective-tissue sheaths derived from the pia mater, from the subarachnoid tissue, and from the dura mater.

Central connections—The olfactory impulses are transmitted by way of the peripheral processes of the olfactory neurones through the cell-bodies and the olfactory nerve-fibers and by way of the glomeruli to the mitral cells. Thence they are carried by the central processes (axones) of the mitral cells, which pass backward along each olfactory tract and its three olfactory striæ. (See Rhinencephalon, p. 940.)

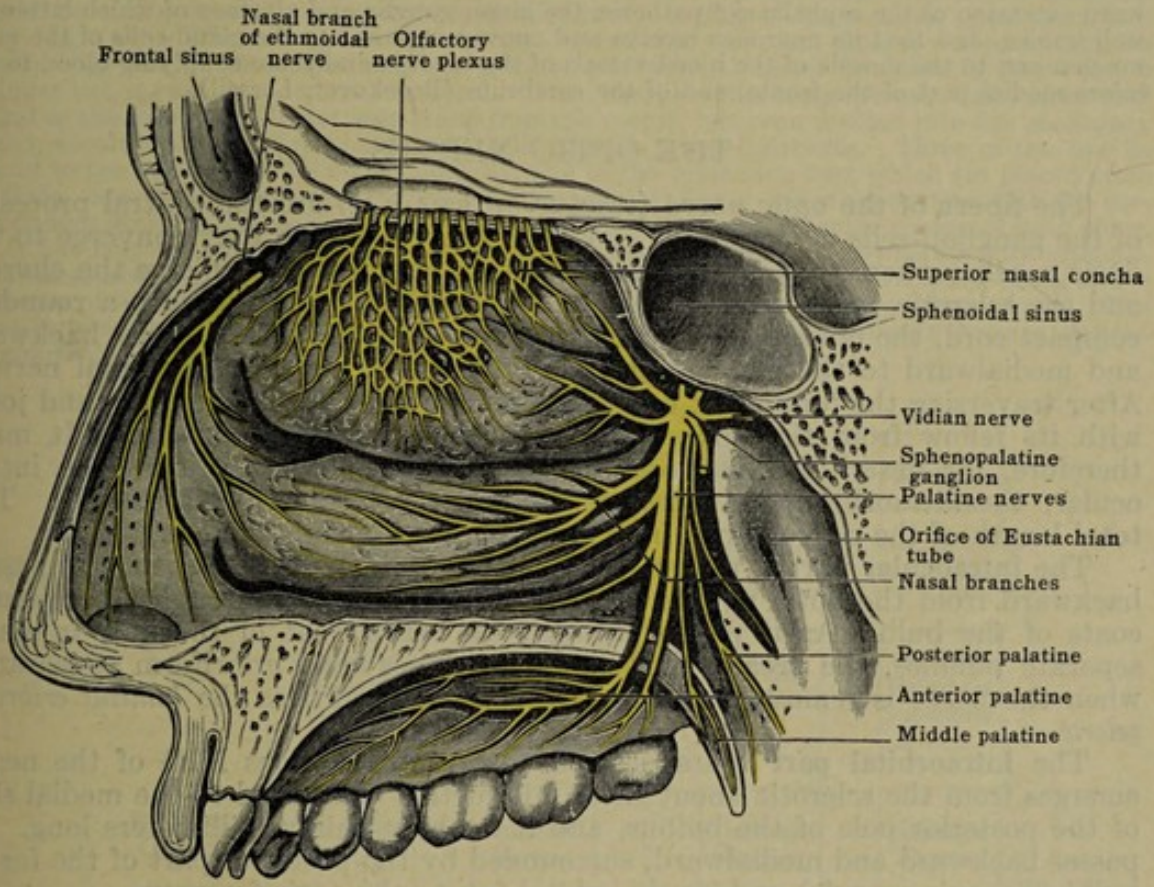

FIG. 801.—NERVES OF THE NASAL CAVITY (SEMI-DIAGRAMMATIC.)

THE TERMINAL NERVE (*Nervus Terminalis*)

In lower vertebrates and recently in those mammals whose sense of smell is relatively much more developed than in man, three nerves have been found in relation with the olfactory apparatus:—(1) The olfactory nerve proper whose fibers, as noted above, are the central processes of the nerve cell-bodies situated in the epithelium of the olfactory region of the nasal mucosa, and which terminate in the olfactory bulb; (2) the vomeronasal nerve, whose fibers are the central processes of nerve cell-bodies situated in the epithelium of the vomeronasal (Jacobson's) organ and which pass caudalward in the submucosa and upward to join the filaments of the olfactory nerve proper and which, in the dog, cat, rabbit, rat, etc., terminate in the accessory olfactory bulb—a small protuberance possessed by these animals on the posteromedial aspect of the olfactory bulb proper; (3) the terminal nerve, a small plexiform nerve, which unlike the other two is ganglionated.

In man, the vomeronasal (Jacobson's) organ is rudimentary after birth and, therefore, the vomeronasal nerve is not present, the only fibers for the vomeronasal region being those of general sensibility from the trigeminus and sympathetic fibers common to the epithelium of the entire nasal fossa.

The terminal nerve has been recently described as present in the human fetus and in the adult of other animals. It is mentioned here because of the expressed belief that it is an added cranial nerve and that it is present in the human adult. From the observations recorded for human and rabbit fetuses and the adult dog, ox, horse, squirrel and cat, the following description may be given: It is variably plexiform throughout its course. Peripheral twigs have been described for it as distributed to the mucosa of the nasal septum, some to the mucosa joining the olfactory

region while other and larger twigs extend further forward and are distributed to the mucosa of the vomeronasal organ, accompanying and sharing in the distribution of the vomeronasal nerve when this is present. It is not certain that many of the fibers of these twigs are not fibers of the trigeminus and vomeronasal nerves. Its central connections are in the form of two or three small roots which pass through the cribriform plate of the ethmoid bone in company with and medial to the vomeronasal nerve and then, still plexiform, extend caudalward over the inferomedial aspect of the olfactory bulb and upon the olfactory peduncle or stalk (olfactory tract) beyond, a root often extending to near the lamina terminalis and optic chiasma. The roots disappear in the medial and inferomedial aspect of the frontal portion of the brain at different localities caudal to the olfactory bulb and usually near the olfactory peduncle, but often one may disappear in the region corresponding to the anterior perforated substance of the adult human brain.

Numerous small groups of ganglion-cells are found interposed along both the peripheral and intracranial course of the terminal nerve. A group, larger in size than the others and situated in the intracranial course of the nerve, is called the *ganglion terminale*. The fibers of the nerve are non-medullated. Both the ganglion-cells and the fibers of the nerve are described as having more the appearances characteristic of sympathetic neurones than of craniospinal. On the other hand, our conceptions of sympathetic neurones do not permit of their terminating within the central system except for the innervation of its blood-vessels. It may result that, instead of being an independent nerve as has been claimed, the nervus terminalis is a part of the forward extension of the cephalic sympathetic, the larger ganglia and plexuses of which latter are well known, and that its neurones receive and convey impulses to the gland-cells of the nasal mucosa and to the muscle of the blood-vessels of the mucosa and those supplying blood to the infero-medial part of the frontal end of the cerebrum (Brookover, Larsell).

THE OPTIC NERVES

The **fibers of the optic nerve** (tractus opticus NK) are the central processes of the ganglion-cells of the retina. Within the ocular bulb they converge to the optic papilla, where they are accumulated into bundles which pierce the choroid and the sclerotic coats, and, at the back of the bulb, assemble into a rounded, compact cord, the optic nerve, which traverses the orbital fat to pass backward and medialward to the optic foramen. It is the largest of the cranial nerves. After traversing the foramen it enters the middle fossa of the cranium, and joins with its fellow from the opposite side, forming the optic chiasma. It may, therefore, for descriptive purposes, be divided into four portions—the intraocular, the intraorbital, the intraosseous, and the intracranial (fig. 867). The total length of the nerve varies from forty-five to fifty millimeters.

The **intraocular part** is rather less than one millimeter in length. It passes backward from the optic papilla through the choroid and through the sclerotic coats of the bulb. As it passes through the latter coat of the bulb in many separate bundles, the area of the sclera it traverses has a cribriform appearance when the nerve is removed, and consequently is known as the *lamina cribrosa scleræ*.

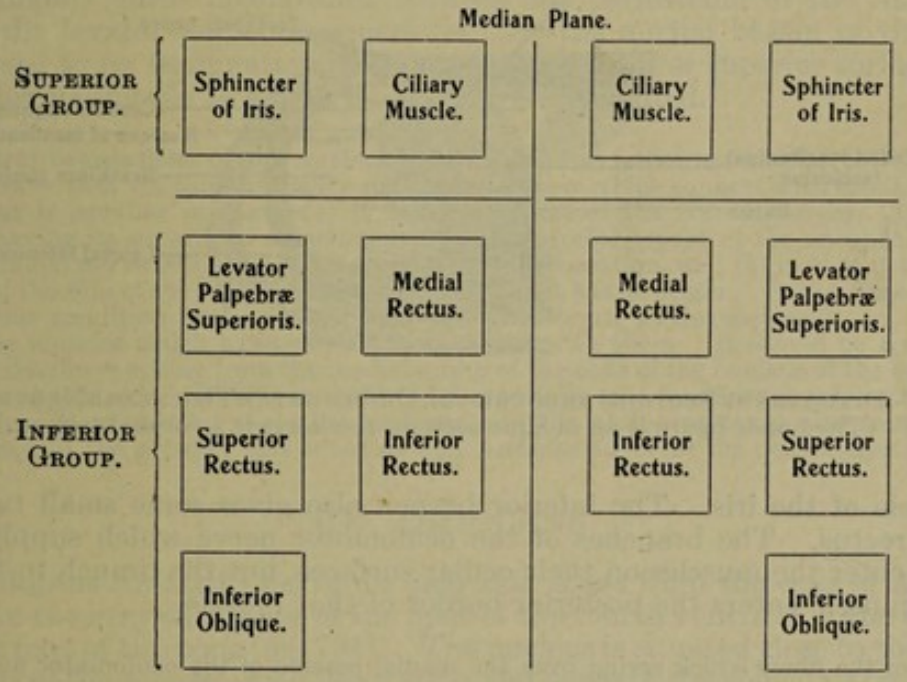
The **intraorbital part** (pars orbitalis of tractus opticus NK) of the nerve emerges from the sclerotic about three millimeters below and to the medial side of the posterior pole of the bulbus, and it is about thirty millimeters long. It passes backward and medialward, surrounded by the posterior part of the fascia bulbi (Tenon's capsule) and by the orbital fat, to the optic foramen.

As it runs backward in the orbit it is in relation above with the nasociliary (nasal) nerve and the ophthalmic artery which pass obliquely from behind and laterally, forward and medialward across the junction of its posterior and middle thirds, and also it is in relation with the superior ophthalmic vein, the superior rectus muscle, and the upper branch of the oculomotor nerve. Below it are the inferior rectus muscle, and the inferior division of the oculomotor nerve. To its lateral side, near the posterior part of the orbit, are the ophthalmic artery, the ciliary ganglion, the abducens nerve, and the external rectus muscle. The anterior two-thirds of this portion of the optic nerve are surrounded by the ciliary arteries and the ciliary nerves and it is penetrated on its medial and lower aspect by the central artery of the retina. As it enters the optic foramen as the intraosseous part, it is in close relation with the ligaments of Lockwood and Zinn (annulus tendineus communis) and with the four recti muscles which arise from them.

The **intraosseous portion** is from six to seven millimeters long. It lies between the roots of the small wing of the sphenoid and the body of that bone, and it is in relation below and laterally with the ophthalmic artery.

The **intracranial portion** (pars cerebralis NK) (fig. 800), which is from ten to twelve millimeters long, runs backward and medialward, beneath the posterior end of the olfactory tract, and above the ophthalmic artery, the medial border of the internal carotid artery and the diaphragma sellæ, to the chiasma. From the chiasma to the central connections of the nerve, the path is known as the optic tract.

Central connections.—The central connections of the fibers of the optic nerve have been considered with the optic chiasma and the optic tract (see pp. 924, 977).



The sheaths of the optic nerve.—The optic nerve receives a sheath from each of the membranes of the brain, and thus prolongations of the subdural and subarachnoid cavities pass outward along it to the posterior part of the sclera. The sclera may be considered as a modified dura mater.

THE OCULOMOTOR NERVES

The oculomotor or third cranial nerve is a motor nerve. Each supplies seven muscles connected with the eye, two of which, the sphincter of the iris and ciliary muscle, are smooth muscle and within the eyeball. The remaining five (skeletal muscle) are in the orbital cavity, and four of them—the superior, inferior, and medial recti and the inferior oblique—are inserted into the eyeball, while the fifth, the levator palpebræ superioris, is inserted into the upper eyelid.

The fibers of the oculomotor nerve spring from their nucleus of origin situated in the gray substance of the floor of the cerebral aqueduct in the region of the superior quadrigeminate body (fig. 741). The cells of this nucleus are divided into two main groups, a superior and an inferior (fig. 742). The **superior group** gives rise to visceral motor (autonomic) fibers and it includes two nuclei, a medial and a lateral. The latter, besides being lateral, is also somewhat dorsal to the former. The **inferior group** (somatic motor) has been divided into five secondary nuclei, according to the eye-muscles the cells of each group innervate. Three of the five lie lateral to the others and somewhat dorsally, and of the remaining two, which are placed more medially, one encroaches upon the midline (*nucleus medialis*) and is continuous with the corresponding group of the opposite side and is common to the oculomotor nerves of both sides.

It has been found, by the study of diseased conditions and by experiments with animals, that the sources of innervation of the eye-muscles supplied by the nerve correspond to the above divisions of both the superior and inferior group of cells into a medial and lateral series. The relative position of the divisions of each group on the two sides and the muscles they are thought to innervate are shown in the following diagram devised by Starr:

As they leave their nucleus of origin in the midbrain, the fibers of the oculomotor nerve form a series of fasciculi, which curve ventrally around and through the red nucleus and the medial part of the substantia nigra, to the oculomotor sulcus on the medial surface of the cerebral peduncle (fig. 800), where they emerge in from six to fifteen root-filaments which pierce the pia mater and collect into the trunk of the nerve. Immediately after its formation along the oculomotor sulcus, the trunk of the nerve passes between the posterior cerebral and the superior cerebellar arteries, and, running downward, forward, and laterally in the posterior part of the cisterna basalis, it crosses the anterior part of the attached border of the tentorium cerebelli at the side of the dorsum sellæ, and, piercing the arachnoid and the inner layer of the dura mater, it courses through the outer wall of the cavernous sinus about midway between the anterior and posterior clinoid processes. Immediately after its entry into the wall of the sinus it lies at a higher level than the trochlear nerve, but the latter soon crosses on its lateral

side and gets above it, and directly afterward the oculomotor nerve divides into a smaller superior and a larger inferior branch (fig. 803). Before its division **communications** join it from the cavernous plexus of the sympathetic about the internal carotid artery, and from the ophthalmic division of the trigeminus. Both branches proceed forward, and the nasal branch of the trigeminus, which has passed upward on the lateral side of the inferior branch of the oculomotor, lies between them. At the anterior end of the cavernous sinus the two branches pass through the superior orbital (sphenoidal) fissure, between the heads of the lateral rectus muscle, and enter the orbital cavity. In the orbit, the **superior branch** (ramus brevis NK) lies between the superior rectus and the optic nerve; it supplies the superior rectus and then turns round the medial border of that muscle and terminates in the levator palpebræ superioris. The **inferior branch** (ramus longus NK) runs forward, beneath the optic nerve, and divides into three branches which supply the inferior and medial recti and the inferior oblique.

The branch to the inferior oblique muscle is connected with the ciliary ganglion by a short thick visceral efferent offset, the **short root of the ciliary ganglion.** Fibers of this offset make synapses with the sympathetic neurones of this ganglion whose axones carry the oculomotor impulses to the ciliary muscle and the sphinc-

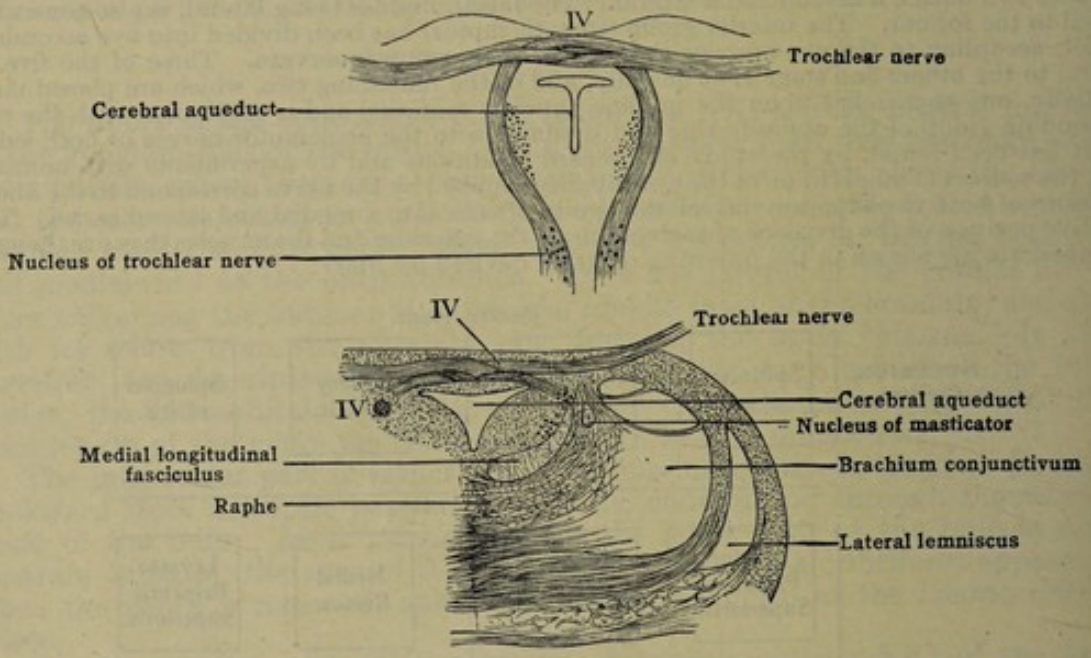


FIG. 802.—DIAGRAMS OF SECTIONS THROUGH THE ORIGIN OF THE TROCHLEAR NERVE. (Stilling.)
(The upper figure is an oblique section, the lower is a coronal section.)

ter muscle of the iris. The inferior branch also gives some small twigs to the inferior rectus. The branches of the oculomotor nerve which supply the recti muscles enter the muscles on their ocular surfaces, but the branch to the inferior oblique muscle enters the posterior border of that muscle.

Some of the fibers which spring from the medial portion of the oculomotor nucleus do not pass into the nerve of the same side, but into that of the opposite side, and it is believed that they are distributed to the opposite medial rectus muscle. Other fibers which arise from the nucleus descend in the medial longitudinal fasciculus and either terminate about the cells of the nucleus of the facial or join the facial nerve, in which they pass to the upper part of the orbicularis palpebrarum. The opening of the eye is controlled by the oculomotor and the closing of the eye by the facial nerve.

Against the common contention that the oculomotor is a purely motor nerve is the claim that it contains some somatic afferent (sensory) fibers carrying impulses of muscular sense from the muscles the nerve supplies. A few branched nerve cell-bodies have been found (Kopsch) scattered among its fibers in serial sections of its root. All the eye-moving nerves receive sensory fibers from the ophthalmic branch of the trigeminus.

Central connections.—The nucleus of the oculomotor is associated with the middle portion of the anterior central gyrus, the posterior end of the middle frontal gyrus and with the cortex about the visual area of the occipital lobe of the same and opposite sides by the pyramidal fibers. It is associated with the superior colliculus, and probably the cerebellum by the fibers in the superior cerebellar peduncles, and with the sensory nuclei of the other cranial nerves by the medial longitudinal fasciculus. To produce the coördinated activities of the eye-moving muscles, it must be associated with the nuclei of the trochlear and abducens.

THE TROCHLEAR NERVES

The fibers of each trochlear or fourth nerve (or patheticus) spring from the cells of a nucleus which lies in the gray substance of the floor of the cerebral aqueduct in line with the oculomotor nucleus, but in the level of the inferior quadrigeminate bodies. As the fibers pass from their origins they run ventrally and laterally in the substance of the tegmentum for a short distance, then they curve medianward and dorsalward, and, in passing through the anterior end of the superior medullary velum, they decussate totally with the fibers of the trochlear nerve of the opposite side (figs. 738, 800, 802). After the decussation the fibers emerge from the surface of the superior medullary velum, at the side of the frenulum veli, usually in two small bundles, which pierce the pia mater and join together to form the slender trunk of the nerve. This trunk curves forward and ventralward to the base of the brain around the sides of the superior peduncle of the cerebellum and the cerebral peduncle of the side opposite to that in which the nerve originates, running parallel with and between the superior cerebellar and posterior cerebral arteries. As it reaches the base of the brain behind the optic tract the nerve enters the cisterna basalis, in which it runs forward, immediately beneath or piercing the free border of the tentorium cerebelli, to the superior border of the petrous portion of the temporal bone, where it pierces the arachnoid and the dura mater and enters the posterior end of the lateral (outer) wall of the cavernous sinus. In the wall of the cavernous sinus it receives **communications** from the cavernous plexus of the sympathetic and, by a small filament, from the ophthalmic division of the trigeminus. It gradually ascends, as it passes forward in the lateral wall of the sinus, and, beyond the middle of the sinus, it crosses the lateral side of the trunk of the oculomotor nerve and gains a higher position (fig. 803). At the anterior end of the sinus the nerve enters the orbit above the lateral rectus and immediately turns medialward between the periosteum of the roof of the orbit and the levator palpebræ superioris. At the medial border of the roof it turns forward to its termination, and enters the orbital or superior surface of the superior oblique muscle to which its fibers are distributed.

The central connections of the nucleus of the trochlear nerve are similar to those of the oculomotor save that its cells probably do not send fibers which connect with the facial nerve. The trochlear is peculiar in that—(1) it is the smallest of the cranial nerves; (2) it is the only nerve having its superficial attachment upon the dorsal aspect of the encephalon; (3) it is the only cranial nerve whose fibers undergo a total decussation, and (4) in that it terminates in a muscle of the side of the body opposite that in which it has its origin. Gaskell has suggested that this latter condition has probably been brought about, phylogenetically, by the transference of the muscles which have carried their nerves with them. It should be remembered that most of the fibers arising from the medial group of the cells of the nucleus of the oculomotor cross to the opposite side. This is thought to be especially true for those supplying the medial rectus muscle. It is claimed that the trochlear and the abducens carry also some somatic sensory fibers, but the proof of this is not so well established as for the oculomotor.

THE ABDUCENS

The abducens (or sixth) nerve on each side arises from the cells of a nucleus which lies in the gray substance of the floor of the fourth ventricle in the region of the inferior part of the pons (fig. 731). The nucleus is situated close to the middle line, ventral to the acoustic medullary striæ and beneath the colliculus facialis and it is in direct linear series with the nuclei of the oculomotor, trochlear and hypoglossal nerves. It is the third of the eye-moving nerves. The fibers which pass from the nucleus into the nerve run inferiorly and ventralward through the reticular formation, the trapezium, and the pyramidal fasciculi, and they emerge from the ventral surface of the medulla in the sulcus at the inferior border of the pons and the upper end of the pyramid of the medulla (fig. 800). From this superficial attachment the nerve runs upward and forward in the subarachnoid space between the pons and the basisphenoid and at the side of the basilar artery. A little below the level of the upper border of the petrous portion of the temporal bone it pierces the dura mater, passes beneath the petrosphenoidal ligament, at the side of the dorsum sellæ, and enters the dura of the medial wall of the cavernous sinus, in which it runs forward along the lateral side of the internal carotid artery. At the anterior end of the sinus it passes through the superior orbital (sphenoidal) fissure between the heads of the rectus lateralis, below the inferior

branch of the oculomotor nerve, and above the ophthalmic vein. In the orbit it runs forward on the inner or ocular surface of the rectus lateralis, and finally it pierces this muscle and terminates upon its fibers.

While it is in the cavernous sinus it receives communications from the carotid plexus of the sympathetic and from the ophthalmic nerve.

All the fibers arising in the nucleus of the abducens do not pass into the nerve. Some of them ascend in the medial longitudinal fasciculus of the same and opposite sides, and terminate about cells of the medial group of the nucleus of the oculomotor nerve, from which the impulses are conveyed to the opposite medial rectus muscle. Thus impulses reaching the abducens nucleus can throw into simultaneous action the lateral rectus of the same side and the medial rectus of the opposite side, and thus turn both eyes in the same direction.

Central connections.—The nucleus of the abducens receives impulses from the anterior central gyrus of the opposite side by the pyramidal fibers, and it is associated with the sensory nuclei of other nerves by way of the medial longitudinal fasciculus, and that of the trigeminus especially through the reticular formation.

THE TRIGEMINUS

The trigeminus is the largest of the cranial nerves with the exception of the optic. It is usually described as the fifth cranial nerve and as possessing both a sensory [portio major] and a motor root [portio minor]. For reasons already given, the 'motor root' is here described separately and given the separate name, *masticator nerve*. The fibers of the trigeminus proper, which are all sensory, spring from cells of the semilunar (Gasserian) ganglion, which corresponds with the ganglion of the dorsal root of a spinal nerve, and they enter the brain-stem through the side of the anterior half of the pons (fig. 800).

The **semilunar (Gasserian) ganglion** (fig. 803) is a semilunar mass which lies in Meckel's cave, a cleft between the layers of the dura mater above a depression in the medial part of the anterior surface of the petrous portion of the temporal bone. The concavity of the ganglion is turned forward, and from it three large nerves, the *ophthalmic*, the *maxillary* and the *mandibular*, are given off. From the convexity, which is directed backward, springs the root of the nerve. The medial end of the ganglion is in close relation with the cavernous sinus and the internal carotid artery at the foramen lacerum, and the lateral end lies to the medial side of the foramen ovale. The surfaces of the ganglion are striated, due to bundles of fibers traversing them. The upper surface is separated by the inner layer of the dura mater from the temporal lobe of the brain, and the lower rests upon the masticator nerve and the outer layer of dura mater upon the petrous portion of the temporal bone.

The fibers of the trigeminus root as they leave the semilunar (Gasserian) ganglion, form from thirty to forty fasciculi which are bound together into a flat band, from 6 to 7 mm. broad, which passes backward over the upper border of the petrous portion of the temporal bone and below the superior petrosal sinus into the posterior fossa of the cranium. In the posterior fossa the root runs backward, medialward, and downward, entering the pons through its continuation into the middle peduncle of the cerebellum. In the tegmentum of the pons region, the fibers bifurcate into ascending and descending branches which terminate about the cells of the nucleus of termination of the trigeminus. This nucleus, large at the level of the entrance of the root, has tapering superior and inferior extremities. The inferior extremity of the nucleus, which is much the longer, descends as low as the upper portion of the spinal cord and the fibers of the root terminating about the cells of this extremity are known as the spinal tract of the trigeminus. (See description of the nuclei under Rhombencephalon.)

Central connections.—The nuclei of termination of the trigeminus send impulses to the somesthetic area of the cortex of the opposite side by the fibers of the medial leminscus (trigeminal lemniscus) and, for reflex actions, to the motor nuclei of other cranial nerves and to ventral horn cells of the cervical spinal cord by the medial longitudinal fasciculus and by fasciculi proprii in the reticular formation of the same, and opposite sides. Of especial interest are the rapid palpebral reflexes mediated through its supratrochlear, infratrochlear, lacrimal and inferior palpebral terminal branches.

Clinical aspects.—The semilunar (Gasserian) ganglion lies at a depth of 5.5–6 cm. (2¼ in.) under the eminentia articularis. In exposing it for the purpose of excision for intractable neuralgia the following structures are encountered: (1) Skin and superficial fascia with branches of the superficial temporal artery; (2) temporal fascia and muscle with deep temporal vessels; (3) squamous bone and great wing of sphenoid, which are trephined, the floor of the middle fossa being gouged away; (4) middle meningeal vessels and dura mater. By elevating the dura mater and superimposed temporal lobe, and securing the middle meningeal artery, the ganglion is exposed, lying in a separate compartment [cavum Meckelii] of the dura, which contains cerebrospinal fluid. The motor nerve for the muscles of mastication lies on the lower and medial aspect of the ganglion, and should not be divided. Division of the sensory root of the ganglion is a simpler operation than removal of the ganglion and the results are more satisfactory.

THE BRANCHES OF THE TRIGEMINUS

The main branches of the trigeminus, given off by the front side of the semilunar ganglion, are three in number (ophthalmic, maxillary, and mandibular), each of which is referred to as a nerve and each of which is purely sensory, though the third branch, or mandibular nerve, is joined by the fibers of the masticator nerve which is motor. For the cutaneous distribution of the trigeminus, see also p. 1098.

(1) The Ophthalmic Nerve or First Division

The ophthalmic nerve, the first division of the trigeminus, is the smallest of the three branches which arise from the semilunar (Gasserian) ganglion. It springs from the medial part of the front of the ganglion and passes forward, in the lateral wall of the cavernous sinus, where it lies below the trochlear nerve and lateral to the abducens nerve and the internal carotid artery (fig. 803). A short distance behind the superior orbital (sphenoidal) fissure the nerve divides into three terminal branches—the frontal, lacrimal, and nasociliary (nasal) nerves. They pierce the dura mater, which closes the fissure, and pass forward into the orbit. Before its division the ophthalmic nerve receives filaments from the cavernous plexus of the sympathetic and it gives off, soon after its origin, a **tentorial (recurrent meningeal) branch** which runs backward, in close association with the trochlear nerve, and ramifies between the layers of the tentorium cerebelli. Further forward three branches spring from the ophthalmic nerve which contribute sensory fibers to the oculomotor, trochlear, and abducens nerves.

The terminal branches.—(*a*) The **frontal nerve** (n. supraorbitalis NK) is the largest terminal branch. It pierces the dura mater and passes into the orbit through the superior orbital (sphenoidal) fissure, above the rectus lateralis and a little below and to the lateral side of the trochlear nerve. In the orbit it runs forward, between the levator palpebræ superioris and the periosteum, and breaks up into three branches, the supraorbital, frontal proper, and supratrochlear.

The **supraorbital nerve** (ramus lateralis n. supraorbitalis NK), the largest of the three branches, leaves the orbit at the supraorbital notch (fig. 803). As it passes through the notch it gives off a small branch which enters the bone and supplies the diploë and the mucous membrane of the frontal sinus. Its terminal branches give twigs to the pericranium and to the skin of the scalp, the upper eyelid, the frontal region, and the parietal region almost as far as the lambdoid suture (fig. 809). One branch running at the upper margin of the orbital cavity unites with a branch of the facial nerve.

The **frontal branch** (ramus medialis n. supraorb. NK), given off at a variable point, lies medial to the supraorbital, passes through the frontal foramen, and is distributed to the skin of the forehead and upper eyelid (fig. 803).

The **supratrochlear branch** runs forward and medialward toward the upper and medial angle of the orbit, where it passes above the pulley of the superior oblique muscle, pierces the palpebral fascia, and ascends to the lower and middle part of the forehead, accompanied by the frontal artery (fig. 803). Before it leaves the orbit it sends a branch downward behind or in front of the pulley of the obliquus superior which joins with the infratrochlear nerve, and as it leaves the orbit it gives off filaments to supply the skin and conjunctiva of the medial third of the upper eyelid. Its terminal branches pierce the orbicularis and frontalis muscles, and, as they pass to the skin of the forehead, they communicate with branches of the facial nerve.

For the **cutaneous nerves of the scalp,** see p. 1098.

(*b*) The **lacrimal nerve** [n. lacrimalis] is the smallest of the three branches of the ophthalmic division. It passes through the superior orbital (sphenoidal) fissure lateral to and slightly below the frontal nerve, and is directed forward and lateralward, along the upper border of the rectus lateralis to the lacrimal gland (fig. 803). On the lateral wall of the orbit it receives a small branch from the zygomatic nerve (the orbital branch of the maxillary nerve). This branch brings to the lacrimal nerve secretory fibers for the lacrimal gland. A small twig passes beyond the gland, pierces the palpebral fascia, supplies filaments to the conjunctiva, and is then distributed to the integument at the lateral angle of the eye and to the skin over the zygomatic process of the frontal bone.

(*c*) The **nasociliary (nasal) nerve** enters the orbit between the two heads of the rectus lateralis and between the superior and inferior branches of the oculomotor nerve. In the orbit it lies at first lateral to the optic nerve, but, as it runs obliquely forward and medialward to the medial wall of the orbital cavity, it crosses above the optic nerve and between it and the rectus superior and, near the border

of the rectus medialis, it divides into its terminal branches, the chief of which are the *infratrochlear* and *anterior ethmoidal* nerves (fig. 803). In addition to those received from the cavernous plexus before the division of the ophthalmic nerve, the nasociliary nerve itself receives numerous sympathetic (secretory and vasomotor) fibers.

Its several **branches** are: (i) The **long root of the ciliary ganglion** which is given off at the superior orbital (sphenoidal) fissure. It is a slender filament which runs forward on the lateral side of the optic nerve to the superior and posterior part of the ciliary ganglion (fig. 803).

(ii) The **long ciliary nerves,** usually two in number, which arise from the nasociliary nerve as the latter is crossing above the optic nerve. They run forward, on the medial side of the optic nerve, pierce the sclerotic, and are distributed with the lower set of short ciliary nerves (fig. 803). The long root of the ciliary ganglion and the long ciliary nerves carry sensory fibers which belong to the nasociliary nerve proper. The long root also carries sympathetic fibers, most of which merely pass through the ganglion. The ciliary branches of the nasociliary and other terminal twigs of the frontal nerve are offered as chiefly explaining the neuralgia in acute iritis, glaucoma and herpes frontalis.

(iii) The **posterior ethmoidal** (n. ethmoidalis minor NK) springs from the posterior border of the nasociliary nerve near the upper border of the rectus medialis. It passes through the

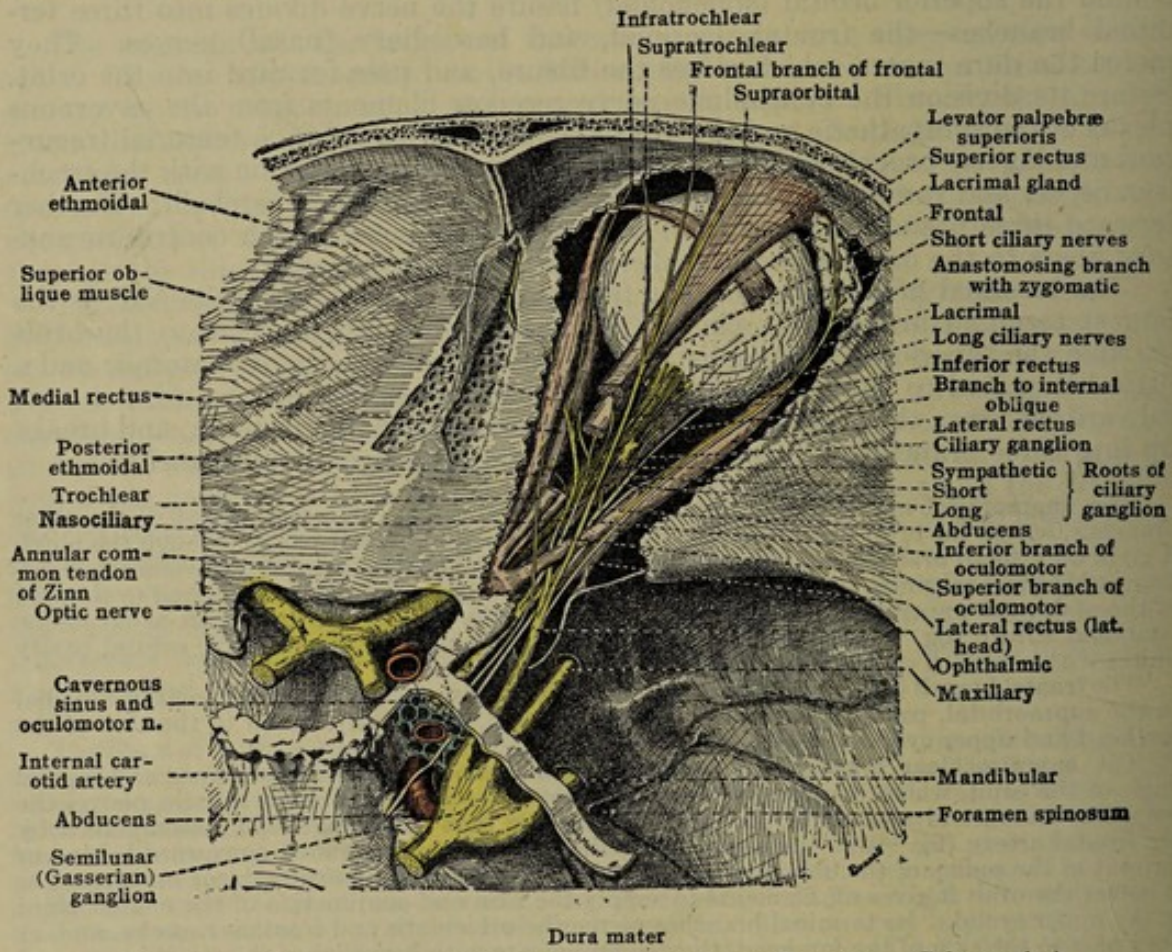

FIG. 803.—NERVES OF THE ORBIT FROM ABOVE AND BEHIND. (Schematic.)

posterior ethmoidal canal and is distributed to the mucous membrane of the posterior ethmoidal cells and the sphenoidal sinus.

(iv) The **infratrochlear nerve** passes forward between the obliquus superior and the rectus medialis, and under the pulley of the former muscle divides into two branches: The **superior palpebral branch** helps to supply the eyelids with sensory fibers and usually anastomoses with the supratrochlear nerve. The **inferior palpebral branch** is distributed to the lacrimal sac, the conjunctiva and skin of the medial part of both eyelids, the caruncle, and the skin of the upper part of the side of the nose.

(v) The **anterior ethmoidal** (n. ethmoidalis major NK) **nerve,** passing forward and medialward between the obliquus superior and the rectus medialis, leaves the orbit through the anterior ethmoidal foramen, accompanied by the anterior ethmoidal vessels, and enters into the anterior fossa of the cranium (fig. 803). It then crosses the lamina cribrosa of the ethmoid, lying outside the dura mater, which separates it from the olfactory bulb, and descends into the nasal fossa through the ethmoidal fissure, a slit-like aperture at the side of the crista galli. In the submucosa of the nasal fossa it terminates by dividing into two sets of *anterior nasal branches:* the internal nasal branches and the external nasal branch (fig. 801).

The **internal nasal branches** divide into the **medial nasal branches** (the septal branches of the nasal nerve), which run downward and forward on the upper and front part of the septum, and the **lateral nasal branches** (the external terminal branch of the nasal nerve), which give

twigs to the anterior extremities of the superior and middle nasal conchæ (turbinated bones), and to the mucous membrane of the lateral wall of the nose (fig. 801).

The **external nasal branch** (the anterior terminal branch of the nasal nerve) runs downward in a groove on the inner surface of the nasal bone. It pierces the wall of the nose between the nasal bone and the upper lateral cartilage, and supplies the integument of the lower part of the dorsum of the nose as far as the tip.

(2) The Maxillary Nerve or Second Division of the Trigeminus

The maxillary nerve is entirely sensory in function and it is intermediate in size between the ophthalmic and mandibular nerves. It springs from the middle of the anterior border of the semilunar (Gasserian) ganglion and runs forward in the lower and outer part of the lateral wall of the cavernous sinus (fig. 804). Leaving the middle fossa of the cranium, by passing through the foramen rotundum, it enters the pterygopalatine (sphenomaxillary) fossa (figs. 801, 803), where it is joined by twigs with the sphenopalatine ganglion; then, changing its name, it passes forward, as the **infraorbital nerve,** through the inferior orbital (sphenomaxillary) fissure into the infraorbital sulcus in the floor of the orbit; continuing forward it traverses the infraorbital canal accompanied by the infraorbital artery, and appears in the face, beneath the levator labii superioris (quadratus) and above the levator anguli oris (caninus) muscles where it divides into four sets of terminal branches which anastomose more or less freely with branches of the facial nerve to form the **infraorbital plexus.**

In cases of intractible neuralgia, the maxillary nerve may be injected with alcohol by passing a needle along the floor of the orbit from its inferolateral angle in a direction backward and slightly medially to the foramen rotundum which lies 4.5 cm. from the surface.

Branches.—The branches of the maxillary nerve are—(*a*) branches given off in the middle fossa of the cranium; (*b*) branches given off in the pterygopalatine (sphenomaxillary) fossa; (*c*) branches given off in the infraorbital sulcus and canal; and (*d*) terminal branches.

(*a*) The **middle (recurrent) meningeal branch** (ramus meningeus NK), given off in the middle fossa of the cranium, breaks up into numerous branches which supply the dura mater with sensory fibers, reinforce the sympathetic plexus on the middle meningeal artery, and anastomose with the spinous nerve (the recurrent branch of the mandibular nerve).

(*b*) The branches given off in the pterygopalatine (sphenomaxillary) fossa are the sphenopalatine nerves, the zygomatic branch of the maxillary nerve, and the posterior superior alveolar nerves.

The **sphenopalatine nerve** has two or three branches which descend in the pterygopalatine fossa and give a small part of their fibers to the sphenopalatine (Meckel's) ganglion (figs. 801, 804), the larger part of their fibers passing through the ganglion into its orbital, nasal, and palatine branches. (See Sphenopalatine Ganglion, p. 1037.)

The **zygomatic (orbital or temporomalar) nerve,** given off from the upper surface of the maxillary nerve, passes forward and lateralward, and, at the end of the inferior orbital (sphenomaxillary) fissure, passes through it into the orbit and divides into two branches, facial and temporal.

The **zygomaticofacial branch** runs forward, passes through a zygomatico-orbital foramen, then through the zygomaticofacial (malar) foramen, pierces the orbicularis palpebrarum, communicates with the zygomatic (malar) branch of the facial nerve, and supplies the skin of the prominence of the cheek. The **zygomaticotemporal branch** runs upward in a groove in the lateral wall of the orbit, passes through a zygomatico-orbital foramen, then through the zygomaticotemporal (sphenomalar) foramen, and enters the temporal fossa. It turns around the anterior border of the temporal muscle, pierces the deep layer of the temporal fascia, and runs backward for a short distance in the fat between the superficial and deep lamellæ, then, turning lateralward, it pierces the superficial lamellæ about an inch above the zygoma, anastomoses with the temporal branch of the facial nerve, and supplies the skin of the anterior part of the temporal region.

The **infraorbital nerve,** that large part of the maxillary nerve lying distal to the sphenopalatine ganglion, enters the orbit through the inferior orbital (sphenomaxillary) fissure, accompanied by the infraorbital artery, and with it passes through the infraorbital canal (fig. 804)) to the face, where it divides into four sets of terminal branches, some of which, by anastomoses with the branches of the facial nerve, form the **infraorbital plexus.**

Three sets of **superior alveolar nerves** arise from the maxillary and the infraorbital nerves, namely, the posterior superior alveolar branches, the middle superior alveolar branch, and the anterior superior alveolar branches.

The **posterior superior alveolar (dental) nerves** (rr. alveolares maxillares aborales NK) are usually two in number, but sometimes arise by a single trunk. They pass downward and lateralward through the pterygomaxillary fissure into the zygomatic fossa, where they give branches to the mucous membrane of the gums and the posterior part of the mouth; then they enter the posterior alveolar (dental) canals and unite with the other alveolar branches to form

the **superior dental plexus,** through which they give branches to the roots and pulp cavities of the molar teeth and to the mucous membrane of the maxillary sinus (fig. 804).

(*c*) The branches given off in the infraorbital sulcus and canal are the middle and anterior superior alveolar (dental) nerves.

(i) The **middle superior alveolar (dental) nerve** (r. alv. maxillaris medius NK) leaves the infraorbital nerve in the posterior part of the infraorbital sulcus, and, passing downward and forward in a canal in the maxilla, it divides into terminal branches that anastomose with the other alveolar branches to form the *superior dental plexus.* Through the plexus it supplies the bicuspid teeth and gives branches to the mucous membrane of the maxillary sinus and also to the gums (fig. 804).

(ii) The **anterior superior alveolar (dental) nerve** (rr. alv. maxillares orales NK) is the largest of the superior alveolar nerves. It is given off by the infraorbital nerve in the anterior part of the infraorbital canal, and passes downward in a bony canal in the anterior wall of the maxilla. After uniting with the other alveolar nerves to form the superior dental plexus, it supplies the canines and the incisors and gives branches to the mucous membrane of the maxillary sinus and the gums (fig. 804). It also gives off a **nasal branch** which enters the nasal fossa through a small foramen, and supplies the mucous membrane of the anterior part of the inferior meatus and the adjacent part of the floor of the nasal cavity.

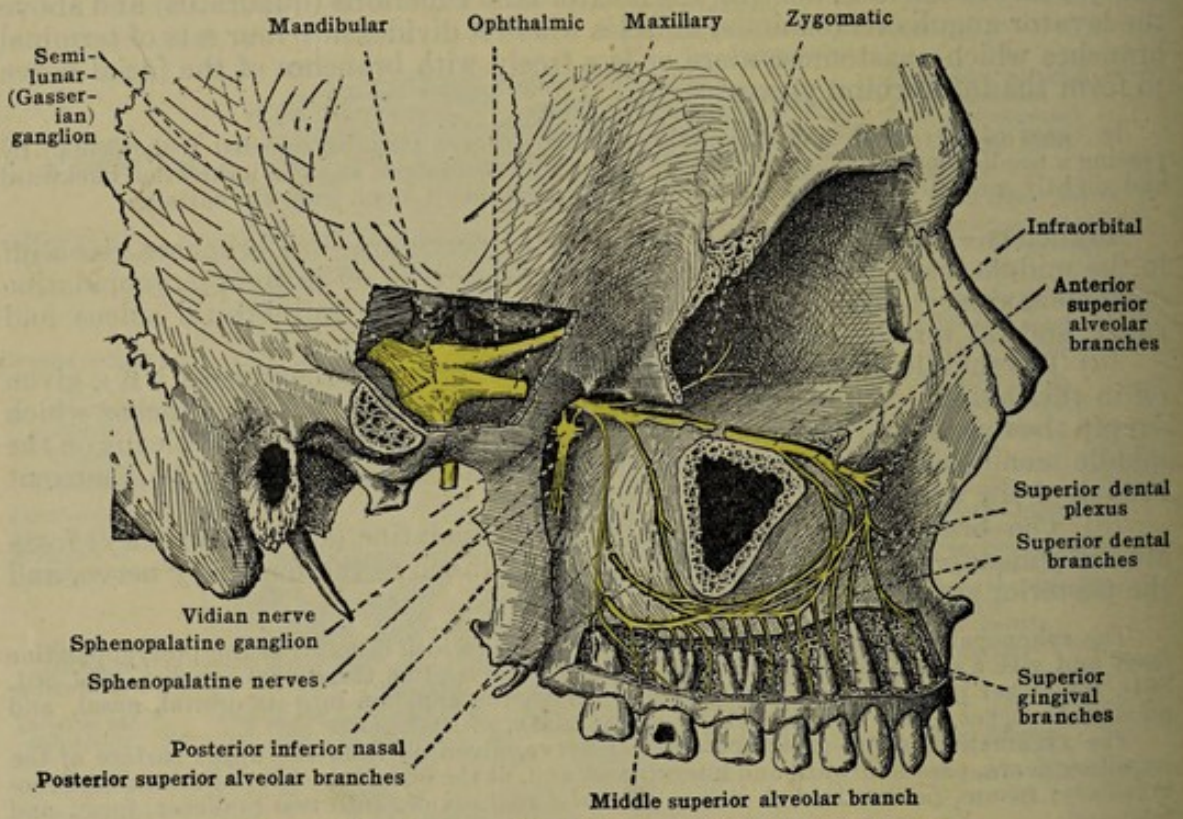

FIG. 804.—LATERAL VIEW OF THE MAXILLARY NERVE.

The **superior dental plexus** (plexus dentalis maxillaris NK) is formed in the bony alveolar canals by the three superior alveolar nerves. It is convex downward and anastomoses across the midline with the corresponding plexus of the other side (fig. 804). From it arise the **superior dental branches** supplying the superior canines and incisors, **superior gingival branches** supplying the gums, and also branches to the mucous membrane of the maxillary sinus and to the bone. On the plexus are two gangliform enlargements, one, called the *ganglion of Valentine,* situated at the junction of the middle and the posterior branches, and the other, called the *ganglion of Bochdalek* at the junction of the middle and anterior branches.

(*d*) The terminal branches of the maxillary nerve are the inferior palpebral, the external and internal nasal (nasal), and the superior labial.

The **inferior palpebral branches** (rr. palpebrales malares NK) usually two, pass upward and supply sensory fibers to all the skin and conjunctiva of the lower eyelid (fig. 809).

The **external nasal branches** pass medialward under cover of the levator labii superioris (quadratus), and supply the skin of the posterior part of the lateral aspect of the nose.

The **internal nasal branches** pass downward and medialward under the lateral wall of the nose, and then turn upward to supply the skin of the vestibule of the nose.

The **superior labial branches** (rr. labiales maxillares NK), three or four in number, as a rule are larger than the palpebral and nasal branches. They pass downward to supply the skin and mucous membrane of the upper lip and the neighboring part of the cheek.

(3) The Mandibular Nerve or Third Division of the Trigeminus

The **mandibular division** is the largest of the three divisions of the trigeminus (figs. 805 and 809). As a nerve, it is usually described as formed by the union of two distinct nerves, namely, the entire masticator nerve and the large bundle of sensory fibers derived from the semilunar (Gasserian) ganglion which pass peripherally as the third division of the trigeminus. These two nerves remain separate until they pass through the foramen ovale and then unite immediately outside the skull to form a large trunk which almost directly after its formation divides into a small *anterior* and a larger *posterior portion*. The trunk is situated between the pterygoideus externus laterally, and the otic ganglion and the tensor veli palatini medially. In front of it is the posterior border of the pterygoideus internus, and behind it, the middle meningeal artery. Two branches arise from the trunk of the nerve before its division, namely, the spinous (recurrent) nerve and the nerve to the pterygoideus internus.

The **spinuous (recurrent) nerve** (r. meningeus NK), after receiving a vasomotor filament from the otic ganglion, enters the cranium through the foramen spinosum, accompanying the middle meningeal artery, and divides into an anterior and a posterior branch. The anterior branch communicates with the meningeal branch of the maxillary division of the trigeminus, furnishes filaments to the dura mater, and ends in the osseous substance of the great wing of the sphenoid. The posterior branch traverses the petrosquamous suture and ends in the lining membrane of the mastoid cells.

The fibers going to form the *nerve to the internal pterygoid muscle* are almost wholly motor fibers and therefore comprise a branch of the masticator nerve and are described as such under the description of the masticator (fig. 806).

Injection of the mandibular nerve with alcohol, by means of a long stout hypodermic needle, is practised in cases of intractable neuralgia as an alternative to excision of the semilunar ganglion. A vertical line is drawn on the cheek downward from the junction of the posterior and middle thirds of the zygomatic arch, and the needle is entered on this line at a point 1.5 cm. from the lower border of the zygoma. It is directed upward and medially so as to pass through the lowest part of the mandibular notch. If the mouth is opened the notch is depressed and more room gained. The needle impinges first against the inferior surface of the great wing of the sphenoid bone, and when the point is lowered a little it engages in the foramen ovale at a depth of 4–4.5 cm. In most cases the needle can be passed through the foramen ovale into the semilunar ganglion. (Harris. Lancet, Jan. 23, 1912.)

The **anterior portion** of the mandibular nerve is smaller than the posterior and is chiefly composed of motor fibers which constitute the branches of the masticator nerve that supply the muscles of mastication, the temporalis, masseter, and pterygoideus externus. Practically all of the sensory fibers of the anterior portion (fibers of the mandibular nerve proper) form the buccinator (long buccal) nerve. The latter is accompanied, in the first part of its course, by a small strand of motor or masticator fibers which leaves it to end in the anterior part of the temporal muscle.

The **buccinator (long buccal) nerve** (n. buccalis NK), entirely sensory, passes between the two heads of the external pterygoid muscle and runs downward and forward under cover of or through the anterior fibers of the temporalis to the cheek (fig. 805). As it passes forward it emerges from under cover of the anterior border of the masseter and lies on the superficial surface of the buccinator, where it interlaces with the buccal branches of the facial nerve and gives off filaments to supply the superjacent skin; finally it pierces the buccinator and supplies the mucous membrane on its inner surface as far forward as the angle of the mouth. The fibers of the anterior deep temporal nerve, a branch of the masticator, are frequently associated with the buccinator until the latter has passed between the heads of the external pterygoid; then the anterior deep temporal nerve separates from the buccinator and passes upward on the lateral surface of the upper head of the external pterygoid.

The **posterior portion** of the mandibular nerve divides into three large branches. Two of these, the lingual and the auriculotemporal nerves, are exclusively sensory; the third, the inferior alveolar (dental) nerve, contains a strand of motor fibers, the mylohyoid nerve, which comprise a branch of the masticator nerve.

The **lingual nerve** is the most anterior branch of the posterior portion of the mandibular nerve (figs. 805, 812). It lies in front and to the medial side of the inferior alveolar (dental) nerve and descends at first on the medial side of the pterygoideus externus, then between the pterygoideus internus and the ramus of the mandible to the posterior part of the mylohyoid ridge, where it passes off the anterior border of the pterygoideus internus. At this point it is situated a short distance behind the last molar tooth and is covered in front by the mucous membrane of the posterior part of the mouth cavity. After leaving the ptery-

goideus internus it crosses the superior constrictor, which is attached to the mandible, and turns forward toward the tip of the tongue, crossing the lateral surfaces of the styloglossus, hyoglossus, and genioglossus. It its course across the hyoglossus it lies first above, then to the lateral side of, and finally below Wharton's duct, and as it ascends on the genioglossus it lies on the medial side of the duct.

Communications and branches.—While it is on the medial side of the pterygoideus externus the lingual nerve is joined, at an acute angle, by the chorda tympani (figs. 805, 812), a branch of the glossopalatine nerve, and as it lies between the ramus of the mandible and the pterygoideus internus it is connected by a branch with the inferior alveolar (dental) nerve, and gives off one or two small branches, the **rami isthmi faucium** (rr. palatini NK), which are ditributed as sensory fibers to the tonsil and the mucous membrane of the posterior part of the mouth (fig. 812).

While it is above the duct it gives a branch, which contains many sensory and visceral efferent chorda tympani fibers, to the submaxillary ganglion (see pp. 1022, 1039), and it receives branches, chiefly sympathetic, from that ganglion. A little further forward it is connected by

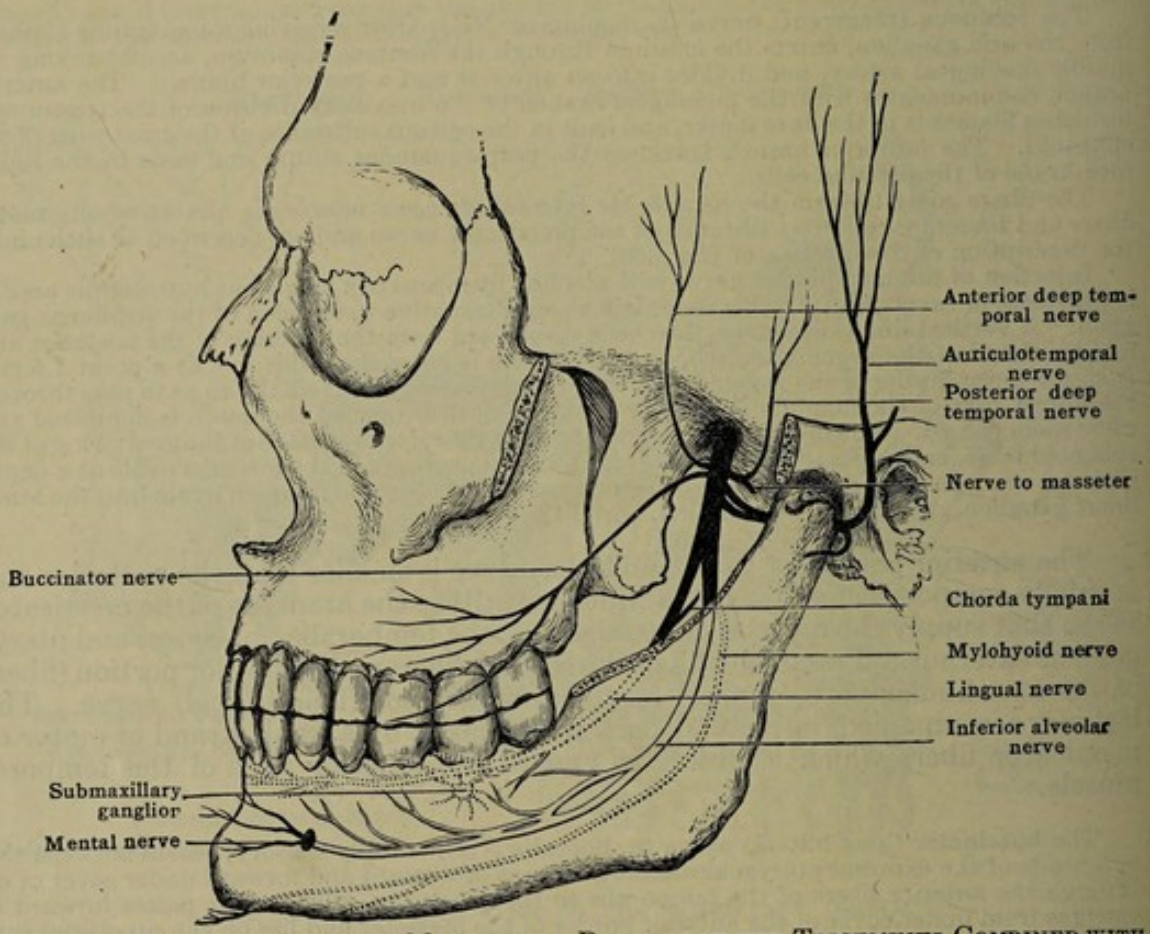

FIG. 805.—DISTRIBUTION OF THE MANDIBULAR DIVISION OF THE TRIGEMINUS COMBINED WITH BRANCHES OF THE MASTICATOR NERVE. (Henle.)

one or two branches, which run along the anterior border of the hyoglossus, with the hypoglossal nerve (fig. 812). It then gives off the **sublingual nerve**, which runs forward to supply the sublingual gland and the neighboring mucous membrane. Its terminal (**lingual**) branches are derived chiefly from the glossopalatine nerve. They pierce the muscular substance of the tongue and are distributed to the mucous membrane of its anterior two-thirds. They interlace with similar branches of the other side and with branches of the glossopharyngeal nerve.

The **inferior alveolar (dental) nerve** (n. alveolaris mandibularis NK) is the largest branch of the posterior portion of the mandibular nerve. It commences on the medial side of the external pterygoid muscle and descends to the interval between the sphenomandibular ligament and the ramus of the mandible, where it receives one or two communicating branches from the lingual nerve. Opposite the middle of the medial surface of the ramus it enters the mandibular (inferior dental) canal, accompanied by the inferior alveolar (dental) artery, which lies in front of the nerve, and it runs downward and forward through the ramus and the body of the mandible (fig. 805). At the mental foramen it divides into two parts, one of which, the *mental nerve*, passes out through the mental foramen, the other, commonly called the *incisive branch*, continues forward in the canal,

and supplies, through the inferior dental plexus, the inferior canine and incisor teeth and the corresponding regions of the gums.

Branches.—The branches of the inferior alveolar (dental) nerve are branches forming the inferior dental plexus, and the mental nerve. A bundle of motor fibers, the *mylohyoid nerve*, a branch of the masticator nerve, is given off just before the inferior alveolar nerve enters the mandibular canal.

The **inferior dental plexus** (plexus dentalis mandibularis NK) is formed by a series of branches which communicate with one another within the bone, giving rise to a fine network. From this plexus two sets of branches are given off: the **inferior dental branches,** corresponding in number to the roots of the teeth, enter the minute foramina of the apices of the roots and end in the pulp; the second set, the **inferior gingival branches,** supply the gums. In operating to relieve neuralgia affecting this plexus, the trephining is done midway between the margins of the mandible at the level of the first molar.

The **mental nerve** is a nerve of considerable size which emerges through the mental foramen (fig. 805). It communicates, near its exit from the bone, with branches of the facial nerve, and then divides into three branches. The smallest branch, turning downward, divides into several twigs, the *mental branches*, which supply the integument of the chin. The other two, *inferior labial branches* (rr. labiales mandibulares NK), pass upward, diverging as they ascend, and divide into a number of twigs. The stoutest twigs ramify to the mucous membrane which lines the lower lip. Other twigs are distributed to the integument and fascia of the lip and chin.

The **auriculotemporal nerve** usually arises from the posterior portion of the mandibular nerve by two roots which embrace the middle meningeal artery and unite behind it to form the trunk of the nerve. The trunk passes backward on the medial aspect of the pterygoideus externus and between the sphenomandibular ligament and the mandibular articulation, lying in close relation with the capsule of the joint. Behind the joint it enters the upper part of the parotid gland, through which it turns upward and lateralward. It emerges from the upper end of the gland, crosses the root of the zygoma close to the posterior border of the superficial temporal artery, and divides into auricular and temporal terminal branches at the level of the tragus of the pinna (figs. 805, 809).

Communications.—(*a*) Each of the two roots of the nerve receives a communication from the otic ganglion containing fibers derived from the glossopharyngeal nerve. These fibers have passed from the glossopharyngeal through the tympanic plexus and the small superficial petrosal nerve and through the otic ganglion.

(*b*) Sensory filaments pass from the auriculotemporal nerve to the temporofacial branch of the facial nerve.

(*c*) Filaments of connection with the sympathetic plexus on the internal maxillary artery.

(*d*) A communication to the inferior alveolar (dental) nerve.

Branches of the auriculotemporal nerve.—(*a*) An **articular branch** to the mandibular joint, given off as the nerve lies on the medial side of the capsule.

(*b*) **Branches to the external auditory meatus.** Two branches, as a rule, are given off in the parotid gland. They enter the meatus by passing between the cartilage and the bone and supply the upper part of the meatus and the membrana tympani by a fine branch, and occasionally the lower branch gives twigs to the skin of the lobule of the pinna. This innervation is supplemented by a twig from the auricular branch of the vagus to the inner part of the meatus.

With cancer and other painful affections of the tongue, there is often experienced '*referred pain*' in the tympanic membrane, meatus, external ear and side of the head. This may be explained as resulting from bifurcation of sensory (trigeminal) fibers at the level of the origin of the auriculotemporal branch from the mandibular nerve, one part of each bifurcation passing into the lingual nerve to the cancer, the other into the auriculotemporal with the sensory supply for the areas mentioned.

(*c*) **Parotid branches** are distributed to the substance of the parotid gland. Sensory or trigeminal fibers for the gland spring either directly from the nerve or from the communicating branches previously given by it to the glossopalatine nerve. The parotid branches also contain fibers derived from the glossopharyngeal nerve which pass successively through its tympanic branch, the tympanic plexus, the small superficial petrosal nerve, the otic ganglion, and the communicating twigs from the otic ganglion to the roots of the auriculotemporal nerve. The parotid branches are later again mentioned as concerned chiefly with the *gangliated cephalic plexus.*

(*d*) The **anterior auricular branches** (nn. auriculares temporales NK), usually two in number, are distributed to the skin of the tragus and the upper and outer part of the auricle.

(*e*) The **superficial temporal branches** supply the integument of the greater part of the temporal region, and anastomose with the temporal branch of the facial nerve.

THE MASTICATOR NERVE (Fig. 806)

The masticator nerve (*motor root or portio minor of trigeminus*). The fibers of the masticator nerve spring from two nuclei, a slender upper or mesencephalic nucleus and a clustered lower or chief nucleus. The fibers arising in the mesencephalic nucleus descend along the lateral aspect of the nucleus to the pons as the *descending* or *mesencephalic root*, here they join the fibers from the chief motor

nucleus and issue with them from the side of the pons in from six to ten root filaments. These blend to form the nerve, which is from 1½ to 2 mm. broad.

At the point where it emerges from the pons the nerve is in front of and ventral to the root of the trigeminus and it is separated from the latter by a few of the transverse fibers of the pons which constitute the *lingula of Wrisberg.*

From its superficial exit from the pons, the masticator nerve passes upward, lateralward, and forward in the posterior fossa of the cranium, and along the medial and anterior aspect of the trigeminus, to the mouth of Meckel's cave.

In this cavity it runs lateralward below the semilunar (Gasserian) ganglion to the foramen ovale, through which it passes to join the mandibular division of the trigeminus immediately outside and below the base of the skull. The nerve is almost entirely motor and its fibers are devoted almost wholly to the muscles having to do with mastication.

Paralysis of the muscles of mastication may result from heedless operations upon the semilunar ganglion or the trunk of the trigeminus for relief of neuralgia.

Central connections.—The nuclei of origin of the masticator nerve are connected with the lower part of the somesthetic area of the cerebral cortex of the opposite side by the pyramidal

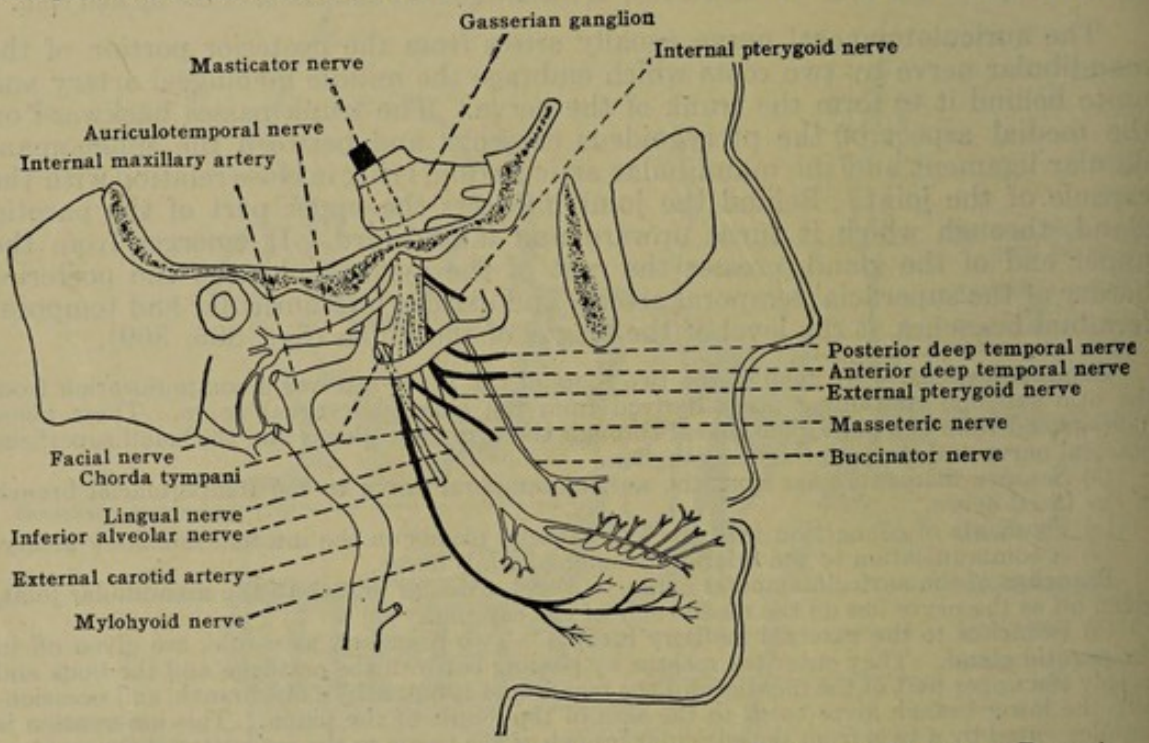

FIG. 806.—DIAGRAM OF THE MASTICATOR NERVE AND ITS BRANCHES (IN HEAVY BLACK).

fibers descending in the genu of the internal capsule, and they are associated with the sensory nuclei of other cranial nerves, especially the trigeminus, through the reticular formation and by the medial longitudinal fasciculus. Recent investigations indicate that the mesencephalic root is not wholly motor but is, at least in part, sensory in character, and that its sensory fibers arise from cell-bodies which have remained within the central system instead of migrating outside to form a ganglion. (See pp. 905, 913.)

Branches.—Almost immediately after joining the trunk of the mandibular nerve, most of the fibers of the masticator leave it to form the greater part of the so-called anterior portion of the mandibular. However, one branch of masticator fibers, the nerve to the internal pterygoid muscle, is given off from the mandibular just before its division into anterior and posterior portions. The masticator branches derived from the anterior portion are the *deep temporal* nerves, the *masseteric* nerve, and the nerve to the *external pterygoid.* One branch, the *mylohyoid* nerve, is carried in the posterior portion of the mandibular and is given off from its inferior alveolar branch.

The **nerve to the internal pterygoid** (n. pterygoideus medialis NK) passes under cover of a dense layer of fascia derived from an expansion of the ligamentum pterygospinosum, and enters the deep surface of the muscle. Near its commencement this nerve furnishes a visceral motor root to the otic ganglion, and small twigs to the tensor tympani and tensor palati.

The **deep temporal nerves,** usually two in number, posterior and anterior, pass between the bone and the upper border of the external pterygoid muscle, and turn upward around the infratemporal crest of the sphenoid bone to end in the deep surface of the temporalis (fig. 805).

The posterior of the two often arises in common with the masseteric nerve. The anterior is frequently associated with the buccinator (long buccal) nerve till the latter has passed between the two heads of the pterygoideus externus. There is frequently a third branch, the **medius,** which passes lateralward above the pterygoideus externus, and turns upward close to the bone to enter the deep surface of the muscle. A small strand of masticator fibers accompanies the buccinator nerve to enter and end in the anterior part of the temporal muscle.

The **masseteric nerve,** which frequently arises in common with the posterior deep temporal nerve, passes between the bone and the pterygoideus externus, and accompanies the masseteric artery through the notch of the mandible to be distributed to the masseter (fig. 805). It is easily traced through the deeper fibers nearly to the anterior border of the masseter. As it emerges above the pterygoideus externus it gives off a twig to the mandibular articulation.

The **nerve to the external pterygoid** (n. pterygoideus lateralis NK), after a course of about 3 mm., divides into twigs which enter the deep surface of the two heads of the muscle. It is usually adherent at its origin to the buccinator nerve.

The **mylohyoid nerve,** carried in the posterior portion of the mandibular nerve, is given off immediately before the inferior alveolar (dental) nerve enters the mandibular (inferior dental) canal. It pierces the lower and back part of the sphenomandibular ligament and runs downward and forward in the mylohyoid groove between the mandible on the lateral side, and the internal pterygoid muscle and the lateral surface of the submaxillary gland on the medial side. In the anterior part of the digastric triangle it is continued forward between the anterior part of the submaxillary gland and the mylohyoideus, and it breaks up into branches which supply the mylohyoideus and the anterior belly of the digastric (fig. 805).

THE FACIAL NERVE

The facial (or seventh) nerve is purely motor and almost entirely somatic motor. It is accompanied a short distance by a bundle usually called its *sensory root* or the *intermediate nerve.* This latter, however, on the basis of its origin, distribution, and mixed instead of sensory character, is described separately below as the *glossopalatine nerve.* It is smaller than the facial, is fused to the trunk of the facial, and the ganglion giving rise to its sensory fibers is situated upon the external genu of the facial (figs. 807, 810).

The fibers of the facial nerve (fig. 807) arise from a nucleus of cells situated laterally in the reticular formation at the level of the lower part of the pons, dorsal to the superior olive, and between the root fibers of the abducens nerve and the laterally placed spinal tract of the trigeminus. From this nucleus the fibers of the nerve pass medially and dorsalward to the floor of the fourth ventricle and just under the floor, they turn anteriorly, passing dorsal to the nucleus of the abducens (fig. 732). At the anterior end of this nucleus they turn sharply ventralward and lateralward, and at this point it is claimed that fibers descending in the near-by medial longitudinal fasciculus from the nucleus of the oculomotor nerve of the same side become intermingled with the fibers of the facial nerve and pass outward with them. This, however, is uncertain. Continuing ventralward through the reticular formation the fibers of the facial emerge from the brain-stem at the inferior border of the pons, lateral to the superficial attachment of the abducens. At the point of its emergence, the facial nerve pierces the pia mater, from which it receives a sheath, and then proceeds forward and lateralward in the posterior fossa of the cranium to the internal auditory meatus, which it enters in company with the glossopalatine nerve and with the cochlear and vestibular nerves. As it lies in the meatus it is situated above and in front of the latter nerves, from which it is separated by the glossopalatine, and it is surrounded, together with these three nerves, by sheaths of both the arachnoid and the dura mater and by prolongations of the subarachnoid and subdural spaces. While it is still in the meatus it blends with the glossopalatine and thus the combined trunk is formed. At the outer end of the meatus this trunk pierces the arachnoid and the dura mater and enters the facial canal (aqueduct of Fallopius), in which it runs forward and slightly lateralward to the hiatus Fallopii, where it makes an angular bend, the external genu [geniculum], around the anterior boundary of the vestibule of the inner ear; this bend is enlarged by the adhesion of the geniculate ganglion (of the glossopalatine) upon its anterior border (fig. 808). From the geniculum the facial nerve runs backward in the facial canal along the lateral wall of the vestibule and the medial wall of the tympanum, above the fenestra vestibuli (ovalis), to the junction of the medial and posterior walls of the tympanic cavity; then, bending downward, it descends in the posterior wall to the stylomastoid foramen. As soon as it emerges from the stylomastoid foramen it turns forward around the lateral side of the base of the styloid process, and plunges into the substance of the parotid gland, where it divides into its cervicofacial and temporofacial terminal divisions. Before its

terminal divisions, the nerve gives off three, and sometimes four, small branches: one, the nerve to the stapedius muscle before it leaves the skull, the others after it leaves the skull.

The **nerve to the stapedius** is given off from the facial nerve as it descends in the posterior wall of the tympanum behind the pyramidal eminence. It is stated that filaments are also given off from the facial to the internal auditory artery (probably visceral motor from the glossopalatine) while the nerve is passing through the internal auditory meatus.

After it leaves the skull the facial nerve (fig. 809) gives off two or three collateral branches and its two terminal divisions, the temporofacial and cervicofacial. The collateral branches are the posterior auricular nerve, a branch to the posterior belly of the digastric, and sometimes a lingual branch.

(1) The **posterior auricular nerve** (n. retroauricularis NK) is the first branch of the extracranial portion of the facial nerve. It passes between the parotid gland and the anterior border of the sternomastoid muscle and runs upward in the deep interval between the external auditory meatus and the mastoid process. In this situation it communicates with the auricular branch of the vagus. It supplies the auricularis posterior, sends a slender twig upward to the auricularis superior, and ends in a long slender branch, **the occipital branch,** which passes backward to supply the occipitalis muscle. It also receives filaments from the small occipital and great auricular nerves, and supplies the intrinsic muscles of the auricle (pinna).

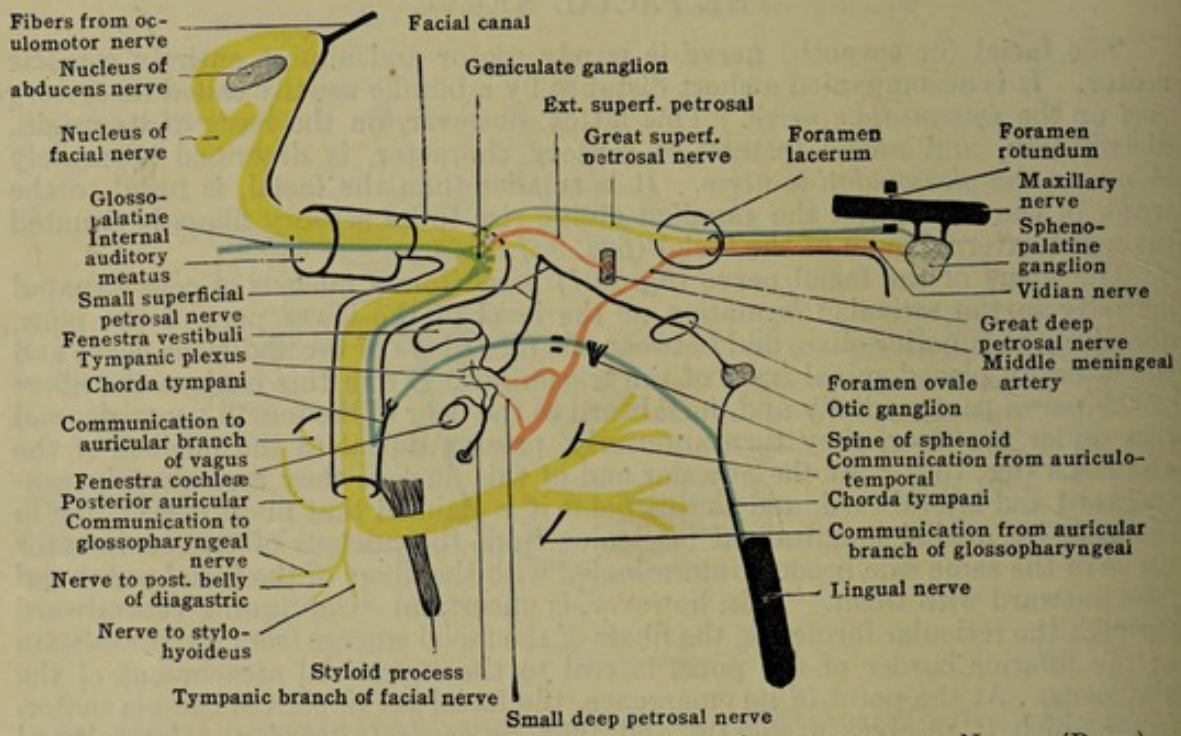

FIG. 807.—DIAGRAM OF THE FACIAL (YELLOW) AND GLOSSOPALATINE NERVE (BLUE).

(2) The **nerve to the posterior belly of the digastric** arises from the facial nerve close to the stylomastoid foramen and enters the muscle near its center, or sometimes near its origin. It usually gives off two branches: the **nerve to the stylohyoid,** which sometimes arises directly from the facial nerve and passes to the upper part of the muscle that it supplies, and the **anastomotic branch,** which joins the glossopharyngeal nerve below its petrous ganglion.

(3) The **lingual branch,** first described by Cruveilhier, is not commonly present. It arises a little below the nerve to the stylohyoideus and runs downward and medialward to the base of the tongue. In its course it passes to the medial sides of the styloglossus and stylopharyngeus, and runs downward along the anterior border of the latter muscle to the wall of the pharynx. It pierces the superior constrictor, insinuates itself between the tonsil and the anterior palatine arch, and it is stated that it gives filaments to the base of the tongue and to the styloglossus and glossopalatinus (palatoglossus) muscles.

The terminal divisions.—In the substance of the parotid gland the two terminal divisions of the facial nerve lie superficial to the external carotid artery and to the posterior facial (temporomaxillary) vein. The way in which these terminal divisions give off their branches varies much in different subjects and often on the opposite sides of the same subject. One of the more common forms is here described.

The **temporofacial** or upper division runs upward and forward, and, after receiving communicating twigs from the auriculotemporal nerve, gives off temporal and zygomatic (malar) branches. The **cervicofacial** or lower division runs downward and forward, receives branches from the great auricular nerve, and

gives off—(1) *buccal branches*, comprising what have been called infraorbital and buccal branches; (2) the *marginal mandibular* (supramandibular) branch; and (3) the *ramus colli* (inframandibular branch). These branches from the two terminal divisions anastomose freely to form the **parotid plexus** (pes anserinus).

The **temporal branches** of the temporofacial, (rr. temporofrontales NK), passing upward, communicate freely with each other and with the zygomatic branches. They also communicate with the zygomaticotemporal branch of the zygomatic nerve (the orbital branch of the maxillary nerve) and with the supraorbital nerve. They supply the frontalis, orbicularis oculi, corrugator supercilii, and auricularis anterior and superior (fig. 809).

The **zygomatic (malar) branches** passing upward and forward, communicate with the buccal branches of the facial nerve; with the zygomaticofacial branch of the zygomatic nerve (the orbital branch of the maxillary nerve); with the supraorbital and lacrimal branches of the ophthalmic nerve, and with the palpebral twigs of the maxillary. They supply both eyelids, the orbicularis oculi, and the zygomaticus (fig. 809).

The **buccal (infraorbital and buccal) branches** of the cervicofacial division arise sometimes from the lower terminal division and sometimes from both the upper and the lower terminal

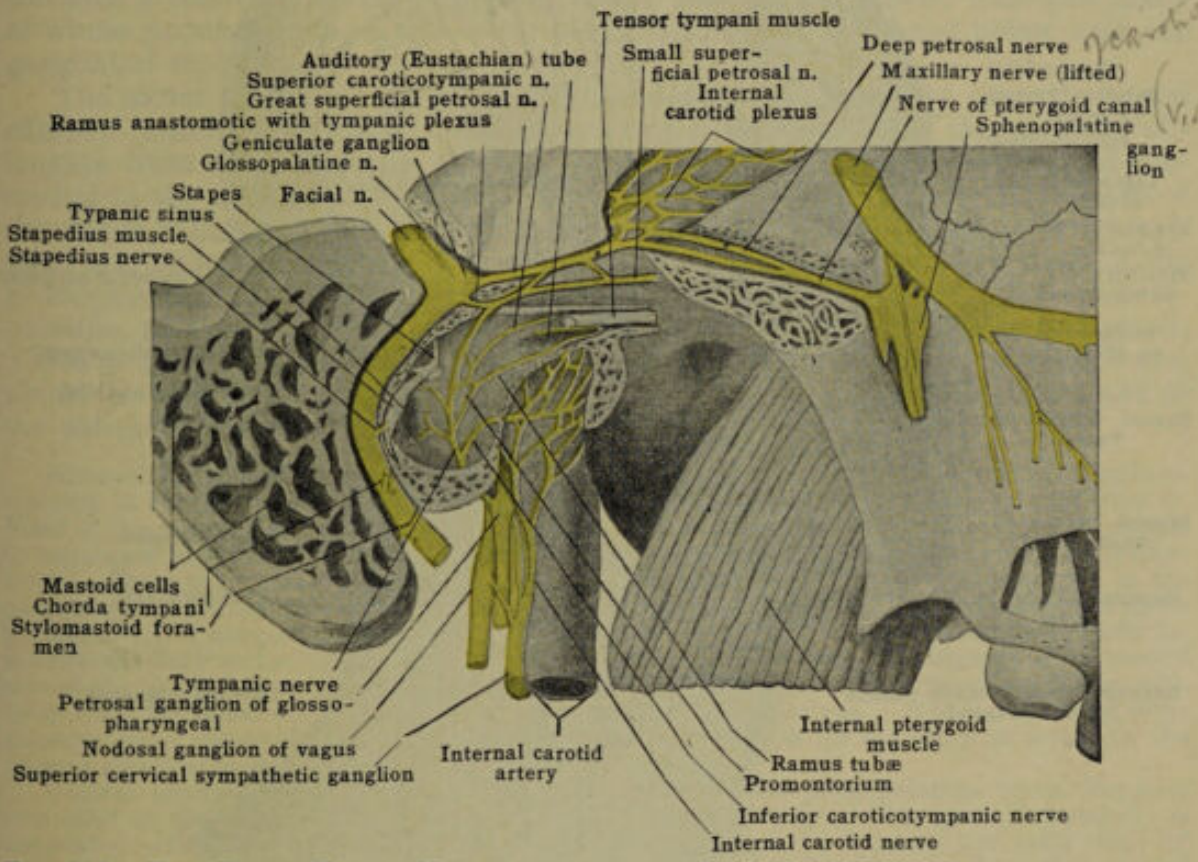

FIG. 808.—THE RIGHT FACIAL NERVE, WITHIN THE SKULL, AND THE RELATIONS OF THE GLOSSOPALATINE AND GLOSSOPHARYNGEAL NERVES WITH THE TYMPANIC AND INTERNAL CAROTID PLEXUSES. (From Sobotta's Atlas, modified.)

divisions. The buccal branches, passing forward upon the masseter and underneath the zygomaticus and quadratus labii superioris, interlace with the zygomatic and marginal mandibular (supramandibular) branches of the facial nerve, with the buccinator (long buccal) branch of the trigeminus, and with the terminal branches of the maxillary nerve, forming with the last-named nerve the **infraorbital plexus.** They supply the zygomaticus, risorius, quadratus labii superioris, caninus, buccinator, incisivi, orbicularis oris, triangularis, quadratus labii inferioris, and the muscles of the nose (fig. 809).

The **marginal mandibular (supramandibular) branch,** passing downward and forward under cover of the risorius and the depressors of the lower lip, communicates with the buccal branches and with the ramus colli of the facial nerve, and with the mental branch of the mandibular nerve. It supplies the quadratus labii inferioris and mentalis.

The ramus colli (inframandibular branch) runs downward and forward under cover of the platysma, which muscle it innervates (fig. 809). Beneath the platysma it forms one or more communicating loops, near its commencement, with the great auricular nerve, and longer loops, lower down, with the superficial cervical nerve.

Central connections.—The nucleus of origin of the facial in the rhombencephalon includes an anterior and a posterior group of cells which give rise respectively to its upper and lower terminal divisions. They are associated with the somesthetic area (lower third of the anterior central gyrus) by way of the pyramidal fasciculi of the opposite and same sides, and with the nuclei of the other cranial nerves, including the nucleus of termination of the trigeminus and glossopalatine, by way of the reticular formation and the medial longitudinal fasciculus.

Clinical aspects.—Operations upon the parotid gland and its ducts require care lest facial palsy result from severing terminal branches of the facial nerve. The buccal branch spreads out just below the main parotid (Stensen's) duct. If the cause of a facial paralysis lies within

the cerebrum (above the pons), the frontal, corrugator supercilii and orbicularis oculi muscles are not affected; while paralysis of the abducens and a hemiplegia of the opposite side of the body will be manifest. Destruction of the trunk of the facial or of its nucleus of origin in the rhombencephalon results in paralysis of the whole side of the face (Bell's paralysis), with drooping angle of the mouth, open eyelids, inability to whistle, frown etc.

GLOSSOPALATINE NERVE

The **glossopalatine nerve** (*sensory root or pars intermedia of facial; nerve of Wrisberg*) (n. intermedius NK) contains both sensory and motor fibers. While it

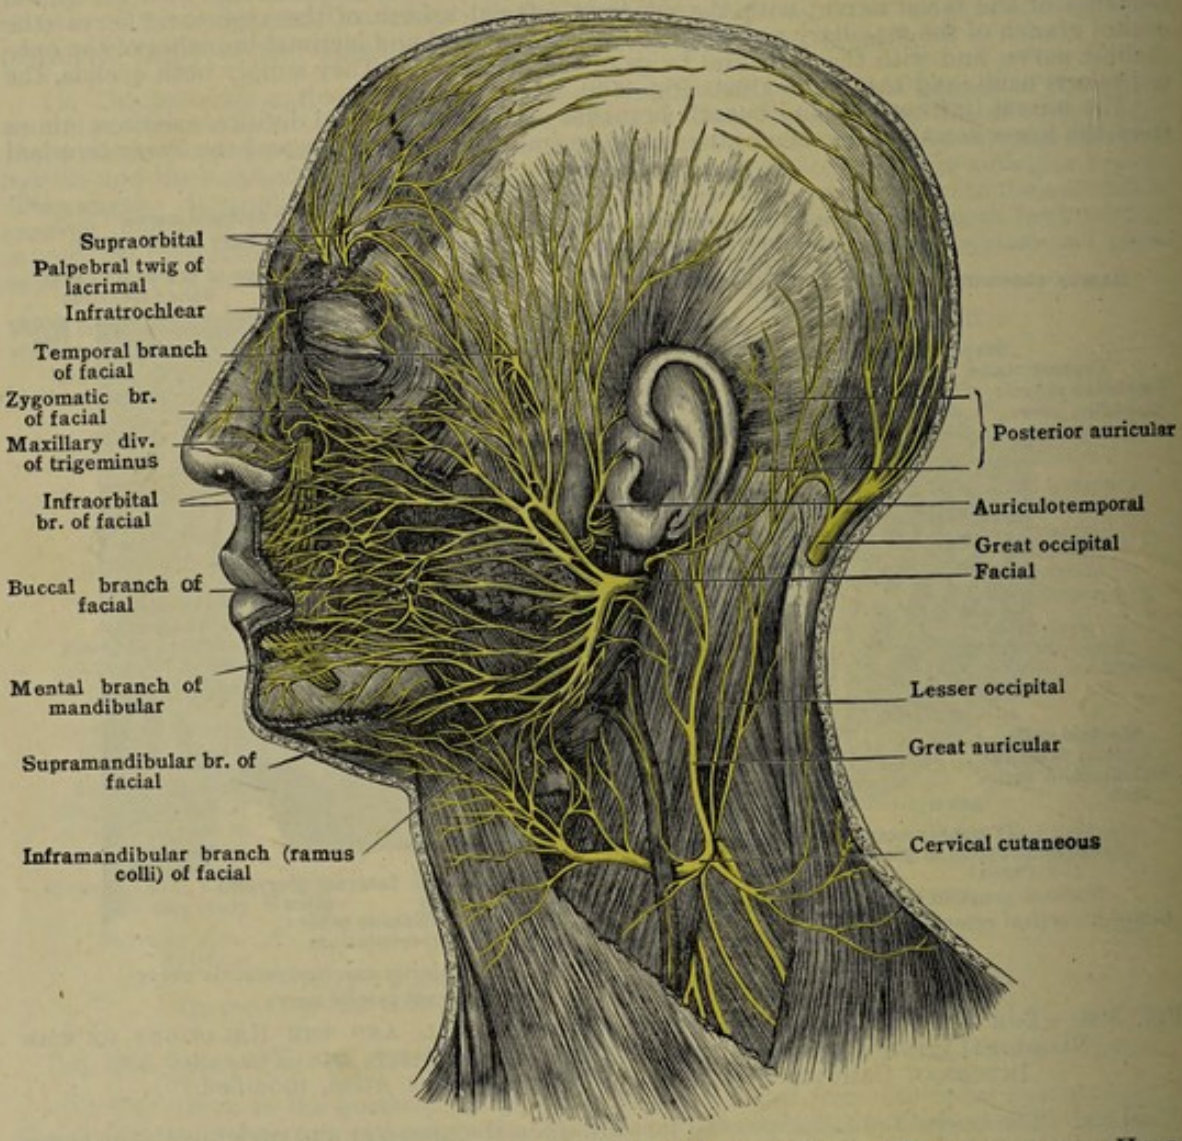

FIG. 809.—SUPERFICIAL DISTRIBUTION OF THE FACIAL AND OTHER NERVES OF THE HEAD. (After Hirschfield and Leveillé.)

has a separate attachment to the medulla, it courses in close company with the facial and, in the internal auditory meatus, it is involved in the same sheath with the facial, which relation is maintained by its larger part thence through the facial canal till a short distance above the stylomastoid foramen (figs. 807, 808, 810). Here this larger part leaves the trunk of the facial as the *chorda tympani* nerve. The origin, central connections and peripheral distribution of the glossopalatine are similar to those of the glossopharyngeal nerve and suggest that it may be considered an aberrant portion of that nerve.

The **sensory portion** is much greater than the motor. Its fibers arise from cells situated in the geniculate ganglion which thus corresponds to a spinal ganglion. The *central processes* from these cells pass medialward in the facial canal (aqueduct of Fallopius) enclosed in the sheath of the facial nerve, which they leave in passing through the internal auditory meatus, to turn slightly downward in the posterior fossa of the cranium and enter the medulla at the inferior border of the pons, between the attachments of the facial and vestibular nerves. They course through the reticular formation of the medulla, medianward and dorsal-

ward to terminate about cells which comprise a superior extension of the nucleus of termination of the glossopharyngeal nerve (nucleus of ala cinerea). The *peripheral processes* from the geniculate ganglion are distributed chiefly to the epithelium covering the soft palate, portions of the glossopalatine arches, and the anterior two thirds of the tongue, the sensory innervation of which latter it shares with the lingual (trigeminal) nerve. It carries some fibers mediating taste sensations.

The **geniculate ganglion** (ganglion geniculi NK) is so named from the fact that it is embedded upon the anterior border of the external genu (*geniculum*) of the facial nerve, behind the hiatus Fallopii. It is somewhat triangular in form. From its superomedial angle leave the central processes of its cells, the root of the nerve; from its inferolateral angle leave the fibers which later leave the sheath of the facial as the chorda tympani, and its anterior angle is connected with the great superficial petrosal nerve (figs. 808 and 810). The geniculate ganglion contains a relatively large number of cell-bodies of sympathetic neurones many of whose processes run in this latter nerve, a relation mentioned below with the gangliated cephalic sympathetic plexus.

The **motor portion** of the glossopalatine consists for the most part of visceral efferent (autonomic) fibers, chiefly secretory. These arise in the medulla oblongata from a small group of cells scattered in the reticular formation dorsomedial to the nucleus of the facial and in line with the dorsal efferent nucleus of the vagus below. It is called the *salivatory nucleus*. The fibers course ventralward and lateralward to their exit, mingle with the entering sensory fibers of the glossopalatine in the sheath of the facial and, through the branches of the glossopalatine, pass to terminate in sympathetic ganglia of the head, large and small. These ganglia send axones which terminate in the smooth muscle of vessels and about the cells of the glands of the lingual and palatine mucous membrane and of the salivary glands proper.

Some of the motor fibers of the nerve terminate in contact with the sympathetic cells remaining in the geniculate ganglion and which give rise to sympathetic fibers issuing from it. Most of the motor fibers pass into the great superficial petrosal nerve and the chorda tympani to terminate in (chiefly) or pass through the sphenopalatine and submaxillary ganglia respectively. Some may pass by the geniculotympanic branch and tympanic plexus to end in the otic ganglion. Many no doubt end in the smaller ganglia involved in the various sympathetic plexuses. It is suggested that the motor part carries secretory impulses destined chiefly for the submaxillary and sublingual glands. A small gangliated plexus on the capsule of the medial side of the parotid gland has been frequently dissected and found to communicate freely with twigs from the facial nerve and twigs concerned with the trigeminus. It is possible that some glossopalatine visceral motor fibers terminate in these ganglia for secretory impulses to the parotid gland as well.

Central connections.—The nucleus of termination of the glossopalatine nerve (superior extension of the nucleus of termination of the sensory portion of the glossopharyngeal) is associated with the somesthetic area of the cerebral cortex of the opposite and same sides by way of the medial lemniscus, and with the salivatory nucleus and motor nuclei of other cranial nerves by way of the reticular formation and medial longitudinal fasciculus. The nucleus of origin of the motor portion (salivatory nucleus) may be associated not only with the nucleus of termination of the sensory part, but with the nuclei of termination of other cranial nerves, and perhaps with the motor area of the cortex of the opposite side by way of the pyramidal fasciculi.

Branches and communications.—Aside from its two or three small collateral twigs of communication, the fibers of the glossopalatine course in two main branches or nerves: (1) the great superficial petrosal nerve, continued through the Vidian nerve, and extended through and beyond the sphenopalatine ganglion as the palatine portion of the glossopalatine (palatine nerve); (2) the chorda tympani, the larger branch, which extends to join and contribute its quota of fibers to the lingual nerve, a branch of the trigeminus.

In the internal auditory meatus the glossopalatine gives two delicate collaterals to the vestibular nerve, and some filaments (visceral motor probably) are described as given to the internal auditory artery and to the temporal bone.

A small **geniculotympanic branch** is given, in the facial canal, from the geniculate ganglion to the small superficial petrosal nerve. This is probably all composed of visceral motor or sympathetic fibers (fig. 810).

There may occur a twig arising from or near the beginning of the chorda tympani and forming a *communication with the auricular branch of the vagus*.

A large part of the **great superficial petrosal nerve** is formed of glossopalatine fibers. This nerve is further described below in its relation to the sphenopalatine ganglion. It arises from the anterior angle of the geniculate ganglion, enters the middle fossa of the cranium

through the hiatus Fallopii, and passes beneath the semilunar ganglion into the foramen lacerum, where it joins with the great deep petrosal nerve to form the Vidian nerve. Thence the glossopalatine portion passes over or through the sphenopalatine ganglion to form the greater part of the small and middle palatine nerves which are distributed to the epithelium and glands of the soft palate, some of the sensory fibers probably terminating in the taste organs found there; the remainder serving as fibers of general sensibility. It is probable that most of the motor glossopalatine fibers in the great superficial petrosal nerve terminate in the sphenopalatine ganglion; some may pass to the carotid plexus and to small ganglia elsewhere.

The chorda tympani consists to a very large extent of sensory fibers (peripheral processes of the cells of the geniculate ganglion), but it also contains motor fibers and is thus also a mixed nerve. It leaves the trunk of the facial nerve a short distance above the stylomastoid foramen, and pursues a slightly recurrent course upward and forward in the canaliculus chordæ tympani (iter chordæ posterius), a minute canal in the posterior wall of the tympanic cavity, and it enters that cavity close to the posterior border of the membrana tympani. It crosses the cavity, running on the medial surface of the tympanic membrane at the junction of its upper and middle

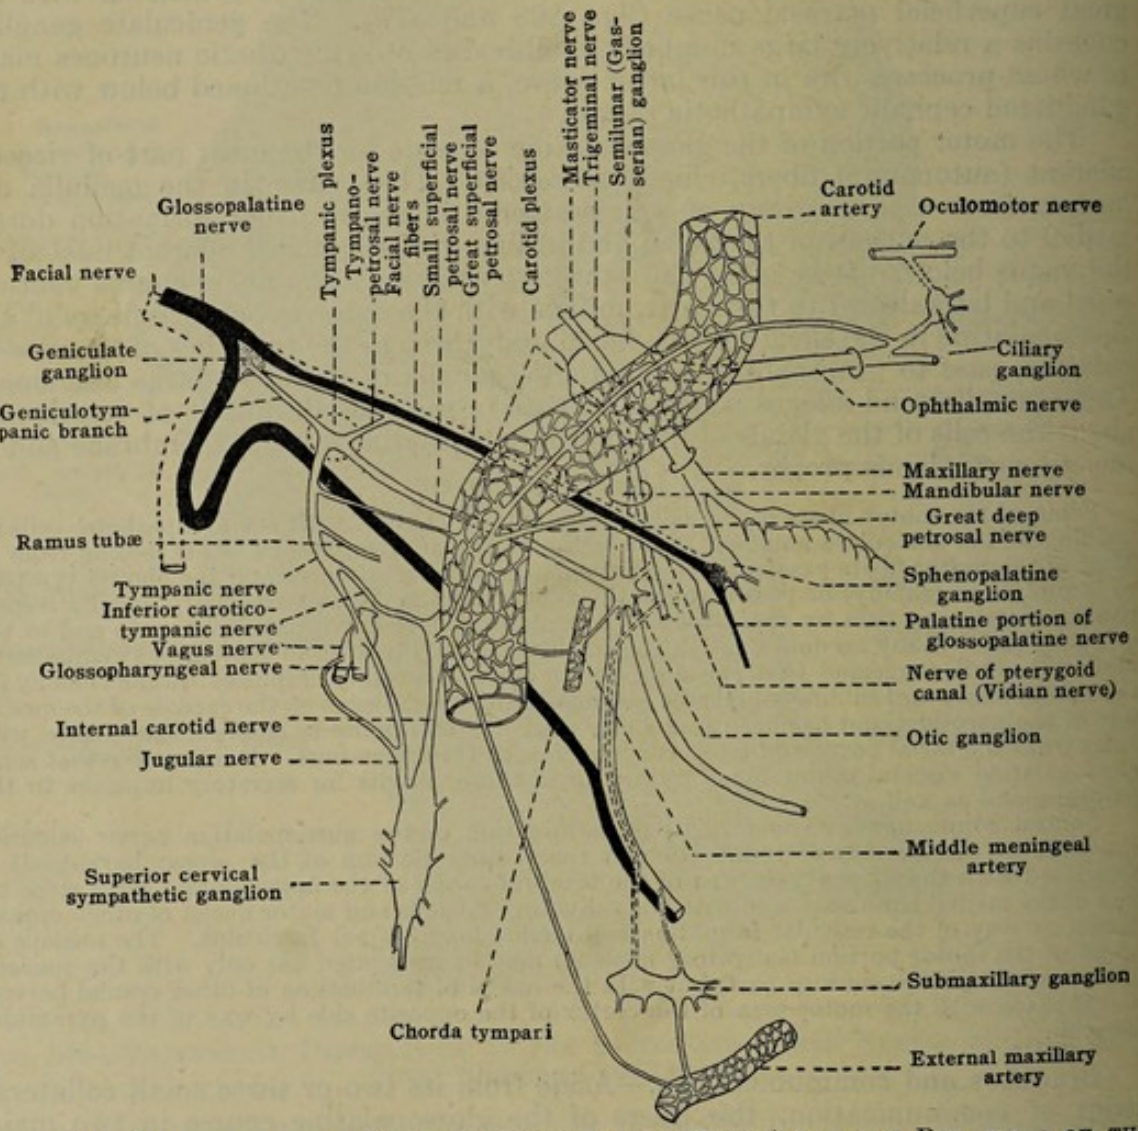

FIG. 810.—DIAGRAM OF THE GLOSSOPALATINE NERVE (BLACK) AND THE RELATIONS OF THE GANGLIATED CEPHALIC PLEXUS TO OTHER CRANIAL NERVES. (After Bean.) Broken lines, motor; continuous lines, sympathetic; glossopalatine (relatively larger than normal) in solid black. Medial view. Left side.

thirds, covered by the mucous membrane lining the tympanic cavity, and passes to the medial side of the manubrium of the malleus above the tendon of the tensor tympani. It leaves the tympanic cavity and passes to the base of the skull through a small foramen (the iter chordæ anterius) at the medial end of the petrotympanic fissure. At the base of the skull it inclines downward and forward on the medial side of the spine of the sphenoid, which it frequently grooves, and, on the medial side of the pterygoideus externus, it joins the posterior border of the lingual nerve at an acute angle. Some of its fibers (visceral motor chiefly) leave the lingual nerve and pass to the submaxillary ganglion, and others (sensory) continue forward to the tongue, where, in company with fibers of the lingual nerve, they terminate in the epithelium covering the anterior two-thirds of the tongue. Some probably serve to convey sensations of taste, most of them are fibers of general sensibility. Before it joins the lingual nerve the chorda tympani receives a communicating twig from the otic ganglion (figs. 807, 810).

Facial paralysis due to injury of the facial nerve within the petrous bone and thus injury of the glossopalatine (chorda tympani) is also known as *petrous paralysis*, that is, facial paralysis

accompanied by deranged salivary secretion, impaired taste and impaired general sensibility of the anterior part of the tongue.

THE VESTIBULAR NERVE

The vestibular (equilibrator) nerve (n. vestibuli or staticus NK) is purely sensory. With the peripheral processes of its ganglion cells of origin ending in the neuroepithelium of the semicircular ducts (canals) and the vestibular maculæ, and their central processes conveying impulses to the gray substance of the medulla, cerebellum and spinal cord, the nerve comprises a most important part of the apparatus for the equilibration of the body. It has been customary to describe the vestibular [radix vestibularis] and the cochlear [radix cochlearis] nerves combined as the **acoustic (auditory) or eighth cranial nerve** (n. statoacusticus NK). While the two are blended in a common sheath from near the medulla to the bottom of the internal auditory meatus, they are likewise partly enclosed in the same sheath with the facial and glossopalatine nerves and the internal auditory artery which accompany them in this meatus. At the bottom of

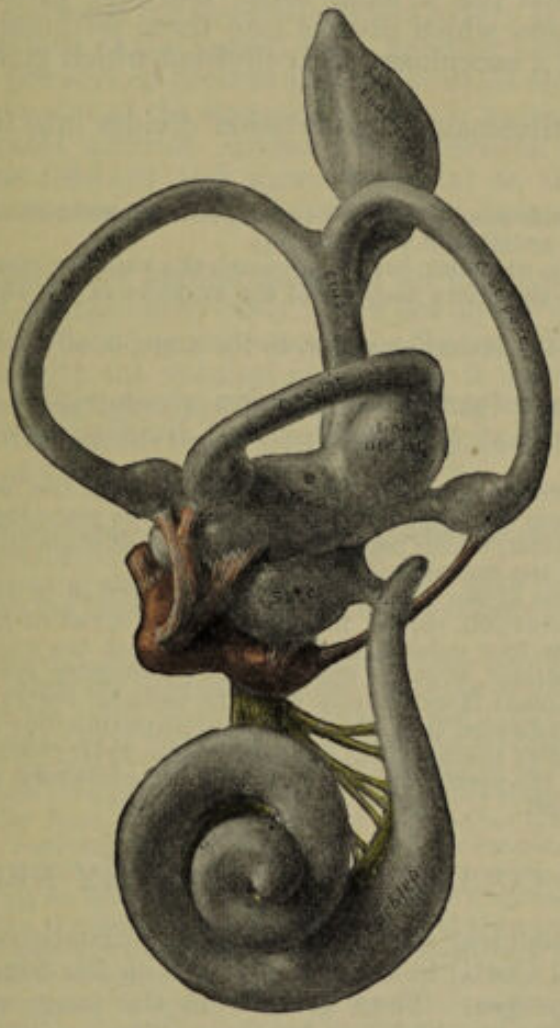

FIG. 811.—THE LEFT MEMBRANOUS LABYRINTH OF A HUMAN FETUS OF 10 WEEKS (30 MM.), LATERAL ASPECT. Vestibular ganglion and nerve, red; cochlear nerve, yellow. (Streeter, American Journal of Anatomy.)

the meatus the vestibular and the cochlear are separate; they are separate at their entrance into the lateral aspect of the medulla oblongata; and their central connections, peripheral distributions and functions are different.

The vestibular is preeminently the nerve of body posture; the labyrinth in which it is distributed serves as a terminal organ for the cerebellum, with which it shares a relation to the sympathetic system in maintaining muscular tone.

The vestibular nerve arises as processes of the cells of the **vestibular ganglion** (ganglion of Scarpa), situated upon and blended within the nerve at the bottom of the internal auditory meatus (fig. 811). Unlike a spinal ganglion to which it corresponds, most of the cells of the vestibular ganglion retain an embryonal,

'bipolar,' form. The *central processes* course with the cochlear nerve in the internal auditory meatus medialward, caudad and slightly downward, inferior to the accompanying facial and glossopalatine nerves, and, arching ventrally around the restiform body, they enter the medulla at the inferior border of the pons, lateral to the glossopalatine and facial and medial to the entrance of the cochlear nerve. They find their nucleus of termination spread in the floor of the fourth ventricle and grouped as the median, the lateral (Deiters'), the superior, and the nucleus of the spinal root of the vestibular nerve. In the internal auditory meatus, the vestibular nerve is connected by two small filaments of fibers with the glossopalatine nerve. These are either visceral motor fibers for the vessels of the domain of the vestibular or are aberrant fibers which course only temporarily with the vestibular and return to the glossopalatine.

The *peripheral processes* of the cells of the vestibular ganglion terminate in the neuroepithelium comprising the *maculæ* in the sacculus and the utriculus and the *cristæ* in the ampullæ of the three semicircular ducts. Thus there are five **terminal branches** of the nerve. None of its fibers terminates in the cochlea. The vestibular ganglion has a lobar form, one lobe giving rise to a superior **utriculoampullar** division which divides into three terminal branches; the other or inferior lobe giving a **sacculoampullar** division which gives two terminals (fig. 811).

The superior or **utriculoampullar division** divides into the following terminal branches:

(1) The **utricular branch** passes through the superior macula cribrosa of the vestibule and terminates in the macula acustica of the utriculus.

(2) Accompanying the utricular branch through the superior macula cribrosa is a branch, the **superior ampullar,** to the crista acustica of the ampulla of the superior semicircular duct, and—

(3) A similar branch, the **lateral ampullar,** to the ampulla of the lateral semicircular duct.

The inferior or **sacculoampullar division** accompanies the cochlear nerve a short distance further than the superior, and divides into—

(4) A branch, the **posterior ampullar,** which passes through the foramen singulare and the inferior macula cribrosa and terminates in the ampulla of the posterior semicircular duct, and—

(5) A branch, the **saccular,** which passes through the middle macula cribrosa and terminates in the macula acustica of the sacculus.

The **central connections** of the vestibular nerve are described in detail on pp. 864, 898–900. Its large nucleus of termination, spread through the area acustica in the floor of the fourth ventricle, and divided into four sub-nuclei, is associated with the nuclei fastigii, globosus, and emboliformis of the cerebellum, with the nuclei of the eye-moving nerves, with the spinal cord, by way of the vestibulospinal fasciculi, and with the cerebral cortex by way of the lemnisci. Experimental work has indicated that fibers of the utriculoampullar division of the vestibular take part chiefly in the reflex chains which have to do with tonic reflexes in the extensors of the forelimbs, while fibers of the sacculoampullar division are concerned chiefly with tonic reflexes for the position of the head.

THE COCHLEAR OR AUDITORY NERVE

The fibers of the cochlear nerve (n. cochleæ or acusticus NK) are distributed to the spiral organ (of Corti) in the cochlea, and so are considered as comprising the auditory nerve proper. They arise from the long, coiled **spiral ganglion** of the cochlea, the cells of which are bipolar. The *peripheral processes* of these cells are shorter than those of the vestibular ganglion. They terminate about the auditory or hair-cells of the spiral organ and thus collect impulses aroused by stimuli affecting these cells. The *central processes* of the ganglion cells continue through the modiolar canal and the tractus spiralis foraminosus of the cochlea, and thence, joining the vestibular nerve through the internal auditory meatus, accompanying the facial nerve and internal auditory artery, they course medialward and downward, approach and enclasp the restiform body (fig. 728) and enter the lateral aspect of brain-stem to terminate in their dorsal and ventral nuclei. A description of these nuclei and the further central connections of the cochlea with the superior olive, the nuclei of the eye-moving nerves, the inferior quadrigeminate bodies, the medial geniculate bodies, and with the cerebellum and temporal lobes of the cerebral hemispheres are given on pages 900, 916.

Experimentation and clinical data suggest that auditory (cochleocortical) sensations are mediated chiefly, if not entirely, by impulses which reach the temporal cortex by way of the

medial geniculate body; that the other connections of cochlear fibers have to do with motor reflexes to sound waves.

THE GLOSSOPHARYNGEAL NERVE

The glossopharyngeal or *ninth* pair of cranial nerves are mixed nerves and each is attached to the medulla by several roots which enter the posterolateral sulcus, dorsal to the anterior end of the olivary body and in direct line with the facial nerve (fig. 800). Some of its sensory fibers are special sensory (taste) and many of its motor fibers are visceral motor (autonomic).

The filaments, when traced lateralward, are seen to blend, in front of the flocculus, into a trunk which lies in front of the vagus nerve, but which passes through a separate opening through the arachnoid and the dura mater and through the jugular foramen. In the foramen this trunk lies in front, and lateral to the vagus nerve and in a groove on the petrous portion of the temporal bone; and in this situation two ganglia are interposed in it, a superior or jugular, and an inferior or petrosal. After it emerges from the jugular foramen the glossopharyngeal descends at first between the internal carotid artery and the internal jugular vein and to the lateral side of the vagus; then, bending forward and medialward, it descends medial to the styloid process and the muscles attached to it, and turning around the lower border of the stylopharyngeus it passes between the internal and the external carotid arteries, crosses the superficial surface of the stylopharyngeus, and runs forward and upward medial to the hyoglossus muscle and across the middle constrictor and the stylohyoid ligament, to the base of the tongue (fig. 812).

Ganglia.—The **superior** or **jugular ganglion** (of Ehrenritter) (g. intracraniale NK), is a small, ovoid, reddish-gray body which lies on the back part of the nerve-trunk in the upper part of the jugular foramen. No branches arise from it. It is sometimes continuous with the petrosal ganglion or it may be absent.

The **inferior or petrosal ganglion** (of Andersch) (g. extracraniale NK), is an ovoid gray body which lies in the lower part of the jugular foramen, and appears to include all the fibers of the nerve.

Branches and communications.—(1) The petrosal ganglion is connected with the superior cervical ganglion of the sympathetic by a fine filament.

(2) It also has a filament of communication with the auricular branch of the vagus which varies inversely in size with the latter branch and sometimes entirely replaces it. This filament may be absent.

(3) An inconstant communication with the ganglion of the root of the vagus.

(4) A short distance below the petrosal ganglion the trunk of the nerve is connected by a twig with that branch of the facial nerve which supplies the posterior belly of the digastric muscle. There is also a small twig (probably sensory) to the stylohyoid.

(5) **From the petrosal ganglion: The tympanic branch** (nerve of Jacobson) arises from the petrosal ganglion and passes through a foramen, which lies in the ridge of bone between the carotid canal and the jugular fossa, into the tympanic canaliculus (Jacobson's canal), where it is surrounded by a small, fusiform mass of vascular tissue, the *intumescentia tympanica*. After traversing the tympanic canaliculus it enters the tympanum at the junction of its lower and medial walls, and, ascending on the medial wall, breaks up into a number of branches which take part in the formation of the **tympanic plexus** on the surface of the promontory (fig. 808). The continuation of the nerve emerges from this plexus as the *small superficial petrosal nerve*, which runs through a small canal in the petrous portion of the temporal bone, beneath the canal for the tensor tympani, and appears in the middle fossa of the cranium through a foramen which lies in front of the hiatus Fallopii. From this foramen it runs forward and passes through the foramen ovale, the canaliculus innominatus, or the sphenopetrosal suture, and enters the zygomatic fossa, where it enters the otic ganglion. While it is in the canal in the temporal bone, the small superficial petrosal nerve is joined by a **geniculotympanic branch** from the geniculate ganglion of the glossopalatine nerve.

(6) **Branches from the tympanic plexus:** (*a*) The **tubal branch** (ramus tubæ), a delicate branch, which runs forward to the mucous membrane of the tuba auditiva (Eustachian tube) and sends filaments backward to the region of the fenestra vestibuli (ovalis) and the fenestra cochleæ (rotunda). (*b*) The **superior and inferior caroticotympanic (carotid) branches** pass medianward to the internal carotid plexus (figs. 808, 810).

The above communications carry fibers almost entirely concerned with the sympathetic plexuses of the head and they will be again mentioned below with the gangliated cephalic plexus.

Branches from the trunk of the nerve: (1) **Pharyngeal branches,** which may be two or three in number, arise from the nerve a short distance below the petrosal ganglion. The principal and most constant of these passes on the lateral side of the internal carotid artery, and after a very short independent course joins with the pharyngeal branch of the vagus and with branches of the superior cervical ganglion to form the pharyngeal plexus (fig. 812).

(2) A **muscular branch** is distributed to the stylopharyngeus muscle. This branch receives a communication from the facial nerve (fig. 812).

(3) The **tonsillar branches** are a number of small twigs which arise under cover of the hyoglossus muscle; they proceed to the tonsil, around which they form a plexus, the **circulus tonsillaris.** From this plexus fine twigs proceed to the glossopalatine arch and to the soft palate.

(4) The **lingual branches** are the terminal branches of the nerve and supply the mucous membrane of the posterior half of the dorsum of the tongue, where, chiefly as taste-fibers, they are distributed to the vallate papillæ. Some small twigs pass backward to the follicular glands of the tongue, and to the anterior surface of the epiglottis. Other twigs are distributed around the foramen cecum, where they communicate with the corresponding twigs of the opposite side.

(5) Hering (Die Karotissinusreflexe, Verlag T. Steinkopff, Dresden u. Leipzig, 1927) describes a **'sinus nerve,'** which is a branch of the glossopharyngeal to the 'carotid sinus,' a slight dilation at the proximal end of the internal carotid artery. The sinus nerve has been found in man, rabbit, dog, cat and monkey. Afferent stimulation of this nerve causes fall in blood pressure and slowing of the heart rate.

The sensory fibers.—The sensory fibers of the glossopharyngeal nerve spring from the superior and petrosal ganglia and pass peripherally and centrally. The **peripheral** processes of the ganglion cells are those which are distributed to the mucous membrane (including taste-buds) of the tongue and pharynx, and the **central** processes pass medialward to the medulla. In the medulla they pass dorsalward and medianward through the reticular formation and, bifurcating into ascending and descending branches, they end in the nucleus of termination of the glossopharyngeal nerve, that is, in the superior part of the nucleus alæ cinereæ and of the nucleus of the tractus solitarius.

The **motor fibers** arise from the nucleus ambiguus in the lateral funiculus of the medulla, in line with the nucleus of origin of the facial nerve. From this nucleus they pass at first dorsalward and then, turning lateralward, they emerge and join the sensory fibers and run with them in the trunk of the nerve (fig. 725).

Van Gehuchten's observations point to the conclusion that one motor nucleus of the glossopharyngeal nerve is separate from and lies above and to the medial side of the nucleus ambiguus, and that a portion of the nucleus of the ala cinerea is also a motor nucleus common to the glossopharyngeal and vagus nerves. It is quite probable that the former motor nucleus is that now considered as the dorsal efferent nucleus of the vagus. An unknown number of the motor fibers are visceral motor and course in the various communications of the glossopharyngeal nerve with the cephalic (sympathetic) plexus.

Central connections.—The nuclei of termination of the glossopharyngeal nerve are associated with the motor nuclei of other cranial nerves by the medial longitudinal fasciculus, and with the somesthetic area of the cortex cerebri of the opposite side by the medial lemniscus (fillet). The motor neurones of the nerve are associated with the somesthetic area by the pyramidal fibers.

THE HYPOGLOSSAL NERVE

The **hypoglossal nerves** are exclusively motor and probably exclusively somatic motor; they supply the geniohyoid and the extrinsic and intrinsic muscles of the tongue (except the glossopalatine). They are usually designated as the twelfth pair of cranial nerves. The fibers of each nerve issue from the cells of an elongated nucleus which lies in the floor of the central canal in the lower half of the medulla and in the floor of the fourth ventricle in the upper half, beneath the trigonum hypoglossi. This nucleus is the upward continuation of the ventromedial group of cells of the ventral horn of the spinal cord. From their origin the fibers run ventralward and somewhat lateralward, probably joined in the medulla by a few fibers from the nucleus ambiguus which is a segment of the upward prolongation of the lateral group of cells of the ventral horn. The conjoined fibers issue from the medulla in the sulcus between the pyramid and the olivary body, in a series of from ten to sixteen root-filaments, which pierce the pia mater and unite with each other to form two bundles (fig. 800). These bundles pass forward and lateralward to the hypoglossal (anterior condyloid) foramen, where they pierce the arachnoid and dura mater. In the outer part of the foramen the two bundles unite to form the trunk of the nerve. At its commencement, at the base of the skull, the trunk of the hypoglossus lies on the medial side of the vagus, but as it descends in the neck it turns gradually around the dorsal and the lateral side of the latter nerve, lying between it and the internal jugular vein, and, a little above the level of the hyoid bone, it bends forward and crosses lateral to the internal carotid artery, the root of origin of the occipital artery, crosses the external carotid, and the loop formed by the first part of the lingual artery (fig. 812). After crossing the lingual artery it proceeds forward on the lateral surface of the hyoglossus, crossing to the medial side of the posterior belly of the digastric, and the stylohyoid muscles. It disappears in the anterior part of the submaxillary region between the mylohyoid and the hyoglossus, and divides into its terminal branches between the mylohyoid and the genioglossus.

As it descends in the neck the trunk lies deeply between the internal jugular vein and the internal carotid artery under cover of the parotid gland, the styloid muscles, and the pos-

terior belly of the digastric, and it is crossed superficially by the posterior auricular and the occipital arteries. As it turns forward around the root of the occipital artery the sternomastoid branch of that vessel hooks downward across the nerve, and as it turns forward on the hyoglossus muscle it lies immediately above the ranine vein. It is crossed by the posterior belly of the digastric and the stylohyoid muscle, and it is covered superficially, behind the mylohyoid, by the lower part of the submaxillary gland. Many of the twigs described as communications and branches contain few or no fibers of the hypoglossus proper.

Communications.—The hypoglossus is connected with the superior cervical ganglion of the sympathetic, with the ganglion nodosum of the vagus, with the loop between the first and second cervical nerves, and with the lingual nerve; the latter communication is established along the anterior border of the hyoglossus muscle (figs. 812 and 813).

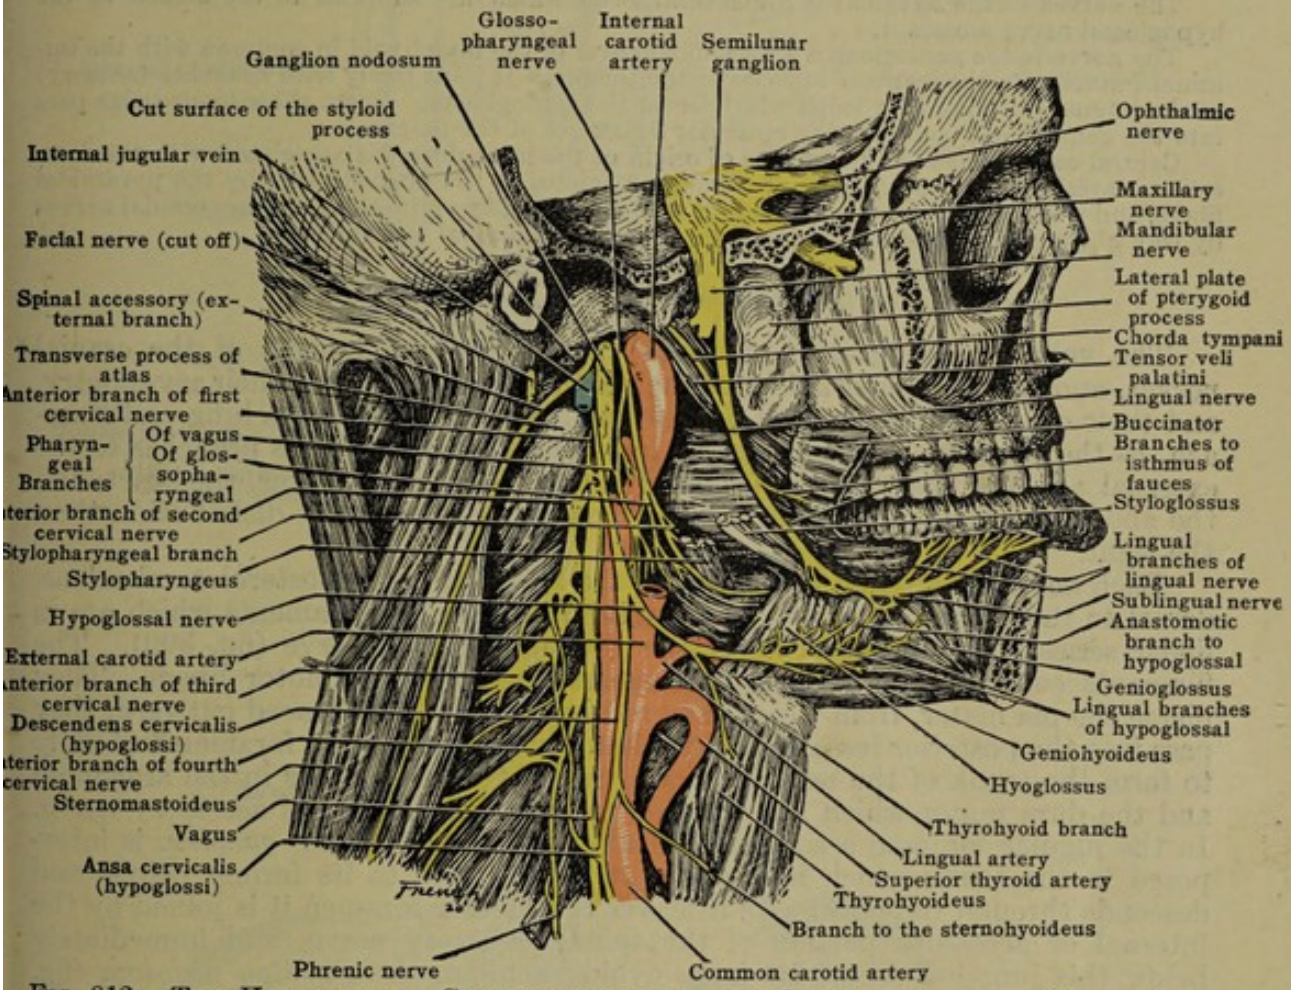

FIG. 812.—THE HYPOGLOSSAL, GLOSSOPHARYNGEAL, AND LINGUAL NERVES. (From Spalteholz, modified.)

Terminal branches.—These include (1) a meningeal branch; (2) branches from the cervical plexus; and (3) branches from the hypoglossus proper.

(1) A meningeal branch, frequently represented by two filaments, is given off in the hypoglossal (anterior condyloid) canal. It passes backward into the posterior fossa of the cranium and is distributed to the dura mater. It does not comprise fibers of the hypoglossus proper. It was believed at one time that the fibers of the meningeal branch were derived from the lingual nerve, but it is now deemed more probable that they are either sensory or visceral motor fibers from the cervical nerves, or from the vagus.

(2) **Branches which consist of fibers derived from the cervical plexus.**—The descendens cervicalis (hypoglossi) and the muscular twig to the thyrohyoid muscle, though apparently arising from the hypoglossal nerve, consists entirely of fibers which have passed into the hypoglossal nerve from the loop between the first two cervical nerves. Therefore, neither of them are branches of the hypoglossus proper. (See fig. 812.)

(a) The **descendens cervicalis (hypoglossi)** (r. descendens NK) parts company with the hypoglossus at the point where the latter hooks around the occipital artery. It runs downward and slightly medialward on the sheath of the great vessels (occasionally within the sheath), and is joined at a variable level by branches from the second and third cervical nerves, forming with them a loop [**ansa hypoglossi**]. The ansa hypoglossi may be placed at any level from a point immediately below the occipital artery to about 4 cm. above the sternum. From this loop all the infrahyoid muscles attached to the hyoid bone are supplied. A twig to the **anterior belly of the omohyoid** arises from the descendens cervicalis in the upper part of its course. The nerves which supply the **sternohyoid, sternothyroid,** and **posterior belly of the omohyoid**

are given off by the cervical loop. Twigs from the first two nerves pass downward in the muscles behind the manubrium sterni and in rare cases communicate with the phrenic nerve within the thorax. The nerve to the posterior belly of the omohyoid runs in a loop of the cervical fascia below the central tendon of the muscle.

(b) The **nerve to the thyrohyoid** leaves the hypoglossus near the tip of the great cornu of the hyoid bone, and runs obliquely downward and medialward to reach the muscle. All the fibers in (a) and (b) are derived from the first, second and third cervical nerves.

(c) The **nerve to the geniohyoid** arises under cover of the mylohyoid, where loops are formed with the lingual nerve from which loops branches pass into the muscle. It probably contains some true hypoglossal fibers.

(3) The **branches of the hypoglossus proper, the rami linguales,** supply the styloglossus hyoglossus, genioglossus, and the intrinsic muscular fibers of the tongue.

The **nerve to the styloglossus** is given off near the posterior border of the hyoglossus. It pierces the styloglossus, and its fibers pursue a more or less recurrent course within the muscle.

The **nerves to the hyoglossus** are several twigs which are supplied to the muscle as the hypoglossal nerve crosses it.

The **nerve to the genioglossus** arises under cover of the mylohyoid in common with the terminal branches to the intrinsic muscles of the tongue. It joins freely with branches (sensory) of the lingual, forming long loops which lie on the genioglossus. From these loops twigs pass into the genioglossus and into the muscular substance of the tongue.

Central connections.—The nucleus of origin of the hypoglossus is associated with the somesthetic area (frontal operculum) of the cortex cerebri of the opposite side by the pyramidal fibers, and it is correlated with the sensory nuclei (nuclei of termination) of other cranial nerves by way of the reticular formation and the medial longitudinal fasciculus.

THE VAGUS NERVE

The **vagi** (pneumogastric or tenth) nerves are the longest of the cranial nerves, and they are remarkable for their almost vertical course, their asymmetry, and their extensive distribution, for, in addition to supplying the lung and stomach, as the old name 'pneumogastric' indicates, each nerve gives branches to the external ear, the pharynx, the larynx, the trachea, the esophagus, the heart, and the abdominal viscera. The left vagus has a more important distribution than the right.

Each nerve is attached to the side of the medulla, in the posterolateral sulcus, dorsal to the olivary body, by from twelve to fifteen root-filaments which are in linear series with the filaments of the glossopharyngeal nerve (fig. 800). The filaments contain both visceral and somatic sensory and motor fibers. They pierce the pia mater, from which they receive sheaths, and, traced outward, they pass into the posterior fossa of the cranium toward the jugular foramen and unite to form the trunk of the nerve, which passes through openings in the arachnoid and the dura mater which are common to it and to the spinal accessory nerve. In the jugular foramen a small spherical ganglion, the *jugular ganglion* is interposed in the trunk which here turns at right angles to its former course and descends through the neck. As it leaves the jugular foramen it is joined by the internal or accessory portion of the spinal accessory nerve, and immediately below this junction occurs its large ovoid ganglion, the *ganglion nodosum* (fig. 812). As it descends through the neck the nerve passes ventral and somewhat lateral to the superior cervical sympathetic ganglion, and in front of the longus capitis and longus colli, from which it is separated by the prevertebral fascia. In the upper part of the neck it is aligned between the internal carotid artery and the internal jugular vein, and in a plane dorsal to them, the artery being ventral and mesial, and the vein ventral and lateral. In the lower part of the neck it occupies a similar position in regard to the common carotid artery and the internal jugular vein, and the three structures are enclosed in a common sheath derived from the deep cervical fascia, but within the sheath each structure occupies a separate compartment (fig. 812). In the root of the neck and in the thorax the relations of the nerves of the two sides of the body differ somewhat, and they must, therefore, be considered separately (fig. 813).

The right vagus passes in front of the first part of the right subclavian artery in the root of the neck and then descends in the thorax, passing obliquely downward and backward on the right of the trachea, and behind the right innominate vein and the superior vena cava, to the back of the root of the right lung. Just before it reaches the right bronchus it lies close to the medial side of the vena azygos as the latter hooks forward over the root of the lung. At the back of the right bronchus the right vagus breaks up into a number of branches which join with the branches of the sympathetic to form the **right posterior pulmonary plexus,** and from this plexus it issues in the form of one or more cords, combined sensory, visceral motor and sympathetic, which descend on the esophagus and break up into branches which join with branches of the left vagus, forming the **posterior esophageal plexus.** At the lower part of the thorax fibers of this plexus become again associated in one trunk which passes through the diaphragm

on the *posterior* surface of the esophagus, and is distributed to the *posterior* surface of the stomach and to the celiac (solar) plexus and its offsets.

The **left vagus** descends through the root of the neck between the carotid and subclavian arteries and in front of the thoracic duct. In the upper part of the superior mediastinum it is crossed in front by the left phrenic nerve, and in the lower part of the same region it crosses in front of the root of the subclavian artery and the arch of the aorta and behind the left superior intercostal vein. Below the aortic arch it passes behind the left bronchus and divides into

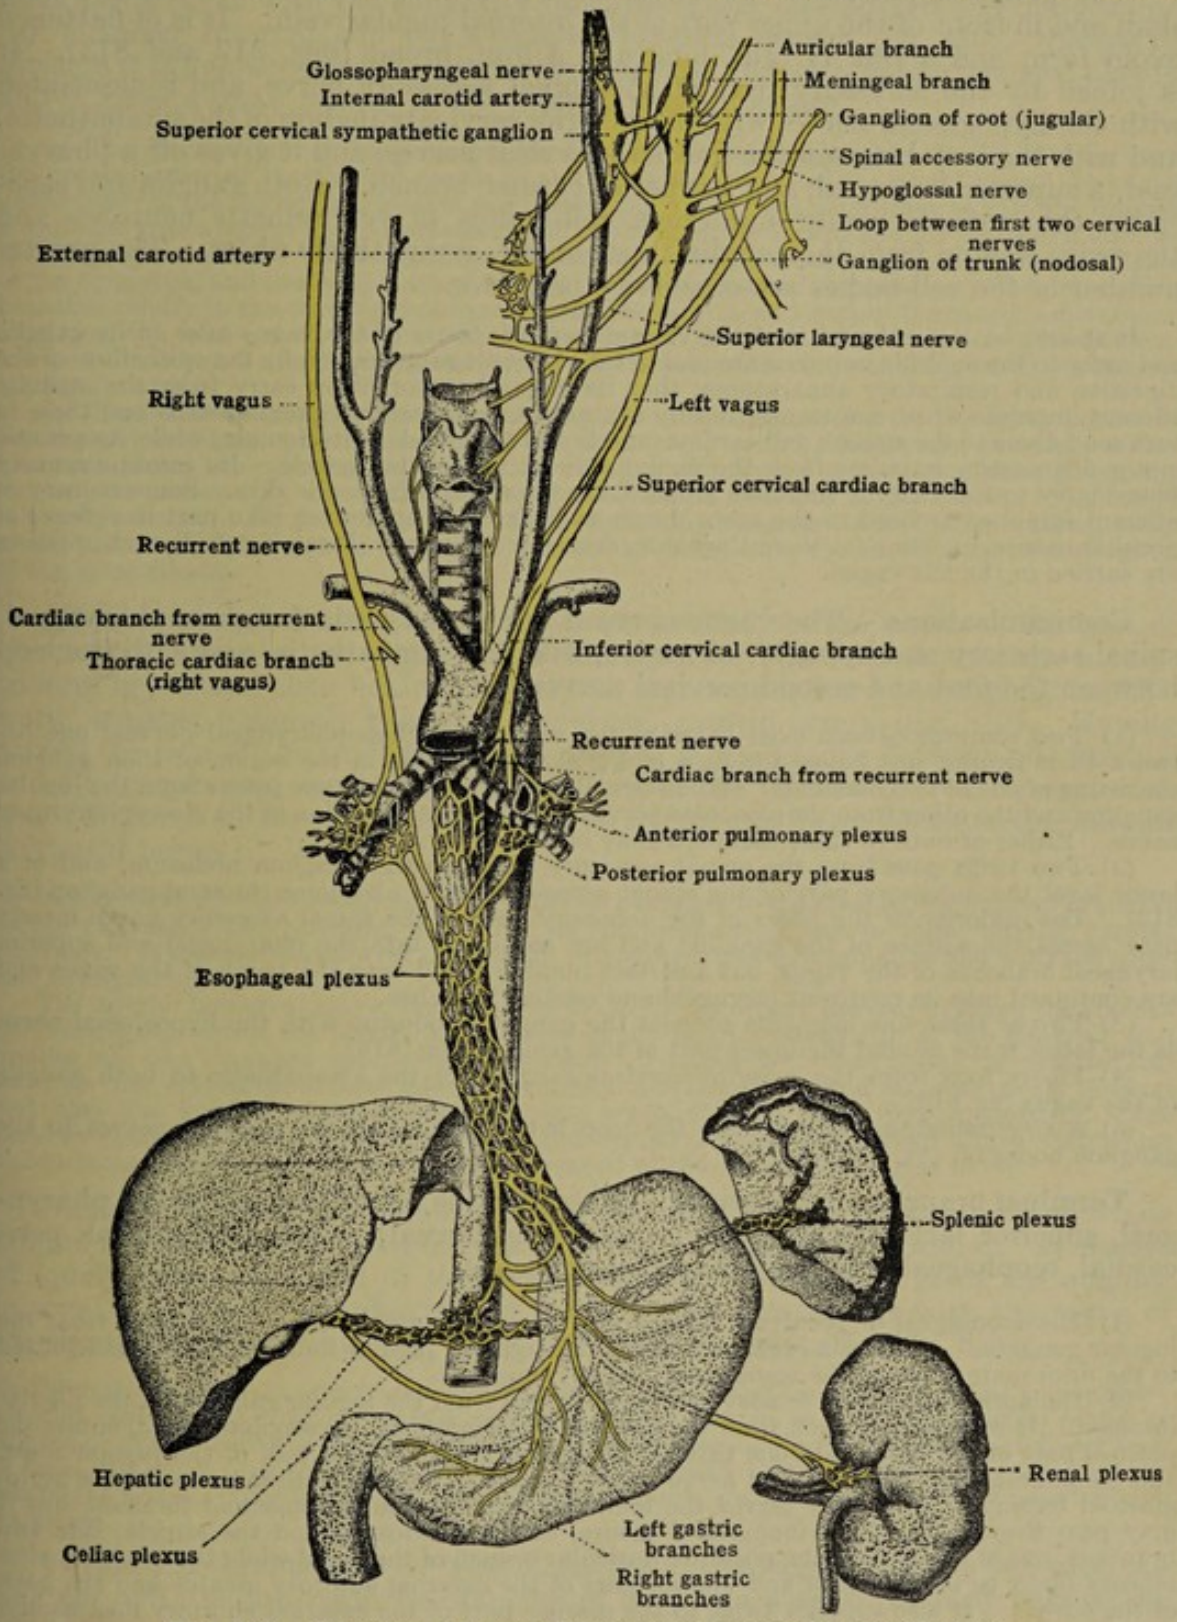

FIG. 813.—DIAGRAM OF THE BRANCHES OF THE VAGUS NERVES.

branches which unite with twigs of the sympathetic to form the **left posterior pulmonary plexus.** From this plexus the fibers of the left vagus issue as one or more cords that break up into anastomosing branches to form the anterior **esophageal plexus.** At the lower part of the thorax this plexus becomes a single trunk, which passes through the diaphragm on the *anterior* surface of the esophagus, and it is distributed to the *anterior* surface of the stomach and to the liver.

In the anastomoses of the two esophageal plexuses fibers from the two vagi are commingled and each of the vagal trunks, assembled below, contains fibers from both the right and left vagus (McCrea).

The **jugular ganglion** (ganglion of the root) is a spherical gray mass about 5 mm. in diameter which lies in the jugular foramen (fig. 813). It is connected with the spinal accessory nerve and with the superior cervical sympathetic ganglion, and it gives off an auricular branch, by means of which it becomes associated with the facial and glossopharyngeal nerves, and a recurrent meningeal branch.

The **ganglion nodosum** (ganglion of the trunk) lies below the base of the skull and in front of the upper part of the internal jugular vein. It is of flattened ovoid form and about 17 mm. long and 4 mm. broad (figs. 812 and 813). It is joined by the accessory part of the spinal accessory nerve, and is associated with the hypoglossal nerve, with the superior cervical ganglion of the sympathetic, and with the loop between the first two cervical nerves, and it gives off a pharyngeal, a superior laryngeal, and a superior cardiac branch. Both ganglia and especially the nodosal retain numerous cell-bodies of sympathetic neurones and the twigs issuing from the ganglia thus contain sympathetic fibers. The greater number of the cell-bodies are of sensory neurones.

It should be remembered that the visceral sensory fibers of the vagus arise in its ganglia and carry to the medulla impulses aroused in the viscera it supplies, chiefly the epithelium of the digestive and respiratory apparatuses; that its visceral motor fibers carry from the medulla efferent impulses which are transferred by synapses to sympathetic ganglion-cells and these in turn send fibers to the smooth and cardiac muscle and the glands of its domain, while its somatic motor fibers carry impulses from the medulla direct to skeletal muscle. Its somatic sensory fibers carry to the medulla impulses aroused, for the most part, in the skin. Some sensory or afferent impulses aroused in the aorta, heart and digestive apparatus take part in reflexes of peculiar nature, meriting for them the name, *depressor impulses*. Most, if not all, such impulses are carried in the left vagus.

Communications.—The vagus nerve is connected with the glossopharyngeal, spinal accessory and hypoglossal nerves, with the sympathetic, and with the loop between the first and second cervical nerves.

(1) Two communications exist between the vagus and glossopharyngeal nerves: one between their trunks, just below the base of the skull, and one, in the region of their ganglia, consisting of one or two filaments. When two filaments are present one passes from the jugular ganglion and the other from the auricular nerve to the petrosal ganglion of the glossopharyngeal nerve. Either or both of these filaments may be absent.

(2) Two twigs pass from the spinal accessory nerve to the ganglion nodosum, and at a lower level the accessory part of the spinal accessory nerve also joins the same ganglion (fig. 813). The majority of the fibers of the accessory part of the spinal accessory nerve merely pass across the surface of the ganglion and are continued into the pharyngeal and superior laryngeal branches of the vagus, but a certain number blend with the trunk of the vagus and are continued into its recurrent laryngeal and cardiac branches.

(3) Two or three fine filaments connect the ganglion nodosum with the hypoglossal nerve as the latter turns around the lower part of the ganglion (fig. 813).

(4) Fibers pass from the superior cervical ganglion of the sympathetic to both ganglia of the vagus (fig. 813).

(5) A twig sometimes passes from the loop between the first two cervical nerves to the ganglion nodosum (fig. 813).

Terminal branches of the vagus.—These are the meningeal, auricular, pharyngeal, superior laryngeal, recurrent (inferior laryngeal), cardiac, bronchial, pericardial, esophageal, and the abdominal branches.

(1) The **meningeal** or **recurrent branch** is a slender filament which is given off from the jugular ganglion. It takes a recurrent course through the jugular foramen, and is distributed to the dura mater around the transverse (lateral) sinus.

(2) The **auricular branch**, or **nerve of Arnold**, arises from the jugular ganglion in the jugular foramen. It receives a branch from the petrosal ganglion of the glossopharyngeal, enters the petrous part of the temporal bone through a foramen in the lateral wall of the jugular fossa, and communicates with the facial nerve or merely lies in contact with it as far as the stylomastoid foramen. It usually leaves the temporal bone by the stylomastoid foramen, but it may pass through the tympanomastoid fissure, and it divides, behind the auricle, into two branches, one of which joins the posterior auricular branch of the facial while the other supplies sensory fibers to the posterior and inferior part of the external auditory meatus and the back of the auricle. It also supplies twigs to the osseous part of the external auditory meatus and to the lower part of the outer surface of the tympanic membrane. This branch of the vagus to the meatus and tympanic membrane may explain the vomiting and cough which occasionally accompany infections of the meatus.

(3) The **pharyngeal branches** may be two or three in number. The principal of these joins the pharyngeal branch of the glossopharyngeal on the lateral surface of the internal carotid artery, and after passing with the latter medial to the external carotid artery it turns downward and medialward to reach the posterior aspect of the pharynx. Here the two nerves are joined by branches from the superior cervical ganglion of the sympathetic, with which they form the **pharyngeal plexus** (figs. 812, 813). Branches from this plexus supply sensory fibers to the mucous membrane of the pharynx, somatic motor fibers to the constrictores pharyngis,

levator palatini, uvulæ, glossopalatinus, and pharyngopalatinus and probably visceral motor to sympathetic ganglion cells.

(4) The **superior laryngeal nerve** arises from the lower part of the ganglion nodosum, and passes obliquely downward and medialward, behind and medial to both the internal and external carotid arteries, toward the larynx. In this course it describes a curve with the convexity downward and lateralward and divides into (a) a larger internal and (b) a smaller external branch (fig. 813). Before its division it is joined by twigs with the sympathetic and with the pharyngeal plexus, and it gives a small branch to the internal carotid artery.

(a) The **internal branch** accompanies the superior laryngeal artery to the interval between the upper border of the thyroid cartilage and the great cornu of the hyoid bone. It passes under cover of the thyrohyoid muscle and pierces the hyothyroid membrane to gain the interior of the pharynx, where it lies in the lateral wall of the sinus piriformis and divides into a number of diverging branches. The ascending branches supply the mucous membrane on both surfaces of the epiglottis, and probably that of a small part of the root of the tongue. The descending branches ramify in the mucous membrane lining the larynx, and supply the mucous membrane adjoining the back of the cricoid cartilage. One of the descending branches passes downward on the internal muscles of the larynx to anastomose with the terminal part of the inferior laryngeal nerve.

(b) The **external branch** runs downward on the inferior constrictor to the lower border of the thyroid cartilage, where it ends, for the most part, in the cricothyroid muscle. A few filaments pierce the cricothyroid membrane and are distributed to the membrane lining the larynx. It occasionally gives off a cardiac branch which joins one of the cardiac branches of the sympathetic; it also furnishes twigs to the inferior constrictor, and communicating twigs to the pharyngeal plexus, and it receives a communication from the superior cervical ganglion of the sympathetic.

(5) The **recurrent nerve** of the **right side** arises from the vagus at the root of the neck in front of the right subclavian artery. It hooks around the artery, passing below and then behind that vessel, and runs upward and slightly medialward, crossing obliquely behind the common carotid artery (fig. 813). Having gained the side of the trachea, it runs upward in the groove between the trachea and the esophagus, accompanying branches of the inferior thyroid artery, and, near the level of the lower border of the cricoid cartilage, becomes the inferior laryngeal nerve.

In its course the right recurrent nerve gives off branches to the trachea, esophageal branches to the esophagus and pharynx, and, near its commencement, one or more **inferior cardiac** branches. It communicates with the inferior cervical sympathetic ganglion and with the superior laryngeal nerve.

The **inferior laryngeal nerve,** the continuation of the recurrent, ascends between the trachea and esophagus, enters the larynx under cover of the inferior constrictor of the pharynx, and divides into two branches, anterior and posterior. The *anterior branch* passes upward and forward on the cricoarytenoideus lateralis and thyroarytenoideus, and supplies these muscles and also the vocalis, arytenoideus obliquus, aryepiglotticus, and thyroepiglotticus. The *posterior branch*, passing upward, supplies the cricoarytenoideus posterior and arytenoideus obliquus, and anastomoses with the medial branch of the superior laryngeal nerve.

On the **left side** the recurrent nerve arises in front of the aortic arch and winds around the concavity of the arch lateral to the ligamentum arteriosum. It crosses obliquely behind the root of the left common carotid artery, gains the angular interval between the esophagus and trachea, and corresponds with the nerve of the right side in the remainder of its course and distribution (fig. 813).

Clinical aspects.—In operations involving severance or ligation of the inferior thyroid artery, especial care must be taken lest the accompanying recurrent or inferior laryngeal nerve be injured or ligated with the artery, resulting in laryngeal speech disorders. In about 80 per cent. of cases, the nerve runs anterior to the artery; in 12 per cent. on the right and 7 per cent. on the left of the artery. The artery may branch lower than is common and the nerve pass through its plexus.

(6) **Cardiac branches.**—Of these branches of the vagus there are two sets, the superior and inferior. All the branches of both sets pass to the deep part of the cardiac plexus except a superior branch on the left side that passes to the superficial part of the cardiac plexus. All contain visceral motor, sympathetic and visceral sensory fibers.

(a) The **superior (superior and inferior cervical) cardiac nerves** arise from the vagus and its branches in the neck (figs. 813, 814, 857). Some of these branches on both sides join with the cardiac branches of the sympathetic in the neck and pass with them to the cardiac plexus. Some on the right side pass independently through the thorax to the deep part of the cardiac plexus, and a branch on the left side passes through the thorax to the superficial part of the cardiac plexus.

(b) The **inferior (thoracic) cardiac branches.**—These branches on the right side arise in part from the recurrent nerve and in part from the main trunk of the vagus, while on the left side they usually arise entirely from the recurrent. All these branches pass to the deep part of the cardiac plexus (figs. 813, 814, 857).

(c) **Depressor nerve.**—Since 1876 when a branch of the vagus meriting this name was described for the rabbit by Cyon and Ludwig, many searches have been made for a depressor nerve in other mammals and especially in man. In the rabbit it may arise as a branch of the vagus alone or from the superior laryngeal alone, or, more rarely, from the nodosal ganglion directly. The depressor effects are produced by stimulation of the central stump of the severed nerve. No such effects are produced through the peripheral stump, thus proving the depressor to be a purely afferent nerve. Searches for a depressor nerve in various other mammals, including man, so far indicate that a nerve fully resembling in function and in course that described for the rabbit is of very rare occurrence or even of doubtful existence. Depressor

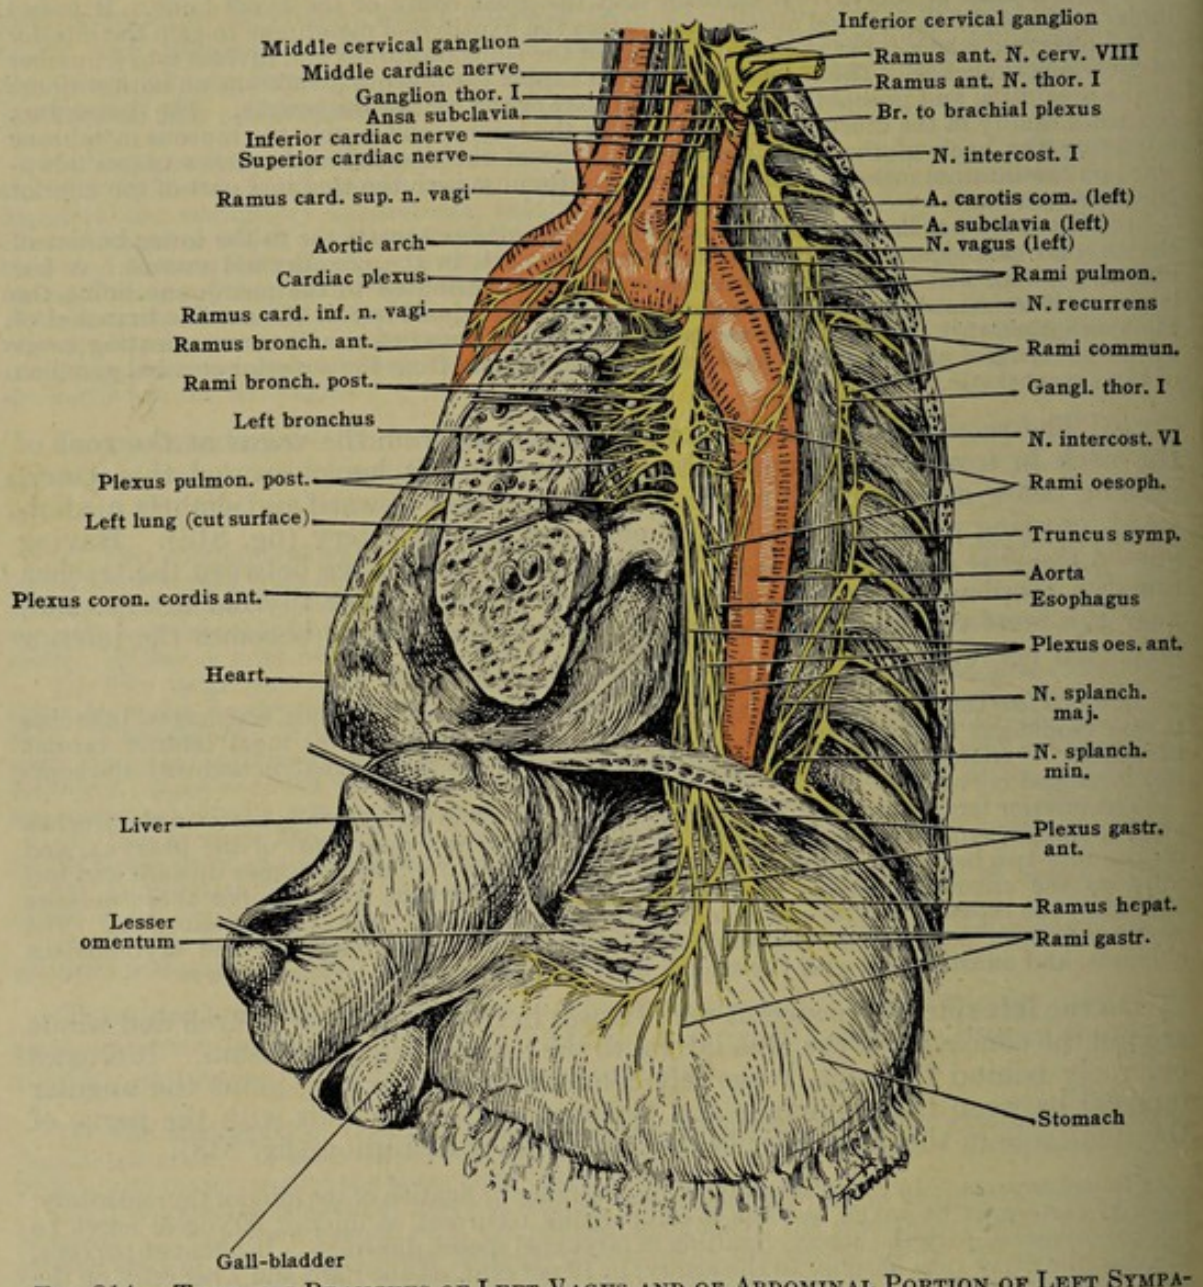

FIG. 814.—THORACIC BRANCHES OF LEFT VAGUS AND OF ABDOMINAL PORTION OF LEFT SYMPATHETIC TRUNK. (After Spalteholz.)

functions have been attributed to certain branches, such as some of the very variable superior cardiac nerves and branches of the vagus, and also branches of the superior laryngeal nerve uniting with one of the cardiac branches of the cervical sympathetic trunk. Bundles arising from fusion of branches of the vagus and superior laryngeal nerve have been found but these almost invariably rejoined the vagus trunk after running very short courses. Doubtless a 'depressor' nerve in man, whenever separate, is but composed of fibers of the same sensory function as possessed by the afferent fibers of the vagus proper, all of which fibers in most mammals are incorporated within the trunk of the vagus, which is known to be the great inhibitory nerve to the heart. Certainly it may be stated that there is in man no other well defined nerve proved to be a cardiac depressor.

While the depressor (sensory) nerve fibers form most important links in neurone chains for heart regulation, it is claimed as quite improbable that impulses conveyed to the central system

via the depressor fibers ever attain the threshold of consciousness. For pain sensations in disease of heart, see p. 1118.

(7) **Bronchial pulmonary branches** are anterior and posterior (figs. 813, 814).

(a) The **anterior bronchial (pulmonary) branches** consist of a few small branches which arise at the upper border of the root of the lung. They pass forward to gain the anterior aspect of the bronchus, where they communicate with the sympathetic and form the **anterior pulmonary plexus**, from which fine twigs pass along the bronchus.

(b) The **posterior bronchial (pulmonary) branches.**—Almost the entire remaining trunk of the vagus usually divides into these branches, which join with branches from the second, third, and fourth thoracic ganglia of the sympathetic trunk to form the **posterior pulmonary plexus** (figs. 813, 814). The plexuses of the two sides join freely behind the bifurcation of the trachea, and branches from the plexus pass along each bronchus into the lung.

(8) The **pericardial branches** pass from the trunk of the vagus or from the bronchial or esophageal plexuses to the anterior and posterior surfaces of the pericardium. They are chiefly sensory.

(9) **Esophageal branches,** given off by the trunk of the nerve above the bronchial plexuses and from the esophageal plexuses lower down, pass to the wall of the esophagus.

(10) **Abdominal branches.**—The terminal part of the left vagus (anterior vagal trunk) divides into many branches, some of which communicate freely along the lesser curvature of the stomach with filaments from the gastric plexus of the sympathetic, and to some extent with branches of the right vagus, to form the elongated **anterior gastric plexus** (figs. 813, 814). From this plexus as well as from the nerve-trunk, **gastric branches** are given to the anterior surface of the stomach. **Hepatic branches** from the trunk or from this plexus pass in the lesser omentum to the hepatic plexus (figs. 813, 814). The terminal part of the right vagus (posterior trunk) divides into many branches, and forms along the lesser curvature of the stomach an elongated **posterior gastric plexus** by communications with branches from the gastric plexus of the sympathetic and with branches from the left vagus. **Gastric branches** are given off by the trunk of the nerve and from this plexus. **Celiac branches** are given by the trunk to the celiac (solar) plexus, and **splenic** and **renal branches,** either directly or through the celiac (solar) plexus, are given to the splenic and renal plexuses (fig. 813). The main gastric branches of both vagi course near the lesser curvature of the stomach. The pyloric canal and sphincter and the superior flexure of the duodenum are chiefly supplied from the hepatic branches instead of direct from the main gastric branches.

Central connections.—The **sensory fibers** of the vagus are processes of the cells of the jugular ganglion and the ganglion nodosum. The peripheral fibers from these cells bring in sensory impulses from the periphery, and their central fibers convey the impulses to the brain. The latter fibers enter the medulla in the filaments of attachment in the posterolateral sulcus, and, in the reticular formation, they bifurcate into ascending and descending branches which end in the nuclei of termination of the vagus, namely, in the nucleus alæ cinereæ in the floor of the fourth ventricle and in the nucleus tractus solitarii. The tractus solitarius consists largely of the descending branches. These and the axones arising from the nuclei of termination of the vagus descend the spinal cord to terminate about ventral horn cells which give origin to the phrenic nerve and to motor fibers supplying other muscles of respiration, and they also convey impulses which are distributed to visceral motor neurones along the spinal cord.

The **motor fibers** spring from the nucleus ambiguus and from the dorsal efferent (visceral motor) nucleus of the vagus, described on page 898. They join the sensory fibers in the reticular formation. Some of the motor fibers, especially those from the dorsal efferent nucleus, are visceral motor fibers.

The central connections of the vagus are similar to those of the glossopharyngeal nerve (fig. 726). Van Gehuchten's observations point to the conclusion that the chief nucleus of termination of the vagus nerve is that of the tractus solitarius.

THE SPINAL ACCESSORY NERVE

The spinal accessory (or eleventh) nerve [n. accessorius] is exclusively motor. It consists of two parts, the accessory or superior, and the spinal or inferior part.

The fibers of the **accessory or superior portion** [ramus internus] (r. medialis NK) spring chiefly from the inferior continuation of the nucleus ambiguus, in common with the motor fibers of the vagus above, and they pass through the reticular formation to the posterolateral sulcus of the medulla, where they emerge as a series of filaments, below those of the vagus. The filaments pierce the pia mater and unite, as they pass outward in the posterior fossa of the cranium, to form a part of the nerve which enters the aperture in the dura mater common to the vagus and spinal accessory nerves. In the aperture this trunk is joined by the spinal portion of the nerve.

The **spinal** or **inferior portion** [ramus externus] (r. lateralis NK) arises from the cells of the ventral horn of the cord as low as the fifth, and rarely the seventh, cervical segment. The fibers pass dorsalward and lateralward from their origins, chiefly from the lateral part of the ventral horn, through the lateral funiculus of white substance, and they emerge from the lateral aspect of the cord behind the ligamentum denticulatum, along an oblique line, the lower fibers passing out immediately dorsal to the ligament, and the upper close to and sometimes in

association with the dorsal roots of the upper two spinal nerves. As the spinal fibers pass out of the surface of the cord they unite to form an ascending strand (fig. 800) which enters the posterior fossa of the cranium, through the foramen magnum, and, turning lateralward, blends more or less intimately with the accessory portion. Thus combined, the nerve enters the jugular foramen in company with the vagus, but here it is again separated into its two branches, which contain chiefly the same fibers as the original superior and inferior parts.

The **superior branch,** or accessory portion of the nerve, gives one or more filaments to the jugular ganglion (ganglion of the root of the vagus), and then joins either the trunk of the vagus directly or its ganglion nodosum, the fibers of the branch being contributed to the pharyngeal, laryngeal, and cardiac branches of the vagus. Fibers corresponding to the white rami communicantes, absent in the cervical nerves, probably enter the cervical sympathetic ganglion through this ramus of the spinal accessory nerve. The fibers which are accessory to the vagus therefore probably include visceral motor and cardioinhibitory fibers.

The **inferior branch** or the spinal portion runs backward and downward under cover of the posterior belly of the digastric and the sternomastoid. It crosses in front of and to the lateral side of the internal jugular vein and, leaving the lateral border of the vein, it passes either in front of or behind the occipital artery; then it pierces the *sternomastoid*, supplies filaments to it, and interlaces in its substance with branches of the second cervical nerve. It emerges from the posterior border of the sternomastoid slightly above the level of the upper border of the thyroid cartilage, passes obliquely downward and backward across the occipital portion of the posterior triangle, and disappears beneath the trapezius at about the junction of the middle and lower thirds of the anterior border of that muscle (fig. 812). In the posterior triangle it receives communications from the third and fourth cervical nerves, and beneath the trapezius its fibers form a plexus. Its terminal filaments are distributed to the *trapezius* and they can be traced almost to the lower extremity of that muscle.

Clinical aspects.—As it emerges from the posterior border of the sternomastoid muscle, this spinal portion of the accessory is often in intimate relation with the small occipital and great auricular nerves, calling for additional care in operations on the upper deep cervical lymph nodes and in all deeper operations in the posterior triangle of the neck. In cases of confirmed facial paralysis, this spinal portion is sometimes anastomosed to the facial with the hope that it may send fibers to the facial muscles along the disintegrating branches of the facial nerve. Also this spinal portion is sometimes resected as a remedy for spasmotic torticollis. Naturally, 'drop shoulder' may result from severing the nerve.

Central connections.—The nuclei of origin, like other motor nuclei, are connected with the somesthetic area of the cerebral cortex of the opposite side by the pyramidal fibers, and they are associated with the sensory nuclei of other cranial nerves by the medial longitudinal fasciculus, and with sensations brought in by the spinal nerves directly and by the fibers of the fasciculi proprii.

THE GANGLIATED CEPHALIC PLEXUS

The Sympathetic Ganglia of the Head and Their Associations with the Cranial Nerves

The sympathetic system of the head, like that of the remainder of the body described below, is arranged in the form of a continuous gangliated plexus subdivided into subplexuses. Unlike the great unpaired prevertebral plexuses in the thoracic and abdominal cavities, all the larger sympathetic ganglia of the head are paired, ganglia corresponding to each other being found on either side. Thus, possibly, they may be considered as an upward extension of the series of paired lumbar, thoracic and cervical ganglia belonging to the sympathetic trunks lying along either side of the vertebral column. Numerous small ganglia, many of them microscopic, occur in the subplexuses throughout the head. These are irregular in size and position and those in the region of the median line are no doubt unpaired.

In origin, the ganglia of the cephalic plexus consist of cell-bodies which, in the early stages of development, migrated from the fundaments of the ganglia of the vagus, glossopharyngeal and glossopalatine nerves, and most especially from that of the semilunar (Gasserian) ganglion of the trigeminus—a developmental relation identical with that of the remainder of the sympathetic system to the ganglia of the spinal nerves. Just as is known for the spinal ganglia, some cell-bodies destined to develop into sympathetic neurones, instead of migrating, remained within the confines of the ganglia of the above nerves, in company with the cell-bodies of their sensory neurones. This is thought to be especially true for the geniculate, the petrosal and the jugular ganglion. Therefore these ganglia must be considered as in small part sympathetic ganglia.

The gangliated cephalic plexus could properly be included as a division of the general sympathetic system described later. However, because its larger ganglia are so intimately associated with branches of the oculomotor, trigeminal, masticator, glossopalatine, glossopharyngeal and vagus nerves, it is customary to describe it in connection with the cranial nerves.

The larger **ganglia,** one on either side of the head, comprise the ciliary ganglion, the sphenopalatine (Meckel's) ganglion, the otic and the submaxillary ganglion.

To these must be added portions of the geniculate, petrosal, jugular and the ganglion nodosum, and a part of the superior cervical sympathetic ganglion. The chief relations of the gangliated cephalic plexus to the cranial nerves are shown in fig. 810.

The so-called **roots and branches of the ganglia** carry three varieties of fibers: (1) Sensory, visceral and somatic, (2) Motor (visceral motor or preganglionic), and (3) Sympathetic proper. Most roots and branches are mixed, the name of a root being determined only by the variety of fibers predominating in it, or by its length. Fibers arising from the cells of a ganglion and passing out of it, usually in one of its branches, are often referred to as postganglionic fibers (sympathetic proper).

A bundle of sensory fibers going to a ganglion is called its **sensory root.** Such, however, cannot comprise a true root since none of its fibers arises in the ganglion and very few or none may terminate in it. The only sensory fibers terminating in a ganglion are the few which may approach it in any of the roots to terminate in its capsule or the capsules of its cells and convey impulses of general sensibility from the ganglion to the central nervous system. Almost all of the fibers of a 'sensory root' merely pass around or through a ganglion and into its branches beyond, which they borrow as paths for reaching their allotted fields of distribution. In this relation it should be realized that while the ciliary, sphenopalatine, otic and submaxillary ganglia are customarily described under the discussion of the trigeminus, this nerve has functionally less to do with them than any of the other cranial nerves with which they are associated.

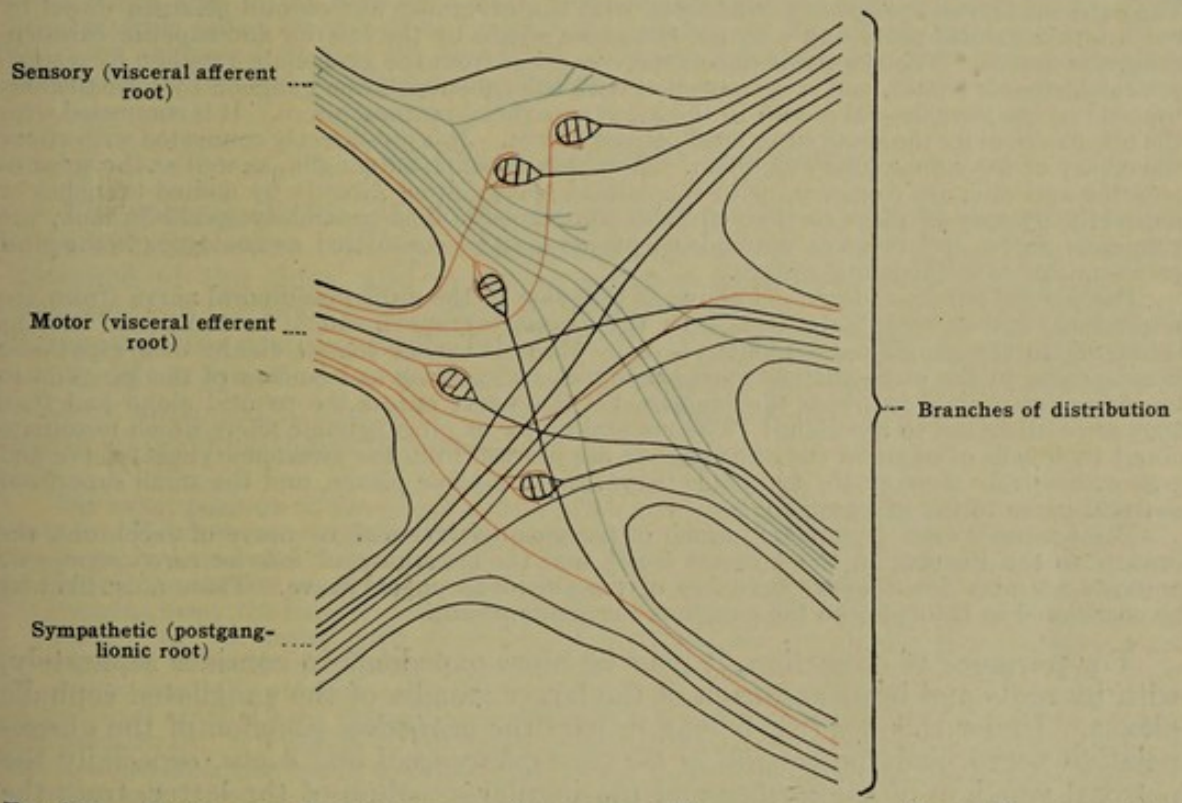

FIG. 815.—DIAGRAM TO ILLUSTRATE THE STRUCTURAL RELATIONS OF THE THREE ROOTS AND THE BRANCHES OF A CEPHALIC SYMPATHETIC GANGLION. Sensory fibers, blue; motor, red; sympathetic, black.

Bundles of trigeminal (sensory) fibers, traceable in gross anatomy because medullated and of appreciable size, pass to the ganglia, but only to pass through them as continuations of the terminal branches of the trigeminus.

The so-called **motor root** of a ganglion may carry two kinds of fibers: (a) visceral motor (preganglionic) fibers, arising in the nuclei of origin in the central system and passing in the trunk and branches of a cranial nerve (oculomotor, masticator, etc.) to enter and terminate in contact with the cell-bodies of the ganglion, which, in their turn, give fibers to the branches of the ganglion; (b) fibers of the same origin, name and course but which may pass through the ganglion to terminate in contact with the cells of a more distant ganglion. Any root, the motor especially, may contain somatic motor fibers, that is, fibers of central origin which pass through the ganglion uninterrupted and into its branches to terminate directly upon the fibers of skeletal muscle.

A **sympathetic root** carries chiefly fibers conforming to the name: fibers arising in other sympathetic ganglia which pass through the ganglion in question to enter its branches and terminate upon their allotted muscular or glandular elements. Obviously it may possibly also carry somatic motor and sensory and visceral sensory fibers. The larger ganglia of the head are described as each possessing the three roots above mentioned.

The **branches of distribution** of the ganglia, the larger of them often called nerves, are those bundles in which the fibers, both arising in or passing through the ganglia, course toward their

terminations upon their allotted tissue elements of the head. In the branches pass fibers (1) motor to the smooth muscle of the vessels of the head, to the intrinsic muscles of the eyeball, to the lacrimal glands, to the mucous membranes (gland cells) of the nasal and oral cavities and to the salivary glands, and (2) sensory fibers conveying impulses from these structures.

The **plexuses** into which the gangliated cephalic plexus is divided, including the roots and branches which connect the ganglia to form it, are numerous and vary greatly in size. They underlie the mucous membranes and they surround all the vessels, ducts and glands. They are named according to their locality. The largest of them are the tympanic plexus and the carotid and cavernous plexuses. They have been repeatedly referred to in their relations to the branches of the cranial nerves.

Of the numerous branches described from the **superior cervical sympathetic ganglion,** the two large ones which pass upward associate it especially with the gangliated cephalic plexus. That branch known as the internal *carotid nerve* may be considered as the direct continuation upward of the gangliated sympathetic trunk ('vertebral ganglia') of the body. Through the branches of this nerve, the caroticotympanic and the deep petrosal nerves, and through the plexuses derived from it, the superior cervical ganglion may be associated with practically all the other sympathetic ganglia of the head (figs. 808 and 810). The other branch from the superior cervical ganglion, the *jugular nerve*, associates it with the ganglia of the glossopharyngeal and vagus nerves, with the petrosal ganglion by a direct branch and with the ganglia of the vagus through the nodosal plexus. These latter ganglia (and the nerves to which they belong) are connected, chiefly by way of the tympanic nerve, which is from the petrosal ganglion, with the tympanic plexus (fig. 810).

The **tympanic plexus** serves as a common point of distribution of fibers from the superior cervical spmpathetic ganglion, the ganglia of the vagus, the petrosal ganglion, and the geniculate ganglion, to the cavernous and carotid plexuses and to the sphenopalatine and otic ganglia. The superior cervical ganglion is associated with the cavernous and carotid plexuses direct by the internal carotid nerve and with the tympanic plexus by the inferior and superior caroticotympanic nerves. The tympanic plexus receives fibers from the geniculate ganglion by a small *geniculotympanic branch*, and it is connected with the sphenopalatine ganglion by a small anastomotic or *tympanopetrosal branch* to the great superficial petrosal nerve. It is connected with the otic ganglion by the small superficial petrosal nerve. It is not directly connected with either the ciliary or the submaxillary ganglion. However, these latter ganglia, as well as the sphenopalatine and otic, are connected with the carotid plexus either directly by named branches or indirectly by way of plexuses derived from the carotid. The geniculotympanic branch, the tympanic nerve, and twigs of the nodosal plexus may be considered as analogous to the rami communicantes of the spinal nerves.

The *parotid branches*, described above as branches of the auriculotemporal nerve (from the trigeminus) and as containing fibers from the glossopharyngeal, should be mentioned here as belonging to the gangliated cephalic plexus. These branches consist chiefly of sympathetic fibers arising in the otic ganglion (postganglionic) and passing as branches of the ganglion to the auriculotemporal in which they remain till this nerve enters the parotid gland and then they are distributed to the gland. The visceral motor or preganglionic fibers which terminate about their cells of origin in the otic ganglion are derived from the glossopharyngeal nerve and pass successively through the tympanic nerve, the tympanic plexus, and the small superficial petrosal nerve to the otic ganglion.

The *tympanic nerve* (tympanic branch of the glossopharyngeal, or nerve of Jacobson), the branch to the Eustachian tube (*ramus tubæ*), and the superior and inferior *caroticotympanic branches* are also described as branches of the glossopharyngeal nerve. These must likewise be considered as belonging to the gangliated cephalic plexus.

For purposes of dissection, it may be more expedient to consider separately, with its roots and branches, each of the larger ganglia of the gangliated cephalic plexus. Under this heading belong in part the *geniculate ganglion* of the glossopalatine nerve, and the *ganglia of the glossopharyngeal and vagus*, especially the petrosal ganglion of the former and the jugular ganglion of the latter, from the fact that these ganglia contain numerous cell-bodies of sympathetic neurones as well as those of the sensory neurones of their nerves.

These latter ganglia, however, have been described with their corresponding cranial nerves. The sensory and motor roots of their sympathetic portions are contained in the roots of their nerves. The geniculate probably has no sympathetic root. The sympathetic roots of the petrosal and jugular ganglia are contained in the branches of the jugular nerve. The chief branches of distribution of the geniculate are the geniculotympanic branch, the great superficial petrosal nerve and the external superficial petrosal nerves. The branches of the petrosal ganglion are the tympanic nerve and its branches of the tympanic plexus. The chief branch of distribution from the jugular ganglion is contained in the auricular branch of the vagus, or nerve of Arnold, supplemented by sympathetic fibers in the trunk of the vagus itself.

The principal cephalic sympathetic ganglia are the ciliary, the sphenopalatine (Meckel's), the otic and the submaxillary.

The Ciliary Ganglion

The ciliary (lenticular, or ophthalmic) ganglion lies in the posterior part of the orbital cavity, about 6 mm. in front of the superior orbital (sphenoidal) fissure, to the lateral side of the optic nerve, and between the optic nerve and the lateral

rectus muscle. It is a small, reddish, quadrangular body, compressed laterally, and it measures about 2 mm. from before backward (fig. 803).

Roots.—(*a*) Its motor or short (preganglionic) root enters its lower and posterior angle and is a visceral motor branch derived from the branch of the inferior division of the oculomotor nerve which supplies the inferior oblique muscle. The fibers of the motor root probably all terminate in the ciliary ganglion by synapses with the cell-bodies of its sympathetic neurones.

(*b*) The sensory or long root passes through the upper and back part of the ganglion. It is a branch of the nasociliary (nasal) nerve and is, therefore, composed of fibers from the trigeminus passing through the ganglion. This root also carries many sympathetic fibers, some of which arise from cell-bodies of the superior cervical sympathetic ganglion and gain the nasociliary nerve by way of the internal carotid nerve and the internal carotid and cavernous plexuses. All sympathetic fibers passing to the ganglion pass through it without interruption.

(*c*) The sympathetic root consists of fibers derived from the cavernous (and internal carotid) plexus of the sympathetic; it passes to the ganglion with the long root, and usually also as a separate sympathetic root carrying fibers similar to the sympathetic fibers of the long root.

Branches.—From three to six **short ciliary nerves** emerge from the anterior border of the ganglion; they divide as they pass forward and eventually form about twenty nerves which are arranged in an upper and a lower group, and the latter group is joined by the long ciliary branches of the nasociliary (nasal) nerve, now sensory and sympathetic (fig. 803). When they reach the eyeball, the ciliary nerves pierce the sclerotic around the optic nerve, and pass forward in grooves on the inner surface of the sclera. The sympathetic fibers contained are distributed as motor fibers to the ciliary muscle, the sphincter of the iris, and to the vessels of these and of the cornea. The dilator pupillæ or radial muscle of the iris is innervated by the fibers which arise in the superior cervical sympathetic ganglion and pass through the ciliary ganglion from either its long or its sympathetic root to enter the short ciliary nerves. These fibers are concerned in the '*skin-pupillary*' (*ciliospinal*) reflex chain by which the pupil dilates in response to stimulus of the skin (fig. 783).

The Sphenopalatine Ganglion

The sphenopalatine (Meckel's) ganglion is associated with the maxillary nerve (figs. 801, 804, 808). It is a small reddish-gray body of triangular form, which is flattened at the sides, and measures about 5 mm. from before backward. It lies deeply in the pterygopalatine (sphenomaxillary) fossa at the lateral side of the sphenopalatine foramen and in front of the anterior end of the pterygoid (Vidian) canal. It is attached to the maxillary nerve (fig. 810), from which it receives its sensory root, and it is connected with the Vidian nerve, which furnishes it with motor and sympathetic filaments.

The exact position of the ganglion depends upon the size and shape of the sphenoidal air-sinuses. When these are small, or high and narrow, the ganglion lies lateral to them; when they are large, or broad and flat, the ganglion lies inferior to them. Sometimes it may lie anterior to them if the sinuses are short from in front backward. The ganglion may be reached with ease by chipping away the bone around the sphenoidal air-sinuses after the skull is divided sagitally.

Roots.—(*a*) Its **motor root,** consisting of visceral motor fibers of the glossopalatine nerve, is contained in the great superficial petrosal nerve which is incorporated in the Vidian nerve. It springs from the anterior angle of the geniculate ganglion and passes through the hiatus of the facial canal (hiatus Fallopii) into the middle fossa of the cranium, where it runs forward and medialward, in a groove on the upper surface of the petrous part of the temporal bone, to the foramen lacerum, and in this part of its course it passes beneath the semilunar (Gasserian) ganglion and the masticator nerve. In the foramen lacerum it joins with the great deep petrosal nerve to form the Vidian nerve (nerve of the pterygoid canal), which passes forward through the pterygoid (Vidian) canal, and its visceral motor fibers terminate in the sphenopalatine ganglion in the pterygopalatine (sphenomaxillary) fossa. The great superficial petrosal nerve contains sensory as well as sympathetic and motor fibers. The *sensory fibers* pass through the ganglion and, in the small palatine nerve, descend to the soft palate, where they terminate in the epithelium covering it and some are probably concerned with taste organs found there. They arise from the cells of the geniculate ganglion and therefore belong to the glossopalatine nerve.

(*b*) The **sympathetic root** is the great deep petrosal portion of the Vidian nerve. This root, which is of reddish color and of soft texture, springs from the carotid plexus which lies on the outer side of the internal carotid artery in the carotid canal. It enters the foramen lacerum through the apex of the petrous portion of the temporal bone, and unites with the great superficial petrosal branch of the glossopalatine nerve to form the Vidian nerve. The great superficial petrosal nerve also carries sympathetic fibers derived from the geniculate ganglion and from the tympanic plexus as well as from the carotid plexus.

The **Vidian nerve** [**n. canalis pterygoidei**] commences by the union of the great superficial and deep petrosal nerves in the foramen lacerum, and runs forward through the pterygoid (Vidian) canal into the pterygopalatine (sphenomaxillary) fossa to the sphenopalatine ganglion. The Vidian nerve often may be seen in a ridge of bone along the floor of the sphenoidal cells and its direction there depends upon the position of the sphenopalatine ganglion. While it is in the pterygoid canal the Vidian nerve is joined by a sphenoidal filament from the otic ganglion, and it gives branches to the upper and back part of the roof and septum of the nose and to the lower end of the Eustachian tube.

(*c*) The **sensory roots** consist of the sensory fibers mentioned above in the great superficial petrosal nerve and of (usually) two sphenopalatine branches from the maxillary nerve. The majority of the fibers of these roots do not join the ganglion, but pass by its medial side and enter the palatine branches.

Branches.—The branches of distribution, containing sensory and vasomotor and secretory fibers, are orbital or ascending, internal or nasal, descending or palatine, and posterior or pharyngeal.

Ascending branches.—The **orbital** or **ascending branches** are two or three small twigs which enter the orbit through the inferior orbital (sphenomaxillary) fissure and proceed, within the periosteum, to the inner wall of the orbit, where they pass through the posterior ethmoidal foramen and through the foramina in the suture behind that foramen to be distributed to the mucous membrane which lines the posterior ethmoidal cells and the sphenoidal sinus.

Internal branches.—The internal or nasal branches are derived in part from the medial side of the ganglion, but are also largely made up of sensory fibers which pass from the sphenopalatine branches of the maxillary nerve without traversing the ganglionic substance. They are disposed in two sets, the lateral and the medial (septal) posterior superior nasal branches.

The **lateral posterior superior nasal branches** (rr. nasales aborales laterales NK) are six or seven small twigs which pass through the sphenopalatine foramen, and are distributed to the mucous membrane covering the posterior parts of the superior and middle nasal conchæ (turbinated bones) (fig. 801). They also furnish twigs to the lining membrane of the posterior ethmodial cells.

The **medial posterior superior nasal (septal) branches** (rr. nasales aborales mediales NK), two or three in number, pass medialward through the sphenopalatine foramen. They cross the roof of the nasal fossa to reach the back part of the nasal septum, where the smaller twigs terminate. The largest nerve of the set, the **nasopalatine nerve (nerve of Cotunnius)** runs downward and forward in a groove in the vomer between the periosteum and the mucous membrane to the incisive (anterior palatine) canal, where it communicates with the nasal branch of the anterior superior alveolar nerve. The two nasopalatine nerves then pass through the foramina of Scarpa in the intermaxillary suture, the left nerve passing through the anterior of the two foramina. In the lower part of the incisive (anterior palatine) canal the two nerves form a plexiform communication (formerly described as Cloquet's ganglion) and they furnish twigs to the anterior or premaxillary part of the hard palate behind the incisor teeth. In this situation they communicate with the anterior palatine nerves.

Descending branches.—The descending branches are the great or anterior, the posterior, and the middle (external) palatine nerves. Like the internal set of branches, they are in part derived from the ganglion and in part are directly continuous with the sphenopalatine nerve (fig. 801).

The **great or anterior palatine** nerve, (n. palatinus major NK), its sensory fibers derived from the maxillary nerve, arises from the inferior angle of Meckel's ganglion, and passes downward through the pterygopalatine canal, accompanied by the descending palatine artery. Emerging from the canal at the greater (posterior) palatine foramen it divides into two or three branches, which pass forward in grooves in the hard palate and supply the glands and mucous membrane of the hard palate and the gums on the inner aspect of the alveolar border of the upper jaw. During its course through the pterygopalatine canal the anterior palatine nerve gives off the **posterior nasal nerves.** These nerves pass through small openings in the perpendicular plate of the palate bone to supply the mucous membrane covering the posterior part of the inferior nasal concha (turbinated bone) and the adjacent portions of the middle and inferior meatuses of the nose.

The **posterior** or **small palatine nerve** (n. palatinus minor NK) passes downward through a lesser palatine foramen (accessory palatine canal), and enters the soft palate, distributing branches to that organ, to the uvula, and to the tonsil. Its sensory fibers are derived from the glossopalatine nerve, through the great superficial petrosal nerve, and pass through the sphenopalatine ganglion. It was formerly believed to convey motor fibers from the facial nerve to the levator veli palatini and azygos uvulæ, but it is now asserted that these muscles are supplied by the spinal accessory nerve through the vagus branches to the pharyngeal plexus.

The **middle (external) palatine nerve** (n. palatinus medius NK), the smallest of the three, in part, likewise from the glossopalatine nerve, traverses a lesser palatine foramen and supplies twigs to the tonsil and to the adjacent part of the soft palate (fig. 801).

Posterior branch.—The small **pharyngeal branch** of the ganglion passes backward and somewhat medialward through the pharyngeal canal accompanied by a pharyngeal branch of the sphenopalatine artery. It is distributed to the mucous membrane of the uppermost part of the pharynx, to the upper part of the choanæ, to the opening of the Eustachian tube, and to the lining of the sphenoidal sinus. Its sensory fibers are derived from the maxillary nerve.

Nerves to the parotid gland.—Of the several possible sources of fibers to the parotid gland, it is thought that its visceral efferent, mostly secretory, fibers are contributed mostly by the glossopalatine and glossopharyngeal nerves. Those fibers from the glossopalatine, the chief secretory supply, arise from its salivatory nucleus and pass via its geniculotympanic branch to terminate in the otic ganglion; those from the glossopharyngeal reach the otic ganglion, some via the tympanic nerve and plexuses but most via the small superficial petrosal nerve. There are very few if any terminal sympathetic ganglia in the parotid gland. The cells in the otic ganglion concerned in the chains give axones which terminate upon the secretory cells of the gland. The *sensory* supply of the parotid is also uncertainly known. Without doubt, most of the sensory fibers are contributed from the trigeminus, via the parotid branches of the auriculotemporal branch of the mandibular nerve. Most of these fibers are distributed directly to the substance of the gland; others pass through the tympanic plexus and through the otic ganglion to the gland. It is held that the glossopharyngeal nerve contributes some sensory fibers via the paths of its visceral efferent supply to the parotid. It is improbable that the gland receives any sensory fibers from the glossopalatine nerve. (See p. 1021.)

The Otic Ganglion

The otic (Arnold's) ganglion (g. oticum NK) is a small reddish-gray body which is associated with the mandibular nerve. It lies deeply in the zygomatic fossa, immediately below the foramen ovale, on the inner side of the trunk of the mandibular nerve. It is in relation medially with the tensor veli palatini, which separates it from the Eustachian tube. In front of it is the posterior border of the pterygoideus internus, and behind it lie the middle and small meningeal arteries. It is compressed laterally, and its greatest diameter, which lies anteroposteriorly, is about 3 mm.

Roots.—The ganglion is closely connected with the nerve to the pterygoideus internus, through which it may receive a motor root from the masticator nerve. Through the small superficial petrosal nerve, which joins the upper and back part of the ganglion, it receives a motor root from the glossopalatine nerve and sensory and motor fibers from the glossopharyngeal nerve. It receives also a slender *sphenoidal filament* from the Vidian nerve. The **sympathetic roots** are derived from the small superficial petrosal nerve and from the sympathetic plexus on the middle meningeal artery.

Branches.—The communicating branches which pass from the ganglion are: (1) The filaments to the chorda tympani, some of whose fibers probably pass through the otic to terminate in the submaxillary ganglion; (2) filaments to the auriculotemporal nerve; (3) filaments to the spinous nerve (the recurrent branch of the mandibular nerve). The branches of distribution are sympathetic to the vessels and somatic motor branches to the tensor tympani, and tensor veli palatini, with sensory fibers (probably) to all of these.

The Submaxillary Ganglion

The submaxillary ganglion (ganglion submandibulare NK) is suspended from the lingual division of the mandibular nerve by anterior and posterior branches (fig. 810). It is a small reddish body of triangular or fusiform shape, which lies between the mylohyoideus and hyoglossus and above the duct of the submaxillary gland.

Roots.—The **sensory root** is received from the lingual nerve. The **motor root** (preganglionic) is from both the masticator nerve by way of the lingual nerve, and from the glossopalatine nerve by way of the chorda tympani. The motor fibers pass from the chorda tympani after it has joined the lingual, and the sensory fibers come directly from the lingual nerve. The **sympathetic root** is formed by filaments from the sympathetic plexus on the facial artery.

Branches.—(*a*) Five or six glandular (postganglionic) branches are given to the submaxillary gland and to Wharton's duct. (*b*) Branches to the lingual nerve and the sublingual gland. (*c*) To the mucous membrane of the floor of the mouth.

II. THE SPINAL NERVES

The spinal nerves are arranged in pairs, the nerves of each pair being symmetrical in their attachment to either side of their respective segment of the spinal cord, and, in general, symmetrical in their course and distribution. There are usually thirty-one pairs of functional spinal nerves. For purposes of description these are topographically separated into *eight* pairs of *cervical* nerves, *twelve* pairs of *thoracic* nerves, *five* pairs of *lumbar*, *five* pairs of *sacral*, and *one* pair of *coccygeal* nerves. Occasionally the coccygeal or thirty-first pair is rudimentary, while, on the other hand, there may be found small filaments representing one or even two additional pairs of coccygeal nerves below the thirty-first pair. These **rudimentary coccygeal nerves** are probably not functional. They never pass outside the vertebral canal, and often even remain within the tubular portion of the filum terminale. There sometimes occurs an increase in the number of vertebræ in the vertebral column and in such cases there is always a corresponding increase in the number of the spinal nerves.

Origin and attachment.—Each spinal nerve (unlike the cranial nerves) is attached to the spinal cord by two roots: a sensory or afferent **dorsal root** [radix posterior] and a motor or efferent **ventral root** [radix anterior]. Each dorsal root has interposed in its course an ovoid mass of nerve-cells, the **spinal ganglion,** and the nerve-fibers forming the root arise from the cells of this ganglion and are thus of peripheral origin. The fibers composing the ventral root, on the other hand, are of central origin; they arise from the large motor cells of the ventral horn of the gray column within the spinal cord (figs. 816, 818).

Each dorsal root-fiber upon leaving its cell of origin pursues a short tortuous course within the spinal ganglion and then undergoes a T-shaped bifurcation, one product of which passes toward the periphery, where it terminates for the collection of sensations and is known as the

peripheral branch, or, since it conveys impulses toward the cell-body, the *dendrite* of the spinal ganglion neurone. It is more correct, however, to consider the T-fiber as a bifurcated axone. The other product of the bifurcation, the *central branch*, passes into the spinal cord and in its course toward the cord contributes to form the dorsal root proper.

The central branches, upon emerging from the spinal ganglion, form a single compact bundle at first, which passes through the dura mater of the spinal cord and then breaks up into a series of **root-filaments** [fila radicularia]. These thread-like bundles of fibers spread out vertically in a fan-like manner and enter the cord in a direct linear series along its posterolateral sulcus. The fibers of the ventral root emerge from the cord in a series of more finely divided root filaments, which, unlike the entering filaments of the dorsal root, are not arranged in direct linear series, but make their exit over a strip of the ventrolateral aspect of the cord in some places as much as 2 mm. wide.

As they enter the spinal cord the fibers of the dorsal roots undergo a Y-shaped division, both products of which course in the cord longitudinally, as ascending and descending branches. The descending or caudal branches are usually shorter than the ascending, and soon enter and terminate about cells within the gray column of the cord, forming either associational, commissural, or immediate reflex connections, or about cells whose fibers form cerebellar or cerebral connections. The ascending or cephalic branches are either short, intermediate, or long. The short and intermediate branches are similar in function to the descending branches, save that they transfer impulses to the gray substance of segments of the cord above rather than below the level of their entrance. The long branches convey impulses (chiefly proprioceptive) destined

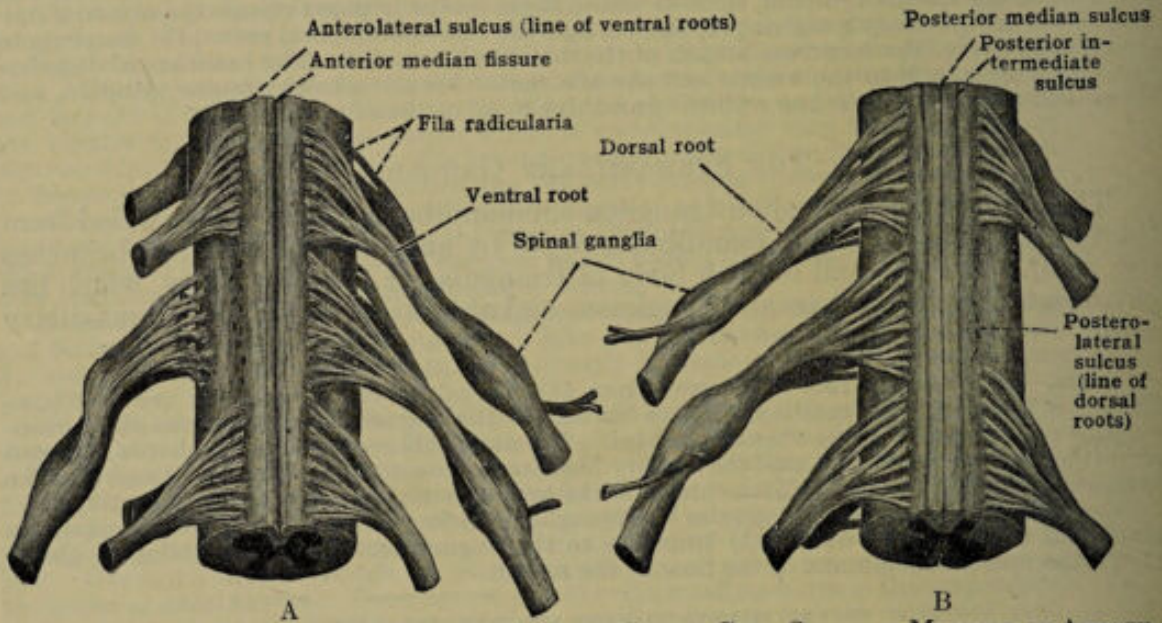

FIG. 816.—A, VENTRAL AND B, DORSAL VIEWS OF SPINAL CORD SHOWING MANNER OF ATTACHMENT OF DORSAL AND VENTRAL ROOTS.

for the structures of the brain, and pass upward in the fasciculus gracilis or fasciculus cuneatus of the cord, and terminate in the nuclei of these fasciculi in the medulla oblongata (figs. 697 and 699).

Aberrant spinal ganglia.—In serial sections on either side of the spinal ganglion of a nerve there may often be found outlying cells either scattered or in groups of sufficient size to be called small ganglia. Such are more often found in the dorsal roots of the lumbar and sacral nerves. These cells are nothing more than spinal ganglion-cells displaced in the growth processes, and have the same origin and function as those in the ganglion. In some animals occasional cells very rarely have been found in the outer portion of the ventral root. These probably represent afferent fibers which enter the cord by way of the ventral root. Likewise, especially in the birds and amphibia, it has been shown that occasional efferent fibers may pass from the gray substance of the cord to the periphery by way of the dorsal instead of the ventral root.

Relative size of the roots.—The sensory or dorsal root, with one constant exception, is larger than the ventral root, indicating that the sensory area to be supplied is greater and perhaps more abundantly innervated than the area requiring motor fibers.

It has been shown that in the entire thirty-one spinal nerves of one side of the body of man the dorsal root-fibers number 653,627, while all the corresponding ventral roots contain but 203,700 fibers, a ratio of 3.2 : 1. (Ingbert.) In the increase in the size of the nerves for the supply of the limbs the gain of dorsal root or sensory fibers is far greater than the gain of ventral root-fibers. The first cervical or the suboccipital nerve is an exception to the general rule; its dorsal root is always smaller than its ventral, and in rare cases may be rudimentary or entirely absent. The spinal ganglion and, therefore, the sensory root of the coccygeal nerve, is also quite frequently absent. Ranson and his collaborators have shown that there are far more nonmedullated fibers in the roots than was once supposed, and that there is a greater proportion of these in the dorsal than in the ventral roots. These nonmedullated fibers were not included in Ingbert's counts.

The dorsal and ventral root-fibers of each spinal nerve proceed outward from their segment of attachment to the spinal cord, pierce the pia mater and arachnoid, collect to form their respective roots, and pass into their respective intervertebral foramina. On the immediate peripheral side of the spinal ganglion the two roots blend, giving origin to the thus mixed **nerve-trunk.** As the trunk, the sensory and motor fibers make their exit from the vertebral canal through the intervertebral foramen.

Relation to the meninges.—The root-filaments of each nerve receive connective tissue support from the pia mater and arachnoid in passing through them. In the subarachnoid cavity they become assembled into their respective nerve-roots; and the roots, closely approaching each other, pass into the dura mater, from which they receive separate sheaths at first, but at the peripheral side of the ganglion these sheaths blend into one, which, with the subsequent blending of the roots, becomes the sheath or epineurium of the nerve-trunk. By means of the sheaths derived from the meninges, especially the dura, the nerve-roots and the trunk are attached to the periosteum of the margins of the intervertebral foramina and thus are enabled to give some lateral support to the spinal cord in the upper portion of the canal.

The majority of the spinal ganglia lie in the intervertebral foramina, closely ensheathed, and thus outside the actual sac or cavity of the dura mater. The ganglia of the last lumbar and first four sacral nerves lie inside the vertebral canal, but since the sheath derived from the dura mater closely adheres to them, they are still outside the sac of the dura mater. The ganglia of the last sacral and of the coccygeal nerves (when present) lie in tubular extensions of the subdural cavity, and thus not only within the vertebral canal, but actually within the sac of the dura mater. The trunk of the first cervical nerve is assembled within the sac of the dura mater, and, therefore, the spinal ganglion of this nerve, when present, may lie within the sac.

Course and direction of emergence.—Invested with the connective tissue sheath derived from the meninges, each thoracic, lumbar and sacral nerve emerges from the vertebral canal through the intervertebral foramen below its corresponding vertebra, and all the nerves are in relation with the spinal rami of the arteries and veins associated with the blood-supply of the given localities of the spinal cord.

The first cervical nerve does not pass outward in an intervertebral foramen proper, but between the occipital bone and the posterior arch of the atlas and beneath the vertebral artery. Thus the eighth or last cervical nerve emerges between the seventh cervical and the first thoracic vertebra.

The first and second pairs of cervical nerves pass out of the vertebral canal almost at right angles to the levels of their attachment to the spinal cord. During the early periods of development the level of exit of each pair of spinal nerves is opposite the level of its attachment to the cord, but, owing to the fact that in the later periods the vertebral column grows more rapidly than the cord and increases considerably in length after the cord has practically ceased growing, all the spinal nerve roots, with the exception of the first two pairs, pass downward as well as outward. The obliquity of their course from the level of attachment to the level of exit increases progressively from above downward, and, as the cord ends at the level of the first or second lumbar vertebra, the roots of the lower lumbar and of the sacral nerves pass at first vertically downward within the dura mater, and form around the filum terminale a tapering sheaf of nerve-roots, the **cauda equina** (horse's tail) (fig. 692).

Topography of attachments.—It is of much practical importance to be familiar with the relations of the spinous processes of the vertebræ to the levels of attachment of the spinal nerves to the cord and to the levels of their exit from the vertebral canal. These relations are of especial need in determining localities affected by disease or injury of the spinal cord or of the spinal nerves.

Levels of attachment.—The relations between the levels of attachment of the spinal nerves to the cord and the spinous processes of the vertebræ situated opposite these levels have been worked out in greater detail by Nuhn and by Reid. The following table, compiled by Reid, gives the extreme limits of attachment as observed in six subjects.

Clinical aspects.—In palpation to determine the level of a nerve, it will be found that the tips of the spinous processes of the upper cervical vertebræ can be scarcely made out even by deep pressure. That of the epistropheus may be detected in a lean subject. The first prominent spine is that of the seventh cervical vertebra, 'vertebra prominens.' The superior cervical sympathetic ganglion lies at the level of the spines of the second and third cervical vertebræ. The levels of attachment of the eight cervical nerves to the cord correspond to the interval between the occiput and the tip of the sixth cervical spine. The third thoracic spine is to be noted as on a level with the medial end of the spine of the scapula while the seventh thoracic spine is in line with the lower angle of the scapula. The upper six thoracic nerves are attached to the cord extending in the level between the tip of the sixth cervical spine and the spine of the fifth thoracic vertebra. Most of the thoracic spines, projecting obliquely downward, are below the heads of their corresponding ribs and thus below the levels of exit of their

TABLE OF TOPOGRAPHY OF ATTACHMENT OF SPINAL NERVES TO THE SPINAL CORD. (Reid.)

(A) signifies the highest level at which the root filaments of a given nerve are attached to the cord, and (B) the lowest level observed. For example, the root filaments of the sixth thoracic nerve *may* be attached as high as the lower border of the spinous process of the second thoracic vertebra, or some may be attached as low as the upper border of the spinous process of the fifth thoracic vertebra, but in a given subject they do not necessarily extend either as high or as low as either of the levels indicated.

corresponding spinal nerves. Each spine from the second to the tenth thoracic projects more nearly in line with the exit of the nerve in the second foramen below it. The attachments to the cord of the lower six of the thoracic nerves lie in the level between the fourth and ninth thoracic spines. The spines of the eleventh and twelfth thoracic project more at right angles

to the vertebral column and their caudal borders are in line with the levels of exit of their corresponding nerves. The five lumbar nerves are attached to the cord in the level between the eleventh and twelfth thoracic spines. The second lumbar spine marks the level of termination of the spinal cord. The levels of attachment of the sacral nerves to the cord correspond to the body of the first lumbar vertebra (first lumbar spine). For more detailed study, see the table of topography of attachments of the nerves given above and fig. 819.

In making **lumbar puncture** for anesthesia of the spinal nerves or for relieving pressure of cerebrospinal fluid, the needle is inserted in the midline of the back between the spines of the third and fourth, or the fourth and fifth, lumbar vertebræ and directed slightly upward. Since the cord terminates above this level, the needle can penetrate merely the bulbous ending of the dural sac containing only the nerve roots forming the cauda equina. The absence of spinous processes and the deficiency of dorsal lamina for the fourth and fifth segments of the sacrum, resulting in the sacral hiatus, offers a weak point in the protection of the spinal cord and nerves. Infections about the hiatus may ascend to involve to meninges and thus the cord. Injections for local anesthesia are sometimes made through the hiatus, mayhap puncturing a dural sac around the roots of a sacral nerve.

Relative size of the nerves.—The size of the different spinal nerves varies greatly. Just as the spinal cord shows marked enlargements in the cervical and lumbar regions necessitated by the greater amount of innervation required of these regions for the structures of the upper and lower limbs, so the nerves attached to these regions are considerably larger than elsewhere.

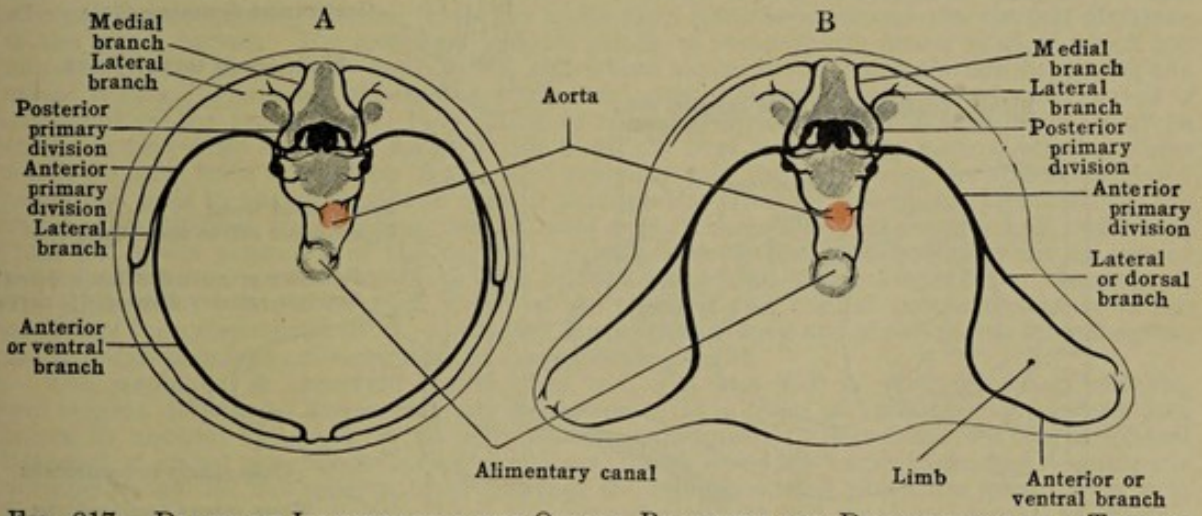

FIG. 817.—DIAGRAMS ILLUSTRATING THE ORIGIN, BRANCHES AND DISTRIBUTION OF A TYPICAL SPINAL NERVE.

A, in thoracic region; B, in region of a limb (highly schematic).

The smaller nerves are found at the two extremities of the cord and in the midthoracic region. The smallest nerve is the coccygeal, and the next in order of size are the lower sacral and the first two or three cervical nerves. The largest nerves are those which contribute most to the great nerve trunks for the innervation of the skin and muscles of the limbs:—the lower cervical and first thoracic for the upper limbs and the lower lumbar and first sacral for the lower limbs. The nerves gradually increase in the series in passing from the smaller toward the larger.

The primary divisions of the nerve-trunk (figs. 817, 834).—A typical spinal nerve (middle thoracic, for example), just as it emerges from the intervertebral foramen, divides into four branches:—the two large primary divisions; viz., the **posterior primary division** [ramus posterior] and the **anterior primary division** [ramus anterior]; third, the small **ramus communicans,** by which it is connected with the sympathetic; and fourth, the smaller, **ramus meningeus** (*recurrent branch*), which immediately turns centralward for the innervation of the membranes and vessels of the spinal cord.

In general, the **posterior primary division** passes dorsalward between the arches or transverse processes of the two adjacent vertebræ and in relation with the anterior costotransverse ligament, and then divides (with the exception of the first cervical, the fourth and fifth sacral, and the coccygeal nerves) into a **medial branch** and a **lateral branch.** The medial branch turns toward the spinous processes of the vertebræ, and supplies the bones and joints and the muscles about them, and may or may not supply the skin overlying them. The lateral branch turns dorsalward and also supplies the adjacent muscles and bones, and, if the medial branch has not supplied the overlying skin, it also terminates in cutaneous twigs.

In the upper half of the spinal nerves the medial branches supply the skin; in the lower half, it is the lateral branches which do so. Both branches of almost all the posterior divisions, especially those of the lower nerves, show a tendency to run caudalward and thus are distributed to muscles and skin below the levels of their respective intervertebral foramina. They never supply the muscles of the limbs, though their cutaneous distribution extends upon the buttock, the shoulder, and the skin of the back of the head as far upward as the vertex. The posterior primary divisions, with the exception of those of the first three cervical nerves, are much smaller than the anterior primary divisions.

As their mixed function suggests, the posterior primary divisions contain nerve-fibers both from the ventral roots and the peripheral processes of the spinal ganglion-cells. If the nerve-trunk on the immediate peripheral side of the spinal ganglion be teased, bundles of ventral root-fibers may be seen crossing the trunk obliquely to enter the posterior division, and fibers from the spinal ganglion may be also traced into it. Also the sympathetic fibers, derived chiefly by way of the ramus communicans, are known to course in it for distribution in the walls of the blood-vessels, etc., of the area it supplies (fig. 818).

The anterior primary divisions run lateralward and ventralward. With the exception of those of the first two cervical nerves, which contribute the hypoglossal loop, they are larger than the posterior primary divisions, and appear as direct continuations of the nerve-trunks. Only in case of most of the thoracic nerves do they remain independent in their course. In these they run lateralward and ventralward in the body-wall. In general, these divisions supply the

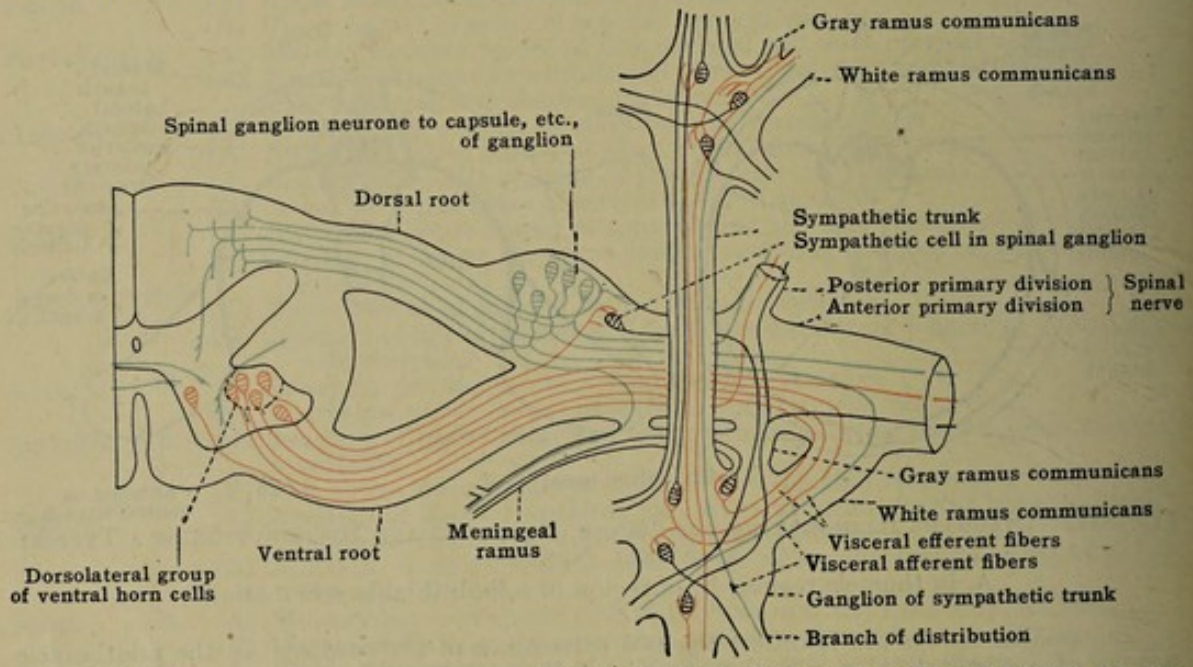

FIG. 818.—DIAGRAM ILLUSTRATING THE ORIGIN OF THE COMPONENT NERVE-FIBERS OF THE PRIMARY DIVISIONS OF A TYPICAL THORACIC OR LUMBAR SPINAL NERVE.

lateral and ventral parts of the body, the limbs, and the perineum. In the cervical, lumbar, and sacral regions they lose their anatomical identity by dividing, subdividing, and anastomosing with each other so as to give rise to the three great spinal plexuses of the body—the **cervical,** the **brachial,** and the **lumbosacral plexuses.** The majority of the thoracic nerves retain the typical or primitive character in both their anterior and posterior primary divisions. In them the anterior division (intercostal nerve) divides into a **lateral** and an **anterior** (or ventral) branch, both of which subdivide. The lateral branch is chiefly cutaneous; it pierces the superficial muscles and, in the subcutaneous connective tissue, divides into a smaller posterior and a larger anterior ramus, which respectively supply the skin of the sides and the lateral part of the ventral surface of the body. The anterior branch continues ventralward in the body-wall, giving off twigs along its course to the adjacent muscles and bones, and, as it approaches the ventral midline of the body, it turns sharply lateralward and sends rami medialward and lateralward to supply the skin of the ventral aspect of the body. In the region of the limbs the typical arrangement is interfered with in that what corresponds to the lateral and anterior branches of the division are carried out into the limbs for the skin and muscles there, instead of supplying the lateral and ventral parts of the body-wall.

Nerve-fibers arising in the spinal ganglion and fibers from the ventral root pass directly from the nerve-trunk into the anterior primary division of the spinal

nerve. This division also receives sympathetic nerve-fibers by way of the ramus communicans. These latter accompany the division and are distributed to their allotted elements in the territory it supplies.

The rami communicantes are small, short, thread-like branches by which the nerve-trunks are connected with the nearest ganglion of the vertically running gangliated cord of the sympathetic (sympathetic trunk). The trunk or anterior primary division of every spinal nerve has at least one ramus; most of the nerves have two, and sometimes there are three. The nerves of the cervical region usually have but one, and this is composed largely of sympathetic fibers (gray ramus). Where there are two, one usually contains medullated fibers, chiefly visceral motor from the ventral root, sufficient to give it a whiter appearance (white ramus).

In the upper cervical and in the sacral regions one sympathetic ganglion may be connected with two or more spinal nerves, and sometimes one nerve is connected with two ganglia. The rami communicantes of the spinal nerves are equivalent to the communicating rami connecting certain of the cranial nerves with the sympathetic system (trigeminus, glossopharyngeal, vagus). The medullated fibers of the rami and, therefore, the white rami consist chiefly of fibers from the spinal nerves, viz,, fibers from the spinal ganglion-cells which enter and course to their distribution through branches of the sympathetic nerves, **visceral afferent fibers,** and fibers from the ventral roots of the spinal nerves which terminate in the sympathetic ganglia, **visceral efferent** (preganglionic) **fibers.** Thus the white rami have been termed the **visceral divisions** of the spinal nerves. The gray rami consist chiefly of sympathetic fibers, most of which are non-medullated or partially medullated, and which course to their distribution by way of the spinal nerves. The usual absence of white rami communicantes from the cervical nerves is explained on the grounds—(1) that probably relatively fewer visceral efferent fibers are given to the sympathetic from this region of the cord; (2) that many of the visceral efferent fibers which do arise from this region of the cord probably join the rootlets of the spinal accessory nerve and pass to the sympathetic system through the trunk of this nerve, and through the vagus with which it anastomoses; and (3) that such of these fibers, as are given off, especially from the lower segments of the cervical region, descend the cord and pass out by way of the upper thoracic nerves which give very evident white rami to the sympathetic. In general, the white rami (visceral efferent fibers) of the thoracic and lumbar nerves terminate in the ganglia of the sympathetic trunk, while such fibers of the cranial and sacral nerves stream across the trunk to terminate in more distant sympathetic ganglia.

The meningeal or recurrent branch (figs. 817, 818, and 834) is very small and variable, and is often difficult to find in ordinary dissections. It is given off from the nerve-trunk just before its anterior and posterior primary divisions are formed. It consists of a few peripheral branches of spinal ganglion cells (sensory fibers) which leave the nerve-trunk and re-enter the vertebral canal for the sensory innervation of the meninges, and which are joined by a twig from the gray ramus or directly from the nearest sympathetic ganglion (vasomotor fibers). There is considerable evidence, both physiological and anatomical, obtained chiefly from the animals, which shows that at times certain of the peripheral spinal ganglion or sensory fibers may turn backward in the nerve-trunk and pass to the meninges within the ventral root instead of contributing to a recurrent branch. The occurrence of such fibers in the ventral root explains the physiological phenomenon known as '*recurrent sensibility.*' Likewise, sympathetic fibers entering the trunk through the gray ramus may pass to the meninges by way of the ventral root, and at times the recurrent branch is probably absent altogether, its place being taken entirely by the meningeal fibers passing in the ventral root. Possibly, some reach the meninges through nonmedullated fibers by way of the dorsal root.

Areas of distribution of the spinal nerves.—Both the posterior and anterior primary divisions divide and subdivide repeatedly, and their component fibers are distributed to areas of the body more or less constant for the nerves of each pair, but the distribution of the different pairs is very variable. Corresponding to their attachment, each to a given segment of the spinal cord, the nerves have primarily a segmental distribution, but, owing to the developmental changes and displacement of parts during the growth of the body, the segmental distribution becomes greatly obscured and in some nerves practically obliterated. Naturally it is more retained by the nerves supplying the trunk than by those contributing to the innervation of the limbs and head, and the areas supplied by the posterior primary divisions are less disturbed than those supplied by the anterior. The segmental areas of cutaneous distribution of the posterior divisions are more evident than the areas of muscle supplied by these divisions, from the fact that the segmental myotomes from which the dorsal muscles arise fuse together and overlap each other considerably during development. No nerve has a definitely prescribed area of distribution, cutaneous or muscular, for its area is always considerably overlapped by the areas of the nerves adjacent to it. The midthoracic nerves more nearly supply a definitely prescribed belt of the body.

A. DISTRIBUTION OF POSTERIOR PRIMARY DIVISIONS

As above stated, the posterior primary divisions of the spinal nerves spring from the trunks immediately outside the intervertebral foramina, and they pass dorsalward between the adjacent transverse processes. With the exceptions of the first and second cervical nerves they are smaller than the corresponding anterior primary divisions, which in these nerves are smaller

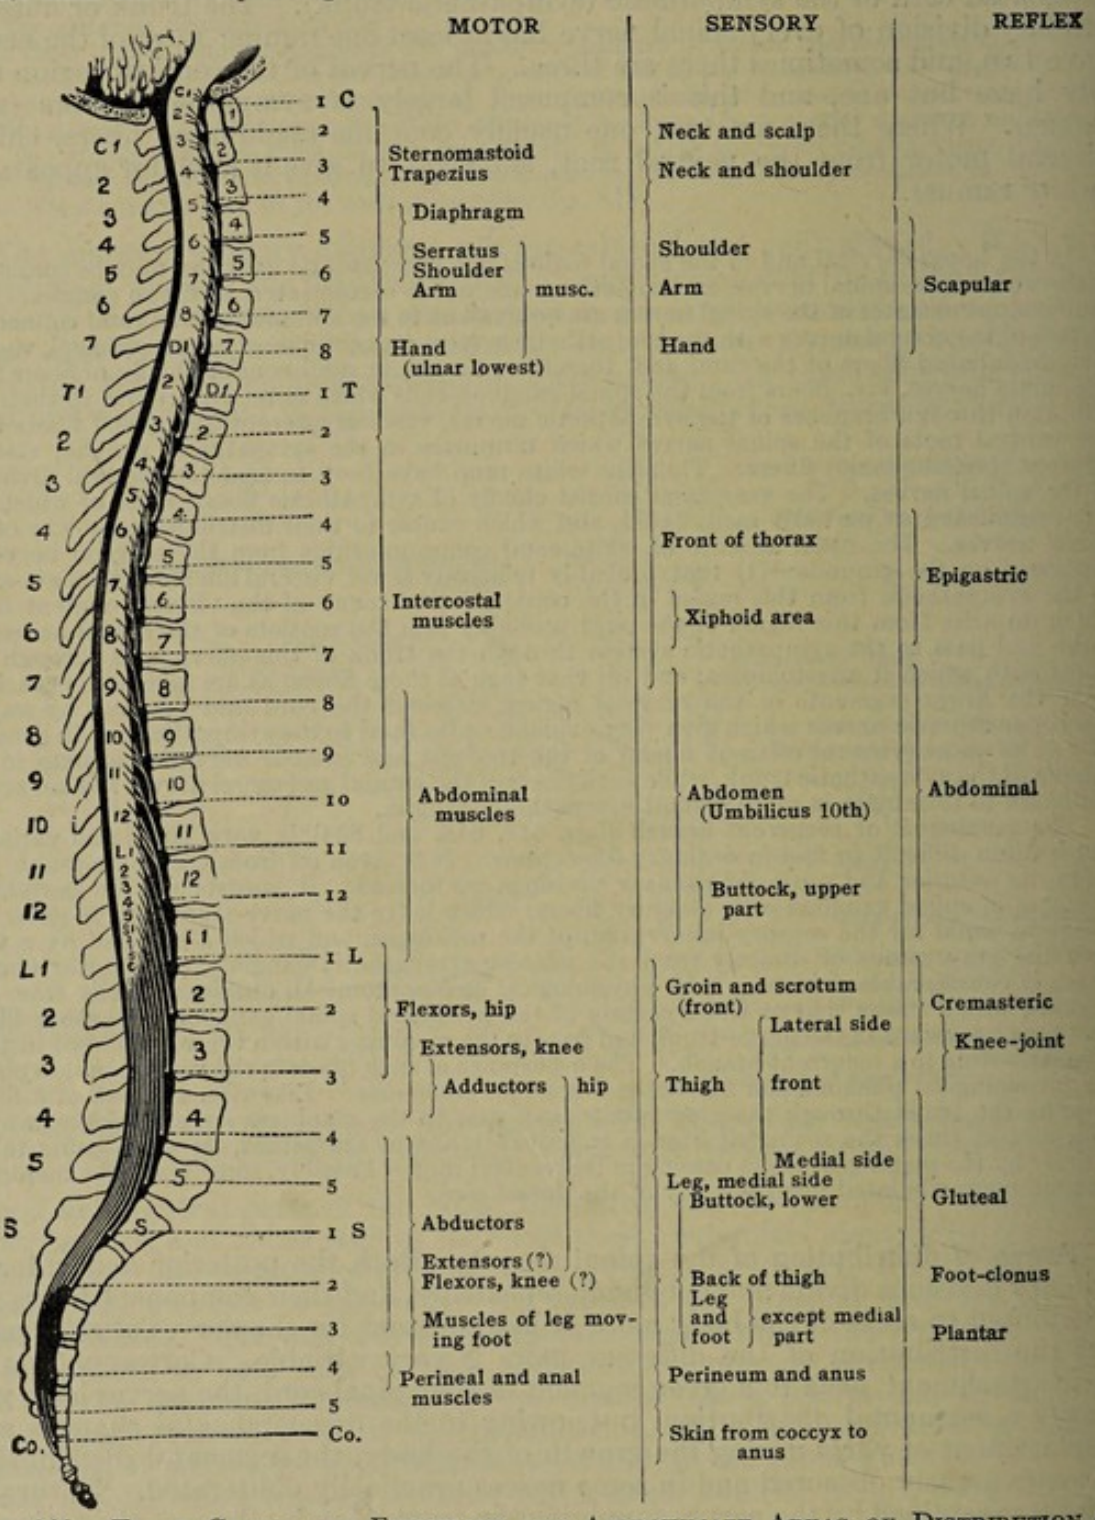

FIG. 819.—TABLE GIVING THE FUNCTIONS AND APPROXIMATE AREAS OF DISTRIBUTION OF THE DIFFERENT SPINAL NERVES WITH A DIAGRAM SHOWING THEIR RESPECTIVE LEVELS OF EXIT FROM THE VERTEBRAL COLUMN. (Arranged by Dr. Gowers.)

from the fact that a large portion of them go over into the hypoglossal (or cervical) loop. The posterior primary divisions, after passing between the transverse processes into the region of the back, divide into medial and lateral branches. This division, however, does not occur in the cases of the first cervical, the last two sacral, and the coccygeal nerves.

1. CERVICAL NERVES (Figs. 820, 821)

The posterior primary division of the first cervical or suboccipital nerve springs from the trunk, between the vertebral artery and the posterior arch of

the atlas, passes dorsalward into the suboccipital triangle, and breaks up into branches which supply the superior oblique, the inferior oblique, and the major rectus capitis posterior muscles, which form the lateral boundaries of the triangle. It also gives a branch across the posterior surface of the major rectus capitis posterior to the minor rectus capitis posterior, and a branch to the semispinalis capitis (complexus) in the roof of the triangle.

It communicates with the medial branch of the posterior primary division of the second cervical nerve, either through or over the inferior oblique muscle, and it occasionally gives a cutaneous branch to the skin of the upper part of the back of the neck and the lower part of the scalp.

The **posterior primary division of the second cervical nerve** is the largest posterior division of all the cervical nerves. It divides into a small lateral branch and a very large medial branch. The **lateral branch** gives a twig to the inferior oblique and terminates in branches which supply the splenius and longissimus capitis (trachelomastoid) muscles. The **medial branch** is the **great occipital nerve** (fig. 823). It turns around the lower border of the inferior oblique, crosses the suboccipital triangle obliquely, pierces the semispinalis capitis (complexus), the tendon of the trapezius, and the deep cervical fascia, passing through the latter immediately below the superior nuchal line of the occipital bone, and it divides into several terminal sensory branches which ramify in the superficial fascia of the scalp.

It gives one or two motor twigs to the semispinalis capitis (complexus), and its terminal branches, which are accompanied by branches of the occipital artery, supply the skin of the scalp, above the superior nuchal line, as far forward as the vertex. Occasionally one branch reaches the pinna and supplies the skin on the upper part of its medial aspect. As it turns around the inferior oblique it gives branches which join with the medial branches of the posterior primary divisions of the first and third cervical nerves, and in this manner a small looped plexus is formed beneath the semispinalis capitis (complexus) muscle, the *posterior cervical plexus of Cruveilhier.*

The **posterior divisions of the third, fourth, and fifth cervical nerves** divide at the lateral border of the semispinalis colli into medial and lateral branches. The **medial branches** of the third, fourth, and fifth nerves run backward between the semispinalis colli and capitis (complexus), supplying both muscles. Then, after passing backward between the semispinalis capitis and the ligamentum nuchæ, they pierce the origin of the trapezius and supply the skin of the back of the neck. The greater part of the medial branch of the third nerve, which runs upward in the superficial fascia to the scalp, is an inconstant branch called the **third occipital nerve**; it interlaces with the great occipital nerve, and it supplies the skin of the upper part of the back of the neck, near the midline, and the skin of the scalp in the region of the external occipital protuberance.

The **medial branches** of the posterior primary divisions of the **sixth, seventh, and eighth cervical nerves** pass to the medial side of the semispinalis cervicis, between it and the subjacent multifidus spinæ, and they end in the neighboring muscles. The **lateral branches** of the posterior primary divisions of the **last five cervical nerves** are small and they are distributed to the longissimus capitis (trachelomastoid), the iliocostalis cervicis (cervicalis ascendens), the longissimus cervicis (transversalis cervicis), the semispinalis capitis (complexus), and the splenius muscles.

2. Thoracic Nerves

The **posterior primary divisions of all the thoracic nerves** divide into medial and lateral branches while in the vertebral groove (fig. 820). The **medial branches of the upper six thoracic nerves** pass dorsalward between the semispinalis dorsi and the multifidus spinæ; they supply the spinalis dorsi, the semispinalis dorsi, the multifidus spinæ, the rotatores spinæ, the intertransversales, and the interspinales muscles; and they end in cutaneous branches which, after piercing the trapezius, turn lateralward in the superficial fascia of the back, and supply the skin as far as the middle of the scapula. The cutaneous branch of the second nerve is the largest; it can be traced lateralward as far as the acromion process. The **medial branches of the lower six thoracic nerves** run dorsalward, between the longissimus dorsi and the multifidus spinæ; they chiefly end in twigs to the adjacent muscles, but not uncommonly they give small cutaneous twigs which

pierce the latissimus dorsi and the trapezius and end in the skin near the midline of the back.

The **lateral branches of the upper six thoracic nerves** pass between the longissimus dorsi and the iliocostalis dorsi (accessorius) and end in those muscles, but the **lateral branches of the six lower nerves** are longer; they pass into the interval

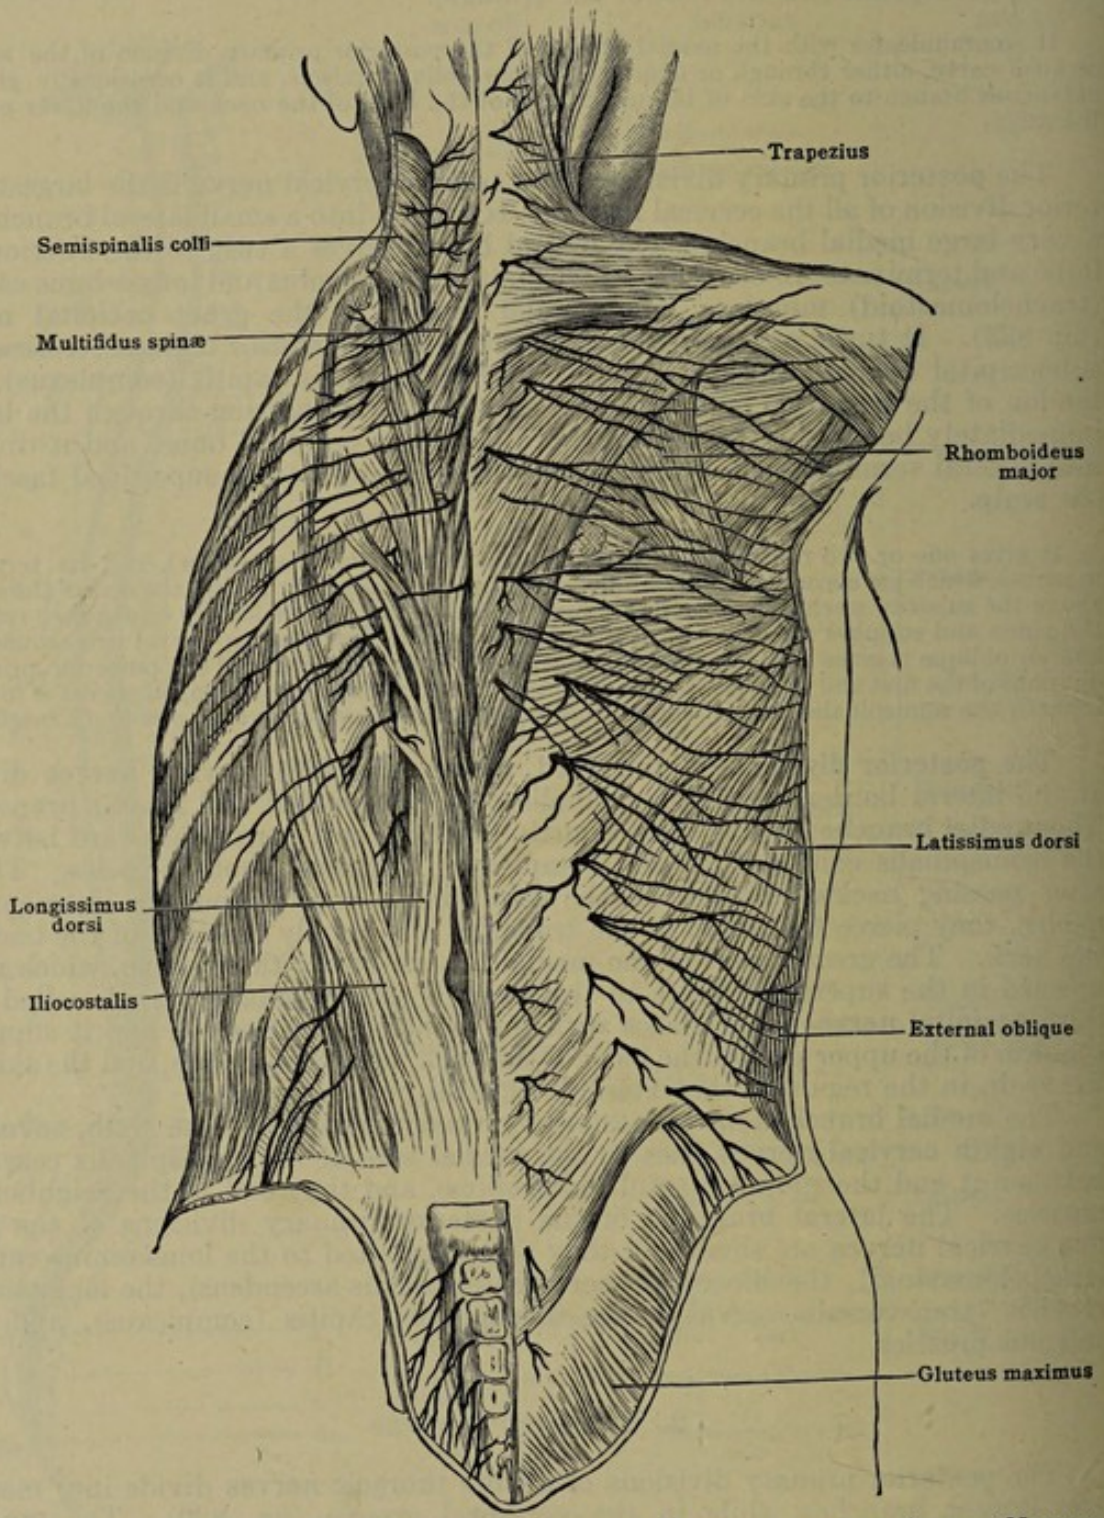

FIG. 820.—DISTRIBUTION OF THE POSTERIOR PRIMARY DIVISIONS OF THE SPINAL NERVES. (Henle.)

between the longissimus dorsi and the iliocostalis dorsi and give branches to them, and then they pierce the latissimus dorsi and are distributed to the skin of the lower and lateral part of the back.

3. LUMBAR NERVES (Fig. 820)

The **medial branches** of the posterior primary divisions of all the lumbar nerves end in the multifidus spinæ and those of the three lower nerves send very small branches to the skin of the sacral region.

The **lateral branches of the upper three nerves** pass obliquely lateralward, supplying twigs to the adjacent muscles, pierce the posterior layer of the lumbar aponeurosis at the lateral border of the sacrospinalis (erector spinæ) and enter the subcutaneous tissue. They are, for the most part, cutaneous, forming the **superior clunial nerves,** which cross the crest of the ilium and pass downward to occupy different planes in the thick superficial fascia which covers the upper part of the gluteus medius.

The lateral branch from the first lumbar nerve is comparatively small, and occupies the most superficial plane. The second occupies an intermediate position. The lateral branch from the third nerve is the largest of the three, and occupies the lowest position; it distributes branches over the gluteus maximus as far as the great trochanter. The three branches anastomose with one another and also with the cutaneous branches from the posterior primary divisions of the two upper sacral nerves.

The lateral branch of the posterior primary division of the fourth lumbar nerve is of small size and ends in the lower part of the sacrospinalis (erector spinæ). That of the fifth lumbar is distributed to the sacrospinalis and communicates with the first sacral nerve.

4. Sacral Nerves (Fig. 820)

The posterior primary divisions of the upper four sacral nerves escape from the vertebral canal by passing through the posterior sacral foramina; those of the fifth sacral pair pass out through the hiatus sacralis between the posterior sacrococcygeal ligaments. Those of the upper three sacral nerves divide in the ordinary manner into medial and lateral branches. Those of the lower two sacral nerves remain undivided.

The **medial branches** of the upper three sacral nerves are of small size, and are distributed to the multifidus spinæ. The **lateral branches** anastomose with one another and with the lateral branch of the last lumbar nerve, forming loops on the posterior surface of the sacrum from which branches proceed to the posterior surface of the sacrotuberous (great sacrosciatic) ligament, where they anastomose and form a second series of loops, from which loops two or three branches are given off. These branches pierce the gluteus maximus and come to the surface of that muscle in a line between the posterior superior spine of the ilium and the tip of the coccyx. Then, as the **middle clunial nerves,** they are distributed to the integument over the medial part of the gluteus maximus, and communicate, in their course through the superficial fascia, with the posterior branches of the lumbar nerves.

The posterior primary divisions of the **lower two sacral nerves** unite with one another, with the posterior division of the third sacral, and with the coccygeal nerve, forming loops from which twigs pass to the integument over the lower end of the coccyx.

The **posterior primary division of the coccygeal nerve** is also undivided. It separates from the anterior division in the sacral canal and emerges through the hiatus sacralis, pierces the ligaments which close the lower part of that canal, receives a communication from the posterior division of the last sacral nerve, and ends in the skin over the dorsal aspect of the coccyx.

B. ANTERIOR PRIMARY DIVISIONS

The anterior primary divisions of the spinal nerves are larger than the posterior primary divisions, and each is joined near its origin by a gray ramus communicans from the sympathetic trunk (figs. 821, 822, 834). Beginning with the first thoracic nerve and ending with the second or third lumbar nerve, each anterior division sends to the sympathetic trunk a white ramus communicans. The same is true of the second and third or of the third and fourth sacral nerves. All these white rami are approximately designated the **visceral branches** of the spinal nerves, being composed chiefly of visceral efferent (preganglionic) and some visceral afferent fibers. The anterior primary divisions of the cervical, lumbar, sacral, and coccygeal nerves unite with one another to form **plexuses,** but the anterior primary divisions of the thoracic nerves, except the first and last, remain separate, pursue independent courses, and each divides, in a typical manner, into a lateral and an anterior or ventral branch (fig. 817). Separation of anterior primary division into lateral and anterior branches is not confined to the thoracic nerves, however, for it occurs also in the lower cervical, the lumbar, and the sacral nerves. But such a separation cannot be clearly distinguished either in the upper cervical nerves or in the coccygeal nerve.

1. CERVICAL NERVES

The anterior primary divisions of the **upper four cervical nerves** unite to form the **cervical plexus,** and each receives a communicating branch from the superior cervical sympathetic ganglion. The anterior divisions of the **lower four cervical**

nerves are joined by the greater part of the first thoracic nerve and they unite to form the **brachial plexus** (figs. 821, 824, 825). The fifth and sixth cervical nerves receive communicating branches from the middle cervical sympathetic ganglion, and the seventh and eighth from the inferior cervical ganglion, while the first thoracic nerve is connected with the first thoracic sympathetic ('stellate') ganglion by a gray ramus (figs. 821, 858) and also by one or often two white rami communicantes (Johnson and Mason).

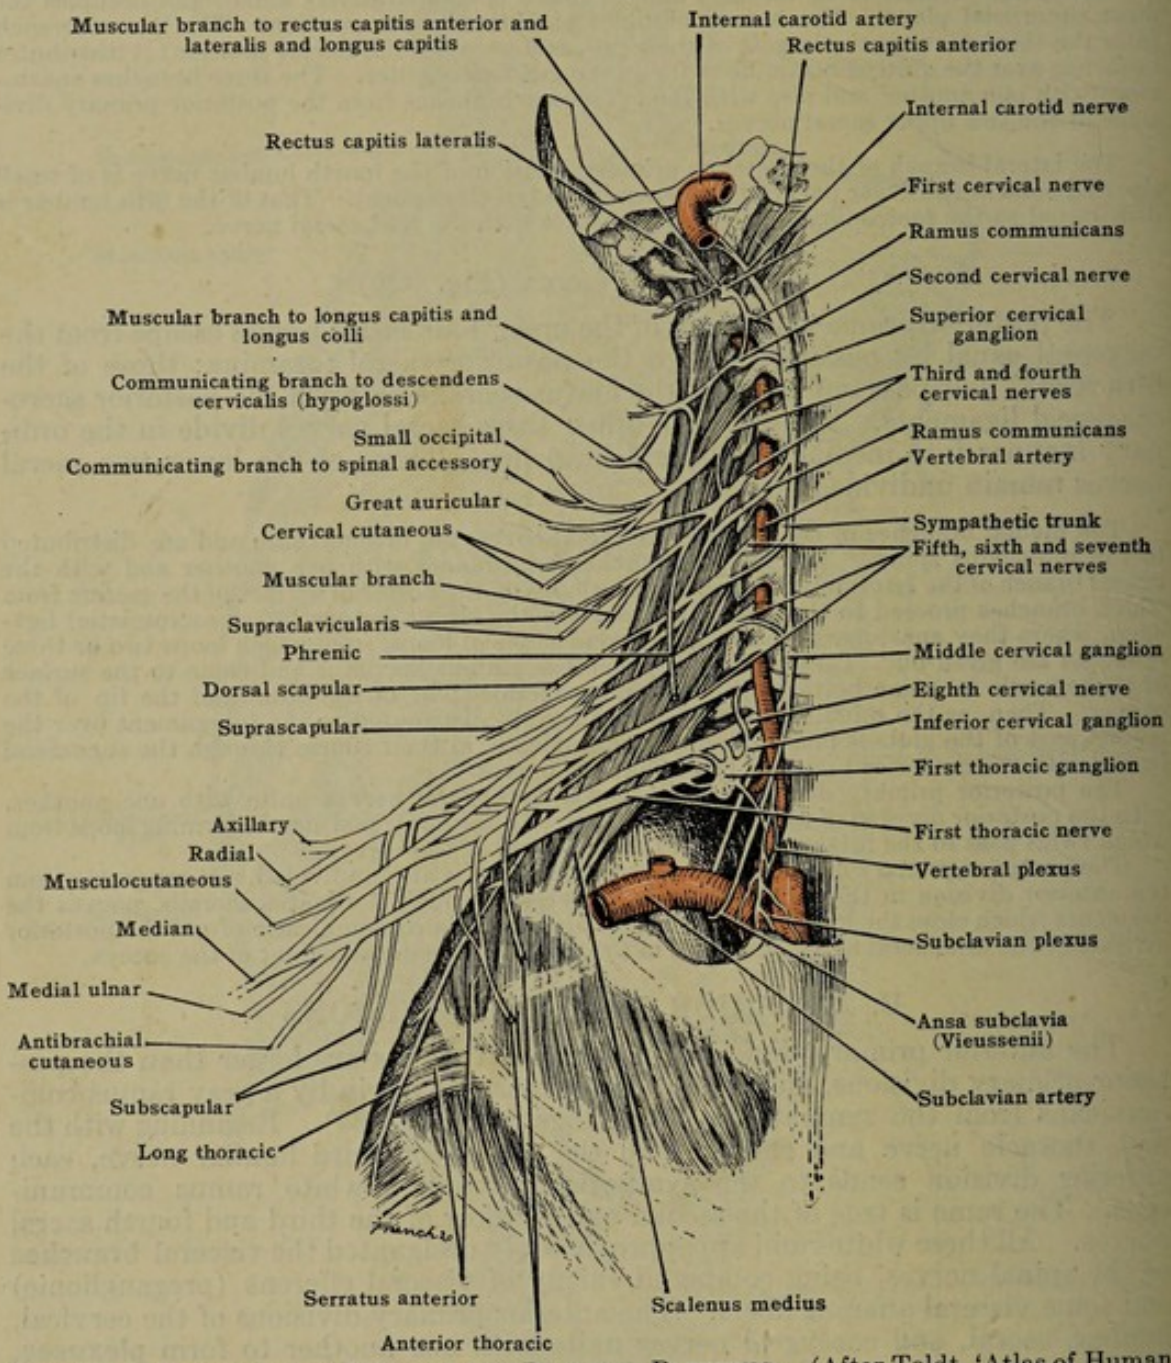

FIG. 821.—ORIGIN OF THE CERVICAL AND BRACHIAL PLEXUSES. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

THE CERVICAL PLEXUS

The cervical plexus (figs. 821-823) is formed by the anterior primary divisions of the upper four cervical nerves which constitute the roots of the plexus. It lies in the upper part of the side of the neck, under cover of the sternomastoid, and upon the levator scapulæ and the scalenus medius. It is a looped plexus, consisting of three loops.

A large part of the anterior primary division of the **first cervical nerve** is given to the ansa hypoglossi; the remainder passes to the cervical plexus and in doing so it runs lateralward on the posterior arch of the atlas beneath the vertebral artery, then it turns forward, between the vertebral artery and the outer side

of the upper articular process of the atlas, and finally it descends, in front of the transverse process of the atlas, and unites with the upper branch of the second nerve, forming with it the first loop of the plexus. It gives branches to the rectus capitis lateralis, longus capitis (major rectus capitis anterior), and to the rectus capitis anterior (minor). The division communicates with the ganglion of the trunk of the vagus and with the superior cervical ganglion of the sympathetic system (fig. 822). From the first loop of the plexus, two branches of the division pass over into the sheath of the hypoglossal nerve and descend with it to contribute to the ansa hypoglossi or better, the *cervical loop*. The fibers entering the

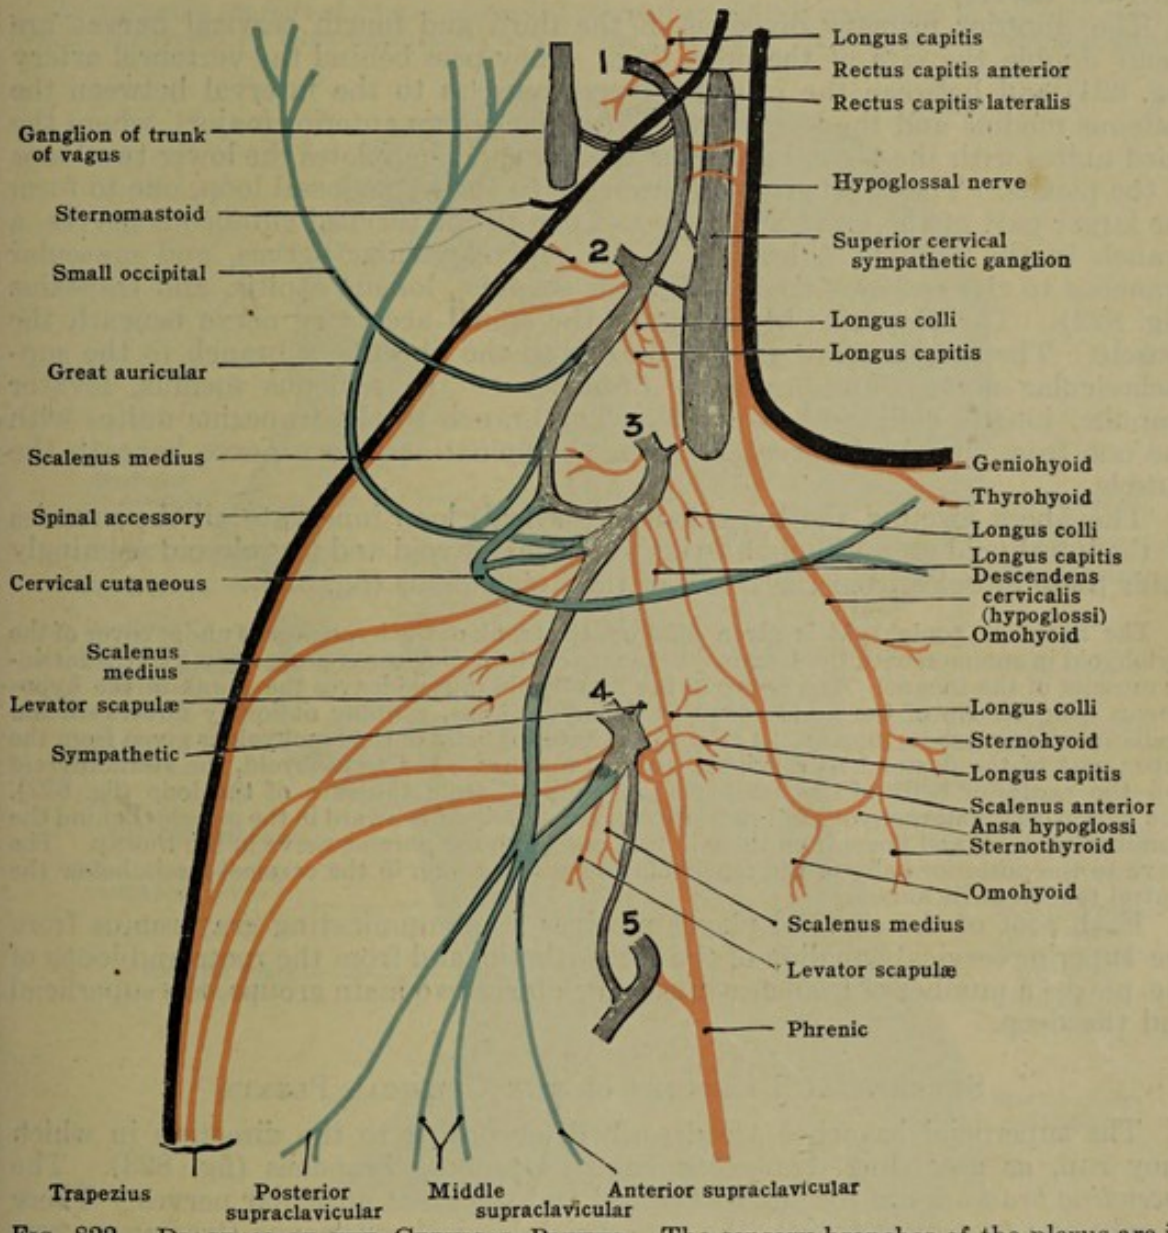

FIG. 822.—DIAGRAM OF THE CERVICAL PLEXUS. The sensory branches of the plexus are in blue, the motor in red (muscles named).

sheath of the hypoglossus, after giving a few twigs to the geniohyoid and thyrohyoid muscles, leave the sheath as the **descendens cervicalis.** This latter joins the *communicans cervicalis*, (the portion of the loop from the second and third cervical nerves) and unites with the ansa hypoglossi.

The ansa usually may be found between the sheaths of the sternomastoid muscle and the carotid artery, superficial to the internal jugular vein; sometimes it may lie in the carotid sheath between the carotid artery and the internal jugular vein; rarely it may lie dorsal to both the artery and vein. Sometimes it is relatively long, descending toward the sternum below the level of the thyroid cartilage; again it is quite short and occurs near the level of the hyoid bone. The descendens cervicalis (hypoglossi) parts company with the hypoglossal nerve at the level at which the nerve curves around the occipital artery. It runs downward and slightly medialward on the sheaths of the great vessels and occasionally within the sheath of one of them.

The **second cervical nerve** (anterior primary division) passes behind the upper articular process of the axis and the vertebral artery, and between the inter-

transverse muscles extending from the first to the second cervical vertebræ, to the interval between the scalenus medius and the longus capitis (rectus capitis anterior major), where it divides into two parts. The upper part ascends and unites with the first nerve to form the first loop of the plexus, and the lower branch passes downward and dorsalward and joins the upper branch of the third nerve in the second loop of the plexus (figs. 821, 822). This branch gives off the small occipital nerve and a filament to the sternomastoid, which communicates with the spinal accessory nerve in the substance of the muscle, and it gives branches which assist in forming the ansa hypoglossi, the cervical cutaneous and the great auricular nerves.

The anterior primary divisions of the **third** and **fourth cervical nerves** are about double the size of the preceding. They pass behind the vertebral artery (fig. 821) and between the intertransverse muscles to the interval between the scalenus medius and the longus capitis (rectus capitis anterior major), where the third unites with the second and fourth nerves and completes the lower two loops of the plexus. The third gives off branches to the hypoglossal loop, one to form the larger part of the great auricular and one to the cervical cutaneous nerves, a branch to the phrenic, a branch to the supraclavicular nerves, and muscular branches to the scalenus medius, levator scapulæ, longus capitis, and trapezius (fig. 822). The trapezius branch joins the spinal accessory nerve beneath the muscle. The fourth nerve gives a branch to the phrenic, a branch to the supraclavicular nerves, and muscular branches to the scalenus medius, levator scapulæ, longus colli, and trapezius. The branch to the trapezius unites with the one from the third nerve and joins the spinal accessory nerve beneath the muscle.

The fibers forming the hypoglossal (cervical) loop innervate all the muscles of the infrahyoid group, though twigs to the geniohyoid and thyrohyoid seemingly enter these muscles from the trunk of the hypoglossus (fig. 822).

The nerve to geniohyoid is given off from the trunk of the hypoglossus under cover of the mylohyoid in common with the terminal branches of the hypoglossus proper going to the intrinsic muscles of the tongue. **The nerve to the thyrohyoid** muscle leaves the trunk of the hypoglossus near the tip of the great cornu of the hyoid bone, running obliquely downward and medianward to reach its muscle. A twig to the anterior belly of the **omohyoid** is given from the upper part of the descendens cervicalis and the **nerves for the sternohyoid, the sternothyroid** and the posterior belly of the **omohyoid** are supplied from the turn of the loop (fig. 822). The nerves to the sternohyoid and sternothyroid send twigs downward in the muscles behind the manubrium sterni and fibers from these in rare cases join the phrenic nerve in the thorax. The nerve to the posterior belly of the **omohyoid** courses as a loop in the cervical fascia below the central tendon of its muscle.

Each root of the cervical plexus receives a communicating gray ramus from the superior cervical ganglion of the sympathetic, and from the roots and loops of the plexus a number of branches arise which form two main groups, the superficial and the deep.

Superficial Branches of the Cervical Plexus

The superficial branches are described, according to the direction in which they run, as ascending, transverse, and descending branches (fig. 823). The *ascending branches* are the small occipital and the great auricular nerves. There is only one *transverse branch*, the superficial cervical cutaneous (transverse cervical) nerve. The *descending branches* are distinguished as the supraclavicular nerves and the cervical (hypoglossal) loop. For cutaneous distribution see also p. 1099.

The ascending branches.—(1) The **small occipital nerve** (figs. 822, 823) arises from the second and third cervical nerves, or from the loop between them, and runs upward and dorsalward to the posterior border of the sternomastoid, where it hooks around the lower border of the spinal accessory nerve and then ascends along the posterior border of the muscle to the mastoid process. It pierces the deep cervical fascia and passes across the posterior part of the insertion of the sternomastoid into the superficial fascia of the scalp, in which it breaks up into auricular, mastoid, and occipital terminal branches.

(*a*) The **auricular branch** runs upward and slightly forward to reach the integument on the upper median part of the auricle (pinna), which it supplies. (*b*) The **mastoid branch** is distributed to the skin covering the base of the mastoid process. (*c*) The **occipital branches** ramify over the occipitalis muscle and are distributed to the skin of the scalp; they communicate with one another and with the great occipital nerve. The branches of the small occipital nerve

anastomose with twigs of the posterior auricular, great auricular, and great occipital nerves (fig. 823).

(2) The **great auricular nerve** arises from the second and third cervical nerves (figs. 822, 823). It accompanies the small occipital to the posterior border of the sternomastoid, but at that point it diverges from the small occipital and runs upward and forward across the sternomastoid toward the angle of the mandible. When it is about half-way across the muscle it begins to break up into its terminal branches, which are named, according to the area of their distribution, as mastoid, auricular, and facial.

As the nerve ascends obliquely across the sternomastoid it is embedded in the deep cervical fascia, is covered by superficial fascia and by the platysma. It lies parallel with and slightly

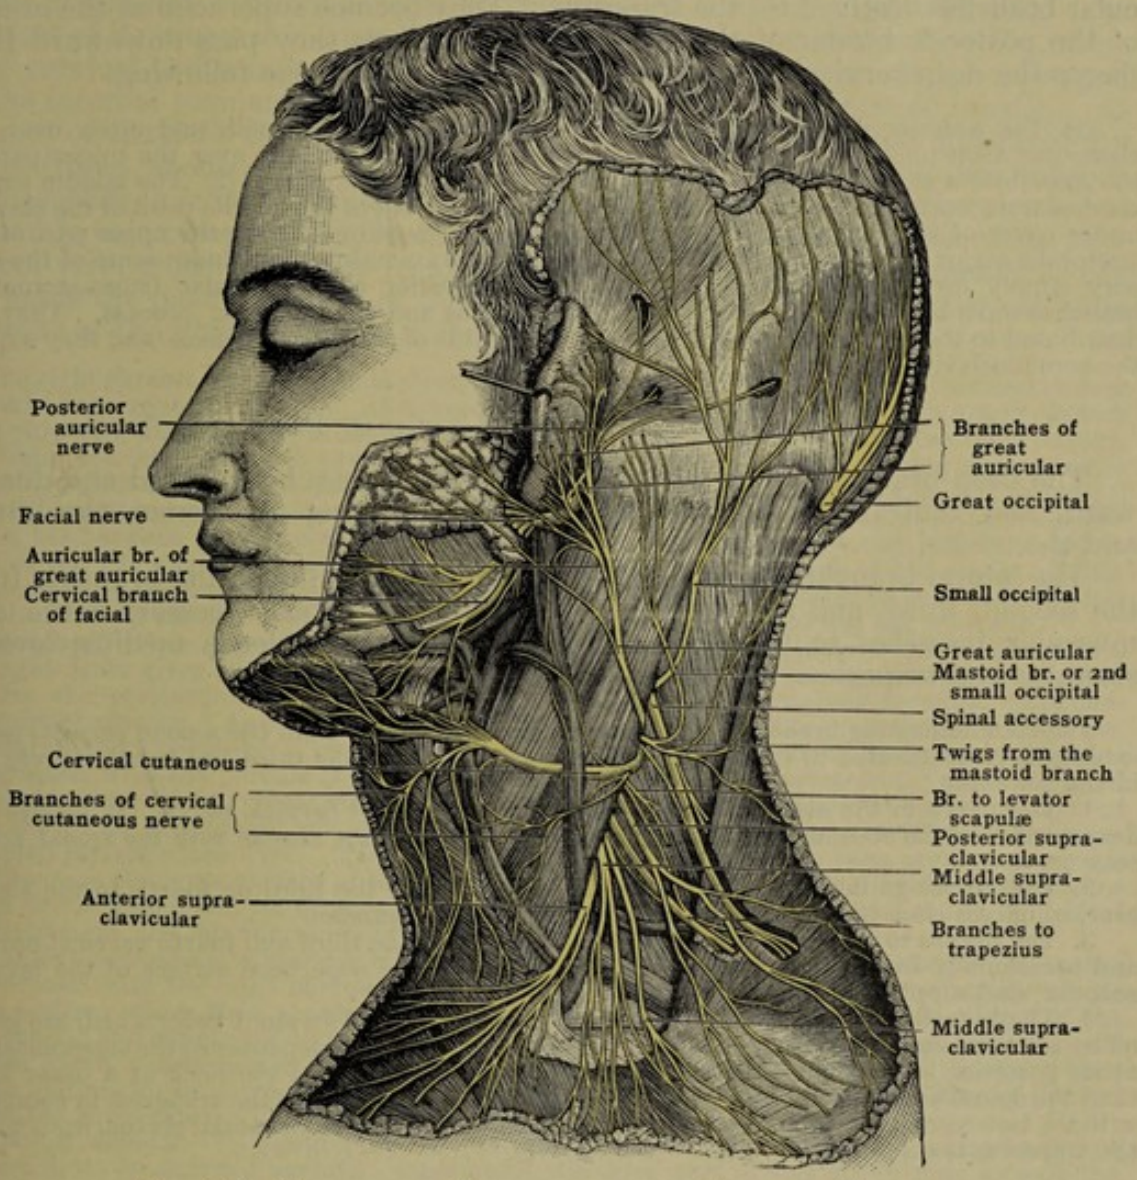

FIG. 823.—SUPERFICIAL BRANCHES OF THE CERVICAL PLEXUS.
(After Hirschfeld and Leveillé.)

dorsal to the external jugular vein. (*a*) The **mastoid branch** is small, and is distributed to the integument covering the mastoid process. It anastomoses with the posterior auricular and small occipital nerves. (*b*) The **auricular branches** are three or four stout twigs which interlace with the branches of the posterior auricular nerve; they cross the superficial surface of the posterior auricular branch of the facial, and are distributed to the skin on the back of the auricle with the exception of its uppermost part. One or two twigs pass through fissures in the cartilage of the auricle, and are distributed to the integument on the lateral surface of the lobule and the lateral surface of the lower part of the helix and anthelix. (*c*) The **facial** branches pass upward and forward among the superficial lobules of the parotid gland, and supply the skin over that gland and immediately in front of it, and they anastomose in the substance of the gland with the cervicofacial division of the facial nerve. In some cases fine twigs may be traced forward nearly to the angle of the mouth.

Transverse branch of the cervical plexus.—The **cervical cutaneous nerve** [n. cutaneous colli] arises from the second and third cervical nerves (figs. 821, 822),

and appears at the posterior border of the sternomastoid, a little below the great auricular nerve. It passes transversely across the sternomastoid under cover of the integument, platysma, and external jugular vein, and divides into a number of twigs which spread out after the manner of a fan, and, as they approach the middle line, extend from the chin to the sternum (fig. 823).

The upper two or three of these twigs unite, beneath the platysma, with the cervical (inframandibular) branch of the facial and thus form loops. From the terminal branches of the nerve numerous twigs arise which pierce the platysma and end in the skin of the front part of the neck.

The descending or supraclavicular branches.—These are derived from the third and fourth cervical nerves (figs. 821, 822), and arise under cover of the sternomastoid. At their commencements they are usually united with the muscular branches destined for the trapezius. They become superficial at the middle of the posterior border of the sternomastoid, and as they pass downward they pierce the deep cervical fascia (fig. 823). They include the following:

(1) The **anterior supraclavicular (suprasternal) branches** are small, and cross over the clavicular attachment of the sternomastoid to reach the integument over the upper part of the manubrium sterni. They also supply the sternoclavicular joint. (2) The **middle supraclavicular nerves** are of considerable size. They cross in front of the middle third of the clavicle under cover of the platysma, and are distributed to the skin covering the upper part of the pectoralis major as low as the third rib. This distribution naturally includes some of the sensory supply for the mammary gland. (3) The **posterior supraclavicular (supra-acromial) branches** cross the clavicular insertion of the trapezius and the acromion process. They are distributed to the skin which covers the upper two-thirds of the deltoid muscle and they supply the acromioclavicular joint.

Deep Branches of the Cervical Plexus

The deep branches of the plexus (figs. 821, 822) pass lateralward and dorsalward, and ventralward and medialward, thus forming two series, the lateral and the medial.

The **lateral branches** of the deep series include communicating branches from the second, third, and fourth cervical nerves to the spinal accessory nerve, and muscular branches to the sternomastoid and to the scalenus medius, levator scapulæ, and trapezius.

The **communicating branches.**—The communicating branch from the second cervical nerve is ultimately distributed to the sternomastoid, and those from the third and fourth nerves end in the trapezius.

1 The **nerve to the sternomastoid** arises from the second cervical nerve. It pierces the deep surface of the sternomastoid, and communicates within the muscle with the spinal accessory nerve.

2. The **nerves to the scalenus medius** are derived from the third or fourth to the eighth cervical nerves close to their exit from the intervertebral foramina.

3. The **nerves to the levator scapulæ** are derived from the third and fourth cervical nerves, and occasionally from the second or fifth. They pierce the superficial surface of the levator scapulæ, and supply the upper three divisions of that muscle.

4. The **branches to the trapezius** are usually in the form of two stout twigs which are given off by the third and fourth cervical nerves. They emerge from under cover of the sternomastoid at its posterior border and cross the posterior superior triangle of the neck at a lower level than the spinal accessory nerve (fig. 823). They pass under cover of the trapezius in company with the last-named nerve, and communicate with it to form the **subtrapezial plexus**, from which the trapezius is supplied.

The **medial branches** of the deep series also comprise communicating and muscular branches.

The **communicating branches** (figs. 821, 822) include (1) branches which connect each of the first four cervical nerves with the superior cervical ganglion of the sympathetic; (2) a branch to the vagus; (3) a branch to the hypoglossus; and (4) branches which pass from the second and third cervical nerves to the *descendens cervicalis* (*hypoglossi*). The ultimate distribution of the twigs connected with the sympathetic and the vagus nerves is not known, but the fibers which pass to the hypoglossal nerve pass from it to the thyrohyoideus muscle and to the descendens cervicalis, and the latter joins with the branches from the second and third cervical nerves, forming with them the cervical or **hypoglossal loop** [ansa hypoglossi] which lies on the carotid sheath. From this loop the two bellies of the omohyoid muscle and the sternohyoid and sternothyroid muscles are supplied as described above.

The **muscular branches** supply the rectus capitis lateralis, the longus capitis (rectus capitis anterior major), the rectus capitis anterior (minor), the scalenus anterior, and the diaphragm. The nerve to the latter muscle is the phrenic.

1. The **branch to the rectus capitis lateralis** is furnished to that muscle by the first cervical nerve as it crosses the deep surface of the muscle.
2. The **nerve to the rectus capitis anterior** (minor) is given off by the first nerve at the upper part of the loop in front of the transverse process of the atlas.
3. The **longus capitis** (rectus capitis anterior major) receives twigs from the upper four cervical nerves.
4. The **longus colli** receives branches from the second, third, and fourth cervical nerves, and additional branches also from the fifth and sixth nerves.

5. The **phrenic nerve** (figs. 821, 822) springs chiefly from the fourth cervical, but it usually receives a twig from the third and another from the fifth cervical nerve, a small communicating branch from the sympathetic, and, rarely, a branch from the vagus. The twig from the fifth cervical nerve is frequently connected with the nerve to the subclavius. After the union of its roots the phrenic nerve passes downward and medialward on the scalenus anterior (figs. 537, 825). In this part of its course it is crossed by the tendon of the omohyoid and by the transverse cervical and transverse scapular (suprascapular) arteries. It is overlapped by the internal jugular vein, and it is covered by the sternomastoid muscle. At the root of the neck the left phrenic nerve lies behind the terminal portion of the thoracic duct, and each nerve passes off the anterior border of the scalenus anterior and descends in front of the first part of the subclavian artery and the pleura immediately below that artery; each nerve passes dorsal to the terminus of the subclavian vein, crosses either in front of or dorsal to the internal mammary artery and gains the medial surface of the pleural sac. From the root of the neck the relations of the phrenic nerves differ (fig. 537).

The **right phrenic nerve** descends along the medial surface of the right pleural sac and crosses in front of the root of the lung. It is accompanied by the pericardiacophrenic artery (comes nervi phrenici), and it is in relation medially, and from above downward, with the right innominate vein, the superior vena cava, and the pericardium, the latter membrane separating it from the wall of the right atrium. The **left phrenic nerve** descends along the medial surface of the left pleural sac accompanied by the pericardiacophrenic artery. In the superior mediastinum it lies between the left common carotid and the left subclavian arteries, and it crosses in front of the left vagus, the left superior intercostal vein, and the arch of the aorta. Below the arch of the aorta it crosses in front of the root of the left lung, and then lies along the left lateral surface of the pericardium, which separates it from the wall of the left ventricle.

Branches.—Both phrenic nerves distribute branches to the pericardium and to the pleura. The right nerve gives off a branch, **pericardiac,** which accompanies the superior vena cava and supplies the pericardium. Each phrenic nerve divides into numerous terminal **phrenicoabdominal** branches. As a rule, the *right phrenic* nerve divides into two main terminal branches, an anterior and a posterior. The *anterior* branch runs forward and one of its terminal filaments anastomoses with the phrenic of the opposite side in front of the pericardium; others descend between the sternal and costal attachments of the diaphragm into the abdomen, where some of them supply the diaphragm and others descend in the falciform ligament to the peritoneum on the upper surface of the liver. The *posterior* branch passes through the vena caval opening and ramifies upon the lower surface of the diaphragm, anastomosing with the diaphragmatic plexus of the sympathetic, and its terminal branches supply the muscular fibers of the right half of the diaphragm, the inferior vena cava, and the right suprarenal gland.

The *left phrenic* nerve divides into several branches. One of the most anterior branches anastomoses with the right phrenic nerve; the others pierce the diaphragm and ramify on its lower surface, where they anastomose with filaments of the left diaphragmatic plexus of the sympathetic and supply the left half of the diaphragm and the left suprarenal gland. The left phrenic nerve is considerably longer than the right nerve, partly on account of the lower level of the diaphragm on the left side, and partly on account of the greater convexity of the left side of the pericardium.

Clinical aspects.—In ligating the subclavian artery, inclusion of a phrenic nerve in the ligature must be guarded against. Ligation of the third part of this artery may include the nerve to the subclavius muscle and this nerve sometimes carries a considerable proportion of phrenic fibers. In pulmonary tuberculosis, division of the phrenic nerve (phrenicotomy) is sometimes made in order to cause a one-sided paralysis with immobilization of the diaphragm

THE BRACHIAL PLEXUS

The **brachial plexus** (figs. 821, 824, 825) is formed by the anterior primary divisions of the **four lower cervical nerves** and the greater part of that of the **first thoracic nerve.** It is usually joined by small twigs from the **fourth cervical** and **second thoracic nerves.**

The anterior primary divisions of the lower four cervical nerves, after passing dorsal to the vertebral artery and between the anterior and posterior parts of the intertransverse muscles, pass into the posterior triangle of the neck between the adjacent borders of the anterior and middle scalene muscles, where those of the fifth and sixth nerves receive a gray ramus communicans each from the middle cervical sympathetic ganglion, and those of the seventh and eighth nerves each

receives a gray ramus from the inferior cervical sympathetic ganglion. The anterior primary division of the first thoracic is connected by two rami communicantes with the first thoracic sympathetic ganglion, and it divides into a smaller and a larger branch. The smaller branch passes along the intercostal space as the first intercostal nerve, and the larger branch, after being joined by a twig from the second thoracic nerve, passes upward and lateralward, in front of the neck of the first rib and behind the apex of the pleural sac, into the lower part of the posterior triangle of the neck, where it takes part in the formation of the plexus.

Trunks and branches.—The anterior primary divisions of those cervical nerves that form the brachial plexus show typically the following relations (fig. 824). The fifth and sixth cervical divisions unite to form the *upper trunk;* the seventh cervical forms the *middle trunk;* the eighth cervical and first thoracic form the *lower trunk* of the plexus. Each of these trunks divides into an *anterior* and a *posterior branch.* Variations in the mode of formation of the trunks and branches are so numerous that many different forms of the plexus have been described.

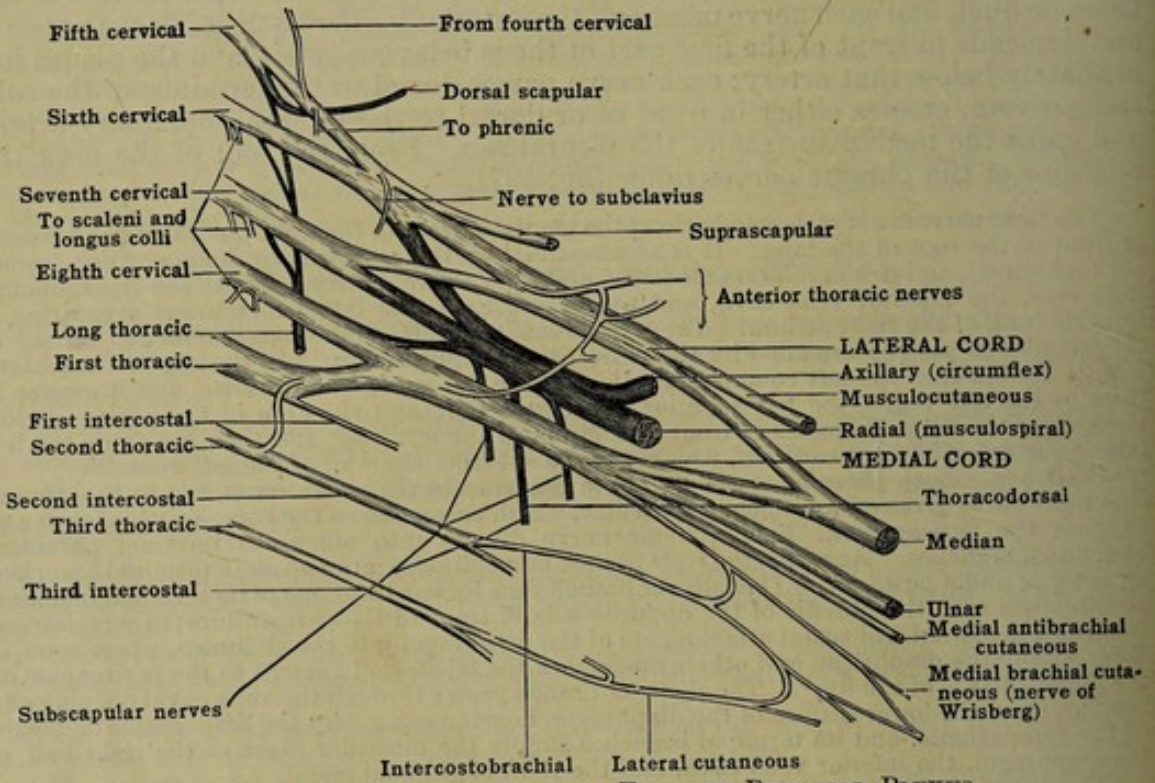

FIG. 824.—DIAGRAM OF A COMMON FORM OF BRACHIAL PLEXUS.
The posterior branches and cord of the plexus are darkly shaded.

Three cords [fasciculi] are formed from these branches in the following manner:—(1) The **lateral** (outer) **cord** [fasciculus lateralis] is formed by the anterior branches of the upper and middle trunks (anterior primary divisions of the fifth, sixth, and seventh nerves); (2) the **medial** (inner) **cord** [fasciculus medialis], by the anterior branch of the lower trunk (eighth cervical and first thoracic nerves); and (3) the **posterior cord** [fasciculus posterior], by the posterior branches of all of these trunks and nerves.

In a study of 175 brachial plexuses, Kerr found that over 62 per cent. of them receive a communication from the anterior primary division of the fourth cervical nerve. Of those which receive no branch from this nerve, nearly 30 per cent. of the 175 plexuses studied receive the entire anterior primary division of the fifth cervical nerve. In most of the remaining 10 per cent., a part of the fifth nerve helps to form the cervical plexus. Brachial plexuses receiving the branch from the fourth cervical nerve are found more cephalic with reference to the vertebral column than those which do not receive it. Those which receive the largest part of the fifth cervical nerve are most caudal. He divides the plexuses studied into three groups and within these pictures eight types of forms.

Relations.—The plexus extends from the lateral border of the scalenus anterior, where the roots of its constituent nerves appear, to the lower border of the pectoralis minor, where each of its three cords divides into two terminal branches. It lies in the posterior triangle, in the root of the neck, and in the axillary fossa. In the posterior triangle and in the root of the neck it is in relation behind with the scalenus medius (figs. 821, 825). In the posterior triangle it is covered superficially by the skin and superficial fascia, by the platysma, the supraclavicular

branches of the cervical plexus, and the deep fascia, and it is crossed by the lower part of the external jugular vein, by the nerve to the subclavius, by the transverse cervical vein, the transverse scapular (suprascapular) vein, the posterior belly of the omohyoid muscle and by the transverse cervical artery. At the root of the neck it lies behind the clavicle and the subclavius muscle, and the transverse scapular (suprascapular) artery crosses in front of it. In the axillary fossa the cords are arranged around the axillary artery, the lateral cord lying lateral to the artery, the medial cord medial to it, and the posterior cord dorsal to the artery. In this region the posterior relations of the plexus are the fat in the upper part of the fossa and the subscapularis muscle, and it is covered in front by the pectoral muscles and the coracoclavicular fascia. The lower border of the plexus is in relation in the posterior triangle and at the root of the neck with the pleura and the first rib, and it is overlapped in front by the third part of the subclavian artery. In the axillary fossa the medial cord, which forms the lower border of

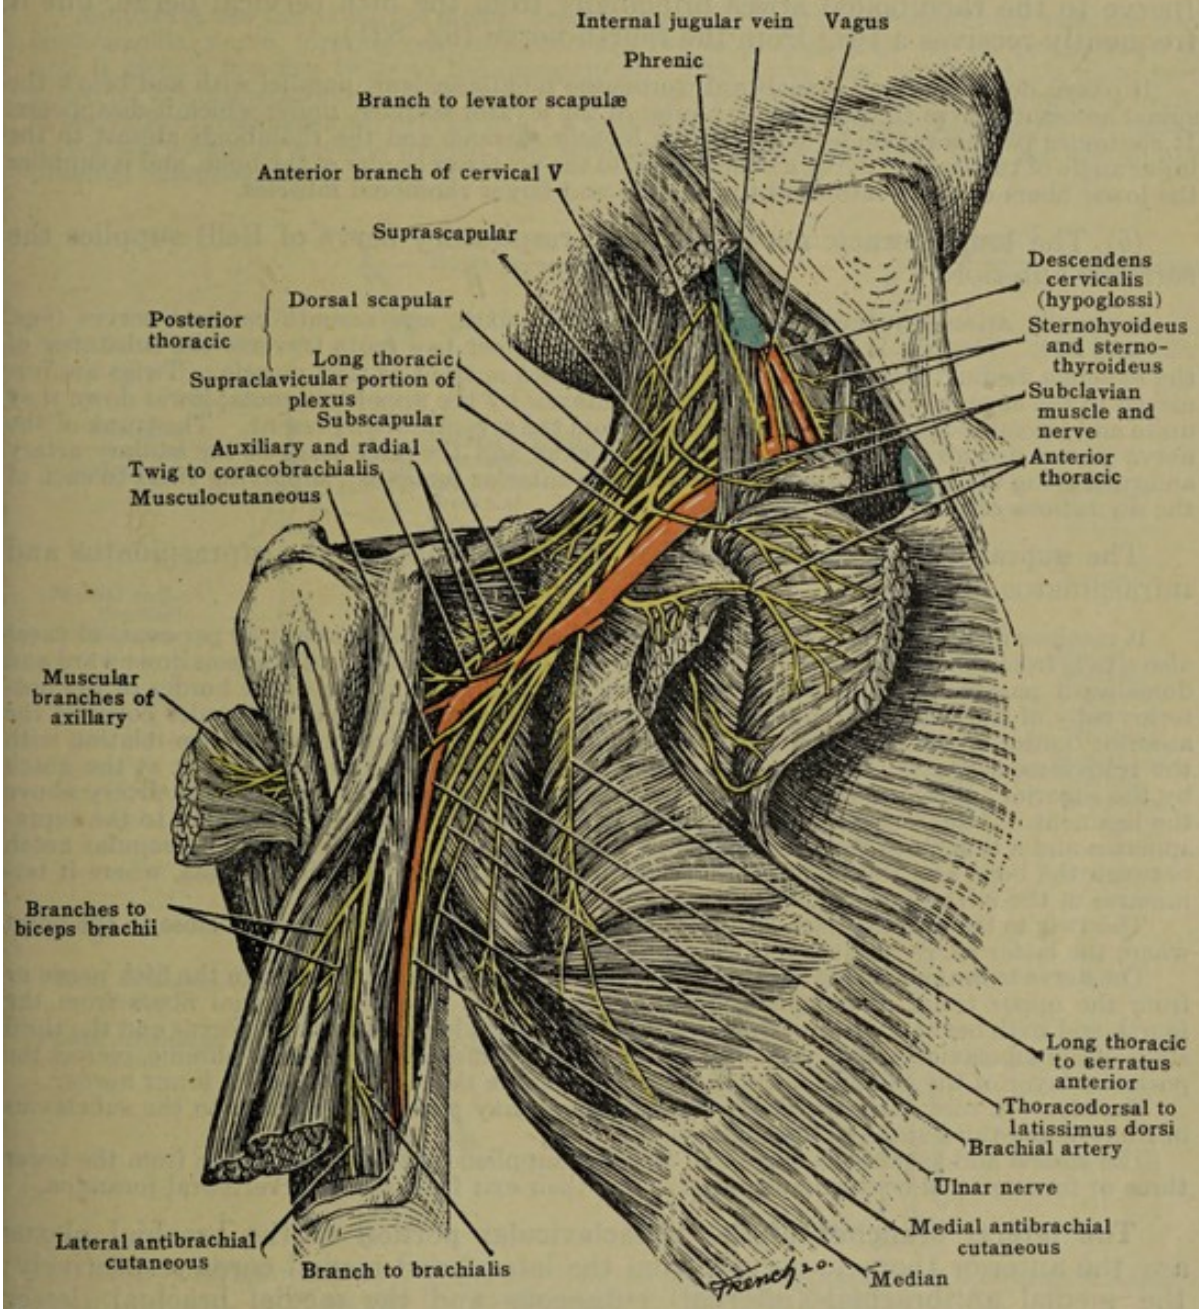

FIG. 825.—THE BRACHIAL PLEXUS AND ITS BRANCHES OF THE REGION OF THE NECK AND SHOULDER. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

the plexus, is overlapped anteriorly by the axillary vein. The upper and lateral border of the plexus has no very important relations.

In summary the brachial plexus may be formulated as beginning with five nerves and terminating in five nerves, with its intermediate portions displayed in sets of threes. It begins with the fifth, sixth, seventh and eighth cervical and first thoracic nerves (anterior primary divisions); it terminates as a plexus with the formation of the musculocutaneous, radial, axillary, median, and ulnar nerves. In its intermediate portions, first, three main trunks are formed and these divide into two sets of threes which, by union, give rise to the three cords. The **branches from the cords** are three main lateral branches from each and the terminal

branches of the plexus. The *lateral branches*, according as they are given off above and below the clavicle, are grouped as the *supraclavicular and infraclavicular portions* of the plexus (figs. 824, 825).

The branches of the supraclavicular portion.—After the roots of the plexus have received communications from the sympathetic, which have already been referred to, they give off a series of muscular branches, viz.—the posterior thoracic nerves (the dorsal scapular and the long thoracic nerve), the suprascapular nerve, a twig to the phrenic, the nerve to the subclavius, and small twigs to the scalene muscles and the longus colli muscle.

The **posterior thoracic nerves** are two in number:—(*a*) the **dorsal scapular** (nerve to the rhomboids) arises principally from the fifth cervical nerve, but it frequently receives a twig from the fourth nerve (fig. 821).

It passes downward and dorsalward, across the middle scalene, parallel with and below the spinal accessory nerve to the anterior border of the levator scapulæ, under which it disappears. It continues its descent under cover of the levator scapulæ and the rhomboids almost to the lower angle of the scapula, lying a little medial to the posterior border of the bone, and it supplies the lower fibers of the levator and the smaller and larger rhomboid muscles.

(*b*) The **long thoracic nerve** (external respiratory nerve of Bell) supplies the serratus anterior.

It usually arises, by three roots, from the fifth, sixth, and seventh cervical nerves (figs. 821 and 824. The last is sometimes absent. The upper two roots traverse the substance of the scalenus medius; the root from the seventh passes in front of that muscle. Twigs are furnished to the superior portion of the serratus anterior by the upper two roots; lower down they unite and are subsequently joined by the root from the seventh when present. The trunk of the nerve passes downward behind the brachial plexus and the first stage of the axillary artery and runs along the axillary surface of the serratus anterior (magnus), supplying twigs to each of the digitations of that muscle (fig. 825).

The **suprascapular nerve** (figs. 821, 824, 825) supplies the supraspinatus and infraspinatus muscles.

It receives fibers from the fifth and sixth cervical nerves, and in about 50 per cent. of cases also a twig from the fourth nerve. It is a nerve of considerable size, and it passes downward and dorsalward parallel with the dorsal scapular nerve, at first along the upper border of the posterior belly of the omohyoid muscle, then internal to the latter muscle and under cover of the anterior border of the trapezius to the suprascapular notch, where it comes into relation with the transverse scapular (suprascapular) artery. It is separated from the artery at the notch by the superior transverse ligament, the nerve passing through the notch and the artery above the ligament. After entering the supraspinous fossa the nerve supplies branches to the supraspinatus and a branch to the shoulder-joint; then it descends through the great scapular notch between the bone and the inferior transverse ligament to the infraspinous fossa, where it terminates in the infraspinatus muscle.

The **twig to the phrenic** (figs. 821, 824) arises from the fifth cervical nerve close to the point where the latter nerve receives its twig from the cervical plexus.

The **nerve to the subclavius** (figs. 824, 825) is a small twig which arises from the fifth nerve or from the upper trunk of the plexus, but occasionally it receives additional fibers from the fourth and sixth nerves. It runs downward in front of the lower part of the plexus and the third stage of the subclavian artery and, after giving off sometimes a branch to the phrenic, pierces the posterior layer of the coracoclavicular fascia, and enters the subclavius at its lower border.

Variety.—In rare cases the entire phrenic nerve may pass *via* the nerve to the subclavius in front of the third stage of the subclavian artery.

The *scaleni* and *longus colli* (figs. 821, 824) are supplied by twigs which arise from the lower three or four cervical nerves immediately after their exit from the intervertebral foramina.

The lateral branches of the infraclavicular portion of the brachial plexus are the anterior thoracic nerves, from the lateral and medial cords respectively; the medial antibrachial (internal) cutaneous and the medial brachial (lesser internal) cutaneous nerves from the medial cord, and the subscapular and thoracodorsal nerves from the posterior cord.

The **lateral anterior thoracic nerve** joins with the medial to form a loop which supplies the pectoralis major and minor.

It arises from the lateral cord of the plexus and contains fibers from the fifth, sixth, and seventh cervical nerves (figs. 821, 824, 825). After joining the medial anterior thoracic it pierces the coracoclavicular fascia and ends in branches that supply the pectoralis major muscle.

The **medial anterior thoracic nerve** arises from the medial cord (figs. 821, 824, 825), contains fibers from the eighth cervical and first thoracic nerves, and passes forward between the first stage of the axillary artery and the axillary vein. It unites with a branch from the lateral anterior thoracic, to form a loop which is placed in front of the first stage of the axillary artery; it gives branches to the pectoralis minor, and branches which pass through the latter muscle and end in the pectoralis major. From the loop additional branches are furnished to the pectoralis major.

The **medial brachial cutaneous nerve** (n. cutaneus brachii ulnaris NK) (or nerve of Wrisberg, figs. 824, 826), arises from the medial cord of the brachial plexus and in 90 per cent. of the cases contains fibers from the eighth cervical and first thoracic nerves, but sometimes fibers from the first thoracic nerve alone. It runs downward on the medial side of the axillary vein, being separated by that vessel from the ulnar nerve, and it continues downward with a slight inclination dorsalward under cover of the deep fascia on the inner side of the arm. At the middle of the arm it pierces the deep fascia, and near the bend of the elbow it turns somewhat sharply dorsalward to supply the integument which covers the olecranon process (fig. 826).

As it traverses the axilla the medial brachial cutaneous nerve communicates with the intercostobrachial nerve, forming one, or sometimes two loops (fig. 824). In its course down the arm it gives a few fine twigs to the integument. This nerve may be absent, its place being taken by the intercostobrachial or by part of the posterior brachial (internal) cutaneous branch of the radial (musculospiral) or, rarely, by a branch from the first intercostal nerve. It usually leaves the plexus as a single branch, but sometimes it leaves combined with the medial antibrachial cutaneous nerve.

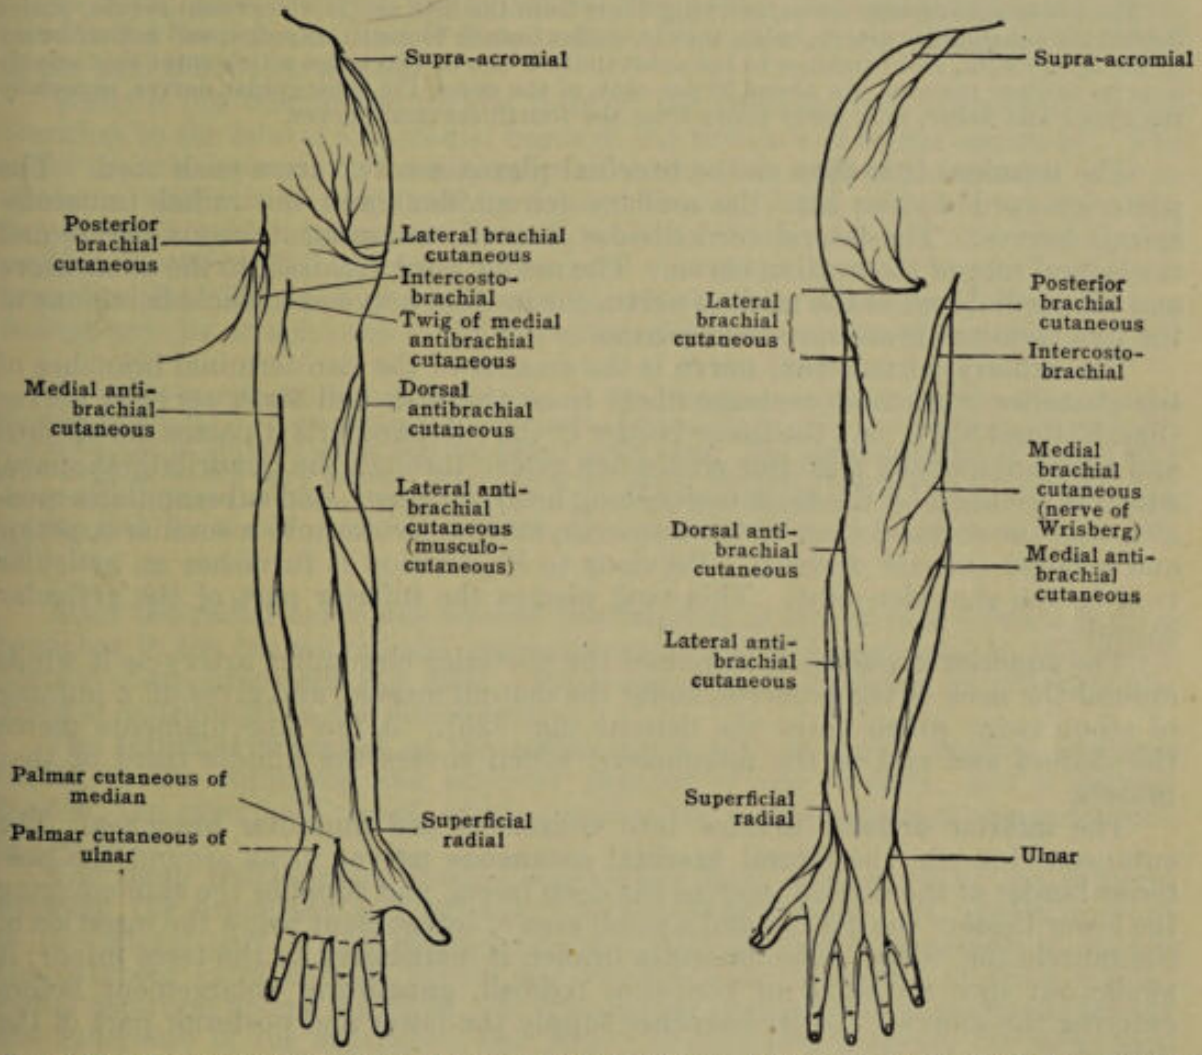

FIG. 826.—DISTRIBUTION OF CUTANEOUS NERVES ON THE ANTERIOR AND POSTERIOR ASPECTS OF THE UPPER EXTREMITY. (Cf. also fig. 831.)

The **medial antibrachial cutaneous nerve** (n. cut. brachioantibrachii ulnaris NK) (figs. 821, 824) arises from the medial cord in close relation with the ulnar nerve. It contains fibers from the eighth cervical and first thoracic nerves. At its origin it lies directly on the medial side of the axillary artery (fig. 825), but it soon becomes more superficial and then lies in the groove between the artery and the vein. In the upper two-thirds of the arm it lies in front and to the medial side of the brachial artery. It divides into two branches (volar and ulnar) which supply the medial aspect of the forearm.

At the junction of the middle and lower thirds of the arm this nerve pierces the deep fascia, in company with the basilic vein, and divides into an anterior and a posterior branch. Previous to its division it gives off twigs which pierce the deep fascia and supply the integument of the upper and medial part of the arm. The **volar (anterior) branch** is larger than the ulnar (pos-

terior); it passes in front of or dorsal to the median basilic vein, and divides into several twigs which run down the forearm, supplying the integument covering its anterior and medial aspect as far as the wrist, and anastomosing with the branches of the ulnar nerve. The **ulnar (posterior) branch** passes downward and dorsalward in front of the medial condyle of the humerus, and divides into branches which supply the skin on the posteromedial aspect of the forearm. It anastomoses with the dorsal antibrachial (inferior external) cutaneous branch of the radial (musculospiral) nerve and the dorsal branch of the ulnar nerve.

The **subscapular nerves** are branches of the posterior cord (fig. 824). They are usually three in number, distinguished as upper, thoracodorsal or middle and lower, and are distributed to the subscapularis, latissimus dorsi, and teres major muscles.

The **upper or short subscapular nerve** is derived from the fifth and sixth cervical nerves. It lies in the upper and posterior part of the axillary fossa, and it is distributed exclusively to the subscapularis muscle. It is occasionally double.

The **thoracodorsal (middle, or long subscapular) nerve** consists mainly of fibers from the seventh and eighth cervical nerves, but it may contain fibers from the fifth or the sixth nerve. It passes behind the axillary artery, accompanies the subscapular artery along the axillary margin of the subscapularis muscle, and ends in the latissimus dorsi (fig. 825).

The **lower subscapular nerve**, carrying fibers from the fifth and sixth cervical nerves, passes behind the subscapular artery, below the circumflex branch (dorsalis scapulæ), and is distributed to the teres major, and furnishes to the subscapularis one or two twigs which enter that muscle near its axillary margin. In about 50 per cent. of the cases, the subscapular nerves, especially the upper and lower, may carry fibers from the fourth cervical nerves.

The **terminal branches** of the brachial plexus are two from each cord. The posterior cord divides into the axillary (circumflex) and the radial (musculospiral) nerves. The lateral cord divides into the musculocutaneous nerve, and the lateral root of the median nerve. The medial cord divides into the ulnar nerve and the medial root of the median nerve, the median nerve as a whole being one of the five terminal branches of the plexus.

The **axillary (circumflex) nerve** is the smaller of the two terminal branches of the posterior cord, and contains fibers from the fifth and sixth cervical nerves (figs. 821 and 824). At the lower border of the subscapularis it passes dorsalward and accompanies the posterior circumflex artery through the quadrilateral space, which is bounded by the teres major, long head of triceps, and subscapularis muscles, and the surgical neck of the humerus, and it divides into a smaller superior and a larger inferior division. Previous to its division it furnishes an articular twig to the shoulder-joint. This twig pierces the inferior part of the articular capsule.

The **superior division** accompanies the posterior circumflex artery as it winds around the neck of the humerus under the deltoid muscle, and gives off a number of stout twigs which enter the deltoid (fig. 825). A few fine filaments pierce the deltoid and end in the integument which covers the middle third of that muscle.

The **inferior division** divides into cutaneous and muscular branches. The cutaneous branch, the **lateral brachial cutaneous nerve,** turns around the posterior border of the deltoid, pierces the deep fascia, and supplies the skin covering the lower third of the deltoid and a small area of integument below the insertion of the muscle (fig. 826). One muscular branch is distributed to the teres minor; it swells out into an ovoid or fusiform, reddish, gangliform enlargement before entering the muscle. Other branches supply the lower and posterior part of the deltoid.

The **radial (musculospiral) nerve** [n. radialis] is the largest branch of the brachial plexus. It contains fibers from the sixth, seventh, and eighth cervical and often from the fifth cervical or first thoracic nerve (figs. 821, 824). The fourth cervical nerve also occasionally contributes fibers to it. It commences at the lower border of the pectoralis minor, as the direct continuation of the posterior cord of the brachial plexus, and passes downward and lateralward in the axillary fossa behind the third part of the axillary artery (fig. 825) and in front of the subscapularis, latissimus dorsi, and teres major muscles. From the lower border of the axillary fossa it descends into the arm, where it lies, at first, on the medial side of the upper third of the humerus, behind the brachial artery and in front of the long head of the triceps; then it runs obliquely downward and lateralward behind the middle third of the humerus, in the groove for the radial nerve (musculospiral groove), and between the lateral and medial heads of the triceps. It is accompanied, in this part of its course, by the profunda artery. At the junc-

tion of the middle and lower thirds of the humerus it reaches the lateral side of the arm, pierces the external intermuscular septum, and runs downward and forward between the brachioradialis and extensor carpi radialis longus externally, and the brachialis internally (fig. 828), and it terminates, a short distance above the capitulum, by dividing into deep and superficial terminal branches. In the last part of its course it is accompanied by the anterior terminal branch of the profunda artery.

Branches.—The branches of the radial (musculospiral) nerves are *cutaneous*, *muscular*, *articular*, and *terminal*, but for practical purposes it is best to consider them in association with the situations of their origins. While it is in the axillary fossa the radial nerve gives branches to the medial and long heads of the triceps (fig. 828), and a medial cutaneous branch. The branch to the long head of the triceps at once enters the substance of the muscle, that to the medial head breaks into branches which terminate in the muscle at different levels, and one of them, the *ulnar collateral nerve*, accompanies the ulnar nerve to the lower part of the arm. The **posterior brachial cutaneous branch** crosses the tendon of the latissimus dorsi, passes dorsal to the intercostobrachial (intercostohumeral) nerve, pierces the deep fascia, and is distributed to the skin of the middle of the back of the arm below the deltoid.

While it lies behind the middle third of the humerus, the radial nerve gives branches to the lateral and medial heads of the triceps and to the anconeus. The latter branch descends in the substance of the median head of the triceps, close to the bone, and it is accompanied by a small branch of the profunda artery. The **dorsal antibrachial cutaneous branch**, passing down between the lateral and median heads of the triceps, divides near the elbow into its upper and lower branches (fig. 826), each of which perforates either the lateral head of the triceps muscle near its attachment to the humerus or the external intermuscular septum.

The **upper branch**, much the smaller, pierces the deep fascia in the line of the external intermuscular septum; it accompanies the lower part of the cephalic vein, and supplies the skin over the lower half of the lateral and anterior aspect of the arm. The **lower branch** is of considerable size. It pierces the deep fascia a little below the upper branch, runs behind the external condyle, and supplies the skin of the middle of the back of the forearm as far as the wrist, anastomosing with the medial antibrachial (internal) cutaneous and musculocutaneous nerves (fig. 829).

After the radial nerve has pierced the external intermuscular septum it gives branches to the brachioradialis, extensor carpi radialis longus, and to the lateral portion of the brachialis (fig. 829). From one of these branches an articular filament is distributed to the elbow-joint.

The **terminal branches** of the radial nerve are:—a motor branch, the *deep radial*, to the supinator and extensor muscles of the forearm, and a sensory branch, the *superficial radial*, which supplies the dorsal aspect of the radial half of the hand.

The **deep radial nerve** [ramus profundus] runs downward in the interval between the brachialis and extensor carpi radialis longus. It passes in front of the lateral part of the elbow-joint, and after giving off branches to supply the extensor carpi radialis brevis and supinator, it is crossed in front by the radial recurrent artery (fig. 829). It then runs downward and dorsalward through the substance of the supinator, and enters the interval between the superficial and deep layers of muscles at the back of the forearm, where it comes into relation with the posterior interosseous artery, and accompanies it across the abductor pollicis longus. At the lower border of the latter muscle it gives off a branch to the extensor pollicis longus, and another which crosses this muscle to the extensor indicis proprius.

Continuing distalward as the *dorsal interosseous* nerve the deep radial leaves the posterior interosseous artery, dips beneath the extensor pollicis longus, and joins the volar interosseous artery. It accompanies this artery upon the interosseous membrane and, upon the back of the radius, passes through the groove for the extensor digitorum communis and extensor indicis proprius to the dorsum of the wrist, and terminates in a gangliform enlargement which gives branches to the carpal articulations. The muscles supplied by the deep radial nerve are the extensor carpi radialis brevis, brachioradialis (supinator longus), extensor digitorum communis, extensor digiti quinti proprius, extensor carpi ulnaris, extensor indicis proprius, and the extensor muscles of the thumb. The supinator (brevis) receives two twigs, one of which is given off before the nerve pierces the muscle and the other while it is passing through it. The characteristic 'wrist-drop' due to paralysis of the deep radial nerve is shown in fig. 833D.

The **superficial radial nerve** [ramus superficialis n. radialis] is somewhat smaller than the deep radial (posterior interosseous), and is a purely cutaneous nerve. It runs downward under cover of the brachioradialis, passing in front of the elbow-joint, the radial recurrent artery, and the supinator (brevis). At the lower border of the supinator it approaches the radial artery at an acute angle, and runs, parallel to the lateral side of that vessel in the middle third of the forearm, across the pronator teres. At the lower border of the pronator teres it bends dorsalward on the deep surface of the tendon of the brachioradialis, and appears on the back of the forearm. It pierces the deep fascia and is directed

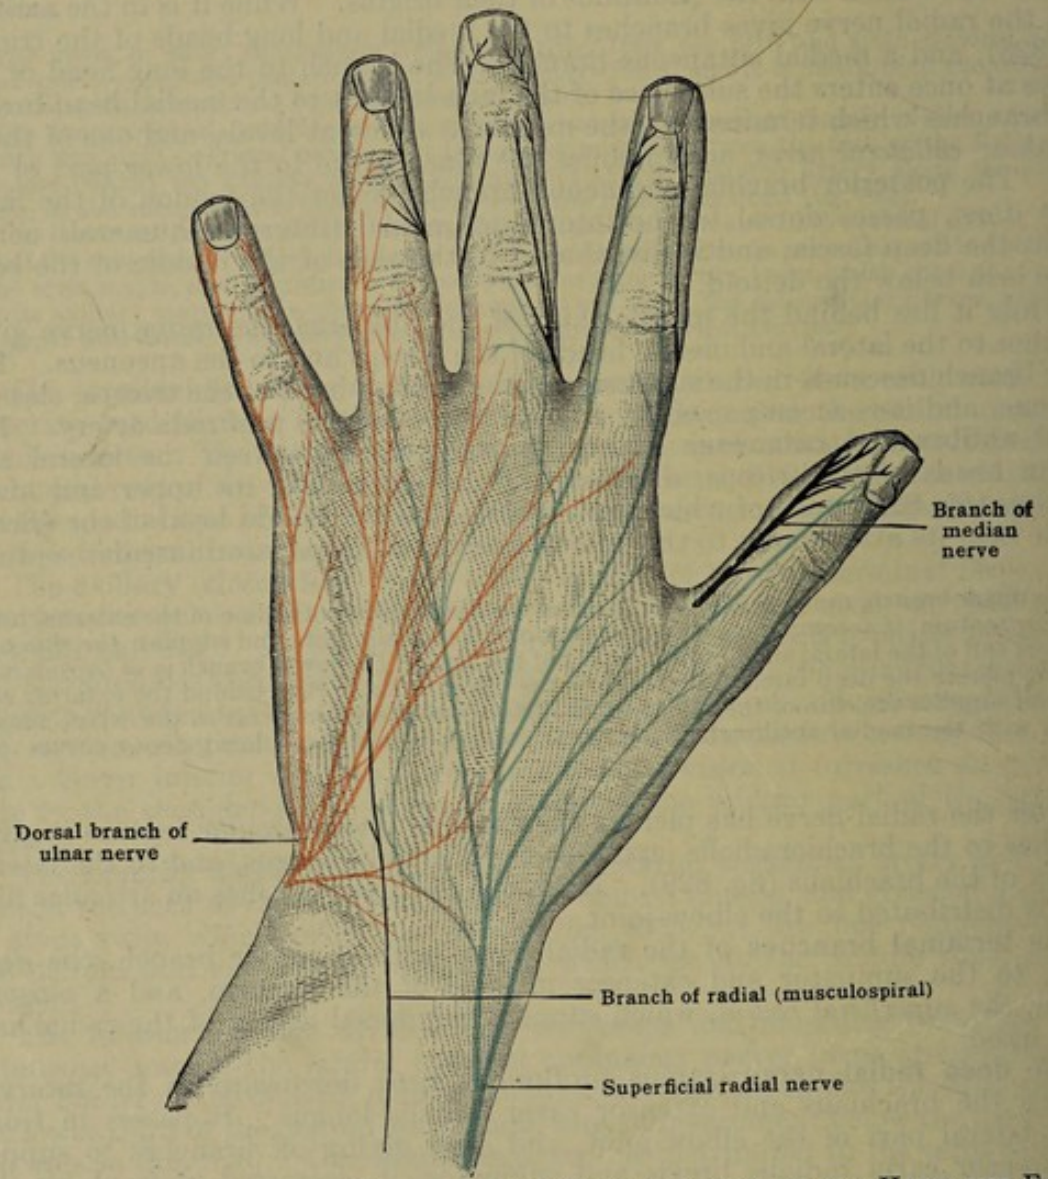

FIG. 827.—THE CUTANEOUS NERVES ON THE DORSAL ASPECT OF THE HAND AND FINGERS. (H. St. J. B.)

The branches of the median nerve are shown in black.

across the dorsal carpal (posterior annular) ligament toward the dorsum of the wrist, where it divides into its terminal branches (figs. 827, 831).

The most lateral of these branches supplies the skin on the radial part of the thenar eminence; the most medial, designated the **ulnar anastomotic branch,** communicates with the dorsal branch of the ulnar nerve. The other terminal branches, the **dorsal digital nerves,** supply to a variable extent the skin on the dorsum of the first digit, both sides of the second and the radial side of the third digit. These branches usually extend to the base of the nail of the first digit, to the distal interphalangeal joint of the second, not quite to the proximal interphalangeal joint of the third, and to the metacarpophalangeal joint of the fourth digit.

Clinical aspects.—In general the course of the radial nerve may be traced on the skin by a line beginning in the axillary fossa just behind the third part of the axillary artery, down the arm behind the proximal part of the brachial artery and medial to the upper part of the humerus; and then, just below the posterior border of the axilla, curving backward behind the humerus just below the insertion of the deltoid and running slightly downward along the musculospiral groove of the nerve behind the middle third of the humerus. The line of the main trunk again turns toward the front at about the junction of the middle and lower thirds of the humerus to

reach the lateral side of the arm by piercing the lateral intermuscular septum. It then passes downward, in front of the lateral supracondylar ridge, to the level of the lateral epicondyle, in front of which the nerve terminates by dividing into its deep and superficial branches. The superficial branch accompanies the radial artery to the front of the forearm leaving it about three inches above the wrist joint.

To expose the nerve, the incision should begin below, over the lateral intermuscular septum, in which it courses between the brachioradialis and brachialis muscles. Careless use of splints or tight bandages over the cubital fossa may easily result in paralysis in the forearm, not only ischemic paralysis from compression of the brachial artery and the branches of the basilic and cephalic veins, but also paralyses from pressure upon the median and radial nerves as they traverse this region. The radial nerve may be injured in the region of the axilla by crutch pressure, by the use of Esmarch's bandage, or by careless use of the foot braced in the axilla in the reduction of dislocated shoulder.

The **terminal branches of the lateral cord** of the brachial plexus are the musculocutaneous and the *lateral component* of the median nerve. The latter nerve will be described with the medial cord.

The **musculocutaneous nerve** is composed of fibers derived chiefly from the anterior divisions of the fifth and sixth cervical nerves, together in about 50 per cent. of the cases with some fibers from the fourth and seventh (figs. 821, 824). The nerve to the coracobrachialis usually consists of two or three twigs given off from the nerve close to its origin before it enters the muscle (fig. 825). Sometimes, however the fibers from the seventh cervical nerve pass directly to this muscle without joining the main trunk. The musculocutaneous nerve is placed at first close to the lateral side of the axillary artery (fig. 825), but soon it leaves that vessel and, piercing the coracobrachialis muscle, it passes obliquely downward and lateralward between the biceps and brachialis muscles. Soon after piercing the coracobrachialis it gives off **muscular branches** to each head of the *biceps* and to the *brachialis* (fig. 828). It also gives twigs to the *humerus*, to the *nutrient artery*, and gives the chief supply to the *elbow-joint*. Below the branch to the brachialis the cutaneous portion of the nerve forms the **lateral antibrachial cutaneous nerve** (figs. 826, 828). This portion continues downward between the biceps and brachialis, pierces the deep fascia at the lateral border of the former muscle a little above the bend of the elbow, receives a communication from the upper branch of the dorsal antibrachial (upper external) cutaneous branch of the radial (musculospiral) nerve, passes dorsal to the median cephalic vein, and divides into an anterior and a posterior branch.

The **anterior branch** runs downward on the lateral and anterior part of the forearm, supplying the integument of that region, and it terminates in the skin covering the middle part of the thenar eminence (fig. 829). A short distance above the wrist, after it has received a communicating twig from the superficial radial nerve, it gives off an articular branch to the carpal joints. This branch pierces the deep fascia and accompanies the radial artery to the dorsum of the wrist. The **posterior terminal branch** is small, and is directed downward and backward in front of the external condyle of the humerus, to be distributed to the skin on the lateral and posterior aspect of the forearm as low as the wrist (fig. 826). It anastomoses with the superficial radial and with the lower branch of the dorsal antibrachial (lower external) cutaneous branch of the radial nerve.

Clinical aspects.—Among the *paralyses of the newly born* which sometimes result from violent manipulation of the body during birth, that involving the upper part of the lateral cord is one of the most common. Rending of the fibers from the fifth cervical nerve and others going to the axillary and median nerves may give a partial or total loss of elevation and abduction at the shoulder and loss of flexion of the elbow, known as *upper radiuclar brachial paralysis* or 'Erb's palsy.' Paralysis of the muscles supplied by the medial cord is known as 'Klumpke's palsy.'

The **terminal branches of the medial cord** of the brachial plexus are the ulnar nerve and the *medial component* of the median nerve. Neither of these gives any branches in the upper arm, and thus they differ from the other terminal branches of the plexus. They both supply the muscles and joints of the forearm, and the muscles, joints, and integument of the hand.

The **ulnar nerve,** which is the largest branch of the medial cord of the brachial plexus, contains fibers from the anterior primary divisions of the eighth cervical and first thoracic nerves (figs. 824 and 825). It commences at the lower border of the pectoralis minor and runs downward in the axillary fossa in the posterior angle between the axillary artery and vein. In the upper half of the arm it lies on the medial side of the brachial artery (fig. 825), but at the level of the insertion of the coracobrachialis it passes backward at an acute angle, and, accompanied by the superior ulnar collateral (inferior profunda) artery, it pierces the medial intremuscular septum. After passing through the septum it runs downward, in a groove in the medial head of the triceps (fig. 828), to the interval between the ole-

cranon process and the medial condyle of the humerus, and in this part of its course it is closely bound to the muscle by the deep fascia. Immediately below the medial condyle it passes between the two heads of the flexor carpi ulnaris, along the medial side of the medial collateral ligament of the elbow, and it comes into relation with the dorsal ulnar recurrent artery.

In the upper forearm the ulnar nerve lies on the flexor digitorum profundus, covered by the flexor carpi ulnaris. Near the junction of the upper and middle thirds of the forearm it is joined by the ulnar artery, which accompanies it to its termination, lying throughout on its radial side

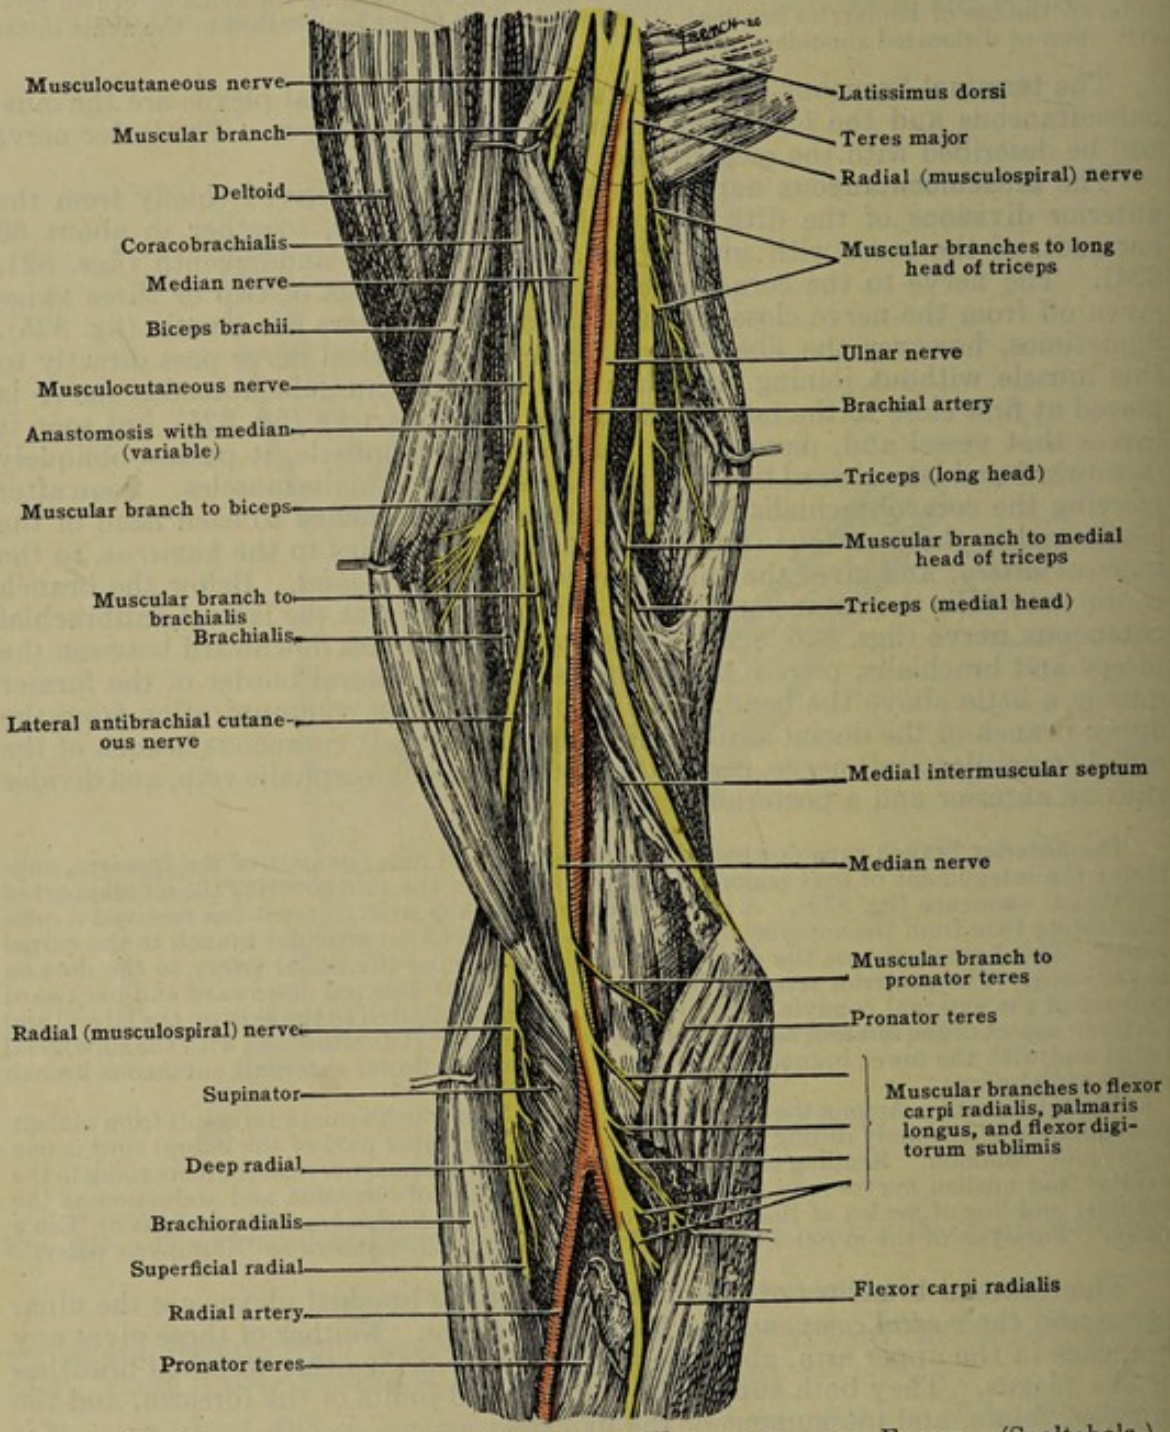

FIG. 828.—NERVES OF THE RIGHT UPPER ARM VIEWED FROM IN FRONT. (Spalteholz.)

(fig. 829). In the lower part of the forearm it still rests on the flexor digitorum profundus, but between the flexor carpi ulnaris and flexor digitorum sublimis, and is covered by skin and fascia. At a variable point in this part of the forearm, usually about 5 to 8 cm. from the carpus the nerve divides into its two terminal branches, a dorsal branch to the dorsal aspect of the hand and a volar branch to the volar aspect.

Branches.—The ulnar resembles the median nerve in not furnishing any branches to the upper arm. As it passes between the olecranon process and the medial condyle it gives off two or three fine filaments to the elbow-joint. In the upper part of the forearm it supplies the flexor carpi ulnaris and the medial

portion of the flexor digitorum profundus, and in the lower half it gives off the three cutaneous branches. In the palm of the hand it supplies the integument of the hypothenar eminence, the fifth digit, and half of the fourth digit, and the ulnar half of the skin of the dorsum (fig. 831). It also supplies the short intrinsic muscles of the hand with the exception of the abductor pollicis, the opponens, the lateral head of the flexor pollicis brevis, and the two lateral lumbricales.

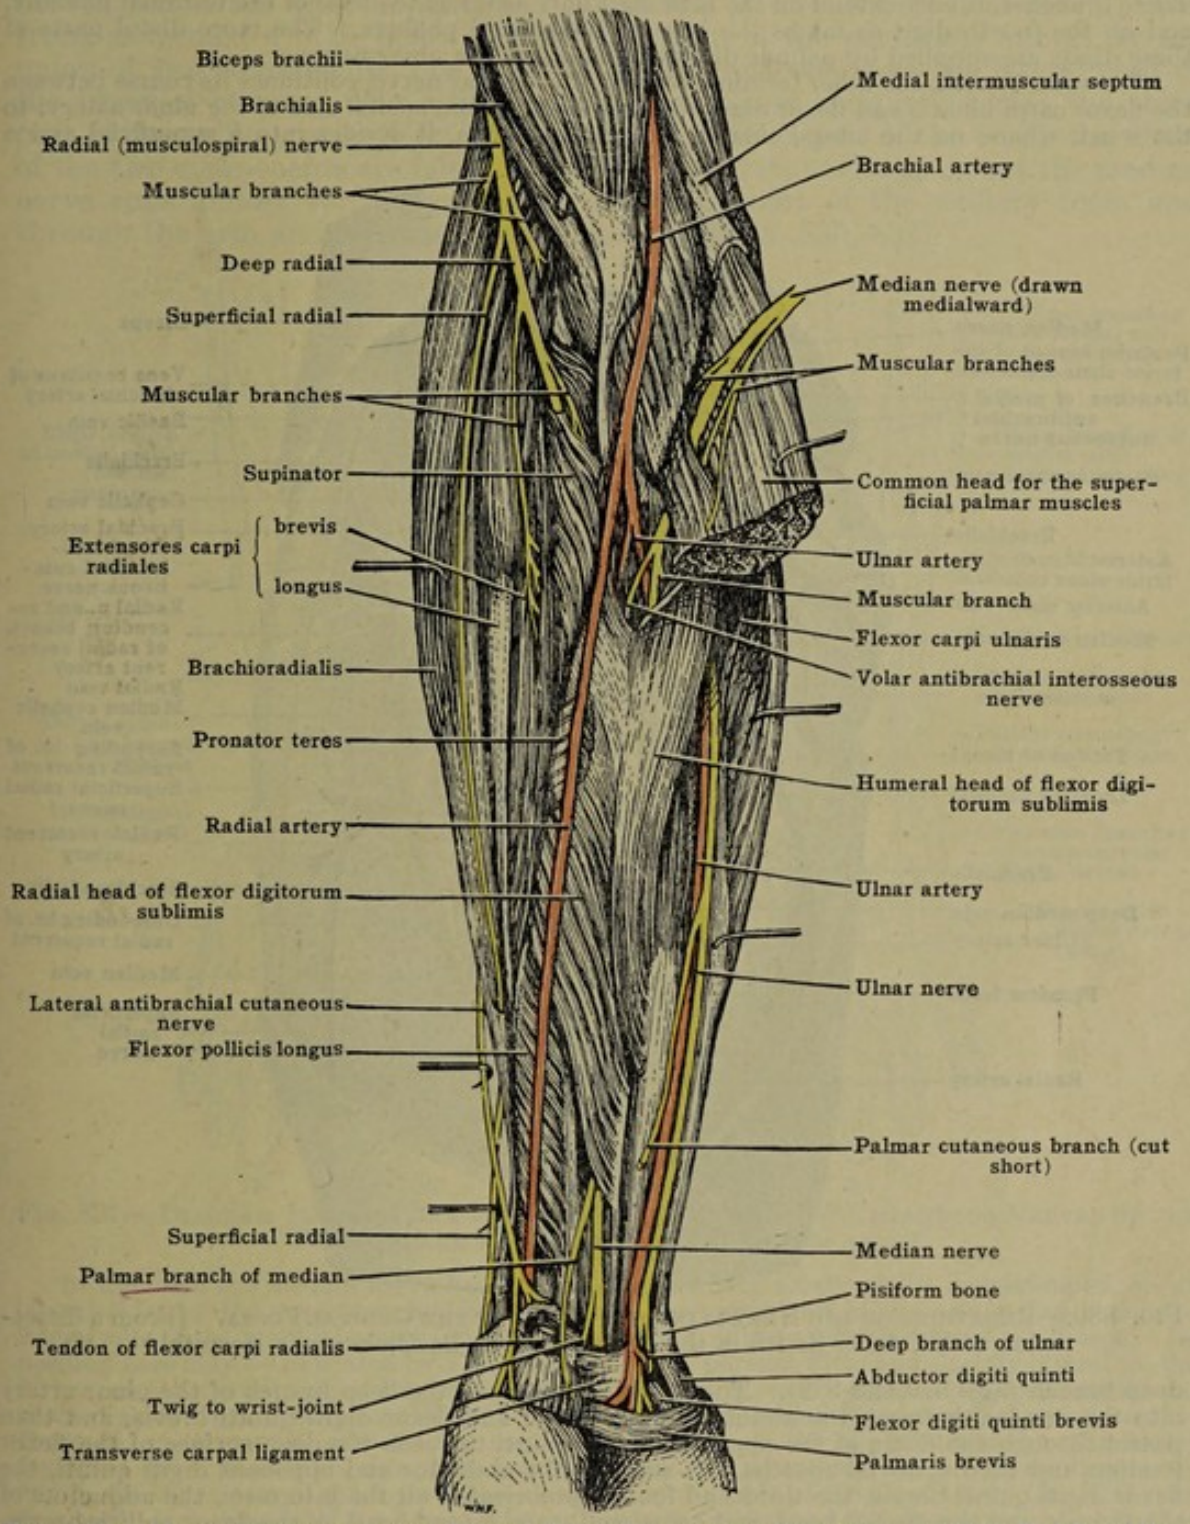

FIG. 829.—DEEP NERVES OF THE VOLAR SURFACE OF THE FOREARM. (After Toldt, 'Atlas of Human Anatomy,' The Macmillan Company.)

The **nerves to the flexor carpi ulnaris** and to the medial two divisions of the **flexor digitorum profundus** arise from the ulnar nerve in the upper third of the forearm.

Cutaneous branches.—About the middle of the forearm the ulnar nerve gives off two cutaneous branches:—one pierces the fascia and anastomoses with the volar branch of the medial antibrachial (internal) cutaneous nerve, and the other, the **palmar cutaneous branch,** runs downward in front of the ulnar artery (fig. 829) and is conducted by this vessel into the palm (fig. 832). It furnishes some filaments to the vessel, supplies a few twigs to the skin of the hypothenar eminence, and ends in the integument covering the central depressed surface of the palm, sharing this surface with the palmar branches of the median nerve

The **dorsal or posterior cutaneous branch,** usually the smaller of the terminal branches, arises about 5 cm. above the wrist-joint, and passes backward under cover of the flexor carpi ulnaris to reach the dorsal aspect of the wrist (fig. 831), where it gives off delicate branches to anastomose with branches of the medial antibrachial (internal) cutaneous, the dorsal antibrachial (external) cutaneous branch of the radial (musculospiral), the lateral antibrachial cutaneous of the musculocutaneous nerve, and with branches of the superficial radial, and then divides into five branches, the **dorsal digitals** (figs. 828 and 831), distributed to the ulnar sides of the third, fourth, and fifth digits and the radial sides of the fourth and fifth digits. These branches usually extend on the fifth digit only as far as the base of the terminal phalanx, and on the fourth digit as far as the base of the second phalanx. The more distal parts of these digits are supplied by palmar digital branches of the ulnar nerve.

The **volar branch,** the other terminal branch of the ulnar nerve, continues its course between the flexor carpi ulnaris and flexor digitorum sublimis, on the medial side of the ulnar artery, to the wrist, where, on the lateral side of the pisiform bone, it divides into a **superficial** and a

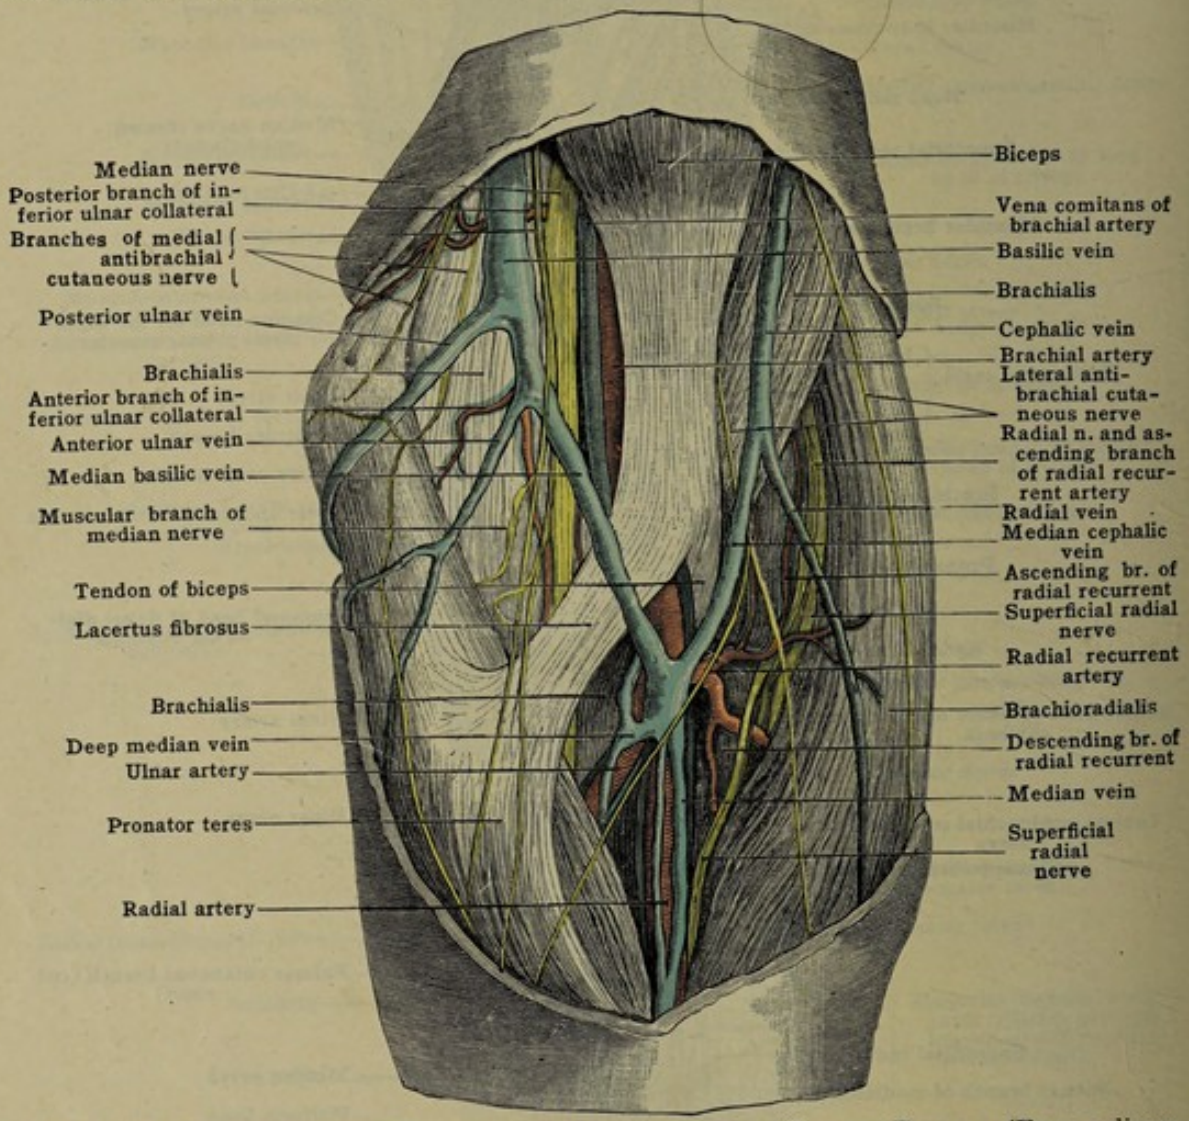

FIG. 830.—RELATIONS OF THE NERVES IN THE REGION OF THE CUBITAL FOSSA. (From a dissection of Dr. Adler Smith in the Museum of St. Bartholomew's Hospital.)

deep branch (figs. 829 and 832). The latter accompanies the deep branch of the ulnar artery into the interval between the abductor digiti quinti and flexor digiti quinti brevis, and then passes through the fibers of the opponens digiti quinti to reach the deep surface of the flexor tendons and their synovial sheaths. It supplies the abductor and opponens digiti quinti, the flexor digiti quinti brevis, the third and fourth lumbricales, all the interossei, the adductors of the thumb, and the medial head, and occasionally the lateral head, of the flexor pollicis brevis. The **superficial branch** gives off a branch to supply the palmaris brevis muscle, an anastomosing branch to the median nerve, and then divides into two branches, the **proper volar digital branch,** which is distributed to the medial side of the fifth digit on its volar aspect, and the **common volar digital branch,** which passes underneath the palmar aponeurosis and divides into two branches, which supply the contiguous margins of the fourth and fifth digits. These branches usually supply also the dorsal surface of the second and third phalanges of the same digits.

Clinical aspects.—The general course of the ulnar nerve may be given as a surface line from about the middle of the axillary fossa, along the medial side of the axillary and brachial arteries, to the middle of the upper arm; thence, along the medial border of the coracobrachialis and more medially, through the medial intermuscular septum, to the interval between the medial epicondyle and the olecranon process; and thence, to and along the medial side of the ulnar artery to the terminal branches of the nerve just above the ulnar side of the wrist. Its course

must be kept in mind in operations involving the medial head of the triceps. It passes so superficially over the elbow and back of the medial condyle that it is subject to blows, giving the condyle the name 'funny bone.' Damage here to the ulnar nerve, and possibly an open elbow joint, may result from injury to the epiphysis of the medial epicondyle, an injury which occurs more often prior to the eighteenth year when the epiphyseal line is still cartilaginous. Postural effects of paralysis of the ulnar nerve are indicated in fig. 833, B and C.

The **median nerve** contains fibers of the sixth, seventh, and eighth cervical nerves and of the first thoracic, and sometimes of the fifth cervical nerve. The trunk is formed a little below the lower margin of the pectoralis minor, by the union of two components, one from the medial and one from the lateral cord of the brachial plexus. The medial component passes obliquely across the third part of the axillary artery (fig. 825), and in the upper part of the trunk the fibers of the two components are felted together. From its commencement the median nerve runs almost vertically through the lower part of the axillary fossa and through the arm and forearm to the hand (figs. 828, 830, 832).

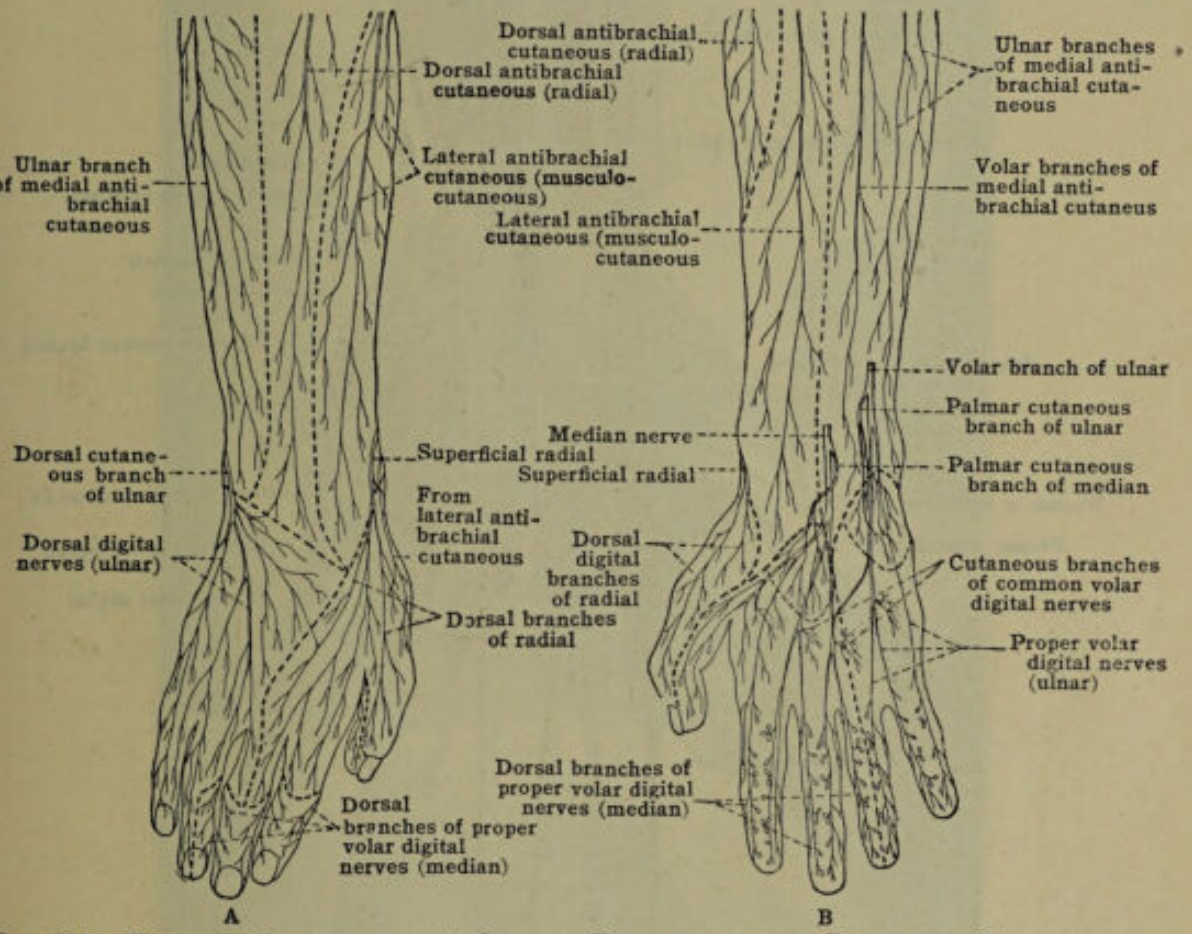

FIG. 831.—DIAGRAM ILLUSTRATING A COMMON DISTRIBUTION OF CUTANEOUS NERVES OF THE FOREARM AND HAND; A, dorsum; B, volar aspect.

In the fossa the median nerve lies lateral to the axillary artery and it is overlapped, on its lateral side, by the coracobrachialis muscle. In the upper half of the arm it lies along the lateral side of the brachial artery, and it is overlapped by the medial border of the biceps. Its position here may be indicated by a surface line drawn parallel with, and slightly lateral to, the furrow on the medial side of the prominence of the biceps; here the nerve lies deep and lateral to the basilic vein. At the middle of the arm it passes in front of the brachial artery, and it descends, on the medial side of the artery, to the elbow. In the upper part of the antecubital fossa it is still at the medial side of the brachial artery, but separated from it by a small interval, and in the lower part of the fossa it lies along the medial side of the ulnar artery (fig. 828). In case of the high division of the brachial artery, when the radial and the ulnar arteries lie together in the upper arm, the median nerve may pass between them and then one or the other of the arteries will be superficial to the nerve. As it leaves the antecubital fossa it passes between the two heads of the pronator teres, and it crosses in front of the ulnar artery (figs. 828 and 829), from which it is separated by the deep head of the pronator. In the forearm it passes vertically downward, accompanied by the median (comes nervi mediani) artery. In the upper two-thirds of this region it lies deeply, between the flexor digitorum sublimis and the flexor digitorum profundus, but in the lower third it becomes more superficial, and is placed beneath the deep fascia, between the flexor carpi radialis on the radial side and the palmaris longus and flexor digitorum sublimus tendons on the ulnar side. It crosses beneath the transverse carpal (anterior annular) ligament, in front of the flexor tendons, and in the palm at the lower border of the ligament it enlarges and divides into three branches, the **common volar digital nerves** (fig. 831).

Branches.—The median nerve does not supply any part of the upper arm. Very rarely, it may receive a small branch from the musculocutaneous nerve. In front of the elbow-joint it furnishes one or two filaments to that articulation. In the forearm it supplies all the superficial anterior muscles (with the exception of the flexor carpi ulnaris) directly from its trunk, and it supplies the deep muscles (with the exception of the ulnar half of the flexor digitorum profundus) by its volar (anterior) interosseous branch. Thus in general it supplies the pronator and flexor muscles of the forearm (radial side). In the hand it supplies the group of short muscles of the thumb, which are placed on the radial side of the tendon of the flexor pollicis longus, the two lateral lumbricales, the integument covering the central part of the palm and ulnar aspect of the thenar eminence, and the dorsal and palmar aspects of the first, second, third, and radial half of the

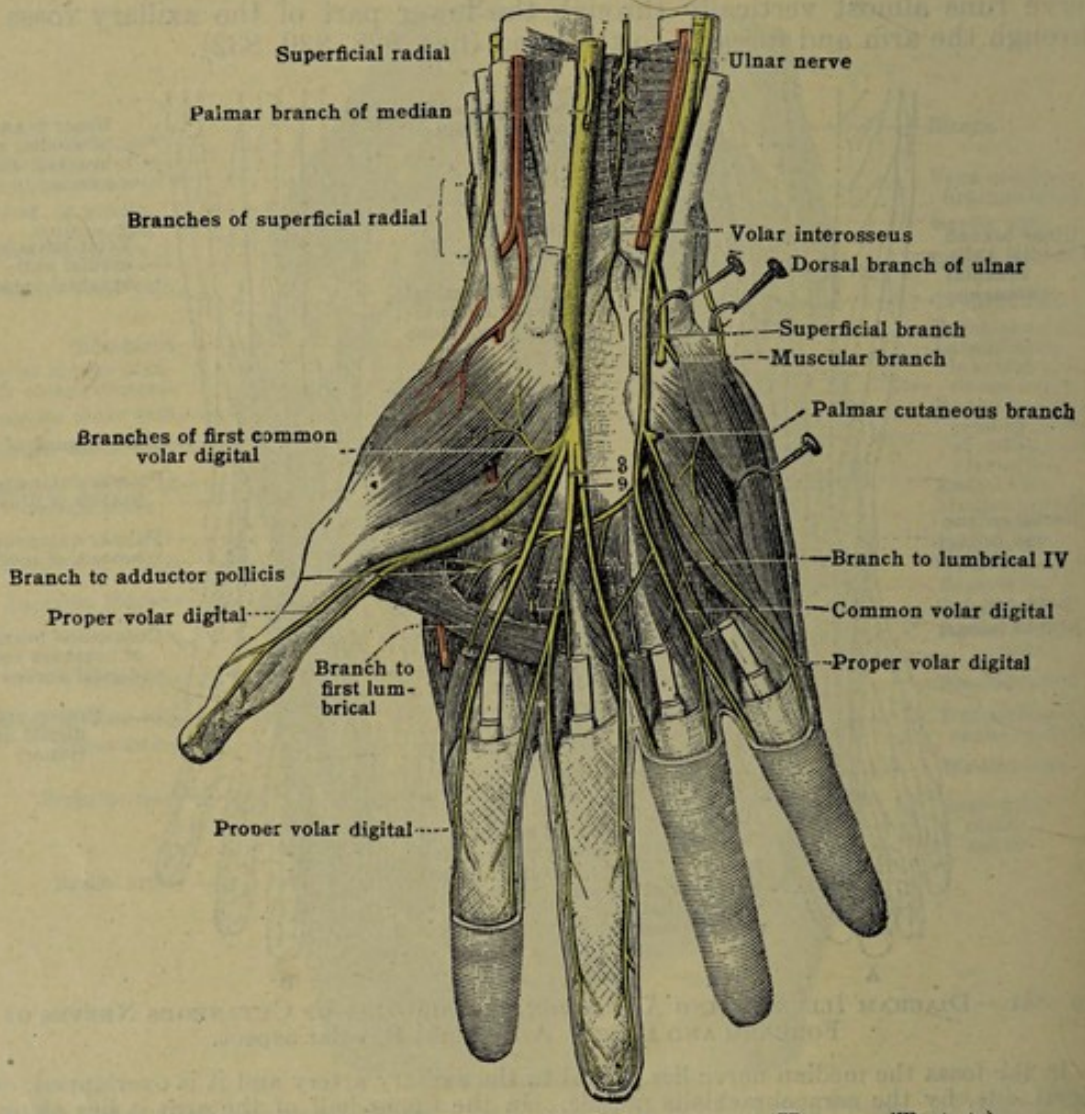

FIG. 832.—NERVES OF THE PALMAR SURFACE OF THE HAND. (Testut.)
The transverse carpal (anterior annular) ligament, superficial volar arch, the flexor tendons of the digits, and the proximal portions of the lumbrical muscles have been removed.

fourth digits (fig. 832). The effects of paralysis of the median nerve are shown in fig. 833, A.

The **nerve to the pronator teres** usually arises a little above the bend of the elbow, and pierces the lateral border of the muscle (figs. 829, 830 and 832). It may arise in a common trunk with the following nerves:—

The nerves to the **flexor carpi radialis, palmaris longus,** and **flexor digitorum sublimis** arise a little lower down, and pierce the pronator-flexor mass of muscles to end in the respective members of the group for which they are destined (fig. 828).

The **volar (anterior, antibrachial) interosseous nerve** arises from the median at the level of the bicipital tubercle of the radius (fig. 829), and runs downward, on the interosseous membrane, accompanied by the volar (anterior) interosseous artery. It passes under cover of the pronator quadratus, and pierces the deep surface of that muscle, which it supplies. The volar interosseous nerve also furnishes a twig to the front of the wrist-joint, and supplies the flexor digitorum profundus and the flexor pollicis longus. The nerve to the former muscle arises from the volar interosseous near its commencement; it supplies the lateral two divisions of the

muscle, and it communicates within the substance of the muscle with twigs derived from the ulnar nerve.

It also supplies a branch to the interosseous membrane which runs downward upon, or in, the membrane, supplying it and giving branches to the volar (anterior) interosseous and nutrient arteries and to the periosteum of the radius, the ulna, and the carpus.

The **palmar cutaneous branch** [ramus palmaris] arises immediately above the transverse carpal (anterior annular) ligament and passes between the tendons of the flexor carpi radialis and the palmaris longus (fig. 829). It then crosses the superficial surface of the transverse carpal ligament, and is distributed to the integument and fascia on the central, depressed sur-

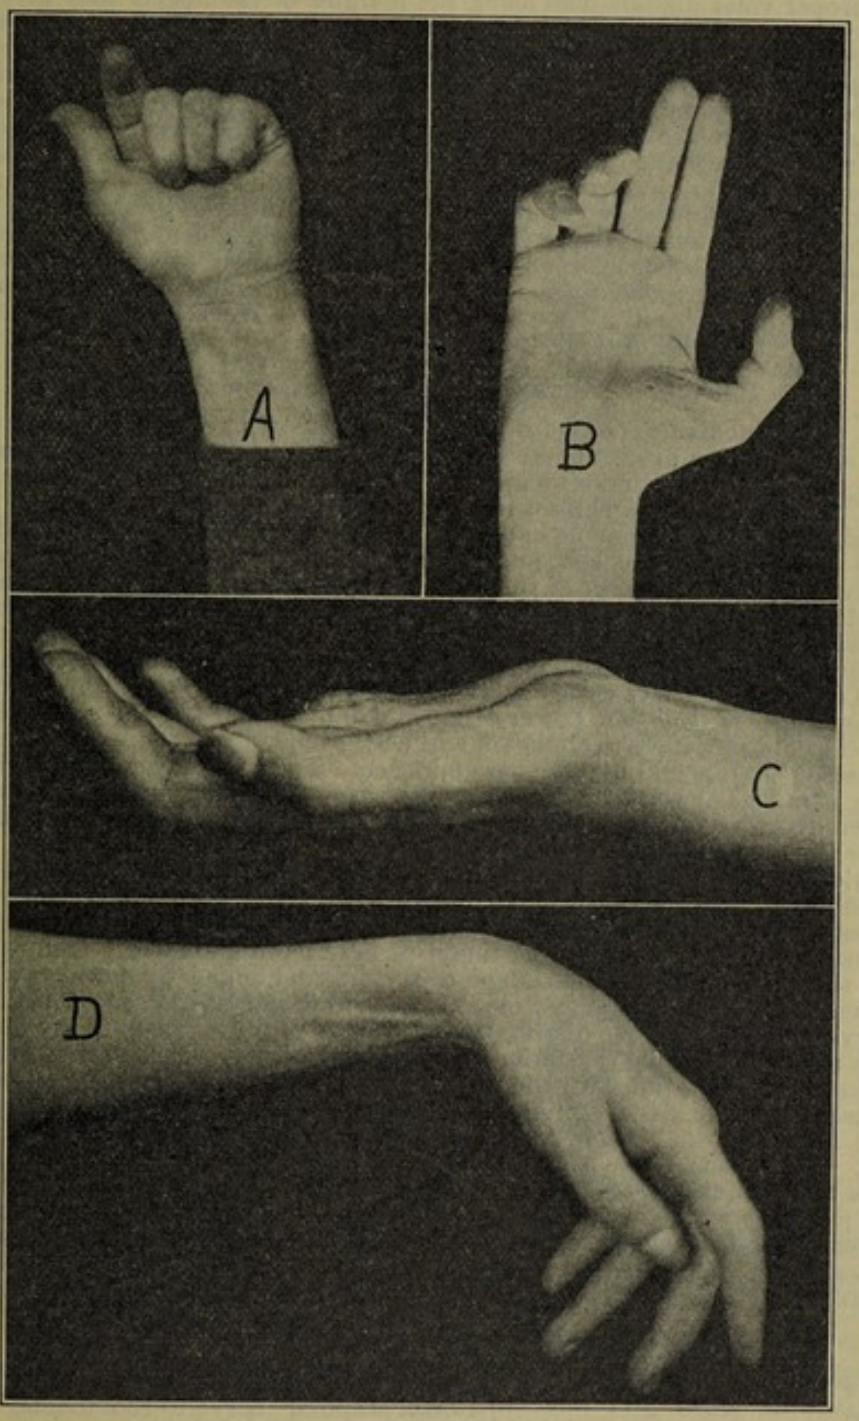

FIG. 833.—CHARACTERISTIC DEFORMITIES OF THE HAND IN PARALYSIS OF VARIOUS NERVES.

face of the palm. It also supplies a few twigs to the medial border of the thenar eminence; these twigs communicate with the musculocutaneous and superficial radial nerves.

The three **common volar digital nerves** pass in the palm of the hand dorsal to the superficial volar arch and its digital branches, while the **proper volar digitals**, branches of these nerves, lie on the volar side of the digital arteries.

The **first** of the common volar digital nerves gives off a branch to supply the abductor pollicis, the opponens, and the superficial head of the flexor pollicis brevis, and joins by a delicate branch with the deep branch of the ulnar nerve. It then divides into three **proper volar digitals** (fig. 832). The lateral of these passes obliquely across the long flexor tendon of the thumb and runs along the radial border of the thumb to its extremity. It gives numerous branches to the pulp of the thumb, and a strong twig which passes to the dorsum to supply the matrix of the

nail. The second of these proper volar digitals supplies the medial side of the volar aspect of the thumb and gives off a twig to the matrix of the thumb nail. The third supplies the radial side of the second digit and gives a twig to the first lumbrical muscle.

The **second** common volar digital sends a twig to the second lumbrical muscle, and divides a little above the metacarpophalangeal articulation into two **proper volar digitals**, which respectively supply the adjacent sides of the second and third digits (fig. 831).

The **third** common volar digital communicates with the ulnar nerve, often gives a branch to the third lumbrical muscle, and divides into two **proper volar digitals** which supply the adjacent sides of the third and fourth digits.

As the proper volar digitals pass along the margins of the fingers they give off twigs for the innervation of the skin on the dorsum of the second and third phalanges and the matrix of their nails. Each of the nerves terminates in filaments to the pulp of the finger.

Clinical aspects.—Because of the frequency of wounds on the front of the wrist and in the palm, the following are some of the important locations of volar nerves which especially should be kept in mind. The median nerve passes into the hand through the mid-point of the front of the wrist, usually under the tendon of palmaris longus. The volar branch of the ulnar nerve (with the artery) comes to its superficial position between the tendons of the flexor carpi ulnaris and the superficial flexor of the fourth digit. Its palmar cutaneous branches and most of those of the median nerve pass superficial to the transverse carpal ligament. The main volar trunks of both the ulnar and median nerves break up into their volar digital branches beneath the central part of the palmar aponeurosis. The branches of the ulnar to the palmar muscles of the fourth and fifth digits course in the hypothenar eminence. Wasting of the first dorsal interosseous muscle is an indication of injury to the ulnar nerve.

Paralyses of the Forearm and Hand (Fig. 833)

Paralysis of the median nerve.—(*a*) *In forearm:* Loss of pronation. (*b*) *At wrist:* Diminished flexion and tendency toward ulnar adduction. (*c*) *In the hand:* Power of grasp is lessened especially in the thumb and index finger. Owing to the loss of flexion in the phalanges of these fingers the phalanges are liable to become overextended by the action of the extensors and interossei. The thumb remains extended, adducted, and applied to the index finger, the human characteristic being thus lost, and the 'ape's hand' of Duchenne produced. **Sensation** will be lost over the palmar aspect of the thumb and lateral two and one-half fingers and over the distal ends of the same fingers, to a varying degree, according to the sensory distribution of the median and other cutaneous nerves. The above applies to lesions of the trunk. If the nerve be injured at the wrist, flexion of the wrist and fingers is less interfered with.

Paralysis of the ulnar nerve.—(*a*) *At wrist:* Power of flexion is diminished and that of ulnar adduction lost. (*b*) *In the hand:* Power of grasp will be lessened in the ring and little fingers. The interossei will be powerless to abduct or adduct the fingers, and there will be marked wasting of the interosseous spaces and hypothenar eminence. The thumb cannot be adducted. After a time, from paralysis of the lumbricals and interossei, the hand becomes 'clawed'—the first phalanges overextended, and the second and third flexed (**main en griffe**). **Sensation** will be lessened over the area supplied by the nerve.

Paralysis of the radial (musculospiral) nerve.—(*a*) *In the forearm.* This is flexed, extension being impossible. The forearm is pronated, supination being impossible save by biceps, which acts now most strongly on a flexed elbow-joint. (*b*) *In the wrist:* This is dropped, owing to the loss of extension. (*c*) *In the hand:* The thumb is flexed and adducted. Some slight power of extension of the second and third phalanges of the fingers remains by means of the lumbricales and interossei. **Sensation** is impaired over the posterior and lateral aspect of the forearm and lost to a varying extent over the distribution of the radial on the back of the hand.

Paralysis of the deep radial (posterior interosseous) nerve.—The evidence here is somewhat similar to that just given, but with the following differences. (*a*) *In the forearm:* There is no loss of extension, and the loss of supination is less as the brachio-radialis is not paralysed. (*b*) *At the wrist:* The 'drop' and loss of extension are not so marked, as the extensor carpi radialis has escaped. **Sensation**: There is no loss.

Paralysis of the musculo-cutaneous nerve.—*Forearm:* Power of flexion is impaired, owing to complete paralysis of the biceps and partial of the brachialis (anterior). **Sensation**: This is impaired over the lateral aspect of the forearm, both back and front.

Table Showing Relation of Cervical and Thoracic Nerves to Branches of Brachial Plexus

Nerves Contributing	Nerves, Branches of Plexus
5 C.	Dorsal scapular (nerve to rhomboids) Nerve to subclavius Suprascapular
5 and 6 C.	Nerve to subclavius Upper subscapular Lower subscapular Axillary (circumflex)
5, 6, and 7 C.	Long (posterior) thoracic Lateral anterior thoracic.
5, 6 (and 7) C.	Musculocutaneous
(5), 6, 7, 8 C.	Radial (musculospiral)
(5), 6, 7, 8 C and 1 T.	Median
7 and 8 C.	Thoracodorsal (middle or long subscapular)
8 C and 1 T.	Medial anterior thoracic Ulnar Medial antibrachial (internal) cutaneous
1 T.	Medial brachial (lesser internal) cutaneous

TABLE SHOWING THE RELATIONS OF THE CERVICAL NERVES TO THE MUSCLES OF THE UPPER EXTREMITY

NERVES CONTRIBUTING	MUSCLES	NERVES TO MUSCLES
Accessory, 2C	Sternomastoid	Spinal accessory
Accessory, 3, 4C	Trapezius	Spinal accessory, 3 and 4 C.
3 and 4C	Levator scapulæ	3 and 4 C.
5 and 6 C	Subclavius	Nerve to subclavius
	Supraspinatus	Suprascapular
	Infraspinatus	Suprascapular
	Subscapularis	Upper and lower subscapular
	Teres major	Lower subscapular
	Teres minor	Axillary (circumflex)
	Deltoid	Axillary (circumflex)
	Brachialis	Musculocutaneous
	Biceps	Musculocutaneous
6 C	Brachioradialis	Radial (musculospiral)
	Supinator	Deep radial (posterior interosseous)
	Pronator teres	Median
	Flexor carpi radialis	Median
	Palmaris longus	Median
6 and 7 C	Ext. carpi radialis longus	Radial (musculospiral)
	Ext. carpi radialis brevis	Deep radial (posterior interosseous)
	Abductor pollicis brevis	Median
	Opponens pollicis	Median
	Flexor pollicis brevis (superf. head)	Median
5, 6 and 7 C	Serratus anterior	Long (posterior) thoracic
7 C	Coracobrachialis	Musculocutaneous
	Ext. digitorum comm.	Deep radial (posterior interosseous)
	Ext. digiti quinti proprius	Deep radial (posterior interosseous)
	Ext. carpi ulnaris	Deep radial (posterior interosseous)
	Abductor pollicis longus	Deep radial (posterior interosseous)
	Extensor pollicis brevis	Deep radial (posterior interosseous)
	Extensor pollicis longus	Deep radial (posterior interosseous)
	Ext. indicus proprius	Deep radial (posterior interosseous)
7 and 8 C	Latissimus dorsi	Thoracodorsal (long subscapular)
	Triceps	Radial (musculospiral)
	Anconeus	Radial (musculospiral)
5, 6, 7 and 8 C	Pectoralis major	Lat. and med. ant. thoracic
8 C	Dorsal interosseus	Ulnar
	Volar interosseus	Ulnar
	Add. pollicis	Ulnar
	Add. pollicis trans.	Ulnar
	Flex. pollicis brev. (deep)	Ulnar
7, 8 C and 1 T	Pectoralis minor	Med. ant. thoracic
	Flex. digit. subl.	Median
	Lumbricalis	Median and ulnar
8 C. and 1 T	Flex. carpi ulnaris	Ulnar
	Flex. digit. prof.	Ulnar and median
	Flex. pollicis long.	Median
	Pronator quadratus	Median

2. THE THORACIC NERVES

The **anterior primary divisions of the thoracic nerves,** with the exception of the first and usually the twelfth, retain, in the simplest form, the characters of anterior primary divisions of the typical spinal nerve. They do not form plexuses, but remain distinct from each other. Each divides into an easily recognizable lateral or dorsal and anterior or ventral branch (primary division) (figs. 834 and 835), and they are not distributed to the limbs. The first, second, and last thoracic nerves, on account of their peculiarities, require separate description. The remainder are separable into two groups, an upper and a lower. The **upper group** consists of four nerves, the third to the sixth inclusive, which are distributed entirely to the thoracic wall. The **lower group** contains five nerves, the seventh to the eleventh inclusive, which are distributed partly to the thoracic and partly to the abdominal wall. The upper group is therefore purely thoracic in distribution, and the lower thoracoabdominal. All the thoracic nerves are connected with the sympathetic trunk by means of both white and gray rami communicantes.

The **first thoracic nerve** is connected with the first thoracic sympathetic ganglion, and it frequently is joined by a small branch with the second nerve (fig. 824). Its anterior primary division is distributed chiefly to the upper limb. Opposite the superior costotransverse ligament of the second rib it divides into a larger and

a smaller branch; the larger passes upward and lateralward, between the apex of the pleura and the neck of the first rib, and on the lateral side of the superior intercostal artery, to the root of the neck, where it joins the brachial plexus. The smaller branch continues along the intercostal space, below the first rib and between the intercostal muscles in which, as a rule, all its fibers terminate.

However, the smaller branch may give off a lateral cutaneous branch which connects with the medial brachial (lesser internal) cutaneous nerve and with the intercostobrachial nerve in the axillary fossa; and occasionally it terminates in an anterior cutaneous branch at the anterior extremity of the first intercostal space.

The **second thoracic nerve,** as it lies between the pleura and the superior costotransverse ligament of the third rib, gives a branch to the first nerve, then it pierces the posterior intercostal membrane and passes between the external and internal intercostal muscles in the second intercostal space. In the dorsal part of the space it sends branches backward, through the external intercostal muscle, to supply the second levator costæ and the serratus posterior superior, and then it divides into a *lateral* and an *anterior* branch (fig. 834). The two branches run forward together to the midaxillary line, where the lateral branch pierces the
